Several hierarchical clustering techniques, for example single linkage and the median method, have a tendency to cluster together, at a relatively low level, individuals linked by a series of isolated intermediates. This property, known generally as *chaining*, may cause the method to fail to resolve relatively distinct clusters when there are a small number of such individuals between them. Methods based on single linkage which attempt to avoid the chaining problem are described in Wong [51] and Wong & Lane [52].

A notable advantage of both single and complete linkage clustering emphasized by Johnson [25] is their invariance under monotonic transformations of the original dissimilarity matrix. Consequently, only the ordinal properties of the dissimilarities are of concern, and the difficulties generally involved in scaling and combining different variables into a measure of dissimilarity are lessened. (Complete linkage is not satisfactory when the dissimilarity matrix contains ties.)

Jardine & Sibson [24] object to many hierarchical clustering methods on mathematical grounds. Briefly, what these authors show is that a cluster method that transforms a dissimilarity matrix into a hierarchic dendrogram may be regarded as a procedure that imposes the ultrametric inequality which is satisfied by the heights of the dendrogram, i.e. $h_{ij} \leq \max[h_{ik}, h_{kj}]$, on a dissimilarity coefficient which originally may have satisfied only the weaker metric inequality. Jardine & Sibson then specify certain simple conditions, for example continuity, minimum distortion, etc. that any such transformation should satisfy and demonstrate that only single linkage satisfies the specified requirements. Consequently, Jardine & Sibson recommend single linkage as the method with greatest mathematical appeal. Such a recommendation has been criticized by many authors, for example Williams et al. [49] and Gower [20], and certainly in practice, single linkage has often been found to be the *least* successful method.

The centroid and median methods have the unsatisfactory property that they can produce *reversals* in the dendrogram, in the sense that a group i may be contained in a group j, i.e. $i \in j$, but $h_i > h_j$. Reversals can be prevented by adding the requirement that d_{ij} be no less than $\max[h_i, h_j]$. Necessary and sufficient conditions for an absence of reversals in the dendrogram produced by the algorithm defined in (4) are

$$\begin{aligned} \gamma &\geq -\min(\alpha_i, \alpha_j), \\ \alpha_i + \alpha_j &\geq 0, \\ \alpha_i + \alpha_j + \beta &\geq 1. \end{aligned} \tag{6}$$

A number of empirical investigations of hierarchical clustering techniques have been performed to investigate the extent to which standard clustering algorithms recover known types of structure in data. Cunningham & Ogilvie [8], for example, compare seven hierarchical techniques and find that group average clustering performs most satisfactorily overall for the data sets considered; in addition, however, they find a large interaction in the results between types of input data and the particular clustering method used. Kuiper & Fisher [26] investigate six hierarchical techniques and find that for equal-sized groups, Ward's method classifies almost as well as Fisher's linear discriminant function (*see* **Discriminant Analysis, Linear**) when the groups are specified a priori; with unequal sized groups, however, centroid, group average, and complete linkage clustering are more successful. A study by Hands & Everitt [21] using **binary data** found similar results; Ward's method performed very well when the data contained approximately equally sized clusters, but poorly when the clusters were of different sizes. A review of **Monte Carlo** studies in this area is given in Milligan [35]. The only overall conclusion that can be reached is that no particular method can be claimed to be superior for all types of data.

Cheng & Milligan [4] investigate the influence of individual coordinate locations in a multivariate space and demonstrate that differences between clustering methods help to explain some of the results in previous validation research of these methods.

Validation

The clustering algorithms described in previous sections always produce a hierarchical classification and it is important to validate the results, in particular to investigate whether a hierarchical structure is appropriate and whether the derived

solution misrepresents the pattern in the data in any way. (Here we are referring to the entire dendrogram rather than to a solution corresponding to a particular number of groups.) Some authors have argued that the only relevant criteria for assessing a classification are its utility and interpretability. But as pointed out by Gordon [17], there are dangers in this approach; "human ingenuity is quite capable of providing a *post hoc* justification of dubious classifications".

According to Gordon [17], "there is no uniquely obvious way of specifying the absence (or presence) of class structure in data", which probably accounts for the lack of suitable, practical tests for the absence of structure hypothesis. Those tests that have been suggested by Fillenbaum & Rapoport [15], Ling [30], and Baker & Hubert [1], among others, have low power against some alternative hypotheses, and can be markedly influenced by a small number of outliers [16].

The suitability of a hierarchical classification for a data set can be assessed by comparing the original dissimilarities with the heights in the derived dendrogram. A data set can only be accurately represented by a hierarchical classification if little distortion is imposed in transforming from the dissimilarity matrix, d_{ij}, to the ultrametric matrix, h_{ij}. One common procedure for assessing the match between the dendrogram and the dissimilarity matrix is the *cophenetic correlation coefficient*. This is simply the product–moment **correlation** between the $n(n-1)/2$ entries in the lower half of the observed dissimilarity matrix and the corresponding terms in the so-called *cophenetic matrix*, **C**, containing the heights in the derived dendrogram at which individuals i and j first occur in the same cluster. Since the latter satisfy the ultrametric inequality, the match between dendrogram and data cannot be perfect unless the entries in the dissimilarity matrix are also ultrametric, a situation which seldom occurs in practice. For the example involving the application of three agglomerative algorithms given previously, the corresponding values of the cophenetic correlation coefficient are as follows:

$$\text{single linkage} = 0.82,$$

$$\text{complete linkage} = 0.85,$$

$$\text{average linkage} = 0.85.$$

Rohlf & Fisher [40] studied the distribution of the cophenetic correlation coefficient under the hypothesis that the individuals are randomly chosen from a *single* **multivariate normal distribution** (i.e. have no cluster structure). They found that the average value of the coefficient tends to decrease with n and to be almost independent of the number of variables. They also suggest that values of the cophenetic correlation above 0.8 indicate a nonartifactual hierarchical structure, although in a later paper, Rohlf [39] indicates that even values close to 0.9 are not necessarily a guarantee that the dendrogram serves as a sufficiently accurate summary of the relationships between the individuals.

Several other measure of the distortion produced by transforming a dissimilarity matrix into a dendrogram are described in Gordon [17].

The amount of support for hierarchical structure in a data set has also been assessed by *stability studies*, in which the original classification is compared with a classification of a modified version of the data obtained, for example by adding an error term to the dissimilarity matrix, or by deleting a small number of individuals. Large differences between the resulting two classifications would shed some doubt on the suitability of clustering for the data. A related approach is to divide the individuals randomly into two and compare the results of separate cluster analyses applied to each half.

Partitions from a Hierarchy – the Number of Groups Problem

As remarked earlier in the article, when the hierarchical clustering technique are used in practice the investigator is not usually interested in the complete hierarchy but only in one or two partitions found by "cutting" the dendrogram at a hopefully appropriate point. Deciding on the "best" fitting partition for a particular data set, i.e. choosing the correct number of clusters, is not straightforward, although a considerable number of methods *have* been suggested. One very informal procedure which is often used is simply to examine the dendrogram looking for "large" changes in level. The dendrogram shown in Figure 6, for example, suggests a two-group solution.

More formal approaches to the number of groups problem have been suggested by Duda & Hart [10], Calinski & Harabasz [3], and Mojena [37]. All such methods are considered in a detailed investigation reported by Milligan & Copper [36]; none appears completely satisfactory.

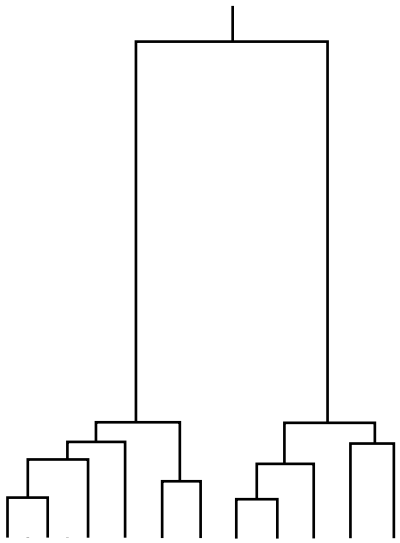

Figure 6 Dendrogram indicating two groups

Some Examples

Corbet et al. [5] describe a study to compare British populations of water voles with others from Europe. The original data consisted of recordings of the presence or absence of 13 characteristics on about 300 water vole skulls divided into samples from 14 populations; these data were converted into the matrix of *population* dissimilarities shown in Table 2 by a procedure involving the percentage incidence of each characteristic in each population (see the original paper for full details). The British populations are those numbered 1–6, and arise from the following areas:

1. Surrey
2. Shropshire
3. Yorkshire
4. Perthshire
5. Aberdeen
6. Eileen Gambia

The non-British populations are from two species, *Arvicola terrestris* (7–11) and *Arvicola sapidus* (12–14). The corresponding areas are:

7. Alps
8. Yugoslavia
9. Germany
10. Norway
11. Pyrenees I
12. Pyrenees II
13. North Spain
14. South Spain.

The dendrograms from applying single linkage, complete linkage, and average linkage to the dissimilarities are shown in Figures 7, 8, and 9. The two-group solutions given by single linkage and average linkage are identical and correspond to the following division of the 14 populations:
Group 1: 12, 13, 14
Group 2: 1–11

The two-group solution for complete linkage, however, is
Group 1: 1, 2, 3, 4, 5, 6, 9, 10
Group 2: 7, 8, 11, 12, 13, 14

Even on a small data set such as this, different hierarchical clustering methods may give different solutions.

Wastell & Gray [46] describe the use of hierarchical clustering for the development of a classification of **pain** distribution in patients with temporomandibular joint pain dysfunction syndrome (TMJPDS). This refers to a complex symptom group involving facial pain, limitation and deviation of mandibular movements, joint noises, and muscle tenderness. Symptoms vary with the stage of the disease; etiology is equally complex and both physical and psychogenic factors have been implicated. Pain is the most commonly recorded symptom, but its facial distribution does not conform to a single pattern.

Wastell & Gray's main aim was to use clustering techniques to develop an objective typology for classifying facial pain in terms of its spatial distribution. Clinically the hope was that the derived classification would be useful in identifying different stages of the disease, which would be of help in defining more directed treatment plans.

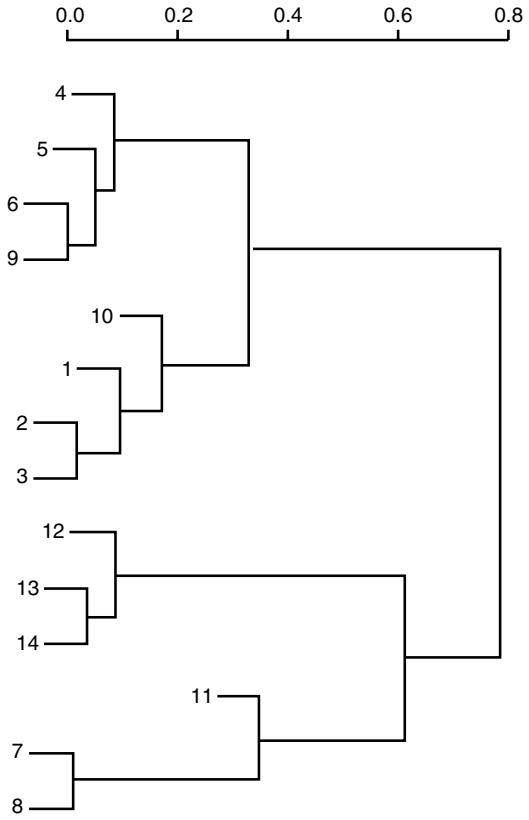

Figure 8 Complete linkage dendrogram for water vole data

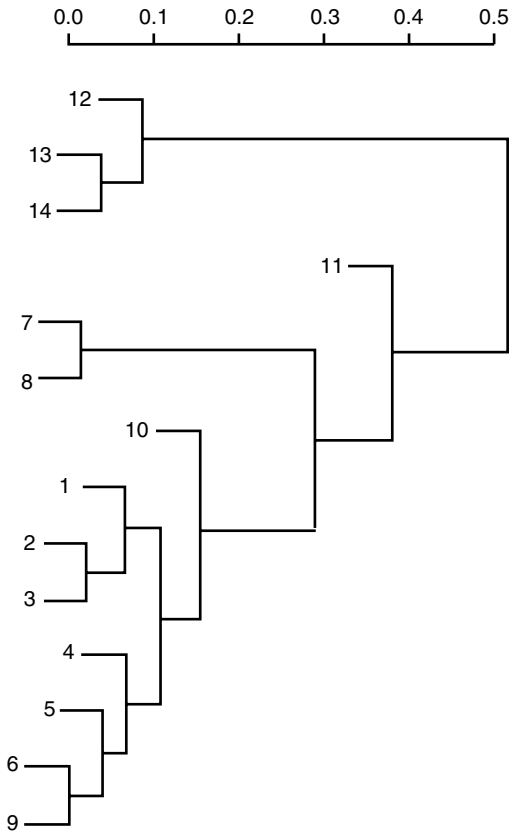

Figure 9 Average linkage dendrogram for water vole data

Data were collected from 127 patients attending the temporomandibular joint clinic of a university hospital complaining of classic TMJPDS. Patients were asked to trace the boundary of their pain-affected area with the tip of their index finger. The examiner recorded this outline on a diagram of the lateral profile of the face (see Figure 10) and this was adjusted until patients were satisfied that the outline matched their own pain area.

The squares of the grid shown in Figure 10 falling within the perimeter of a pain area were scored 1; those without, 0. In this way any patient's pain distribution may be described by a string of binary variables. In practice all distributions lay within a central rectangle with horizontal extension, J–T, and vertical extension, 11–28, giving $11 \times 18 = 198$ binary variables for analysis. The similarity between each pair of patients was calculated using Jaccard's coefficient, which is simply the proportion

of one-to-one matches for the two patients after ignoring the zero-to-zero matches. (See Everitt [13] for an explicit definition of this coefficient.)

Ward's method of clustering was used in this application and the resulting dendrogram is shown in Figure 11. The structure of the dendrogram appears to indicate three major classes, with a further possible subdivision of each of these into two. A composite pain distribution matrix for each class was constructed by simple matrix addition of the pain matrices of its constituent members. The authors' description of the pain classes was as follows:

Pain Class A:. The pain distribution of Class A was concentrated over the temporomandibular joint

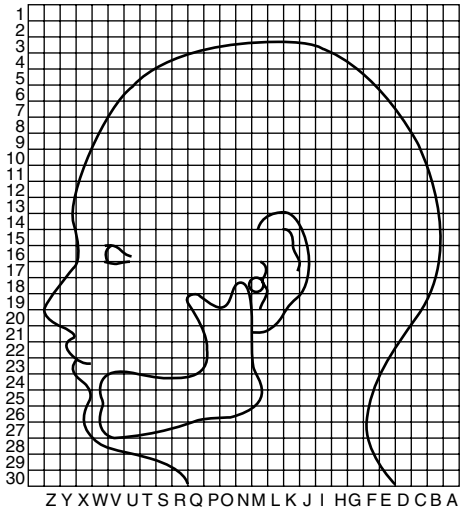

Figure 10 TMJPDS data collection method

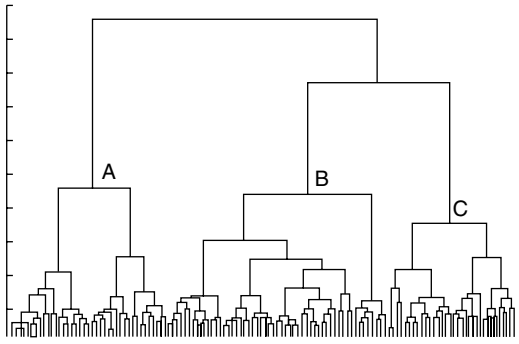

Figure 11 Ward's method dendrogram for TMJPDS data

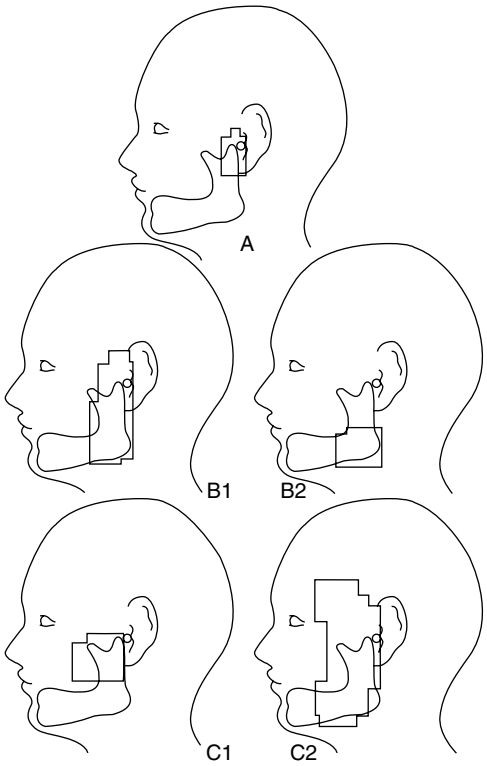

Figure 12 Pain distribution of cluster solution on TMJPDS data

(see Figure 12). The two subclasses were much alike, apart for a small vertical difference in their centroids.

Pain Class B:. The pain distribution of Class A differed from that of Class B in involving the vertical portion of the mandible (the ramus). The two subclasses of B were quite different: Class B2 showed a distribution to the lower point of the ramus and Class B1 showed a much wider distribution, covering all the ramus and the interior part of the temple (see Figure 12).

Pain Class C:. The pain distribution of Class C differed from the other two classes in involving an anterior projection over the zygomatic arch. The two subclasses were again distinct: Class C1 showed a distribution confined to the temporomandibular joint and the zygomatic arch; Class C2 showed a much wider distribution spreading over the temple as well as covering the ramus (see Figure 12).

The final conclusion, after careful validation, was that the groups could be interpreted in terms of a chronological model of the development of TMJPDS. Other interesting applications of hierarchical classification methods are described in Murtagh [38], Duflou et al. [11], and Coste et al. [6].

Summary

The concept of the hierarchical representation of a data set applies most satisfactorily in biology and related disciplines. Although any cluster analysis exercise with biological data need not necessarily replicate the structure implicit in the traditional structure of Linnaean Taxonomy, i.e. species, genera, etc., there nevertheless remains a strong inclination amongst biologists for hierarchical classifications. When used in other areas, however, the justification for a hierarchical rather than a nonhierarchical structure may be less clear, and there is then the danger of imposing rather than discovering structure. Careful validation of solutions is a clear requirement in any clustering exercise. No particular hierarchical clustering technique can be recommended as likely to be "best" in most situations, although Everitt [13] gives some suggestions as to which methods might be more generally useful, on the basis of the results of a number of Monte Carlo studies.

BRIAN S. EVERITT

Cluster Analysis of Subjects, Nonhierarchical Methods

Cluster analysis is concerned with investigating a set of data to discover whether or not it consists of relatively distinct groups of observations. The groups are unknown a priori so that cluster analysis is distinguished from the activity of allocating individuals to one of a set of existing groups, an activity usually referred to as *assignment* or *discrimination* (*see* **Discriminant Analysis, Linear**).

Uncovering the group structure (if any) of a set of data is clearly of considerable importance in understanding the data and in using them to answer substantive subject matter questions. In medicine, for example, separating diseases that require different treatments will often be the primary goal of any classification exercise.

A very broad division of cluster analysis techniques is into those that produce *hierarchical classifications* (*see* **Cluster Analysis of Subjects, Hierarchical Methods**) and those where the groupings are not necessarily constrained in this way, the so-called *nonhierarchical* methods. This article is concerned with the latter.

Data

The raw data to be analyzed by cluster analysis methods usually consists of a set of p variable values for each of the n individuals to be clustered. Such data are commonly represented by an $n \times p$ matrix, $\mathbf{X}$, given by

$$\mathbf{X} = \begin{pmatrix} x_{11} & x_{12} & \dots & x_{1p} \\ x_{21} & x_{22} & \dots & x_{2p} \\ \vdots & \vdots & \vdots & \vdots \\ x_{n1} & x_{n2} & \dots & x_{np} \end{pmatrix}. \qquad (1)$$

When $p = 2$ simply plotting the data may provide, via the excellence of the eye–brain pattern recognition system, a simple method of "clustering". The three "clusters" in Figure 1, for example, are immediately apparent without the application of any formal method, or indeed, without making the meaning of the term "cluster" explicit.

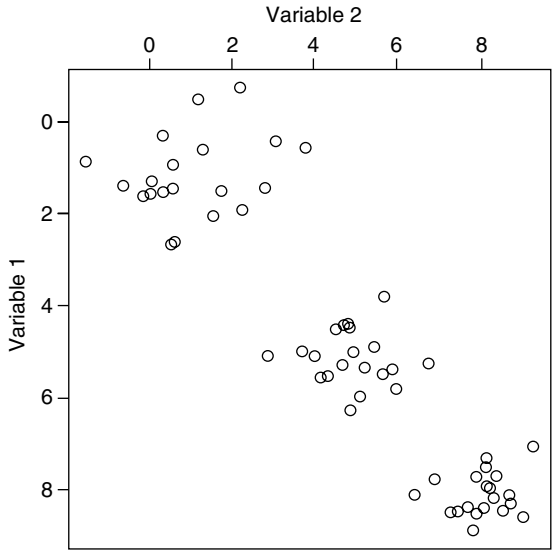

Figure 1 Data containing three distinct clusters

When $p > 3$ such a direct approach is not possible, but plots of the data in the space of the first two or three principal components may then be helpful (*see* **Principal Components Analysis**; **Multivariate Graphics**).

Optimization Methods

The cluster analysis methods described in this entry produce a partition of the individuals into a *particular* number of groups, by optimizing some numerical criterion. The basic idea behind these techniques is that associated with each partition of the n individuals into the required number of groups, g, is an index, $f(n, g)$, the value of which reflects how successful the partition is in describing the data. For some indices, partitions corresponding to high values are good and so the "best" partition is found by maximizing the index. For other indices, low values are sought and the search is for the partition with minimum value. Associating a numerical value with each partition allows competing partitions to be compared. Differences between the methods in this class arise both because of the different clustering indices that can be used, and the alternate **algorithms** which can be employed to optimize the selected index. In the next section a number of possible clustering indices

are described and in the following section the optimization problem is discussed. It will be assumed that the variables describing each individual are continuous, and that the spatial distribution of the individuals, represented as points in a p-dimensional space, can be meaningfully summarized by the location of the center of gravity of each cluster and by the sample scatter matrix of each cluster. (Clustering criteria suitable for binary and ordinal variables (*see* **Ordered Categorical Data**) are described in [23].)

A problem common to all the procedures to be described is that of selecting the most appropriate number of groups for a data set; some discussion and suggestions will be given later.

Clustering Indices

Many numerical indices for clustering have been suggested, but those most commonly used arise from consideration of three matrices, **T**, **B**, and **W**, which can be calculated from a partition of the data into g groups as follows:

$$\mathbf{T} = \frac{1}{n}\sum_{i=1}^{g}\sum_{j=1}^{n_i}(\mathbf{x}_{ij} - \bar{\mathbf{x}})(\mathbf{x}_{ij} - \bar{\mathbf{x}})',$$

$$\mathbf{W} = \frac{1}{n_g}\sum_{i=1}^{g}\sum_{j=1}^{n_i}(\mathbf{x}_{ij} - \bar{\mathbf{x}}_{ij})(\mathbf{x}_{ij} - \bar{\mathbf{x}}_{j})', \qquad (1)$$

$$\mathbf{B} = \sum_{i=1}^{g} n_i(\bar{\mathbf{x}}_i - \bar{\mathbf{x}})(\bar{\mathbf{x}}_i - \bar{\mathbf{x}})',$$

where $\mathbf{x}_{ij}$ represents the jth, p-dimensional observation in group i, $\bar{\mathbf{x}}_i$ is the mean vector of group i, $\bar{\mathbf{x}}$ is the mean vector of all the observations, and n_i is the number of observations in group i.

The $p \times p$ matrices defined above represent, respectively, total dispersion **T**, within-group dispersion **W**, and between-group dispersion **B**; they are related as follows:

$$\mathbf{T} = \mathbf{W} + \mathbf{B}. \qquad (2)$$

For $p = 1$ this equation represents a relationship between scalars, namely the division of the total sum of squares for a variable into the within- and between-group sum of squares familiar from one-way **analysis of variance**. Here a natural candidate for a clustering index is the within-group sum of squares, with a partition having minimum value being sought. Fisher [7] describes a procedure to find a partition into g groups for which the within-group sum of squares is minimized. For $p > 1$ the derivation of clustering criteria from (2) is not quite so clear-cut, and several possibilities have been suggested.

1. trace(**W**).

An obvious extension of the within-group sum of squares criterion when $p > 1$ is the sum of the separate within-group sum of squares for each variable, i.e. a partition minimizing trace(**W**) is looked for. [Minimizing trace(**W**) is equivalent to maximizing trace(**B**).] This criterion was suggested explicitly by Singleton & Kautz [22] and is also implicit in the clustering procedures described by Forgey [9], Jancey [13], MacQueen [16], and Ball & Hall [1].

Despite its popularity, the minimization of trace(**W**) approach to clustering suffers from a number of serious problems. One is that it is scale dependent so that different solutions may be obtained from the raw data than from the data standardized in some particular way. Since the question of the appropriate standardization in cluster analysis is a difficult one (see, for example, [8]), this lack of invariance can cause severe problems in practice.

A further problem with the use of this criterion is that it has a strong tendency to produce spherically shaped clusters, even when the natural clusters in the data are of other shapes – see [5] for an example. Consequently, its use may *impose* an artifactual structure on the data rather than uncover their true structure.

2. det(**W**).

In **multivariate analysis of variance** one of the tests for differences in population mean vectors is based on the ratio of the determinants of the within and total dispersion matrices (see [14]). Large values of det(**T**)/det(**W**) indicate a difference between the mean vectors. In a clustering context this implies that seeking a partition that maximizes the ratio of the two determinants would lead to clusters with widely separated mean vectors relative to their within-cluster dispersion. The maximization of det(**T**)/det(**W**) as a method of cluster analysis was first suggested by Friedman & Rubin [10].

Since, for all partitions of the n individuals into g groups, **T** remains the same, maximization of det(**T**)/det(**W**) is equivalent to minimizing det(**W**), the generalized variance of a set of multivariate data.

This particular criterion has been studied in some detail by Marriott [17, 18].

A major advantage of the det(**W**) criterion over the trace(**W**) criterion discussed earlier is that it is invariant under nonsingular linear transformations of the original data matrix. Consequently, problems with standardization do not arise. A further advantage of the det(**W**) criterion is that it does not restrict clusters to being "hyperfootballs", although it does assume that all the clusters have the same shape and orientation; Everitt [5] gives an example where the criterion can lead to the "wrong" clusters when this assumption does not hold.

3. trace($\mathbf{BW}^{-1}$).

A further criterion suggested by Friedman & Rubin [10] is the maximization of the matrix obtained from the product of the between-groups dispersion matrix and the inverse of the within-groups matrix. This function also appears in the context of multivariate analysis of variance (see [14]), and is equivalent to what Rao [20] calls the generalization of the **Mahalanobis distance** to more than two groups.

Both trace($\mathbf{BW}^{-1}$) and det(**T**)/det(**W**) may be expressed in terms of the **eigenvalues**, λ_i, of $\mathbf{BW}^{-1}$ as follows:

$$\text{trace}(\mathbf{BW}^{-1}) = \sum_{i=1}^{p} \lambda_i, \tag{3}$$

$$\frac{\det(\mathbf{T})}{\det(\mathbf{W})} = \prod_{i=1}^{p} (1 + \lambda_i). \tag{4}$$

For $g = 2$ partitions given by maximizing trace($\mathbf{BW}^{-1}$) and minimizing det(**W**) will be the same. In other cases the former procedure has a tendency to produce long thin clusters strung out along a single direction (see [10]).

Scott & Symons [21] and Banfield & Raftery [2] demonstrate how the clustering criteria described above arise from considering a likelihood approach to the clustering problem, an approach which also leads to a number of other possible indices for clustering. The probability model assumed is that the population of interest consists of g different subpopulations, and that the density of a p-dimensional observation $\mathbf{x}$ from the kth subpopulation is $f_k(\mathbf{x}; \boldsymbol{\theta})$ for some unknown vector of parameters $\boldsymbol{\theta}$. Given observations $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n$ and defining identifying labels $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_n)'$, where $\gamma_i = k$ if $\mathbf{x}_i$ comes from the kth subpopulation, the required likelihood function can be written as

$$L(\boldsymbol{\theta}; \boldsymbol{\gamma}) = \prod_{i=1}^{n} f_{\gamma_i}(\mathbf{x}_i; \boldsymbol{\theta}). \tag{5}$$

In the so-called *classification maximum likelihood procedure*, $\boldsymbol{\theta}$ and $\boldsymbol{\gamma}$ are chosen so as to maximize this likelihood.

When $f_k(\mathbf{x}; \boldsymbol{\theta})$ is a **multivariate normal** density with mean vector, $\boldsymbol{\mu}_k$, and covariance matrix, $\boldsymbol{\Sigma}_k$, then the likelihood in (5) becomes

$$L(\boldsymbol{\theta}, \boldsymbol{\gamma}) = \text{const} \prod_{k=1}^{g} \prod_{i \in E_k} |\boldsymbol{\Sigma}_k|^{-1/2} \times \exp\left[-\tfrac{1}{2}(\mathbf{x}_i - \boldsymbol{\mu}_k)' \boldsymbol{\Sigma}_k^{-1} (\mathbf{x}_i - \boldsymbol{\mu}_k)\right], \tag{6}$$

where $E_k = \{i; \gamma_i = k\}$ defines a particular partition of the data. Scott & Symons [21] and Banfield & Raftery [2] demonstrate the following:

1. If $\boldsymbol{\Sigma}_k = \sigma^2 \mathbf{I}, k = 1, \ldots, g$ then the likelihood is maximized by choosing $\boldsymbol{\gamma}$ to minimize trace(**W**). Consequently, this particular clustering criterion is essentially only suitable when the clusters in the data are spherical in shape and of approximately equal sizes (equal number of observations).
2. If $\boldsymbol{\Sigma}_k = \boldsymbol{\Sigma}, k = 1, \ldots, g$, then the likelihood is maximized by choosing $\boldsymbol{\gamma}$ to minimize det(**W**). Consequently, this clustering criterion is suitable only when the clusters have the same orientation and shape, although this is not constrained to being spherical.
3. When the $\boldsymbol{\Sigma}_k$ are not constrained in any way, the likelihood is maximized by choosing $\boldsymbol{\gamma}$ to minimize $\sum_{k=1}^{g} n_k \log[\det(\mathbf{W}_k / n_k)]$, where $\mathbf{W}_k$ is the sample cross-product matrix for the kth cluster. This particular criterion does not appear to have been used as a basis for cluster analysis, which Banfield & Raftery [2] suggest is due to its very generality and lack of parsimony.

Banfield & Raftery [2] use the classification likelihood formulation of the clustering problem as the basis for suggesting a number of other clustering criteria that allow some features of cluster distributions (orientation, size, and shape) to vary between clusters, while constraining others to be the same. The

key to this is a reparameterization of the covariance matrix $\mathbf{\Sigma}_k$ in terms of its eigenvalue decomposition

$$\mathbf{\Sigma}_k = \mathbf{D}_k \mathbf{\Lambda}_k \mathbf{D}_k', \tag{7}$$

where $\mathbf{D}_k$ is the matrix of **eigenvectors** and $\mathbf{\Lambda}_k$ is a diagonal matrix with the eigenvalues of $\mathbf{\Sigma}_k$ on the diagonal. The orientation of the principal components of $\mathbf{\Sigma}_k$ is determined by $\mathbf{D}_k$, while $\mathbf{\Lambda}_k$ specifies the size and shape of the density contours.

One example of Banfield & Raftery's approach leads to a generalization of the sum of squares criterion described previously, in which clusters, though still assumed spherical, are allowed to be of different sizes. The resulting criterion to be minimized is

$$\sum_{k=1}^{g} \log \left[\text{trace} \left(\frac{\mathbf{W}_k}{n_k} \right) \right]. \tag{8}$$

Other criteria allow cluster orientations to vary while keeping size and shape constant. All the suggested criteria can be implemented in the **S-PLUS** software available for applying this form of cluster analysis.

Banfield & Raftery [2] also consider the situation when the f_k are *not* multivariate normal and when there are "noise" points in the data that do not follow the general mixed distribution pattern.

Optimizing a Clustering Criterion

Once a suitable numerical clustering criterion has been selected, consideration needs to be given to how to choose the g group partition of the data which leads to its optimization. In theory, of course, the problem is simple, at least to "Dr. Idnozo Hcahscror-Tenib", that "super galactician hypermetrician" who featured in Thorndike's 1953 presidential address to the Psychometrika Society [24]: "Is easy. Finite number of combinations. Only 563 billion billion billion. Try all keep best."

Unfortunately, in practice the problem is not so straightforward since the number of partitions is enormously large and even with the fastest computers available, complete enumeration of *every* possible partition of n individuals into g groups is simply not possible. A general expression for the number of partitions, N, is given by Liu [15]:

$$N = \frac{1}{g!} \sum_{i=0}^{g} (-1)^{g-i} \binom{g}{i} i^n. \tag{9}$$

Table 1

n	g	N
15	3	2375101
20	4	45232115901
25	8	690223721118368580
100	5	10^{68}

Some specific examples are given in Table 1.

The impracticability of examining every possible partition has led to the development of algorithms designed to search for the optimum value of a clustering criterion by a nonexhaustive search procedure usually involving the rearrangement of an existing partition and keeping the new one *only* if it provides an improvement in the criterion value. Many such algorithms have been proposed, all differing in some more or less subtle ways; the *common* steps in the majority of these algorithms, however, are as follows:

1. Find some initial partition of the individuals into the required number of groups. Possible sources of such initial partitions are the solutions from a hierarchical clustering.
2. Calculate the change in the clustering criterion produced by moving each individual from its own to another cluster.
3. Make the change which leads to the greatest improvement in the value of the clustering criterion.
4. Repeat steps 2 and 3 until no move of a single individual causes the clustering criterion to improve.

Different initial partitions can lead to different *local* optima of the clustering criterion, although with well-structured data it is probably reasonable to expect convergence to the same, hopefully global, optimum from most starting configurations. Marriott [18] suggests that slow convergence and widely different partitions arising from different starting points may indicate that g has been wrongly chosen, in particular that there is no evidence of clustering.

Deciding on the "Best" Value for g

A variety of methods have been suggested for selecting the most appropriate number of clusters for a data set. The most commonly used procedure is simply to plot the value of the clustering criterion against the

number of groups and look for "large" changes of level, such changes perhaps being indicative of a particular number of groups. Clearly, such an approach may be very subjective.

More formal methods have been proposed by Beale [3], Calinski & Harabasz [4], Marriott [17], and Banfield & Raftery [2]. Marriott, for example, suggests taking the value of g for which $g^2 \det(\mathbf{W})$ is a minimum. For unimodel distributions, Marriott shows that this is likely to lead to accepting that $g = 1$, and for strongly grouped data it will indicate the appropriate value of g.

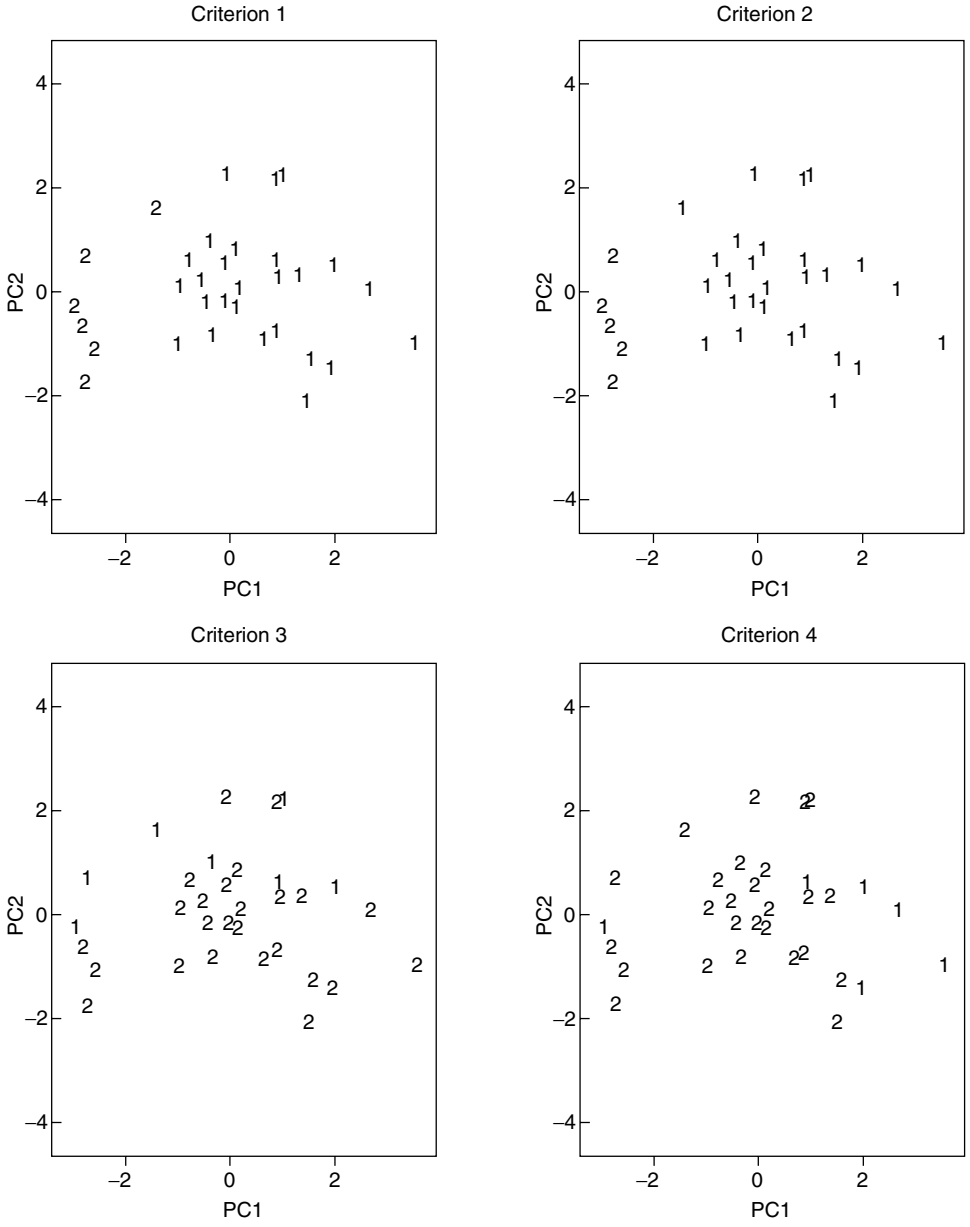

Figure 2 Two group cluster solutions of Tibetan skull data from four nonhierarchical clustering methods, displayed in the space of the first two principal components of the data

Banfield & Raftery [2] suggest an approximate **Bayesian** procedure for choosing the number of clusters and give a relatively crude estimate of $P(g|\mathbf{X})$. The maximum value of this estimate for different values of g could be used to estimate the number of clusters, although Banfield & Raftery recommend considering several values for g guided by the estimated posterior probabilities.

Some Applications of Nonhierarchical Cluster Analysis

Tibetan Skulls

Morant [19] describes data collected by Colonel L.A. Waddell on 32 skulls found in the south-western and eastern districts of Tibet (*see* **Anthropometry**). According to Morant the data can be divided into two groups. The first (type 1) comprises 17 skulls found in graves in Sikkim and neighboring areas of Tibet. The remaining 15 skulls (type 2) were picked up on a battlefield in the Lhasa district and were believed to be those of native soldiers from the eastern province of Khams. These skulls were of particular interest because it was thought at the time that Tibetans from Khams might be survivors of a particular fundamental human type, unrelated to the Mongolian and Indian types which surrounded them. On each skull the following five measurements (all in millimetres) were obtained:

x_1 : greatest length of skull
x_2 : greatest horizontal breadth of skull
x_3 : height of skull
x_4 : upper face height
x_5 : face breadth, between outermost points of cheek bones.

The data are reproduced in Hand et al. [11]. Here the a priori group structure will be ignored apart from comparing it with the two cluster solutions found from a number of optimization techniques described previously.

The clustering criteria used in this application were as follows:

1. minimization of trace($\mathbf{W}$)
2. minimization of $\sum_{k=1}^{g}, n_k \log[\text{trace}(\mathbf{W}_k/n_k)]$
3. minimization of det($\mathbf{W}$)
4. minimization of $\sum_{k=1}^{g} n_k \log[\det(\mathbf{W}_k/n_k)]$.

The resulting two group solutions found by each method are displayed graphically in Figure 2 by plotting them in the space of the first two principal components of the correlation matrix of the data. (These two components are the only ones with eigenvalues greater than one, and together they account for 60% of the variation in the data.) For comparison, the two groups as defined by Morant are shown, also in the space of the first two principal components, in Figure 3. Clearly, the four clustering solutions are considerably different from one another and each differs from the a priori grouping.

MRI Brain Scan

Banfield & Raftery [2] describe a fascinating application of optimization clustering methods to data collected from MRI scans of human brains. A randomly chosen set of 522 voxels (three-dimensional volume elements) were subjected to optimization clustering using a particular criterion (see original paper for details) and a seven-cluster solution

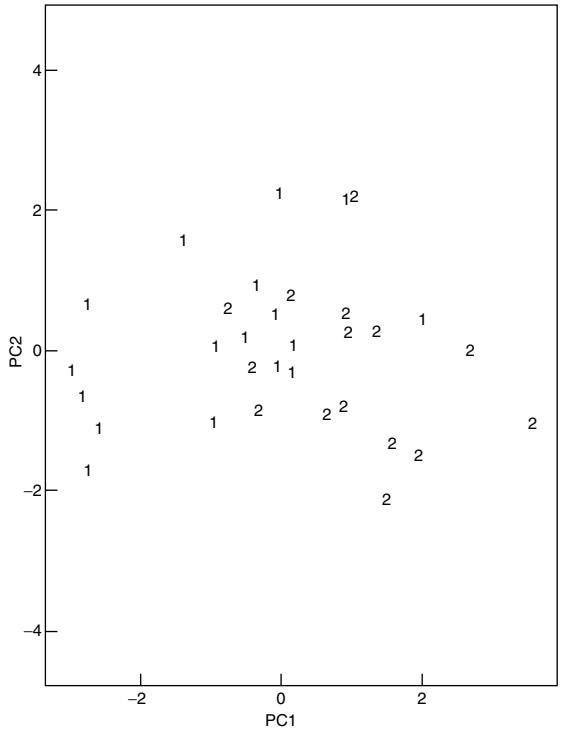

Figure 3 Original two groups in Tibetan skull data displayed in the space of the first two principal components of the data

was suggested by the Bayesian criterion mentioned earlier. The clusters were found to correspond to distinct anatomical structures. Simpler clustering techniques such as complete linkage and Ward's method (see [5]) tended to group together dissimilar anatomical voxels.

Other biostatistical applications of optimization clustering can be found in Everitt et al. [6] and Heinrich et al. [12].

Conclusions

Optimization clustering techniques produce a partition of a set of multivariate data into a particular number of groups by maximizing or minimizing some numerical index of clustering. Several such indices have been suggested, these differing in the implicit assumptions made about the shape of any clusters present. Many of the suggested criteria arise from considering a likelihood approach to the clustering problem.

Cluster Analysis, Variables

Cluster analysis is a process of clustering objects into groups where the groups (or clusters) are unknown a priori. Clusters are formed in such a way that objects in the same cluster are similar to each other, while members of different clusters are considerably different from each other. Similarity or dissimilarity of objects are often measured by some indices of association. These indices can be correlations, cosines, coefficients of agreement, covariances, Euclidean distances between standardized measures, **Mahalanobis generalized distances**, and other problem-oriented indices (*see* **Similarity, Dissimilarity, and Distance Measure**). The objects of clustering can be *subjects* or *variables*, but clustering subjects is probably more common than is clustering variables. For discussions on the cluster analysis of subjects, *see* **Cluster Analysis of Subjects, Hierarchical Methods** and **Cluster Analysis of Subjects, Nonhierarchical Methods**. In this article we consider techniques of performing *cluster analysis of variables*. The variables can be measurements, **ranks**, or dichotomies (*see* **Binary Data**).

Cluster analysis of variables can be applied to a wide range of problems in different fields. Popular applications relate to the construction of scorable subsets (*see* **Principal Components Analysis**; **Cluster Score**) and **battery reduction**. Most of the procedures and **algorithms** discussed in the cluster analysis of subjects can be applied to the cluster analysis of variables with the appropriate index of association, where the objects for clustering are now variables rather than subjects. Here we discuss only the type of methods that cluster variables on the basis of the **correlation** structure of the variables or on the factorial structures of the variables. Factorial structure means a structure obtained from a **factor analysis** or **principal component analysis**. Examples will be provided to demonstrate how to perform some of the techniques. The reader should note that cluster analysis of variables can differ from factor analysis even though they both examine the common factor structure of the variables. In factor analysis we are concerned with the underlying dimension of the data and in identifying latent factors that measure the dimension. In cluster analysis we desire to group variables together, often to produce sets from which cluster scores can be produced. These subsets may contain only part of the set of variables associated with a factor.

An Intuitive Approach

A simple intuitive approach to cluster analysis uses the results of a factor analysis or a principal component analysis by forming clusters of variables that have high loadings on the same factor. **Factor loadings** are the elements of the final factor matrix and they represent the correlations between the variables and the factors. We can use these loadings as indices of association for measuring the similarity or dissimilarity of the variables in question (*see* **Principal Components Analysis**; **Factor Analysis, Overview**, for procedures to obtain the final factor matrix).

Example

To illustrate this intuitive approach, we selected seven variables from the **Framingham** offspring data. These variables are the systolic blood pressure (SPF), diastolic blood pressure (DPF), height (HGT), total volume capacity (TVC), triglycerides (TG), total cholesterol (SCL), and high density lipoprotein cholesterol (HDL). These variables are selected solely for the purpose of illustration and not for substantive interpretation. There is a total of 2370 nondiabetic males included in the analysis. A factor analysis with **varimax rotation** was performed on this data. Three factors were retained. The initial factor matrix as well as the final rotated factor matrix are presented in Table 1. In this example we use the factor matrix from a factor analysis. In practice, we could also perform a principal components analysis and also we could use other types of rotation. Comparisons between a factor analysis and a principal components analysis can be found in the articles on **Principal Components Analysis** and **Factor Analysis, Overview**.

Using the rule of thumb of Cureton & D'Agostino [1] we use 0.3 as the minimum threshold for considering a loading "significant" and so also for putting a variable into a cluster. With a 0.3 threshold, three disjoint clusters are formed: (i) SPF and DPF (with their first factor loadings equal to 0.867 and 0.866); (ii) HGT and TVC (with their second factor

Table 1 Initial and rotated factor matrices

	Initial factor matrix		
Variable	*a*	*b*	*c*
SPF	0.815	0.236	−0.194
DPF	0.833	0.242	−0.125
HGT	−0.126	0.626	0.194
TVC	−0.309	0.599	0.123
TG	0.396	−0.146	0.497
SCL	0.391	−0.187	0.251
HDL	0.069	0.002	0.421

	Rotated factor matrix[a]		
Variable	*a*	*b*	*c*
SPF	0.867	−0.047	0.067
DPF	0.866	−0.028	0.136
HGT	0.043	0.665	0.030
TVC	−0.111	0.669	−0.095
TG	0.168	−0.107	0.621
SCL	0.218	−0.209	0.399
HDL	−0.055	0.096	0.412

[a]Varimax rotation.

loadings equal to 0.665 and 0.669); and (iii) TG, SCL, and HDL (with their third factor loadings equal to 0.621, 0.399, and 0.412). We do not always obtain disjoint clusters as presented in this example although this is usually considered ideal. It is possible to obtain clusters with overlapping variables.

One available **software** package in SAS, PROC VARCLUS, always produces clusters with nonoverlapping elements [8]. This is an oblique component analysis related to multiple group factor analysis. Standardized scoring coefficients are provided for the computations of cluster scores.

Graphical Cluster Analysis of Variables

Tryon [9] proposed finding clusters of variables on the basis of the profiles of the correlations of the variables. He suggested plotting each row of the correlation matrix, having the variable number on the abscissa and the numerical value of the correlation coefficient on the ordinate. We denote the correlation coefficient by r_{ij}, where $i, j = 1, \ldots, p$ and p is the number of the original variables. Each row of points (i.e. $r_{i1}, r_{i2}, \ldots, r_{ip}$) is connected by a jagged line, leaving a gap at r_{ii}. A cluster is then identified by the subset of *approximately parallel proportional* profiles. An example of a correlation profile plot is given in Figure 1. These are the correlations for the seven variables of the Framingham offspring data. The correlation matrix is displayed in Table 2.

From Figure 1, SPF and DPF can be seen to have high correlations with each other and their profiles are very close throughout. Thus, they form a cluster. HGT and TVC are moderately correlated with each other and they exhibit approximately parallel proportional profiles across the plot. It seems reasonable to group them in one cluster. TG and SCL have some correlations with each other and they have very similar correlation patterns with other variables except with HDL. Based on the general profiles, we can put them in a cluster. The profile of HDL does not show any resemblance to the profiles of any other variables, therefore it forms a cluster by itself. We sometimes call a variable in such a cluster an *outlier*. On the basis of this plot, we may conclude that there are four clusters: (i) SPF-DPF, (ii) HGT-TVC, (iii) TG-SCL, and (iv) HDL. In practice, it is not easy to identify the subsets of profiles because these profiles often exhibit similar shape but different height, and the gaps at the r_{ii}s make the profiles quite difficult to follow.

Table 2 Correlation matrix

Variable	SPF	DPF	HGT	TVC	TG	SCL	HDL
SPF	1.000	0.829	0.011	−0.146	0.197	0.205	−0.026
DPF	0.829	1.000	0.036	−0.141	0.228	0.250	0.018
HGT	0.011	0.036	1.000	0.558	−0.042	−0.097	0.084
TVC	−0.146	−0.141	0.558	1.000	−0.154	−0.196	0.006
TG	0.197	0.228	−0.042	−0.154	1.000	0.404	0.335
SCL	0.205	0.250	−0.097	−0.196	0.404	1.000	0.013
HDL	−0.026	0.018	0.084	0.006	0.335	0.013	1.000

Note: The matrix is computed from Framingham offspring data.

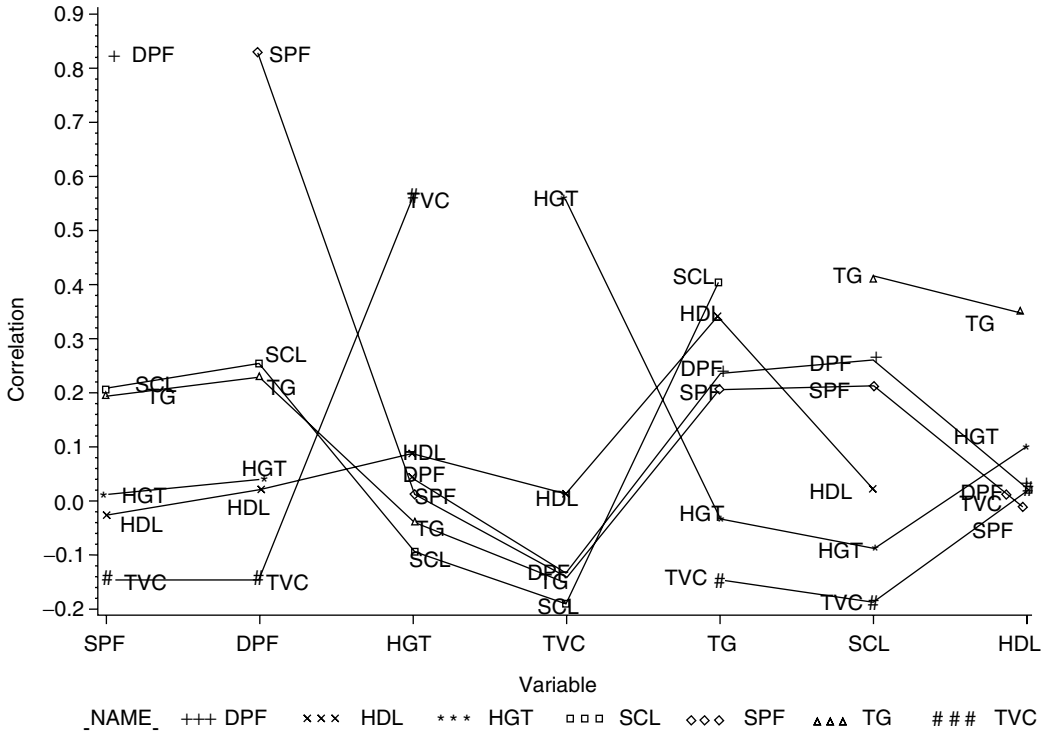

Figure 1 Graphical cluster analysis (correlation profiles), Framingham offspring data (nondiabetic men)

Cureton & D'Agostino [1] present another graphical method based on the profiles of the factorial structures of the variables which usually avoids some of the difficulties in Tryon's procedure. Using their approach, we first compute a row-normalized varimax factor matrix (see [5] and [1]) or a weighted-varimax factor matrix (see [2]). If these varimax factor matrices are not available, then a Landahl transformation to the row-normalized initial factor matrix can be used instead (see [6]). Then we plot each row of this transformed matrix, having the factor number (i.e. 1 to m) on the abscissa and the numerical value of the factor loadings on the ordinate. An example is given in Table 3 to illustrate the step-by-step computations of this Landahl transformed initial factor matrix. The advantages of using the profiles from a transformed row-normalized initial factor matrix over the profiles from a correlation matrix are twofold: (i) this transformed initial factor matrix provides the same information contained in the correlation matrix but there are only m points to plot for each variable instead of $p - 1$ and no gaps are left in the profiles, and (ii) in this factor matrix plot, the profiles belonging to the same cluster exhibit about the same average shape and height, so it is easier to visualize subsets of variables that belong to the same cluster. Sometimes, we may add the profiles of the primary axes (*see* **Primary Factors**). We should try to avoid breaking up the variables that have profiles close to those of the primary axes. If we are not sure about some of the subsets, then we can always quantify the association of the profiles by computing the cosines of angle between each pair of the row-normalized initial factor matrix vectors (*see* **Cosine of Angle Between Two Vectors**; **Matrix Algebra**). The complete cosine matrix, denoted by **K**, is of dimension $p \times p$. It is obtained by postmultiplying the row-normalized initial factor matrix by its transpose. Two variables presumed to lie in the same cluster should have a high cosine value. These cosines are derived as an index of association for the profiles of variables. They can be used to determine numerically the compactness of a cluster. We can also set an acceptance level to control the level of compactness we wish for a cluster. A

variable is accepted as a member of a cluster only if its cosine with the existing members of the cluster is higher than the acceptance level. When an acceptance level is used in the analysis, one should be aware that the choice for this threshold is often arbitrary, but the level we choose may affect the composition of the clusters. An acceptance level that is too high may create many outliers and also result in too many small clusters. But when the acceptance level is too low, the analysis tends to form large clusters with heterogeneous elements in them. Therefore, in practice we should try different acceptance levels to see which result gives the most sensible interpretation.

For illustration we use again the seven variables from the Framingham offspring data. We first perform a factor analysis, and decide to retain three

factors. Table 3 presents the computations of the transformation. A SAS macro [4] is available to perform all these calculations and plot the profile, as shown in Figure 2. In this example a varimax rotation is applied to the primary axes. In practice, we can also employ other types of **orthogonal rotation** or **oblique rotation** (*see* **Rotation of Axes**). A different rotation may produce a different set of primary axes.

In Figure 2, SPF and DPF are close together on each of the three factors so they form a cluster of two variables. HGT and TVC are close together on the scale for factor 3 but moderately apart on the scales for factors 1 and 2. We tentatively put them into the same cluster. TG, SCL, and HDL are close together for factor 1. HDL begins to drift slightly downwards from TG and SCL for factor 2 and then all three variables drift farther apart from each other for factor 3. So, we tentatively call them a cluster. The next step is to check the primary axes. The profile of the primary axis, A, is fairly close to the SPF–DPF cluster and the profile of the primary axis, B, is wholly contained within the HGT–TVC cluster. The profile of the primary axis, C, is close to the TG–SCL–HDL cluster for factor 1 but it moves away from HDL for factor 2. For factor 3, all these variables and the primary axis, C, are lying apart from each other. To verify the tentative clusters, we compute the cosines of angles between each pair of the normalized initial factor matrix vectors. An example of the cosine matrix is provided in Table 4, which is computed from the row-normalized initial factor matrix given in Table 3.

SPF and DPF are a compact cluster with a cosine of 0.997. HGT and TVC are reasonably compact with a cosine of 0.957. As reflected in Figure 2, TG, SCL, and HDL are not quite compact. TG and SCL have a cosine of 0.940, TG and HDL have a cosine of 0.849, while SCL and HDL have a cosine of 0.620. From this graphic cluster analysis we may conclude that SPF–DPF, HGT–TVC, and TG–SCL–HDL are three distinct clusters if no acceptance level is used. But if we use, for example, 0.9 as the acceptance level, then we need to break the last cluster into two smaller clusters and HDL will become an outlier and form a cluster by itself. We obtain the same clustering results for using acceptance levels 0.7 and 0.8. We can see that this clustering is consistent with the result given in the correlation profile.

Elementary Linkage Analysis

The elementary linkage analysis is a crude but simple numerical method that can be applied in the cluster analysis of variables. This method was first described in McQuitty [7] and later modified by Cureton & D'Agostino [1]. Elementary linkage analysis is equivalent to performing a **single linkage** analysis (*see* **Cluster Analysis of Subjects, Hierarchical Methods**) using the cosine of angle between two vectors as the index of association. We start by underlining the highest cosine in each column of **K**, the complete cosine matrix. The general rule is that a variable, V_1, belongs in the same cluster with another variable, V_2, if V_1 has the highest cosine with V_2. If V_1 and V_2 have the same highest cosine with each other, then they are called a *reciprocal pair*. The cluster that is formed by the reciprocal pair is called a *nuclear cluster*, which we should avoid breaking. After finding the nuclear clusters, we look along the row of each member of the nuclear cluster to see if there is other underlined cosine on the row. If there is, then the member of the pair is said to bring in a new member. We continue to check the other members of the cluster and locate any "bring-in" members. If no further underlined cosines are found in all the current members of the cluster, then the cluster is complete. When all the clusters are complete, the standard elementary linkage analysis is done. Again, we can form compact clusters in this analysis by specifying an acceptance level. Using an acceptance level in this analysis, a variable can become an *intrinsic outlier*. It is a variable which has the highest cosine in a column of the cosine matrix but the value is below the acceptance level. A variable can also become a forced outlier if its cosine with one of the existing members of the cluster is below the acceptance level. There is no specified rule on how to handle these outliers in the analysis. It relies on the judgment of the investigator.

Recall the cosine matrix given in Table 4 and underline the highest cosine in each column. According to the definition, SPF–DPF, HGT–TVC, and TG–SCL are the reciprocal pairs and they form three distinct nuclear clusters. These clusters can be represented as follows:

$$\text{SPF} \overset{0.997}{\longleftrightarrow} \text{DPF HGT} \overset{0.957}{\longleftrightarrow} \text{TVC TG} \overset{0.997}{\longleftrightarrow} \text{SCL}$$

The next step is to locate other potential members for each nuclear cluster by checking other underlined cosines along the rows. We can see that TG brings in HDL to the TG–SCL cluster and the relationship is graphically presented as follows:

$$\begin{array}{c} \text{TG} \overset{0.941}{\longleftrightarrow} \text{SCL} \\ \downarrow 0.867 \\ \text{HDL} \end{array}$$

There are no other underlined cosines, so all the clusters are complete and so is the analysis. Of course, if we want to form compact clusters with an acceptance level, say 0.9, then HDL will become a forced outlier and form a cluster by itself. These results are consistent with the results found in the graphical cluster analyses.

Cycle Hunt Analysis

Cureton et al. [3] proposed a more complex system of clustering called a cycle hunt analysis. This analysis consists of two stages: cycle hunt and cycle change. Before we start the cycle hunt stage, we need to set an acceptance level. If the objective of the study is to form clusters from subsets of variables, then we

will also need an exclusion level. An exclusion level is the lowest acceptable **communality** for a variable to be included in a cluster. The communalities are computed from the initial factor matrix before its rows are normalized. We then compute the complete cosine matrix, **K**, as previously defined and delete from **K** the row and column corresponding to each variable whose cosine is below the acceptance level, and also whose communality is below the exclusion level. Then this reduced **K** matrix is used in the rest of the analysis.

The cycle hunt stage forms clusters by performing either one of the three operations: (i) combining two variables, neither of which belongs to any existing cluster; (ii) adding to an existing cluster a variable not previously in any cluster; and (iii) combining two clusters to form a larger cluster. At each step we perform the operation that will leave the lowest within-cluster cosine highest and make sure the cosines between pairs of variables in the clusters are above the acceptance level. At this stage, once a variable is assigned to a cluster, it stays with that cluster for the whole cycle. The cycle hunt terminates when no further operations of type (i) or (ii) can be done without the lowest cosine going beyond the acceptance level.

The cycle change stage starts after the cycle hunt is completed. This second stage is divided into two subcycles. In subcycle 1, we start arbitrarily with a variable, say V. For each cluster, including the one V is in, we find the variable with which V has the lowest cosine. Among all these lowest cosines we find the particular variable, say W, whose lowest cosine with V is the highest. Then, V will join the cluster of W. If V is a forced outlier itself, then we need to make sure that the lowest cosine is above the acceptance level. After the reassignment of V, we proceed to the next variable and repeat the same procedure. When all the variables are considered, we return to the first variable, V, and repeat the entire procedure. Subcycle 1 terminates when there are no changes made throughout the entire procedure. In subcycle 2 we compute the lowest within-cluster cosine that results from combining each pair of clusters. We make sure that the cosine is above the acceptance level, and combine the one pair whose lowest cosine is the highest. We then repeat subcycles 1 and 2 in sequence until, at subcycle 2, no two clusters can be combined without producing a within-cluster cosine below the acceptance level. At this point the cycle change terminates and the cycle hunt analysis is complete. Cureton & D'Agostino [1] suggested that, in practice, we should repeat the cycle hunt analysis using several different acceptance levels but the same exclusion level, if any. We then choose as the final result the one with the highest acceptance level that gives a "sensible" result.

A SAS macro [4] is available to perform this complex algorithm of clustering. Despite its complexity, the cycle hunt system does offer some advantages over the graphical cluster analysis and the elementary linkage analysis. It can handle large numbers of variables. Unlike the elementary linkage analysis the cycle hunt analysis considers not only the indices of association for variables that belong to the same cluster, but also the indices of association for variables that are in different clusters. The associations of the outliers with other variables also get examined.

We now revisit the example based on the Framingham offspring data. We apply the cycle hunt macro in [4] to perform a cluster analysis on the seven variables. Taking advice from Cureton & D'Agostino [1], we repeat the analysis using 0.9, 0.8, 0.7, 0.6, and 0.5 as the acceptance levels. No exclusion level is used in this example. All the analyses except the one using 0.5 as the acceptance level lead to the same clustering: SPF and DPF belong to one cluster; HGT and TVC form another cluster; TG and SCL form the third; and HDL is not included in any cluster. This result is consistent with the results obtained from both the graphical cluster analysis and the elementary linkage analysis using an acceptance level.

Conclusions

The factor matrix, correlation matrix, and cosine matrix are the major indices of association used in the above clustering methods. When the method is based on a factor matrix obtained from a factor analysis, the contributions of the common factors are emphasized in clustering the variables. But there are other alternatives on which we can base the cluster analysis. If we are interested in including the contributions of the unique factors, then we can form the cosine matrix from a component matrix. If we wish to include the specific factors as well as the common factors, but not the error factors, then we can start a cluster analysis from a correlation matrix with reliability coefficients on the diagonal (see the discussions on reliability coefficients in [1, p. 365]).

To summarize, it is clear that each method described above has its own advantages and disadvantages. For the intuitive approach, all we need is a final rotated factor matrix, which is easily obtained from most of the statistical packages. No extra computations are required. However, in practice it is not easy to interpret the final matrix and form clusters that make sense. The VARCLUS procedure produces logical groupings on the basis of various maximization criteria. It is a numerical procedure that does not need subjective input to obtain the clusters. However, to achieve its goal of producing disjoint clusters from a set of variables, the procedure sometimes forces variables to join exactly one cluster, even though the variables may not belong to one cluster exclusively. The graphical method provides an effective means of presenting the somewhat complicated concept of the factorial structure of the variables. Many find it easier to understand a pictorial representation than a display of numbers. However, when there are a large number of unreliable variables involved in the plot, the display of the structure can become confusing. The elementary linkage method is a simple numerical procedure. Reciprocal pairs are used as its basic building block for clusters. The cluster-forming process is rather crude. Some important associations among variables other than reciprocal pairs are not vigorously explored. The cycle hunt analysis remedies some of the weaknesses of the simpler methods. It is able to handle large numbers of variables and it is a more formal technique for finding the subsets of variables. But this system involves a complex algorithm and it is very computer-intensive. Also, the analysis requires the use of an acceptable level while there is no formal rule to decide what level should be used. In a nutshell, there is obviously no one best clustering method. In practice, we recommend applying different methods to the same data and interpreting the clusters carefully to obtain a "sensible" solution. We also recommend repeating the analyses with different acceptance levels, especially when there are large numbers of unreliable variables.

Cluster Randomization

A cluster randomization trial is one in which intact social units, or clusters of individuals, rather than individuals themselves, are randomized to different intervention groups. Trials randomizing clusters, sometimes called **group randomization** trials, have become particularly widespread in the evaluation of nontherapeutic interventions, including lifestyle modification, educational programs and innovations in the provision of health care. The units of randomization in such studies are diverse, ranging from relatively small clusters, such as households or families, to entire neighborhoods or communities, but also including worksites, hospital wards, classrooms and medical practices. There are also reports of trials that have randomized more unusual units, including athletic teams [76], tribes [34], religious institutions [48] and sex establishments [28].

Proper accounting for the clustering of subjects' responses within the units of randomization is a key challenge faced by investigators adopting this design. We begin by describing how such clustering arises and how it reduces the efficiency of cluster randomization relative to individually randomized trials. A brief historical discussion of cluster randomization is then provided, followed by a discussion of ethical issues. More technical material that deals with the impact of cluster randomization on trial methodology, including the selection of a study design, sample size estimation and data analysis, is presented in the next few sections. We conclude by providing some guidelines for trial reporting. The reader interested in a more detailed discussion might wish to consult [20] from which this article was abstracted.

The Impact of Clustering

The degree of similarity among responses within a cluster is typically measured by a parameter known as the intracluster (intraclass) correlation coefficient. Denoted by the Greek letter ρ, this parameter may be interpreted as the standard Pearson correlation coefficient between any two responses in the same cluster. Stating that ρ is positive is equivalent to assuming that the variation between observations in different clusters exceeds the variation within clusters. Under these conditions, we may say that the design is characterized by "between-cluster variation".

The underlying reasons for variation between clusters will differ from trial to trial, but in practice may include the following.

1. Subject selection, where individuals are in a position to choose the cluster to which they belong. For example, in a trial randomizing medical practices, the characteristics of patients belonging to a practice could be related to age or sex differences among physicians. To the extent that these characteristics are also related to patient response, a clustering effect will be induced within practices.
2. The influence of covariates at the cluster level, where all individuals in a cluster are affected in a similar manner as a result of sharing exposure to a common environment. For example, infection rates in nurseries may vary owing to differences in temperature or other environmental conditions, while differences in bylaws between communities could influence the success of smoking cessation programs. Furthermore, when intact families or households are randomized, the combined effect of both environmental and genetic factors will contribute to the observed between-cluster variation.
3. The tendency of infectious diseases to spread more rapidly within than among families or communities. The possibility of outbreaks or epidemics in some clusters, the method by which the infectious agent is spread and its virulence will also affect the degree of between-cluster variation in rates of disease.
4. The effect of personal interactions among cluster members who receive the same intervention. For example, educational strategies provided in a group setting could lead to a sharing of information that create a clustering effect. More generally, as noted by Koepsell [45], just as infectious agents can be spread from person to person, the transmission of attitudes, norms and behaviors among people who are in regular contact can result in similar responses.

Without extensive empirical data, it is usually impossible to distinguish among the potential reasons for between-cluster variation. Regardless of the specific cause, however, such variation invariably leads to a reduction in precision in estimating the effect of intervention, where the size of the reduction increases

with both the magnitude of ρ and the average cluster size.

These effects of clustering may be expressed quantitatively in a fairly simple fashion. Consider an experimental trial in which k clusters of m individuals are randomly assigned to each of an experimental group and a control group. We suppose that the primary aim of the trial is to compare the groups with respect to their mean values on a normally distributed response variable Y having a common but unknown variance σ^2. Estimates of the population means μ_1 and μ_2 are given by the usual sample means $\overline{Y}_1$ and $\overline{Y}_2$ for the experimental and control groups, respectively. From a well-known result in cluster sampling (e.g. Kish [43, Chapter 5]), the variance of each of these means is given by

$$\text{var}(\overline{Y}_i) = \frac{\sigma^2}{km}[1 + (m-1)\rho], \quad i = 1, 2, \qquad (1)$$

where ρ is the intracluster correlation coefficient. If σ^2 is replaced by $P(1-P)$, where P denotes the probability of a success, then (1) also provides an expression for the variance of a sample proportion under clustering.

The intracluster correlation coefficient ρ may be interpreted as the proportion of overall variation in response that can be accounted for by the between-cluster variation. With this interpretation, we may write

$$\rho = \frac{\sigma_A^2}{\sigma_A^2 + \sigma_W^2} \qquad (2)$$

where σ_A^2 is the between-cluster component of variance, σ_W^2 the within-cluster component, and $\sigma^2 = \sigma_A^2 + \sigma_W^2$. A sample estimate of ρ may be obtained using a standard one-way analysis of variance among and within clusters (e.g. Armitage & Berry [2, Section 8.7]).

For **sample size determination**, (1) implies that the usual estimate of the required number of individuals in each group should be multiplied by the variance inflation factor $IF = 1 + (m-1)\rho$ to provide the same statistical power as would be obtained by randomizing km individuals to each group when there is no clustering effect. This expression is also well known in the sample survey literature, in which it is referred to as a "design effect" [43, p. 162]. The special case $\rho = 0$ corresponds to that of statistical independence among members of a cluster. The case $\rho = 1$, on the other hand, corresponds to total dependence. In this case all responses in a cluster are identical, so that the total information supplied by the cluster is no more than that supplied by a single member, i.e. the "effective cluster size" is one. In general, the effective cluster size is given by the simple formula $m/[1 + (m-1)\rho]$.

Given this loss of efficiency relative to individual randomization, the reasons for adopting cluster randomization must clearly rest on other considerations. Basic feasibility considerations were cited by Bass et al. [4] in their choice of a cluster randomized design for evaluating a program to enhance the effectiveness of hypertension screening and management in general practice. It was recognized that such a program would not function effectively if some patients in a practice but not others were entered into it. Randomization at the practice level also enhanced physician **compliance** by avoiding the potential ethical challenges that could arise when not all patients in a practice are offered a new intervention. Finally, randomization at this level also avoids the contamination that could occur when knowledge of the experimental intervention influences the responses of subjects in the control group.

Investigator concerns regarding the possibility of contamination may be particularly acute in trials of infectious diseases where the aim of the study is to reduce the transmission of infection. Individual randomization might prove impractical in such trials because the dynamics of transmission might lead subjects who do not receive the intervention to nevertheless receive protection as a consequence of herd immunity [14, 38].

In some studies randomization by cluster is the only natural choice or a clear necessity, with no special justification required. This was arguably the case in the HIV prevention trial described by Grosskurth et al. [36]. As the authors note, randomization was necessary at the community level since the intervention involved the provision of improved services at designated health facilities, with these services available to the entire population served by each facility.

Historical Development of Cluster Randomization

The British **Medical Research Council's** 1946 study of streptomycin for the treatment of tuberculosis is generally considered to be the first publication

of a clinical trial with a properly randomized control group [54, 60, pp. 17–18]. The success of the streptomycin trial in instilling the virtues of random assignment among clinical researchers was at first quite modest. For example, none of the 29 trials reported in the *New England Journal of Medicine* in 1953 used randomized controls [11]. In spite of a fairly steady and dramatic increase, only 50% of clinical trials published in the late 1970s could claim to have employed **randomization**. There are also very few examples of properly designed and analyzed cluster randomization trials conducted by health care researchers prior to 1978.

However, there were several notable cluster randomization trials conducted by epidemiologists interested in evaluating methods for preventing tuberculosis (e.g. [26]). These investigators randomized 433 groups of hospital wards in double-blind fashion (*see* **Blinding or Masking**) to either an experimental or placebo control group. The test of intervention effect was adjusted for clustering by adapting a method described by Cochran [12] for the analysis of sample survey data.

The statistical features of cluster randomization were first brought to wide attention in the health research community by Cornfield [15]. His paper made it clear that such allocation schemes are less efficient, in a statistical sense, than designs that randomize individuals to intervention groups. This general result, however, was recognized much earlier in the statistical literature (see [75]).

The 1980s saw a dramatic increase in the development of methods for analyzing correlated outcome data in general (e.g. [3] and [77]) and methods for the design and analysis of cluster randomized trials in particular (e.g. [21] and [32]). As might be expected, publication of this work did not immediately translate into any marked improvement in the methodological quality of cluster randomized trials. The difficulties investigators continued to experience with the design and analysis of cluster randomization trials were demonstrated in several methodological reviews (e.g. [22], [70] and [71]). Similar results were reported in each of these reviews, with less than 25% of the studies considered accounting for between-cluster variation when determining trial power. The situation was somewhat improved with respect to data analysis, where the effects of clustering were seen to be accounted for by at least 50% of the trials considered in each review. It is reasonable to expect further improvements in the methodological quality of cluster randomization trials as appropriate methods of analysis and reporting are gradually being incorporated into standard checklists for reporting randomized controlled trials (e.g. [5]).

The Role of Informed Consent

Every randomized trial requires assurance that the proposed study meets commonly accepted ethical standards. This task is particularly complex for cluster randomization trials since almost all ethical guidelines have been written from the sole perspective of trials that randomize individuals. Only recently has attention been given to the unique ethical challenges posed by cluster randomization (e.g. [24] and [33]) (*see* **Medical Ethics and Statistics**).

For instance, according to the World Medical Association Declaration of Helsinki (World Medical Association [79]) consent must be obtained from each patient prior to random assignment. The situation is more complicated for cluster randomization trials particularly when randomizing larger units (e.g. schools, communities, worksites). Then school principals, community leaders or other key decision-makers will usually provide permission for both random assignment and implementation of the intervention. Individual study subjects must still be free to withhold their participation, although they may not even then be able to avoid completely the inherent risks of an intervention that is applied on a cluster-wide level.

The identification of individuals mandated to provide agreement for random assignment may not be a simple task. Typically it is elected or appointed officials who make such decisions. However, as Strasser et al. [73] point out, it is by no means certain when or even if securing the agreement of these officials is sufficient.

The practical difficulties of securing informed consent prior to random assignment do not necessarily arise when smaller clusters such as households or families are the unit of randomization. For instance, Payment et al. [59] evaluated the risk of gastrointestinal disease in households randomly assigned to receive domestic water filters as compared with households using tap water. One of the eligibility criteria was “willingness to participate in a longitudinal trial in which a random half of the households would have a filter installed”.

The relative absence of ethical guidelines for cluster randomized trials appears to have created a research environment in which the choice of randomization unit may determine whether or not informed consent is deemed necessary prior to random assignment. This phenomenon can be seen, for example, in the several published trials of vitamin A supplementation on childhood mortality. Informed consent was obtained from mothers prior to assigning children to either vitamin A or placebo in the household randomization trial reported by Herrera et al. [39]. This was not the case in the community intervention trial of vitamin A reported by the Ghana VAST Study Team [31], where consent to participate was obtained only after random assignment. It seems questionable, on both an ethical and methodological level, whether the unit of randomization should play such a critical role in deciding whether or not informed consent is required.

Selecting an Experimental Design

There are three designs that are most frequently adopted in cluster randomization trials:

1. completely randomized, involving no pre-stratification or matching of clusters according to baseline characteristics;
2. matched-pair, in which one of two clusters in a stratum are randomly assigned to each intervention;
3. stratified, involving the assignment of two or more clusters to at least some combinations of stratum and intervention.

An interesting example of the completely randomized design is given by the ACEH study, as reported by Abdeljaber et al. [1]. This trial was designed to evaluate the effectiveness of vitamin A supplementation on the one-year prevalence of cough, fever and diarrhea among Indonesian children. The completely randomized design was very appropriate for the ACEH trial since there were over 200 villages assigned to each of the experimental and control groups.

Matching or stratification is often considered for community intervention trials in which the numbers of clusters that can be enrolled may be limited by economic or practical considerations. The main advantage of this design is its potential to provide very tight and explicit balancing of important prognostic factors, thereby improving the power for detecting the effect of intervention. An illustrative example is the COMMIT trial which was designed to promote smoking cessation using a variety of community resources [13]. This trial involved 11 pairs of communities matched on the basis of community size, population density, demographic profile, community structure and geographic proximity.

In spite of its obvious potential for creating comparable groups of subjects, there are some important analytic limitations associated with the matched-pair design. These limitations arise because of the inherent feature of this design that there is exactly one cluster assigned to each combination of intervention and stratum. As a result, the natural variation in response between clusters in a matched pair is totally confounded with the effect of intervention. Thus it is impossible to obtain a valid estimate of ρ without making special assumptions (e.g. the intervention has no effect). This difficulty, which complicates both sample size determination and data analysis, is explored further by Klar & Donner [44].

The stratified design is an extension of the matched-pair design in which several clusters, rather than just one, are randomly assigned within strata to each of the intervention and control groups. An example of this design is provided by CATCH [52]. In this study the unit of randomization was the elementary school, while the strata consisted of four cities in the US with 24 schools randomly assigned to the experimental or control group within each city.

The stratified design has been used much less frequently than either the matched-pair or completely randomized design. However, for many studies it would seem to represent a sensible compromise between these two designs in that it provides at least some baseline control on factors thought to be related to outcome, while easing the practical difficulties of finding appropriate pair-matches and avoiding the special analytic challenges raised by the matched-pair design.

Sample Size Estimation

A quantitatively justified sample size calculation is almost universally regarded as a fundamental design feature of a properly controlled clinical trial. Yet, as noted above, methodologic reviews of cluster randomization trials have consistently shown that only

a small proportion of these studies have adopted a predetermined sample size based on formal considerations of statistical power. Moreover, some investigators have designed community intervention trials in which exactly one cluster has been assigned to the experimental group and one to the control group (e.g. [6] and [56]). Such trials invariably result in interpretational difficulties caused by the total confounding of two sources of variation: (i) the variation in response due to the effect of intervention and (ii) the natural variation that exists between communities.

There are several possible explanations for the difficulties investigators have faced in designing adequately powered studies. One obvious reason is that the required sample size formulas still tend to be relatively inaccessible, not being available, for example, in most standard texts or software packages. A second reason is that the proper use of these formulas requires some prior assessment of the intracluster correlation coefficient ρ, either directly or through comparable information on the value of σ_A^2, the between-cluster component of variation. Such information is not always easily available.

Difficulties in obtaining accurate estimates of intracluster correlation are slowly being addressed as more investigators begin publishing these values in the reporting of trial results (e.g. [68]). Summary tables listing intracluster correlation coefficients and variance inflation factors from a wide range of cluster randomization trials and complex surveys are also starting to appear (e.g. [20, Chapter 5]). In practice, estimates of ρ are almost always positive and tend to be larger in smaller clusters [37].

The calculation of sample size also requires the specification of the cluster size m. However, the actual size of the clusters randomized is frequently determined by the selected interventions. For example, households were the natural unit of randomization in the study reported by Payment et al. [59], which, as noted above, considered the effect of domestic water filters on subjects' risk of gastrointestinal disease. Consequently the average cluster size at entry in this trial was approximately four. When, on the other hand, relatively large clusters are randomized, subsamples of individual cluster members may be selected to reduce costs. For example, the end point for the community intervention trial COMMIT was the quit rate of approximately 550 heavy smokers selected from each cluster [13].

Equation (1) may be applied directly to determine the required sample size for a completely randomized design. Let $Z_{\alpha/2}$ denote the two-sided critical value of the standard normal distribution corresponding to the error rate α, and Z_β denote the critical value corresponding to β. Then, if $\overline{Y}_1 - \overline{Y}_2$ can be regarded as approximately normally distributed, then the number of subjects required per intervention group is given [21] by

$$n = \frac{(Z_{\alpha/2} + Z_\beta)^2(2\sigma^2)[1 + (m-1)\rho]}{(\mu_1 - \mu_2)^2}, \qquad (3)$$

and $\mu_1 - \mu_2$ denotes the magnitude of the difference to be detected. Equivalently the number of clusters required per group is given by $k = n/m$. With this allocation, the "effective sample size" for each group would be given by $n/[1 + (m-1)\rho]$. Thus at $\rho = 0$, (3) reduces to the usual sample size specification (e.g. [2, Section 6.6]).

The degree of variance inflation due to clustering can be profound even for very small values of ρ. For example, as part of a pilot study for a planned worksite intervention trial, the estimated intracluster correlation coefficient is given by $\hat{\rho} = 0.04$ [41]. Since approximately 70 subjects were eligible per worksite the required sample size is about four times that required for a comparable individually randomized trial.

In the case of unequal cluster sizes, we may replace m in (3) with the average cluster size $\overline{m}$. This approximation will tend to underestimate slightly the actual required sample size, but the underestimation will be negligible provided the variation in cluster size is not substantial. Further inaccuracy may result due to the inherent imprecision in the estimate of ρ. For example, the pilot study reported by Hsieh [41] included only four clusters, so that the estimated value of ρ computed from this study would be quite imprecise. It is therefore usually advisable to perform sensitivity analyses that explore the effect of different values of ρ on the estimated sample size.

Sensitivity analyses can also be useful for community intervention trials when assessing the effect of the number of clusters per intervention group and the subsample size on statistical efficiency. Such analyses will tend to reveal that greater gains in power will be obtained by increasing the number of clusters rather than the subsample size (see, for example, [41]), an easily demonstrated consequence of (1).

A similar approach may be used to determine sample size for completely randomized or stratified designs when the primary study endpoint (*see* **Outcome Measures in Clinical Trials**) is binary (see, for example, [18]). That is, the number of subjects required per intervention group may be calculated using standard sample size formulas applicable to individually randomized trials after multiplication by the inflation factor $IF = 1 + (m - 1)\rho$.

Unfortunately, the absence of appropriate measures of intracluster correlation for time to event and incidence rate data (see [66]) complicates sample size determination even for completely randomized designs. Alternative procedures for these outcomes have been described by Hayes & Bennett [38].

Difficulties in obtaining measures of intracluster correlation also complicate sample size determination for matched-pair designs. One simple alternative is to determine the sample size by assuming that the trial is completely randomized. Ignoring differences in degrees of freedom between the two designs, this approach will tend to be conservative [53]. Greater precision may be obtained when the effect of matching can be accurately estimated in advance, using, for example, the within-stratum component of variation $\sigma_{AM}^2 = \sigma_A^2(1 - \rho_M)$, where ρ_M measures the effectiveness of the matching. Unfortunately, except for a few notable exceptions (e.g. [29]) it can be quite difficult to match successfully. Donner & Klar [20, Chapter 3] cite examples of trials in which matching may even have resulted in a loss of efficiency.

Unit of Inference and Unit of Analysis

Many of the challenges of cluster randomization arise because inferences are frequently intended to apply at the individual level while randomization is at the cluster level. If inferences were intended to apply at the cluster level, implying that an analysis at the cluster level would be most appropriate, then the study could be regarded, at least with respect to sample size estimation and data analysis, as a standard clinical trial. For example, one of the secondary aims of the Child and Adolescent Trial for Cardiovascular Health (CATCH) was to assess the effect of training food service personnel on how to improve the dietary content of lunch menus. The resulting analyses of dietary content were then naturally conducted at the cluster (school) level.

Analyses are inevitably more complicated when data are available from individual study subjects where the investigator must account for the lack of statistical independence among observations within a cluster. An obvious method of simplifying the problem is to collapse the data in each cluster, followed by the construction of a meaningful summary measure, such as an average, which then serves as the unit of analysis. Standard statistical methods can then be directly applied to the collapsed measures. This removes the problem of nonindependence since the subsequent significance tests and confidence intervals would be based on the variation among cluster summary values rather than on variation among individuals.

An important special case arises in trials having a quantitative outcome variable when each cluster has a fixed number of subjects. In this case the test statistic obtained using the analysis of variance is algebraically identical to the test statistic obtained using a cluster-level analysis [40, 46]. Thus, the suggestion that is sometimes made that a cluster-level analysis intrinsically assumes $\rho = 1$ is misleading, since such an analysis can be efficiently conducted regardless of the value of ρ. It is important to note, however, that this equivalence between cluster-level and individual-level analyses, which holds exactly for quantitative outcome variables under balance, holds only approximately for other outcome variables (e.g. binary, time to event, count). A second implication of this algebraic identity is that concerns for the ecologic fallacy (e.g. [47]) cannot arise in the case of cluster-level **intention to treat analyses** since the assigned intervention is shared by all cluster members.

In practice, the number of subjects per cluster will tend to exhibit considerable variability, either by design or by subject attrition. Cluster-level analyses, which give equal weight to all clusters, may prove to be imprecise. However, the precision of appropriately weighted cluster-level analyses is asymptotically equivalent to individual-level analyses. If there is only a small number of clusters per intervention group, then the resulting imprecision in the estimation of these weights might even result in a loss of power (e.g. [67]). Moreover, the validity of approximate individual-level analyses may then become questionable. In this case it might be preferable to consider exact statistical inferences constructed at the cluster level based on the randomization distribution for

the selected experimental design (e.g. completely randomized, matched-pair, stratified).

We now present methods for the analysis of common study outcomes (e.g. binary, quantitative, count, time to event) typical of cluster randomization trials. The order and detail provided for each study outcome reflect the relative frequency with which these different types of outcome data are encountered in cluster randomization trials.

Analysis of Binary Outcomes

Methods for analyzing binary (dichotomous) outcome data in cluster randomization trials are not as well established as methods for analyzing quantitative outcomes. The analytic issues involved are complicated by the absence of a unique multivariate extension of the binomial distribution analogous to the multivariate normal distribution, and by the fact that there is no single approach that has uniformly superior properties.

It follows that there are several procedures that may be used to test $H_0 : P_1 = P_2$, where P_i is the true event rate for the ith intervention group, $i = 1, 2$. To make ideas concrete, the discussion will take place in the context of a completely randomized, school-based smoking prevention trial [55]. In this study, 12 schools were randomly assigned to each of four conditions including three experimental conditions and a control condition (existing curriculum). For purposes of illustration we are interested in comparing the effect of the Smoke Free Generation intervention with the existing curriculum on the proportion of children who report using smokeless tobacco after two years of follow-up.

The overall observed rates of tobacco use in the experimental and control groups are 0.043 (58/1341) and 0.062 (91/1479), respectively. Investigators frequently use inappropriate methods, such as the Pearson chi-square statistic, to test the effect of intervention in cluster randomization trials [70]. Application of this statistic to comparing the overall event rates in the two groups yields $\chi_P^2 = 4.69$ ($P = 0.03$). This result might be taken to imply that the use of smokeless tobacco among experimental group individuals is significantly reduced as compared with control group individuals. However, a fundamental assumption of this procedure is that the sample observations are statistically independent. This assumption is almost certainly violated here, since it is more reasonable to assume that responses taken on subjects within a school are more similar than responses taken on subjects in different schools, i.e. to assume that the intracluster correlation coefficient ρ is positive. This would imply that the computed P value of 0.03 is likely to be biased downward.

Donner & Donald [19] proposed an adjustment for Pearson's chi-square statistic that depends on computing correction factors for the effect of clustering. For clusters of fixed size m, the adjusted Pearson chi-square test statistic reduces to $\chi_P^2/[1 + (m - 1)\hat{\rho}]$, where $\hat{\rho}$ is the sample estimate of ρ.

For the data from the smoking prevention trial we have $\hat{\rho} = 0.01$, with group-specific correction factors $C_1 = 2.54$ and $C_2 = 2.60$. The adjusted chi-square statistic $\chi_A^2 = 1.83$ ($P = 0.18$), which is not statistically significant at any conventional level.

Similar conclusions can be reached using other simple modifications of the Pearson chi-square statistic, as in, for example, the ratio estimator approach described by Rao & Scott [61]. Cluster-level analyses based on the two-sample t-test comparing the mean event rates, or nonparametric alternatives (e.g. Fisher's two-sample permutation test, the Wilcoxon rank sum test) also provide essentially the same results for this example.

It is possible that the absence of a statistically significant effect of intervention in this example is due, at least in part, to chance imbalance on prognostically important baseline covariates (*see* **Covariate Imbalance, Adjustment for**). Such imbalance, of course, may arise in any randomized trial. However, for a given total number of individuals, the probability of a substantive imbalance will be higher in a trial randomizing clusters, owing to the smaller effective sample size. Provided the number of clusters is sufficiently large, multiple regression models may be used to account for such an imbalance, as well as to help increase the precision with which the intervention effect is estimated.

The effect of covariate adjustment on the estimated effect of intervention for a binary outcome variable may be explored using extensions of logistic regression adjusted for clustering. Two possible choices are the logistic–normal model and the generalized estimating equations (GEE) extension of logistic regression [50, 57]. An advantage of these extensions is that they may be used to account for an imbalance on individual-level (e.g. sex) as

well as cluster-level (percent male, cluster size) characteristics.

The logistic–normal model assumes that the logit transform of the probability of using smokeless tobacco follows a normal distribution across clusters. Likelihood ratio tests will have maximum power to detect the effects of intervention as statistically significant when such parametric model assumptions are satisfied.

In practice it may be difficult to ensure that the assumptions underlying the use of parametric models hold. We therefore limit attention here to the GEE approach, which has the advantage of not requiring specification of a fully parametric distribution. Two distinct strategies are available to adjust for the effect of clustering using the GEE approach. The first can be said to be model-based, since it requires the specification of a working correlation matrix that describes the pattern of correlation between responses of cluster members. For cluster randomization trials the simplest assumption to make is that the responses of cluster members are equally correlated, i.e. exchangeable. The second strategy to adjust for the effect of clustering employs "robust variance estimators" that are constructed using between-cluster information. These estimators consistently estimate the true variance even if the working correlation matrix is misspecified. Moreover, provided there are a large number of clusters, inferences obtained using robust variance estimators will become equivalent to those obtained using the model-based strategy when the working correlation matrix is correctly specified.

The sample odds ratio comparing the use of smokeless tobacco in the experimental vs. the control group may be obtained by fitting a GEE extension of logistic regression with a working exchangeable correlation matrix. The resulting odds ratio is given by 0.67 with a 95% robust confidence interval given by (0.41, 1.09). The corresponding one-degree-of-freedom chi-square test statistic is given by $\chi^2_{LZR} = 2.62$ ($P = 0.11$). Adjustment for subject age and sex results in a stronger observed effect of intervention, giving an adjusted odds ratio estimate of 0.65. As in earlier analyses, however, the association is not statistically significant.

The data from a matched-pair cluster randomization trial with a binary outcome variable and k strata may be summarized in a series of k 2×2 contingency tables. Methods used to evaluate the effect of intervention in matched-pair designs must rely on estimates of variance obtained using between-stratum information. Methods of analysis which may be used to test for an effect of intervention include a version of the one-sample permutation test as proposed by Liang [49] and a paired t-test as applied to the stratum-specific difference in event rates. Note that a naive application of the Mantel–Haenszel test statistic, χ^2_{MH}, is invalid since dependencies among responses of cluster members induce extra variability not accounted for in the test statistic. Thus, the true level of significance associated with χ^2_{MH} may be substantially greater than the nominal significance level if the clustering effect is ignored. These methods have been compared in the context of a hypertension screening and management trial by Donner [17].

Naive application of the Mantel–Haenszel test statistic is similarly inappropriate for analyses of data from stratified cluster randomization trials. The required generalization of the Mantel–Haenszel procedure is given by Donner [18].

Statistical analyses for the stratified design may also be conducted using GEE or other extensions of logistic regression. Unlike the adjusted Mantel–Haenszel procedure, the use of GEE in this context allows adjustment for individual-level as well as cluster-level covariates. However, these extensions of logistic regression are not directly applicable to the analyses of data from matched-pair designs unless the variance term is computed from between-stratum information and under the added assumption that there is no intervention by stratum interaction. A further limitation is that paired designs inevitably have fewer degrees of freedom for the estimation of error than either the completely randomized or stratified designs.

It is important to note, notwithstanding these difficulties, that if the aim of the analysis is limited to the adjustment or control of individual-level covariates in assessing the effect of intervention, then appropriate methods are readily available. These methods take the form of two-stage procedures based on standardizing the data with respect to individual-level covariates in advance of the primary analysis (e.g. [30]).

Analysis of Quantitative Outcomes

Analysis of quantitative outcome data from cluster randomization trials can often be accomplished using mixed-effects linear models [51, 74]. These models

can be most directly used with completely randomized or stratified designs to estimate the effect of intervention, to test if the observed effect is due to chance, and to adjust for imbalance on baseline prognostic factors.

For balanced designs having a fixed number of subjects per cluster, standard analysis of variance (ANOVA) may be used to test for the effect of intervention. As noted above, statistical inferences are then exact and identical to those obtained from cluster-level analyses (e.g. [46]). Of course, in practice the number of subjects per cluster may be highly variable. In this case iterative approaches, such as generalized least squares, are usually the method of choice for fitting mixed effects linear regression models, since the associated procedures provide maximum likelihood estimates of the effect of intervention [64, Section 6.8]. However, the resulting inferences will now be approximate rather than exact [23, Chapter 6], with no unique method for calculating the degrees of freedom [51, Chapter 2].

An interesting application of robust variance estimation is provided by Brook et al. [8] in their analyses of the Rand Health Insurance experiment [58]. In this study approximately 2000 families from the US were randomly assigned to one of 14 health insurance plans to evaluate the extent to which the provision of free care improves health. The analytic approach was based on a strategy suggested by Huber [42], a special case of the more general GEE procedure described by Liang & Zeger [50]. Further discussion is provided by Diggle et al. [16, p. 69].

An alternative to classical ANOVA or mixed effects linear regression is to apply a methodology often referred to in the behavioral and educational literature as multilevel modeling [35] or as hierarchical linear modeling [10]. Results obtained using any of these approaches are likely to be similar owing to their very close algebraic relationship (e.g. see [27]). Note that, in general, the relationship among the various extensions of logistic regression is more complicated, consistent with the greater challenge posed by analyses of binary outcome variables (e.g. [57]).

As noted above, the presence of only two clusters per stratum in the matched-pair design implies that estimates of between-cluster variability are totally confounded with the effect of intervention. Tests of the effect of intervention must therefore be calculated using between-stratum information on variability. One simple option is to apply the standard paired t-statistic to the stratum-specific mean differences. In the presence of obvious non-normality, reasonable alternatives are the Wilcoxon signed rank test or Fisher's one-sample permutation test.

These methods of analysis are illustrated by Donner & Klar [20, Chapter 7] using data from the British Family Heart Study [25]. The purpose of this trial was to examine the effect of a one-year, nurse-led lifestyle intervention on cardiovascular disease risk factors, with participating patients recruited from general practices.

Analysis of Count and Time to Event Outcomes

The primary outcome variable in most cluster randomization trials is either binary or continuous. However, this is not always the case. For example, Payment et al. [59], in a study involving count data, examined the effect of a domestic water filter on reducing the annual number of gastrointestinal episodes for each subject. Standard methods for the analysis of count data (e.g. [7]) were correctly recognized as being inappropriate, since each episode would then be counted as an independent event. Methods that allowed for correlation in the number of episodes per household were adopted instead.

Individual-level analyses for completely randomized designs for count data may be conducted using relatively simple procedures based on the ratio estimator approach [62]. More computer-intensive procedures based on extensions of Poisson regression models which adjust for clustering have also been described (e.g. see [69]).

Subjects in randomized trials are not always followed for the same length of time. Thus, variable follow-up times may occur because some subjects have the event of interest early in the trial while others survive to the end of the trial (i.e. are censored). This was the case in the community intervention trial reported by Sommer et al. [72], which examined the effect of vitamin A supplementation on childhood mortality. In such trials count data are often reported as the number of events that occur relative to the total follow-up time, yielding an incidence rate that accounts for the variable follow-up. Extensions of Poisson regression, which account for clustering, may again be used to assess the effect of intervention.

An alternative analytic approach is to view the primary outcome as a failure time random variable.

The effects of clustering may then be accounted for using, for example, extensions of exponential or Weibull failure time models [65]. A semi-parametric approach based on GEE extensions of the Cox model might also be considered [20, Chapter 8]. These regression models may be applied to the analysis of data from either completely randomized or stratified designs, provided a reasonably large number of clusters has been assigned to each intervention group.

Comparison of mortality experience across intervention groups can be graphically displayed using standard Kaplan–Meier (product–limit) survival curves. However, standard methods for obtaining corresponding variance estimators need to be adjusted for the impact of clustering, since otherwise the resulting statistical inferences will be biased (e.g. [78]).

As an example of a matched-pair design with time-to-event outcomes Ray et al. [63] reported on a randomized trial of a consultation service developed to help prevent falls and associated injuries in high-risk nursing home residents. Seven pairs of nursing homes were enrolled, matched by geographic proximity and the number of available beds. Time on study began when the program assessments were initiated in the nursing homes assigned to the intervention group, thus further matching the homes for calendar time. Study subjects were followed for up to one year after the index date, with observations censored for various reasons including death or discharge. One of the primary endpoints was the 12 month incidence rate of injurious falls (i.e. falls requiring medical attention) calculated separately for each of the 14 nursing homes. While the mean rate of injurious falls was lower for intervention facilities (13.7 falls per 100 person-years) than for control facilities (19.9 falls per 100 person-years) the difference was not statistically significant ($P = 0.22$) using a paired t-test. Similar conclusions were reached by Donner & Klar [20, Chapter 8] using exact permutation tests, as suggested by the results of simulation studies reported by Brookmeyer & Chen [9]. These authors also proposed a two-stage regression approach which may be used to adjust for imbalance on baseline covariates not accounted for by random assignment.

Reporting of Cluster Randomization Trials

Reporting standards for randomized clinical trials have now been widely disseminated (e.g. [5]). Many of the principles that apply to trials randomizing individuals also apply to trials randomizing intact clusters. These include a carefully posed justification for the trial, a clear statement of the study objectives, a detailed description of the planned intervention and the method of randomization and an accurate accounting of all subjects randomized to the trial. Unambiguous inclusion–exclusion criteria (*see* **Eligibility and Exclusion Criteria**) must also be formulated, although perhaps separately for cluster-level and individual-level characteristics. There are, however, some unique aspects of cluster randomization trials that require special attention at the reporting stage. We focus here on some of the most important of these. A more complete account is provided by Donner & Klar [20, Chapter 9].

The decreased statistical efficiency of cluster randomization relative to individual randomization can be substantial, depending on the sizes of the clusters randomized and the degree of intracluster correlation. Thus, unless there is obviously no alternative, the reasons for randomizing clusters rather than individuals should be clearly stated. This information, accompanied by a clear description of the units randomized, can help a reader decide if the loss of precision due to cluster randomization is in fact justified.

Having decided to randomize clusters, investigators may still have considerable latitude in their choice of unit. Since different levels of statistical efficiency are associated with different cluster sizes, it would seem important to select the unit of randomization on a carefully considered basis. However, it is apparent from published reports that this has not always been the case. For example, the review of cluster randomization studies reported by Donner et al. [22] found that only one-quarter of the trials considered provided reasons for their choice of randomization unit. An unambiguous definition of the unit of randomization is also required. For example, a statement that "neighborhoods" were randomized is clearly incomplete without a detailed description of this term in the context of the planned trial.

As noted previously, the consensus that exists in most clinical trial settings regarding the role of informed consent has not tended to apply to cluster randomization trials. By reporting the methods used (if any) to obtain informed consent in their own trials, it may gradually become possible for the research

community to develop reasonably uniform standards regarding this important issue.

The clusters that participate in a trial, simply owing to their consent to be randomized, may not be representative of the target population of clusters. Some indication of this lack of representativeness may be obtained by listing the number of clusters that met the eligibility criteria for the trial, but which declined to participate, along with a description of their characteristics.

A continuing difficulty with reports of cluster randomization trials is that justification for the sample size is all too often omitted. Investigators should clearly describe how the sample size for their trial was determined, with particular attention given to how clustering effects were adjusted for. This description should be in the context of the experimental design selected (e.g. completely randomized, matched-pair, stratified).

It would also be beneficial to the research community if empirical estimates of ρ were routinely published (with an indication of whether or not the reported values have been adjusted for the effect of baseline covariates).

It should be further specified what provisions, if any, were made in the sample size calculations to account for potential loss to follow-up. Since the factors leading to the loss to follow-up of individual members of a cluster may be very different from those leading to the loss of an entire cluster, both sets of factors must be considered here.

A large variety of methods, based on very different sets of assumptions, have been used to analyze data arising from cluster randomization trials. For example, possible choices for the analysis of binary outcomes include adjusted chi-square statistics, the GEE method and logistic–normal regression models. These methods are not as familiar as the standard procedures commonly used to analyze clinical trial data. This is partly because the methodology for analyzing cluster randomization trials is in a state of rapid development, with virtually no standardization and a proliferation of associated **software**. Therefore it is incumbent upon authors to provide a clear statement of the statistical methods used, and accompanied, where it is not obvious, by an explanation of how the analysis adjusts for the effect of clustering. The software used to implement these analyses should also be reported.

Cluster Sampling, Optimal Allocation

Optimal allocation refers to the use of a survey sampling project's resources in a manner that either minimizes sampling **variance** for a fixed cost or minimizes cost to obtain a fixed variance. When a survey has several objectives or population parameters to be estimated, the sampling statistician needs to consider the designs that are optimal for each objective. He or she should then present the alternatives to the client and provide statistical guidance in making an informed choice.

Sampling units may be allocated optimally either across strata (*see* **Stratified Sampling, Allocation in**) or by varying the cluster structure of the population. This article discusses the optimal number of sample clusters and sample units (or *elements*) within clusters [2, 3].

The simplest case is for a one-stage cluster sample (*see* **Cluster Sampling**), where each cluster contains the same number of elements, where we select a **simple random sample** of the clusters; and where we select and measure each unit within each of the sample clusters. An example of this scenario is in area sampling, where we are trying to determine the optimum number of units to group together to form a *chunk* or *segment*. The chunks or segments are the clusters and the number of clusters in a given arrangement of the population is denoted M_a. The number of units in the ith cluster, $i = 1, \ldots, M_a$, is N_{ai} ($= N_a$ for all i since the number of units or elements within clusters is assumed to be the same for all clusters). The total number of units in the population is $N = \sum_{i=1}^{M_a} N_{ai} = M_a N_a$. The sample consists of m_a clusters selected at random, which yields a total of $n_a = \sum_{i=1}^{m_a} N_a = m_a N_a$ sample elements. Suppose we wish to estimate (*see* **Estimation**) the **mean** over all elements of a characteristic, X, which takes on the values x_{ij} for the jth unit in the ith cluster, $j = 1, \ldots N_a$ and $i = 1, \ldots, M_a$. An **unbiased** estimate is $\overline{\overline{x}}_a = \sum_{i=1}^{m_a} \sum_{j=1}^{N_a} x_{ij} \big/ m_a N_a$, which has **variance**

$$\mathrm{var}(\overline{\overline{x}}_a) = \frac{S_{a1}^2}{m_a} \left(\frac{M_a - m_a}{M_a} \right)^2,$$

where S_{a1} is the **standard deviation** of the distribution of cluster means. That is,

$$S_{a1} = \left[\frac{N_a \sum_{i=1}^{M_a} (\overline{X}_{ai} - \overline{\overline{X}})^2}{M_a - 1} \right]^{1/2},$$

$$\overline{X}_{ai} = \frac{\sum_{j=1}^{N_a} X_{ij}}{N_a},$$

and

$$\overline{\overline{X}} = \frac{\sum_{i=1}^{M_a} \sum_{j=1}^{N_a} X_{ij}}{N}.$$

The precision of the estimate depends on the relationship between S_{a1} and m_a. For estimating the mean per unit of a characteristic, the optimum arrangement of the population into clusters can be determined [1, p. 234] from the fact that both the relative cost for a fixed variance, $\mathrm{var}(\overline{\overline{x}})$, and the relative variance for a fixed cost, C, are proportional to $S_{a1}^2 C_a$, where C_a is the relative cost of measuring a cluster in the ath allocation scheme.

The usual procedure for determining N_a is to examine several allocation schemes and select the one that minimizes variance for a fixed cost. For example, suppose the cost to drive to a cluster of any size averages about \$10. Once at the cluster, it may take 5 minutes to measure a unit. If the measurement costs \$15 per hour, then we can measure 12 units in an hour at a cost of \$1.25 per unit. We may want to decide between a plan with 60 units per cluster and one with 30 units per cluster. Suppose that previous surveys have shown the large clusters to have a standard deviation of 10 across clusters and the smaller clusters have a standard deviation of 15. This is the standard deviation of the mean unit characteristic across clusters $S_{60\mathrm{B}}$ and $S_{30\mathrm{B}}$, respectively. The two costs are:

$$C_{30} = \$10 + 30(\$1.25) = \$47.5 \text{ per cluster},$$

and

$$C_{60} = \$10 + 60(\$1.25) = \$85 \text{ per cluster}.$$

The relative variances for a fixed cost are:

$$\text{var}_{30} \propto 47.5 \times 15^2 = 10\,687.5$$

and

$$\text{var}_{60} \propto 85 \times 10^2 = 8500.$$

For this characteristic, the larger cluster would be preferred. The process is then repeated for each survey objective and the client then needs to exercise judgment as to which allocation best fits the project's overall goals.

The next level of complication is to consider clusters of unequal size, N_{ai}. Let $\overline{N}_a = \sum_{i=1}^{M_a} N_{ai} \big/ M_a$ be the average cluster size. An estimator of the mean per unit is $\overline{\overline{x}}_a = \sum_{i=1}^{m_a} \sum_{j=1}^{N_{ai}} x_{ij} \big/ m_a \overline{N}_a$. One approach is to treat the units as if they have approximately equal size by replacing N_{ai} by $\overline{N}_a$ and proceeding as if the cluster sizes were equal. In some circumstances the clusters may be stratified to increase the homogeneity of size.

Another complication occurs when we observe that units within clusters have similar values for the characteristic of interest. This homogeneity of units within clusters implies that measuring all the units within a cluster is very unlikely to provide as much information as obtaining measurements from a few units selected from several clusters. This leads to a two-step or two-stage sampling design (*see* **Multistage Sampling**).

For a two-stage design, m_a clusters are selected at random. Within each selected cluster a sample of n_{ai} units, $i = 1, \ldots, m_a$, are measured. As with simple one-stage cluster sampling there are M_a clusters each containing N_a units. The subscript a indexes the particular allocation scheme. A complete sample contains $n_a = \sum_{i=1}^{m_a} n_{ai}$ units. It is reasonable to fix $n_{ai} = \overline{n}_a$ since the clusters are of equal size. The estimator of the population mean per unit is

$$\overline{\overline{x}}_a = \frac{\sum_{i=1}^{m_a} \sum_{j=1}^{\overline{n}_a} x_{ij}}{m_a \overline{n}_a}.$$

This estimator is unbiased [1, Theorem 10.1, p. 277] and has **standard error**:

$$\text{se}(\overline{\overline{x}}_a) = \left[\left(\frac{M_a - m_a}{M_a} \right) \frac{S_{a1}^2}{m_a} + \left(\frac{N_a - \overline{n}_a}{N_a} \right) \frac{S_{a2}^2}{m_a \overline{n}_a} \right]^{1/2},$$

where

$$S_{a1}^2 = \frac{\sum_{i=1}^{M_a} \left(\overline{X}_{ai} - \overline{\overline{X}} \right)^2}{M_a - 1}$$

and

$$S_{a2}^2 = \frac{\sum_{i=1}^{M_a} \sum_{j=1}^{\overline{N}_a} (X_{ij} - \overline{X}_{ai})^2}{\overline{N}_a - 1}.$$

These two variances have the following practical interpretation:

1. S_{a1} is the between-cluster standard deviation of the cluster means; thus, as clusters become larger this should become smaller.
2. S_{a2} is the within-cluster standard deviation; thus, as the clusters become larger this should become larger.

Optimal allocation means altering the cluster size so as to balance these two sources of variation. The balance is affected by the cost of preparing a cluster for subsampling and the cost of measuring units within the cluster.

Many different cost functions have been examined, but that proposed earlier provides an appropriate model for many situations. Let the total cost depend only on the cost of preparing a cluster, c_1, and the cost of measuring a unit, c_2. The relative survey cost for a particular allocation scheme is then $c_a = c_1 m_a + c_2 m_a \overline{n}_a$. Following **Cochran** [1, p. 280], to find the choice of sample cluster size, $\overline{n}_a$, that optimizes the survey, we write the variance as

$$\text{var}(\overline{\overline{x}}_a) = \frac{1}{m_a} \left(S_{a1}^2 - \frac{S_{a2}^2}{N_a} \right) + \frac{S_{a2}^2}{m_a n_a} - \frac{S_{a1}^2}{M_a}.$$

It follows that the problem reduces to minimizing the following product:

$$C \left(\text{var}(\overline{\overline{x}}_a) + \frac{S_{a1}^2}{M_a} \right) = \left(S_{a1}^2 - \frac{S_{a2}^2}{N_a} + \frac{S_{a2}^2}{n_a} \right) (c_1 + c_2 \overline{n}_a).$$

Using Lagrange multipliers and differentiating we obtain:

$$\overline{n}_{a,\text{opt}} = \frac{S_{a2}}{S_{au}} \left(\frac{c_1}{c_2} \right)^{1/2},$$

where $S_{au}^2 = S_{a1}^2 - (S_{a2}^2/N_a)$ and we assume $S_{au}^2 > 0$. Thus the within-cluster sample should be increased

as the within-cluster standard deviation increases and as the cost of preparing a cluster increases. S_{au} is the between-cluster standard deviation reduced by the relative within-cluster standard deviation. The optimum varies inversely with this term.

Suppose, in our earlier example, we learn that the size 30 segments yield $S_{30,2} = 1$ and $S_{60,2} = 4$. Then

$$S_{30,u} = \left(15^2 - \frac{1^2}{30}\right)^{1/2} \approx 15$$

and

$$S_{60,u} = \left(10^2 - \frac{4^2}{60}\right)^{1/2} \approx 10.$$

The optimum within cluster sizes are

$$n_{30,\text{opt}} = \frac{1}{15}\left(\frac{10}{1.25}\right)^{1/2} = 0.189$$

(or one unit per cluster) and

$$n_{60,\text{opt}} = \frac{4}{10}\left(\frac{15}{1.25}\right)^{1/2} = 1.39$$

or two units per cluster. Solving the cost model for m_a allows us to evaluate the alternative sample sizes:

$$m_{30} = \frac{C}{(10 + 1.25 \times 1)} = C \times 0.0889$$

and

$$m_{60} = \frac{C}{(10 + 1.25 \times 2)} = C \times 0.08.$$

The greatest reduction in variance for fixed cost occurs by maximizing m_a, so we would select a design with 30 units per cluster and select one unit per cluster at random.

The most complex situation for two-stage sampling is when the first-stage units (clusters) are of widely varying size. As a first step, the population of clusters can be stratified by size so as to create more homogeneous clusters (*see* **Stratified Sampling**). These are then sampled as above. Beyond this the allocation problem becomes quite complex. For additional discussion, the relevant material in Cochran [1] is quite complete.

Cluster Sampling

The term *cluster sampling* has been used to categorize sampling designs in which the sampling units are groups (or *clusters*) of enumeration units and there is only one stage of sampling [2, 3]. In other words, cluster sampling involves taking a sample of clusters according to some sampling plan and then selecting every enumeration unit within each cluster that was sampled. In contrast, designs that sample clusters of enumeration units but involve more than one stage of sampling are generally referred to as **multistage sampling**. The term cluster sampling, as used here, is synonymous with terms such as *single-stage cluster sampling* or *one-stage cluster sampling* that have been used widely in the past and may still be seen occasionally in the literature.

The use of cluster sampling is motivated primarily by reasons that involve feasibility and economy. In sampling of human populations, for example, where estimates are desired on a per-person basis, it is not usually possible to construct a **sampling frame** that lists all individuals or even all households in the population. There may, however, be a list of city blocks or other geographical entities that could serve for sampling purposes as the cluster, and individual households (and ultimately individual persons) within each sample cluster can then be enumerated or "listed" and information obtained from them. Even when a frame can be constructed that consists of lists of individual households, it is often more economical to use these larger geographical entities as the sampling unit, especially when the **target population** is dispersed over a wide geographical area.

Our major objective here is to acquaint the reader with the basic concepts and formulation of cluster sampling. Our emphasis will be on the various types of **estimation** procedures and on issues related to the cost–effectiveness of cluster sampling. In the ensuing discussion, we will assume for the sake of simplicity that the enumeration units are also the elementary units.

Terminology

Let us suppose that a population contains N elementary units grouped into M clusters, and that each cluster contains N_i enumeration units ($\sum_{i=1}^{M} N_i = N$); that we are interested in estimating the level of some characteristic χ in this population; and that X_{ij} is the value of χ for enumeration unit j in the ith cluster. Some population parameters are given below for characteristic χ.

Population total for cluster i:

$$X_i = \sum_{j=1}^{N_i} X_{ij}.$$

Overall population total:

$$X = \sum_{i=1}^{M} X_i.$$

Population **mean** for cluster i:

$$\overline{X}_i = \frac{X_i}{N_i}.$$

Overall population mean per cluster:

$$\overline{X} = \frac{X}{M}.$$

Overall population mean per enumeration unit:

$$\overline{\overline{X}} = \frac{X}{N}.$$

Average number of elements per cluster:

$$\overline{N} = \frac{N}{M}.$$

Variance of distribution of cluster totals, X_i over all clusters:

$$\sigma_{1x}^2 = \frac{\sum_{i=1}^{M} (X_i - \overline{X})^2}{M}.$$

Let us also suppose that we are taking a sample of m clusters according to some sample design and, since this is cluster sampling, selecting all enumeration units within each sample cluster. Also, to simplify notation, let us assume that the clusters labeled $1, 2, \ldots, m$ are the sample clusters. The total number, n, of sample enumeration units is equal to $n = \sum_{i=1}^{m} N_i$, and the analogous sample statistics for characteristic χ are shown below.

Sample total for cluster i:

$$x_i = \sum_{j=1}^{N_i} x_{ij}.$$

Overall sample total:

$$x = \sum_{i=1}^{m} x_i.$$

Sample mean per cluster:

$$\overline{x} = \frac{\sum_{i=1}^{m} x_i}{m}.$$

Sample variance of distribution of x_i over all sample clusters:

$$s_{1x}^2 = \frac{\sum_{i=1}^{m} (x_i - \overline{x})^2}{m-1}.$$

One of the characteristics of cluster sampling is that the formulas for estimates and their **standard errors** have a very similar appearance as the estimates for sample designs in which the enumeration units are sampled directly. The major difference is that the cluster totals, x_i, replace the individual values, x_{ij}. We illustrate this below for the scenario in which the clusters are sampled by **simple random sampling**.

Estimation Under Simple Random Sampling of Clusters

In cluster sampling, if simple random sampling is used to select clusters, the design is called *simple cluster sampling* or *simple one-stage cluster sampling*. Under simple cluster sampling, linear estimators such as means and totals are **unbiased** estimators of the corresponding population parameters as shown below. These estimators are shown below.

Estimated population mean per cluster:

$$\overline{x}_{\text{clu}} = \frac{\sum_{i=1}^{m} x_i}{m}. \tag{1}$$

Estimated standard error of $\overline{x}_{\text{clu}}$:

$$\widehat{SE}(\overline{x}_{\text{clu}}) = \left(\frac{1}{\sqrt{m}}\right) s_{1x} \left(\frac{M-m}{M}\right)^{1/2}. \tag{2}$$

Estimated population mean per enumeration unit:

$$\overline{\overline{x}}_{\text{clu}} = \frac{\sum_{i=1}^{m} x_i}{m\overline{N}}. \tag{3}$$

Estimated standard error of $\overline{\overline{x}}_{\text{clu}}$:

$$\widehat{SE}(\overline{\overline{x}}_{\text{clu}}) = \left(\frac{1}{\sqrt{m\overline{N}}}\right) s_{1x} \left(\frac{M-m}{M}\right)^{1/2}. \tag{4}$$

Estimated total:

$$x'_{\text{clu}} = \frac{M}{m} x. \tag{5}$$

Estimated standard error of estimated total:

$$\widehat{SE}(x'_{\text{clu}}) = \frac{M}{\sqrt{m}} s_{1x} \left(\frac{M-m}{M}\right)^{1/2}. \tag{6}$$

One can see that the above equations have the same form as those appropriate for simple random sampling of enumeration units with the cluster totals, x_i replacing the enumeration unit totals, x_{ij}, and the number, M, of clusters replacing the number, N, of enumeration units.

Illustrative Example

Suppose that a health insurance company conducts an audit of the claims reimbursed to a provider of medical care services over a calendar year. The provider was reimbursed for 14 claims submitted on behalf of 49 patients. Since the audit involves detailed examination of patient medical files, economy dictates that a simple cluster sample of patients be taken (implying that all claims reimbursed on behalf of each sampled patient be audited). The audit involved taking a cluster sample of $m = 7$ patients from the population of $M = 49$ patients on behalf of whom reimbursements were made. Table 1 shows the data obtained from this audit.

From the data on overpayment shown in the last column of Table 1, we obtain the following summary statistics:

$$x = \sum_{i=1}^{7} x_i = \$321.50,$$

$$s_{1x} = (\$3739.04)^{1/2} = \$61.15,$$

$$x'_{\text{clu}} = \frac{49}{7}(\$321.50) = \$2250.50,$$

Table 1 Findings of audit on claims made on behalf of seven patients

Patient	Claim ($)	Total reimbursed ($)	Overpayment ($)	Total overpayment per patient (x_i) ($)
1	1	25.00	15.00	15.00
2	1	37.50	18.00	
	2	75.00	26.00	
	3	235.00	95.00	139.00
3	1	87.00	28.00	28.00
4	1	24.00	0.00	
	2	87.00	10.00	10.00
5	1	145.00	49.00	
	2	123.00	40.50	
	3	89.00	40.00	129.50
6	1	37.00	0.00	0.00
7	1	167.00	0.00	
	2	193.00	0.00	
	3	12.00	0.00	0.00

$$\widehat{SE}(x'_{\text{clu}}) = \frac{49}{\sqrt{7}}(\$61.15)\left(\frac{49-7}{49}\right)^{1/2} = \$1048.46.$$

It should be noted that it is not necessary to know the total number, N, of enumeration units in order to perform a simple cluster sample. All that is required is identification of the clusters. Once the sample clusters are chosen, the enumeration units, if not already identified, can be identified as part of the field work, but this need only be done for the clusters actually sampled. Although the formulas (3) and (4), which estimate the mean per enumeration unit and its standard error, require knowledge of the total, N, of enumeration units in the population, an alternative estimator is available that does not require knowledge of N [3]. This alternative estimator is a **ratio estimator** in which the denominator is an estimate obtained from the sample of the total number of enumeration units in the population.

Precision of Estimates from Cluster Sampling

In practice, estimates obtained from cluster sampling often have higher standard errors than those that would have been obtained from a simple random sample of the same number, n, of enumeration units. This is because the variability among units *within* clusters with respect to a characteristic of interest in the survey may be considerably less than that among units in the population as a whole. For example, in a sample survey of a large city with the city blocks serving as clusters, there might be considerable homogeneity among residents of the same block with respect to characteristics such as income level, education level, ethnicity, etc., even though the city, when considered as a whole, has considerable diversity with respect to such characteristics. Since the process of cluster sampling involves sampling every enumeration unit within each sample cluster, there can be considerable "redundancy" of information. Another scenario might arrive in a manufacturing environment in which products are manufactured in "batches" with each batch containing $\overline{N}$ individual products. If the process is such that either all individuals in a particular batch are defective or none is defective, then a cluster sample of batches would be inefficient because it would entail sampling (unnecessarily) every product within each sample batch.

The ratio of the variance of an estimator under any sample design to that at comparable n under simple random sampling is known as its **design effect** and this index is generally used as an indicator of its precision (or lack thereof).

For cluster sampling, the design effect, $DEFF_{\text{clu}}(x'_{\text{clu}})$, of an estimated total is given by

$$DEFF_{\text{clu}}(x'_{\text{clu}}) = \left(\frac{1}{\overline{N}}\right)\left(\frac{\sigma^2_{1x}}{\sigma^2_x}\right)\left(\frac{N-1}{N-\overline{N}}\right). \quad (7)$$

This implies that if the variance, σ^2_{1x}, among cluster totals is large compared with the overall variability, σ^2_x, among enumeration units in the population, then estimated totals from cluster sampling will have high variances relative to those at the same n from simple

random sampling. For the example shown above, we have $\hat{\sigma}_{1x}^2 = 3662.73$, $\hat{\sigma}_x^2 = 715.11$, $\hat{N} = 98$, and $M = 49$, which from relation (7) gives a design effect equal to 2.587. This implies that an estimated total from a simple cluster sample will have a variance that is approximately 2.6 times as high as one that would be obtained from a simple random sample of the same number n of enumeration units.

Survey Costs

Although the variance of an estimate from cluster sampling will invariably be higher at the same sample size, n, than one obtained from simple random sampling, the cost of taking a cluster sample that would yield $n(= m\overline{n})$ enumeration units might be considerably lower than that of taking a simple random sample of n enumeration units. Thus, it is not particularly useful to compare cluster sampling with simple random sampling at the same sample size, n. A more appropriate basis for comparing cluster sampling with simple random sampling (or for that matter with any alternative design) would be at equivalent cost. One can do this by determining the number, m, of clusters that can be sampled at some fixed cost, C, and then determining the number, n, of enumeration units that can be sampled at this same cost, C. The design effect (at fixed cost rather than fixed sample size) would be the ratio of the variance of the estimate from a cluster sample of these m clusters to that of the estimate obtained from a simple random sample of the n enumeration units. Note that in this instance the n described above for the simple random sample is *not equal* to the entity $m\overline{N}$ that would be the total number of enumeration units obtained in the cluster sample.

Illustrative Example

Let us consider the example discussed earlier involving an audit of claims reimbursed to a provider of medical care services over a calendar year. The field costs involved in the survey involve: (i) construction of the sampling frame; (ii) abstraction of the required data; and (iii) processing of the data.

Let us suppose that the insurance company has made payments for $N = 98$ services that the provider made to $M = 49$ patients that calendar year, and that the names of these patients are in the insurance company's database. Let us suppose further that the list of individual claims is not computerized and that some clerical work is need to identify the individual claims, review the medical record, and abstract the data. We list the following cost components associated with these operations:

1. *Identify and list the individual claim*. Let us suppose that it takes 0.50 person hours to identify and list each individual claim.
2. *Abstract and process data from the patient medical record pertaining to each claim*. Let us suppose that it takes on the average 1.25 person hours to review, abstract, and process the relevant data.

From the above assumptions, we can now list the field costs associated with simple random sampling and with cluster sampling.

For simple random sampling, all 98 claims must be listed no matter what the size of the sample will be, and this will take 49.0 person hours. The abstraction and processing costs will be $1.25 \times n$, where n is the size of the sample to be taken. Thus, the total field costs, C, for a simple random sample of n enumeration units is given by the following:

$$C = 0.50 \times N + 1.25 \times n = 49 + 1.25 \times n. \quad (8)$$

For cluster sampling, all claims need to be listed for the m patients selected in the sample, but no listing has to be done for the $M - m$ patients not selected in the sampling. If m clusters are sampled, then the total field costs would be equal to

$$C = 0.50 \times m\overline{N} + 1.25 \times m\overline{N} = 3.50m \quad (9)$$

(since $\overline{N} = 2$). At a cost of 64 person-hours, a simple random sample of 12 claims can be taken based on the cost function for simple random sampling shown in relation (8). At the same cost, we can take a cluster sample of 18 patients (relation 9) which would give us an expected sample of 36 claims. From (6), using the estimated value of σ_{1x} computed earlier, we see that the estimated total overpaid based on a simple cluster sample of $m = 18$ patients would have an estimated standard error equal to \$555.96, whereas that based on a simple random sample of 12 claims would have an estimated standard error of \$708.67. Thus, in this example, at equivalent cost of 64 person-hours, cluster sampling would yield a more reliable estimate than simple random sampling.

The major reason that cluster sampling often produces more reliable estimates at equivalent cost than simple random sampling is that the enumeration units need to be listed only for the clusters that were selected in the sample, whereas in simple random sampling, all enumeration units in the population need to be listed before sampling can take place. If listing costs are high, this can put simple random sampling at a great disadvantage over cluster sampling.

For the purposes of illustration, the above discussion oversimplifies the costs associated with simple cluster sampling and simple random sampling. The specification of relevant cost components is a complex undertaking and requires considerable experience with the operations involved in the conduct of surveys. Groves [1] treats this topic at great length and identifies a number of important references.

Usefulness of Cluster Sampling

Cluster sampling is most useful when the homogeneity among enumeration units within clusters with respect to the levels of the variables being measured in the sample survey is no greater than the homogeneity among listing units in the population as a whole. In such instances, cluster sampling can result in considerable reductions in frame construction and travel costs without resulting in increased sampling errors. This, however, rarely occurs in practice since enumeration units within clusters generally show considerably more homogeneity than is reflected in the population as a whole. Thus, sampling every enumeration unit within a sample cluster (as is prescribed in cluster sampling) results in a considerable amount of redundancy. In practice, this is avoided by using multistage sampling instead of cluster sampling. In multistage designs, within each sample cluster, a subsample of enumeration units is taken rather than every enumeration, and this reduces the redundancy of the sampling. Thus, multistage sampling is a much more widely used procedure than cluster sampling.

Sometimes, however, it is not feasible to subsample within clusters. Levy et al. [4] describes such a situation that occurred in the planning of a sample survey in Shanghai, China, in 1986. The target population was persons 55 years of age and older residing in a District within Shanghai, and the clusters were administrative entities called *neighborhood groups* consisting of contiguous households that are organized for political and social purposes. For each neighborhood group, a listing of households with the names and ages of the members is available from the government.

Because the neighborhood groups consist of contiguous households, it was felt that there would be considerable homogeneity within neighborhood groups with respect to information gathered from each subject of the sample survey. Thus, in the initial planning, a multistage design was proposed with a sample taken of individuals within each sample neighborhood group. The Chinese collaborators, however, felt that within each neighborhood group sampled, any attempt to subsample individuals would seriously compromise the response rate and the overall cooperation of the residents. The major reason that this should be so is that Shanghai residents within the target age group would have difficulty understanding why the study would single out one person for interview but not a neighbor in the same age group. Also, the experience of this population, based on over 40 years of political campaigns under the socialist and earlier regimes, has led to considerable apprehensions among the elderly of their being "singled out" for any kind of interview. Thus, it was felt that a cluster sampling design that specified interviewing all individuals 55 years of age and older within each sample cluster would be the most feasible design.

Cluster Score

In **cluster analysis of variables** we often obtain subsets or clusters of variables for the purpose of producing scores or cluster scores quantifying the subsets. A cluster score may be simply the sum of the original measurements on the variables in the cluster. Often, however, the variables have unequal standard deviations. In this case the variables are usually first standardized. Cluster scores can then be the sum of these standardized measurements. If the variables of the cluster are equally reliable, then this is a good strategy. For the case where the variables of the cluster are not equally reliable and are not too numerous, we can resort to two other methods of forming cluster scores. These involve forming a weighted sum of the original measurements or the standardized measurements on the variables in each cluster.

The first method starts by computing the loadings of the first **principal component** or the first **centroid** component separately for each cluster. A cluster score is then formed as a weighted sum of the standardized measurements of the variables in the cluster. The loadings of the first principal component or the first centroid component are used as the weights. In symbols, the cluster score for a cluster consisting of k variables is given by

$$C = a_1 X_1^* + a_2 X_2^* + \cdots + a_k X_k^*,$$

where $a_1, \ldots, a_k$ are the first component loadings of the variables in the cluster, and $X_1^*, \ldots, X_k^*$ are the standardized measurements of the k variables.

Kelley [3] proposed another cluster score, which is a weighted sum of the original variables in the cluster. The cluster score for a cluster with k variables is given as follows:

$$X = w_1 X_1 + w_2 X_2 + \cdots + w_k X_k,$$

where X_i is the original measurement of the ith variable and $w_i = \sqrt{r_{ii}}/[\sigma_i(1 - r_{ii})]$. r_{ii} is the reliability of the ith variable and σ_i is its standard deviation. This score is useful when the variables are educational and psychological tests, and reliability coefficients consistent with the intercorrelations are available. The reliability coefficients may be obtained by Kuder–Richardson's KR-20 [4], the split-half method, the Spearman–Brown formula, and a reliability approximation given by Cureton et al. [2]. Kelley's method maximizes the reliability of the cluster scores, so it is the preferred method whenever reliability coefficients are available.

Cureton & D'Agostino [1] suggest that cluster scores are more useful than component scores (*see* **Principal Components Analysis**) and the **factor scores**. This is because the cluster scores are measured with little error and the interpretation of a cluster is generally clearer than a factor or component (i.e. the interpretation of a cluster is simply the feature that is common to all the variables in the cluster). They are also more reproducible in other data sets from similar populations than are component or factor scores.

Clustering, Complete Linkage

Complete linkage clustering is one of several agglomerative algorithms used in hierarchical cluster analysis to partition a set of n observations into g groups or clusters based on the data collected on the n observations. (*See* **Cluster Analysis of Subjects, Hierarchical Methods**, in particular for determining an appropriate value of g.)

Specifically, suppose p variables are collected on the n observations. Let the $n \times p$ matrix $\mathbf{X}$ contain these data as follows:

$$\mathbf{X} = \begin{bmatrix} x_{11} & x_{12} \ldots x_{1p} \\ x_{21} & x_{22} \ldots x_{2p} \\ \vdots & \vdots \quad \vdots \\ x_{n1} & x_{n2} \ldots x_{np} \end{bmatrix}.$$

Prior to performing complete linkage clustering, the matrix $\mathbf{X}$ must first be transformed into an $n \times n$ matrix $\mathbf{D}$ containing pairwise distances between observations. For example, one common choice for d_{ij}, the elements of $\mathbf{D}$, are the Euclidean distances

$$d_{ij} = \left[\sum_{k=1}^{p} (x_{ik} - x_{jk})^2 \right]^{1/2}$$

(*see* **Similarity, Dissimilarity, and Distance Measure**). The following steps are taken when performing hierarchical cluster analysis using complete linkage:

1. Initially, consider each of the n variables as n clusters. In other words, at the onset we have n clusters,

   $$C_1^{(1)} = S_1, \qquad C_2^{(1)} = S_2, \ldots, C_n^{(1)} = S_n,$$

   where $C_i^{(1)}$ is the ith cluster, S_i is the ith observation, $i = 1, 2, \ldots, n$, and where the superscript indicates that this is the first level of clustering.
2. Reduce the n observations (clusters) to $n - 1$ clusters by combining the two observations which have the smallest "distance" (d_{ij}) between them into one cluster. Assume, without loss of generality, that observations S_1 and S_2 are the two observations combined, and call the cluster into which they are combined $C_1^{(2)}$. We then have the $n - 1$ clusters

   $$C_1^{(2)} = (S_1, S_2), \qquad C_2^{(2)} = S_3,$$
   $$C_3^{(2)} = S_4, \ldots, C_{n-1}^{(2)} = S_n \tag{1}$$

   or

   $$C_1^{(2)} = (C_1^{(1)}, C_2^{(1)}), \qquad C_2^{(2)} = C_3^{(1)},$$
   $$C_3^{(2)} = C_4^{(1)}, \ldots, C_{n-1}^{(2)} = C_n^{(1)}. \tag{2}$$

3. Determine the distance between each of the clusters in (2) above. In complete linkage clustering, the "distance" between cluster $C_k^{(2)}$ and cluster $C_l^{(2)}$, $k, l = 1, 2, \ldots, n - 1$, is defined as the maximum of all pairwise distances between observations in cluster $C_k^{(2)}$ and observations in cluster $C_l^{(2)}$. This distance is denoted as $D_{kl}^{(2)}$. For example, $D_{13}^{(2)}$ for the clusters from (1) above is the maximum of (d_{13}, d_{23}), where d_{ij} is the distance between observations i and j. Note, at this step, $D_{kl}^{(2)} = d_{kl}$ for k not equal to 1.
4. Reduce the $n - 1$ clusters to $n - 2$ clusters by combining the two clusters in (2) with the smallest value of $D_{kl}^{(2)}$.
5. At subsequent steps, reduce the $n - j$ clusters to $n - j - 1$ clusters, $j = 2, 3, \ldots, n - 2$, until only one cluster (consisting of the entire sample) is obtained. Then choose an appropriate value of g, the final number of clusters into which the data are partitioned.

Note that a general complete linkage formula for determining the distance between a cluster $C_k^{(h)}$ and a cluster $C_l^{(h)}$, where $C_k^{(h)}$ was created by combining clusters $C_i^{(h-1)}$ and $C_j^{(h-1)}$ is

$$D_{kl}^{(h)} = 0.5 \times (D_{il}^{(h-1)} + D_{jl}^{(h-1)}) + 0.5 \times \left| D_{il}^{(h-1)} + D_{jl}^{(h-1)} \right|.$$

Further details can be found in Everitt [1] and McQuitty [2].

JOSEPH M. MASSARO

Clustering, Single Linkage

Single linkage clustering is one of several agglomerative algorithms used in hierarchical cluster analysis (*see* **Cluster Analysis of Subjects, Hierarchical Methods**) to partition a set n observations into g groups or clusters based on the data collected on the n observations (determining an appropriate value of g is covered elsewhere in this Encyclopedia).

Specifically, suppose that p variables are collected on the n observations. Let the $n \times p$ matrix $\mathbf{X}$ contain this data as follows:

$$\mathbf{X} = \begin{bmatrix} x_{11} & x_{12} & \dots & x_{1p} \\ x_{21} & x_{22} & \dots & x_{2p} \\ \vdots & \vdots & & \vdots \\ x_{n1} & x_{n2} & \dots & x_{np} \end{bmatrix}.$$

Prior to performing single linkage clustering, the matrix $\mathbf{X}$ must first be transformed into an $n \times n$ matrix $\mathbf{D}$ containing pairwise distances between observations. For example, one common choice for d_{ij}, the elements of $\mathbf{D}$, are the Euclidean distances

$$d_{ij} = \left[\sum_{k=1}^{p} (x_{ik} - x_{jk})^2 \right]^{1/2}.$$

The following steps are taken when performing hierarchical cluster analysis using single linkage:

1. Initially, consider each of the n variables as n clusters. In other words, at the onset we have n clusters
$$C_1^{(1)} = S_1, \quad C_2^{(1)} = S_2, \dots, C_n^{(1)} = S_n,$$
where $C_i^{(1)}$ is the ith cluster, S_i is the ith observation, $i = 1, 2, \dots, n$, and where the superscript indicates that this is the first level of clustering.
2. Reduce the n observations (clusters) to $n-1$ clusters by combining the two observations which have the smallest "distance" (d_{ij}) between them into one cluster. Assume, without loss of generality, that observations S_1 and S_2 are the two observations combined, and call the cluster into which they are combined $C_1^{(2)}$. We then have the $n-1$ clusters
$$C_1^{(2)} = (S_1, S_2), \quad C_2^{(2)} = S_3,$$
$$C_3^{(2)} = S_4, \dots, C_{n-1}^{(2)} = S_n \qquad (1)$$
or
$$C_1^{(2)} = [C_1^{(1)}, C_2^{(1)}], \qquad C_2^{(2)} = C_3^{(1)},$$
$$C_3^{(2)} = C_4^{(1)}, \dots, C_{n-1}^{(2)} = C_n^{(1)}. \qquad (2)$$
3. Determine the distance between each of the clusters in (2) above. In single linkage clustering, the "distance" between cluster $C_k^{(2)}$ and cluster $C_l^{(2)}$, $k, l = 1, 2, \dots, n-1$, is defined as the minimum of all pairwise distances between observations in cluster $C_k^{(2)}$ and observations in cluster $C_l^{(2)}$. This distance is denoted as $D_{kl}^{(2)}$. For example, $D_{13}^{(2)}$ for the clusters from (1) above is the minimum of (d_{13}, d_{23}), where d_{ij} is the distance between observations i and j. Note, at this step, $D_{kl}^{(2)} = d_{kl}$ for k not equal to 1.
4. Reduce the $n-1$ clusters to $n-2$ clusters by combining the two clusters in (2) with the smallest value of $D_{kl}^{(2)}$.
5. At subsequent steps, reduce the $n-j$ clusters to $n-j-1$ clusters $(j = 2, 3, \dots, n-2)$ until only one cluster (consisting of the entire sample) is obtained. Then choose an appropriate value of g, the final number of clusters into which the data is partitioned.

Note that a general single linkage formula for determining the distance between a cluster $C_k^{(h)}$ and a cluster $C_l^{(h)}$, where $C_k^{(h)}$ was created by combining clusters $C_i^{(h-1)}$ and $C_j^{(h-1)}$, is

$$D_{kl}^{(h)} = 0.5 * (D_{ik}^{(h-1)} + D_{jk}^{(h-1)}) - 0.5 * |D_{il}^{(h-1)} + D_{jl}^{(h-1)}|.$$

Further details can be found in Everitt [1], Florek et al. [2], and Sneath [3], and in the articles **Classification, Overview**, and **Similarity, Dissimilarity, and Distance Measure**.

JOSEPH M. MASSARO

Clustering

Clustering tests are of two basic types – cell count tests where the number of events in predefined regions are examined, and distance tests where the distance between nearest neighbors is examined. Use of matched control sets is a newer development. More work is needed on the definition and estimation of parameters for clustering.

Clustering can be defined as the "irregular" grouping of events from a **stochastic process** in either space or time or simultaneously in both space and time. More generally, it can be studied in any metric space that possesses a uniform or baseline "nonclustered" probability measure for the location of events (point process) under the **null hypothesis** of no clustering.

A major issue in this area, which is particularly acute in the medical context, is the differentiation between clustering as a general phenomenon, and the usually *post hoc* attempt to establish "significance" or "likelihood" of a real causal agent for a previously observed "cluster". The former question is amenable to reasonably standard statistical analysis. Usually, data are available from a large area or time period and a null hypothesis of "no clustering" can be formed. The description of a realistic **alternative "clustered" hypothesis** or family of hypotheses is usually more difficult, but a number of model cluster processes exist, and various *ad hoc* tests have been developed that will consistently detect a wide range of departures from the nonclustered null hypothesis. In many cases, these *ad hoc* tests have much to offer, since most clustering models are too inflexible to encompass the full range of possibilities seen in practice, and **likelihood ratio tests** based on them are usually complicated and may not have good **power** against other alternatives.

Unfortunately, it is far more common to encounter the latter situation, where some measure of "reality" is demanded for a "cluster" that has been identified before any statistical analysis has taken place. In this case, the temporal and/or spatial aspects of the cluster have been well circumscribed in advance and formal **hypothesis testing** is not valid. The problem is aptly illustrated by the Texas sharpshooter who fires his shots first and then positions the target to best advantage *afterwards*. Attempts to allow for this by adjusting for **multiple potential comparisons** are not very helpful, because the adjustment factor depends on the domain used for this, and by taking a large enough spatial or temporal domain, any cluster can be reduced to nonsignificance. In the end, the "reality" of any cluster ultimately depends on finding a cause and establishing that it also causes the disease in question in other circumstances. However, this is a costly and time-consuming process, and the "art of statistics" has an important role to play in helping to focus attention on "clusters" that still appear "highly unusual" after a range of statistical tests have been employed.

Such investigations usually start with readily available information, and clusters that are still interesting are then subjected to more stringent tests that may require the gathering of more data. A guideline for approaching this has been developed by the **Centers for Disease Control**, Atlanta, Georgia, USA [7, 49]. They propose a four-stage process of increasing complexity and cost, in which the investigation can be terminated after any stage if alternative explanations can be found or the evidence for clustering is no longer very compelling. In outline form, the stages are as follows:

Stage 1: Initial contact. The purpose at this stage is to collect information from the person(s) or group(s) first reporting a perceived cluster (hereafter referred to as the caller). The caller must be referred quickly to the responsible health agency unit, and the problem should never be dismissed summarily. The majority of potential cluster reports can be brought to successful closure at the time of initial contact, and the first encounter is often one of the best opportunities for communication with the caller about the nature of clusters.

Stage 2: Assessment. Once the decision has been made at Stage 1 to proceed further with an assessment, it is important to separate two concurrent issues: whether an excess number of cases has actually occurred, and whether the excess can be tied etiologically to some exposure. The first usually has precedence, and may or may not lead to the second. This stage initiates a mechanism for evaluating whether an excess has occurred. Three separate elements are identified:

1. a preliminary evaluation (Stage 2(a)) to assess quickly from the available data whether an excess may have occurred;
2. confirmation of cases (Stage 2(b)) to assure that there is a biological basis for further work; and

3. an occurrence investigation (Stage 2(c)) whose purpose is a more detailed description of the cluster through case-finding, interaction with the community, and **descriptive epidemiology**.

If an excess is confirmed, and the epidemiologic and biologic plausibility is compelling, proceed to Stage 3.

Stage 3: Major feasibility study. The major feasibility study examines the potential for relating the cluster to some exposure. It should consider all the options for geographic and temporal analysis, including the use of cases that are from a different geographic locale or time period and not part of the original cluster. In some instances the feasibility study itself may provide answers to the question under study.

If the feasibility study suggests that there is merit in pursuing an etiologic investigation, then the health agency should proceed to Stage 4. This may entail extensive resource commitment, however, and the decision to conduct a study will be tied to the process of resource allocation.

State 4: Etiologic investigation. Perform an etiologic investigation of a potential disease–exposure relationship. Using the major feasibility study as a guide, a specific protocol for the study should be developed and the study implemented.

Reporting of results. At whatever stage an investigation terminates, administrative closure is critical. Health authorities must remain aware that even internal reports are, in many circumstances, public documents, and can become part of legal proceedings. Even a brief memorandum to the record or a handwritten note summarizing a telephone call are subject to use in court and should be handled accordingly.

Issues of ***Statistics in Medicine*** (April–May 1996, Vol. 15) and the *American Journal of Epidemiology* (July 1990, Vol. 132) have been devoted exclusively to theoretical and practical issues related to clustering. These publications and the book edited by Elliot et al. [16] provide fuller details of points raised below.

Statistical Tests for Clustering

Tests for clustering, either spatially or temporally, fall into four main classes:

1. Methods based on cell occupancy counts for a partition of the region of interest.
2. Methods based on overlapping cells or adjacencies of cells with "high counts".
3. Distance methods.
4. Space–time clustering methods.

Methods can also be distinguished by the form of the null hypothesis. In nonmedical settings, often a uniform process is appropriate in which events occur according to a homogeneous **Poisson process** on the time axis (for temporal clustering) or the plane (for spatial clustering). For medical applications often some degree of inhomogeneity is appropriate for the nonclustered process. For **time series, seasonal** effects may need to be accounted for, and in studying spatial clustering, the nonuniform nature of the population density needs to be considered. In these circumstances, some form of **control** series is needed to allow for variations not related to short-range clustering.

Cell Occupancy Methods

These methods are equally appropriate to both temporal and spatial clustering as they take no account of the geometric structure of the region once it has been partitioned into nonoverlapping cells.

Dispersion Test. The simplest test for clustering is a heterogeneity or dispersion test [10]. When there are n cells, this is a simple **chi-square test** for an $n \times 1$ table. If E_i denotes the expected number of events in cell i, and N_i is the observed number, then the test is given by

$$T_{\mathrm{D}} = \sum_{i=1}^{n} \frac{(N_i - \mathrm{E}_i)^2}{\mathrm{E}_i}.$$

When all the E_i are large (≥ 5), the test has an approximately χ^2 distribution on n degrees of freedom. However, this is usually not the case. Nevertheless, T tends to a **normal distribution** as $n \to \infty$, in general. The **mean** and **variance** depend on whether one conditions on the total number of events $N = \sum N_i$. Usually, this is the case so that the N_i have a **multinomial distribution** with cell probabilities $p_i = \mathrm{E}_i/\mathrm{E}$, where $\mathrm{E} = \sum \mathrm{E}_i$, and total number of observations N. In that case [24, 38],

$$\mathrm{E}(T_{\mathrm{D}}) = n - 1,$$

$$\mathrm{var}(T_{\mathrm{D}}) = 2(n-1) + \sum \mathrm{E}_i^{-1} - \frac{1}{N}(n^2 - 2n + 2),$$

and $[T_D - E(T_D)]/\text{var}^{1/2}(T_D)$ is approximately a **standard normal deviate**.

Potthoff & Whittinghill's Test. Pothoff & Whittinghill [46, 47] considered a cell occupancy model in which the cell counts were Poisson with mean E_i under the null hypothesis. Under the alternative, the E_i were assumed to be multiplied by independent **gamma-distributed** variables with mean one, so that the observed counts had a **negative binomial distribution** (i.e. a compound Poisson-gamma distribution). They computed the **score** test as the variance of the gamma distribution tended to zero while keeping the means fixed, and arrived at a test of the form:

$$T_{PW} = \sum_{i=1}^{n} \frac{N_i(N_i - 1)}{E_i}.$$

Again, the N_i are multinomial and if $\max_i p_i \to 0$ as $n \to \infty$,

$$E(T_{PW}) = N - 1,$$
$$\text{var}(T_{PW}) \cong \frac{2(N-1)^2}{N},$$

and

$$\frac{[T_{PW} - E(T_{PW})]}{\text{var}^{1/2}(T_{PW})} \longrightarrow \mathcal{N}(0, 1).$$

Note that cells contribute nothing to T_{PW} unless there are at least two events in the cell. Also, when all the E_i are the same, this test is equivalent to the dispersion test given above. In general, T_{PW} gives less weight to cells with larger expected values than does T_D.

Dispersion Tests with Controls. In some circumstances, it is appropriate to consider whether the variability in a time series of events is greater than that in a control series. The control series may account for seasonal disease patterns or changing referral patterns and is used as a surrogate for the cell probabilities p_i defined above. An approach based on a chi-square test for independence in a $2 \times n$ table has been proposed by Fleiss & Cuzick [18] in which the case and control series comprise the two rows. The asymptotic distribution is *not* χ^2 on (n − 1) degrees of freedom (df) unless all cell counts are large, but as $n \to \infty$ the test does tend to be a normal with mean $(n - 1)$ and variance [25, 38]

$$\text{var}(T_D) \cong 2(n - 1 - N^*) + (p^* - 2)\left(N^* - \frac{n^2}{N}\right) + 2\left(\frac{n}{N}\right)(1 - p^*) - \left(\frac{n}{N}\right)^2 (5 - p^*) + O\left(\frac{1}{n}\right),$$

where

$$p^* = \overline{p}^{-1} + (1 - \overline{p})^{-1},$$
$$N^* = \sum_{i=1}^{n} N_i^{-1},$$

$\overline{p}$ is the proportion of all events that are in the case series, and N_i is the total number of events in period i for cases and controls combined.

Tests Based on the Maximum Cell Count. When looking for a single cluster, tests based on the maximum cell count are an obvious choice. When done in a *post hoc* fashion, that is, when the cluster has already been identified, the significance is completely dependent on the number of cells included in the sample. A more attractive option is to examine the maximum cell count in a number of short subsets of the data. This approach has an intuitive appeal, and will detect multiple clusters. A weakness is that the cells are chosen in advance and clusters that are split over two cells will not be fully scored. Also, the method assumes equal expected numbers in the different cells. The method was first proposed by Ederer et al. [15]. For their test, the cells are first partitioned into a number of nonoverlapping time series. For example, if the data consisted of quarterly event rates over a 20-year period in a number of localities, the individual time series might be chosen to be the event rates over a five-year period for each locality. These individual series are then self-normalized by conditioning on the total number of events in that subseries. Thus, if N_{ij} denotes the number of events in cell i of series $j, i = 1, \ldots, I, j = 1, \ldots, J$, one computes $M_j = \max_{1 \le i \le I} N_{ij}$ conditional on $N_j = \sum_{i=1}^{I} N_{ij}$.

The overall test statistic is then

$$T_{EMM} = \sum_{j=1}^{J} M_j,$$

and is normalized by the conditional means:

$$\mathrm{E}(T_{\mathrm{EMM}}) = \sum \mathrm{E}(M_j|N_j),$$

and conditional variances

$$\mathrm{var}(T_{\mathrm{EMM}}) = \sum \mathrm{var}(M_j|N_j)$$

to form an approximately standard normal deviate in the usual way.

Thus, this test only looks for evidence of clustering within the subseries and by appropriate choice of the space and time groups can be viewed as a space–time clustering method as well. However, by including only one geographic entity and allowing the subseries to be rather long, it takes on more the character of a purely temporal statistic. An underlying assumption is that all cells in the same subseries have the same expected event rate under the null hypothesis. Thus, some adjustment for seasonal variation can be made by creating subseries based on the same months in successive years, and temporal trends can be accounted for by using short time periods, but it is not possible to adjust for both simultaneously.

Ederer et al. rely on the asymptotic normality of their test and thus it is only necessary to compute $\mathrm{E}(M_i|N_i)$ and $\mathrm{var}(M_i|N_i)$, for which Mantel et al. [35] have given tables for small values of N_i and I. Grimson [22] has obtained the exact distribution of the maximum, based on factorial moments and the inclusion–exclusion formula. Specifically, he shows that when $N_i = r$ and $I = c$:

$$\Pr(M_i \geq m) = i^r \sum_{k=1} (-1)^{k+1} \binom{c}{k} \times \sum_{j_1,\ldots,j_k=m}^{r} (c-k)^{r-j_1-\cdots-j_k} \times \binom{r}{j_1,\ldots,j_k}.$$

Levin [31] has given a large sample approximation based on Edgeworth expansions.

Overlapping or Adjacent Cells Methods

One of the problems with cell occupancy methods is that clusters may span more than one cell. To be valid, the partitioning of space for these methods must be independent of the location of events so that it is likely that any clusters will not match up with the partitioning. Attempts to address this problem have led to tests based on overlapping or neighboring cells.

Scan Tests. For temporal clustering, where events are distributed on a line and cells are often based on equal length intervals (e.g. months), an obvious solution exists. Instead of looking only at the number of events in prespecified intervals (e.g. six months), it is also possible to look at overlapping intervals (e.g. six-monthly intervals beginning every quarter). The most thorough method is to look at all intervals of a fixed size (e.g. six-monthly intervals beginning every day), and consider the maximum number of events in any such interval. However, the fact that overlapping intervals are now being considered greatly complicates the problem of determining the distribution of the scan test. To simplify matters, one usually assumes that the time axis is broken into sufficiently small intervals (e.g. one day) so that one can safely assume that the scan is continuous. Under the null hypothesis, the problem is then transformed into determining the distribution of $n(t, N)$, the maximum number of events in an interval of length t when N events are uniformly distributed on the unit interval. Computations for this probability go back at least as far as the 1940s [2, 33], but Naus [39, 41, 42] was the first to develop this as a test for temporal clustering. Exact calculations require detailed combinational expressions and are very computationally time-consuming in the important case when t is small. Various approximations have been proposed [3, 13, 19, 21, 30, 42, 51] (*see* **Scan Statistics for Disease Surveillance**).

The primary quantity of interest is $p(n, t, N) = \Pr(n(t, N) \geq n)$, and approximations are given in terms of the **binomial** probabilities $b(j, n, p) = \binom{n}{j} p^j (1-p)^{n-j}$. Wallenstein & Neff [51] give the simple approximation:

$$p(n, t, N) \cong \left(\frac{n}{t} - N + 1\right) b(n, N, t) + 2 \sum_{j=n+1}^{N} b(j, N, t),$$

which is accurate when $p(n, t, N)$ is small and, in fact, exact when $n > N/2$ and $t < \frac{1}{2}$. Berman & Eagleson [3] give an upper bound of similar complexity based on a second-order inclusion–exclusion

(Bonferroni) approximation:

$$P(n,t,N) \le (N-n+1)\sum_{j=n-1}^{N} b(j,N,t) - \sum_{j=n-1}^{N}(-1)^{j+n-1}b(j,N,t),$$

which is also a good approximation in some cases. Glaz [20, 21] has developed more complicated expressions on the basis of higher-order **Bonferroni inequalities** and a product-type inequality, all of which have greater accuracy. Two series of expressions are given that increase in complexity (and hopefully accuracy) as L increases.

The first is an upper bound: for $1 \le L \le n \le N/2$:

$$P(n,t,N) \le \sum_{j=1}^{L-1} Q_j^* + (N-n+2-L)Q_L^*,$$

where

$$Q_1^* = \sum_{J=n-1}^{N} b(j,N,t),$$

$$Q_2^* = Q_1^* - \sum_{j=n-1}^{N}(-1)^{j+n-1}b(j,N,t),$$

and for $j \ge 3$

$$Q_j^* = b(n-1,N,t) - b(n,N,t) + \sum_{k=j}^{N-n+1}(-1)^k \prod_{i=1}^{j-2}\left[\frac{1-k(k-1)}{i(i+1)}\right] \times b(n+k-1,N,t).$$

A more accurate approximation is given by

$$P(n,t,N) \cong 1 - \left(1 - \sum_{j=1}^{L} Q_j^*\right) \times \left[\left(1-\sum_{j=1}^{L} Q_j^*\right) \Big/ \left(1-\sum_{j=1}^{L-1} Q_j^*\right)\right]^{N-n+1-L},$$

which is said to be most accurate when $L = n$. Neff & Naus [43] have tabulated $P(n,t,N)$ for $t < \frac{1}{2}$, $3 \le n < N \le 25$.

Approximations for $P(n,t,N)$ under various clustering alternatives are described in Wallenstein et al. [52], which are important for power calculations.

Glaz [21] gives references for approximations of the moments of $n(t,N)$ and various related quantities. He also discusses scan statistics based on the use of a range of different window widths, t_i. Nagarwalla [37] also discusses a scan test with variable window width. Simulation is required to approximate its null distribution.

Extensions of the scan statistic to the plane or higher dimensions have not been very fully developed. There are problems in the choice of metric (e.g. circles or squares) and the structure of overlapping cells is much more complicated in the plane. Naus [40] has some theoretical results for the plane, and Openshaw et al. [44] give an example of an application that uses circles of different radii. This approach is very descriptive, however.

Runs Test. The runs test is a well-established method for evaluating clustering in sequences of **binary** data. For temporal data, such sequences can be created by looking at intervals of fixed length and recording whether one or more events occur in each interval, or, when events are more common, intervals in which an excessive number of events have occurred. The elements of the sequence are then treated as independent Bernoulli trials with fixed success probabilities. As the success probability is usually unknown, one usually is interested in the probability of a run of length at least m in n trials in which there are known to be s successes overall. Denoting this as $P_R(m,s,n)$, the exact distribution is (cf. [5, p. 257])

$$P_R(m,s,n) = \sum_{i=1}^{[s/m]}(-1)^{i+1} \times \binom{n-s+1}{i}\binom{n-im}{n-s} \Big/ \binom{n}{s}.$$

Burr & Cane [6] have developed and surveyed various approximations and Naus [42], on the basis of ideas used for the scan test, suggested

$$P_R(m,s,n) \cong 1 - Q_2^{**}\left(\frac{Q_3^{**}}{Q_2^{**}}\right)^{(n/m)-2},$$

where

$$Q_2^{**} = \left[m \binom{n-m-1}{s-m} + \binom{n-m}{s-m} \right] \Big/ \binom{n}{s},$$

$$Q_3^{**} = \left[2m \binom{n-m-1}{s-m} + \binom{n-m}{s-m} - \binom{m}{2} \binom{n-2m-2}{s-2m} - m \binom{n-2m-1}{s-2m} \right] \Big/ \binom{n}{s}.$$

A simple, but less accurate, approximation is given by Feller [17]:

$$P_R(m, s, n) \cong 1 - \exp(-nqp^m),$$

where $p = 1 - q = s/n$. Tests have also been based on the number of runs greater than a certain size or the total number of runs (change from zero to one or vice versa) in a series [27].

Join–Count Statistics. This approach was first developed by Moran [36], and the test is sometimes called the Geary–Moran statistic. It has been developed for two-dimensional maps, but the ideas are quite general and suitable for other dimensions as well. It can be seen as a hybrid between a cell occupancy method and a distance method. The basic approach is as follows: one starts with a map in which a partition into cells is given. Cells with "large" numbers of events are determined by some scheme chosen separately by the investigator. Common approaches are to choose cells in which the observed number of events exceeds the expected number by a given percentage (standardized incidence ratio) (*see* **Standardization Methods**) or is significantly different at a predetermined level (say 5%). The number of pairs of "such" extreme cells that are adjacent, that is, that share a common boundary (denoted T_{JC}), is then determined and compared against expected numbers. The problem can be reduced to the analysis of a graph in which the cells are vertices and adjacent cells are connected by edges. The null hypothesis is that the "extreme cells" are chosen at random (permutational distribution). Under this hypothesis, the expected number of adjacent cells is

$$E(T_{JC}) = Np_1,$$

where N is the total number of joins (adjacent cells) and for $j = 0, 1, 2, \ldots$,

$$p_j = \prod_{i=0}^{j} \frac{n_0 - l}{n - l},$$

n = number of points, and n_0 = number of "extreme" points, and the variance is

$$\text{var}(T_{JC}) = N(p_1^2 - p_3) - N^2(p_1^2 - p_3) + p_2 \sum_{i=1}^{n} M_i(M_i - 1) - p_3 \sum_{j=1}^{n} K_j,$$

where M_i is the number of joins emanating from point i, and K_j is the number of points to which the points at the ends of join j are both joined.

Asymptotic normality of $[T_{JD} - E(T_{JC})]/\text{var}^{1/2}(T_{JC})$ can be established. Besag [4] has noted that even in the absence of clustering, the null hypothesis may not hold when extreme cells are determined by observed to expected ratios. When the populations in different cells are not the same, and low population cells are next to each other (e.g. rural areas), those cells are more likely to be extreme because of greater random fluctuations, and artefactual aggregation could arise. Contrariwise, if there is general, but unaccounted for, extra Poisson variation, and significance levels based on the Poisson distribution are used to determine extreme cells, then cells with large underlying populations could be over-represented. In these circumstances, more complicated expressions for the mean and variance of T_{JC} are needed, or **simulation** must be used to assess the significance level.

Distance Methods

Nearest Neighbor Tests for Uniform Populations. Under the assumption of a uniform (or homogeneous Poisson) distribution, tests for clustering have been based on the distance to the kth nearest neighbor of any particular case [9, 32]. If d_k denotes the distance to the kth nearest point from any arbitrary point in the plane, then when the number of points is large (so edge effects can be discounted), d_k has a gamma (μ, k) distribution:

$$P(d_k > t) = \frac{\sum_{j=0}^{k-1} \mu^j e^{-\mu}}{j!},$$

where $\mu = 2\pi\lambda d_k^2$ and λ is the event rate of the underlying Poisson process. Tests have been based on the mean of d_k, often with $k = 1$, that is, the average distance from an arbitrary point to its nearest neighbor. Other approaches based on more complicated sampling plans are surveyed in [48, Chapter 7].

Covariance Function. An alternative approach is to use the k function associated with homogeneous **point processes** [13]. Specifically, for a homogeneous point process with event rate λ per unit area, define $k(t) = \lambda^{-1}\mathrm{E}$ (number of events within distance t of an arbitrary event). For a Poisson process with unit intensity, $k(t) = \frac{1}{2}\pi t^2$. Empirical estimates $\hat{k}$ can be formed in an obvious way and compared with $k(t)$ to see if more or fewer events are occurring near to an arbitrary event.

Nearest Neighbor Tests for Nonuniform Populations. Work with homogeneous populations arose from questions in ecology and geography and is generally not applicable to questions of disease association in populations because of the nonhomogeneous distribution of the population. In this case, some estimate of the local population density is also required. Cuzick & Edwards [11, 12] have developed a variety of tests in this setting. When the population density is known precisely, this test consists of creating circles of different radius but constant expected number of events around each case and counting the number of observed events in all such circles. If the expected number is taken to be λ and O_i is the observed number of events in the circle around event i, then this takes the form

$$T_{1s} = \sum_i (O_i - \lambda),$$

with

$$\mathrm{E}(T_{1S}) = 0,$$
$$\mathrm{var}(T_{1S}) = n\lambda + 2n^{-1}N_S + n^{-1}N_t - n\lambda^2,$$

where n is the number of points, N_S is the number of pairs of points in each other's neighborhood, and $N_t = \sum M_i(M_i - 1)$, where M_i is the number of points for which point i falls in its neighborhood. In many circumstances, precise information about the geographic location of the population is unavailable and information about this must be replaced by a control series selected in an appropriate way. Cuzick & Edwards [11] developed a test on the basis of the number of cases in the k nearest neighbors ($k - NN$) to each case; see also Schilling [50] and Henze [26]. Specifically, cases and controls are labeled from $1, \ldots, N$ and

$$T_k = \sum_{i=1}^{N}\sum_{j=1}^{N} a_{ij}\delta_i\delta_j,$$

where δ_i is the indicator for the ith event to be a case and a_{ij} is the indicator for event j to be among the $k - NN$s of event i. This test can also be viewed as formally similar to a join–count test, except that the a_{ij} is not in general symmetric (although it is easily converted by replacing a_{ij} with $\frac{1}{2}(a_{ij} + a_{ji})$). The permutational distribution of T_k can be computed as before (assuming cases are selected at random from the set of cases and controls) and yields

$$\mathrm{E}(T_k) = p_1 kn,$$

where p_1 is as in the section on join–count statistics, where n_o denotes the number of cases and n the total number of points, and

$$\begin{aligned}\mathrm{var}(T_k) = {} & (kn + N_s)p_1(1 - p_1) \\ & + [(3k^2 - k)n + N_t - 2N_s](p_2 - p_1)^2 \\ & - [k^2(n^2 - 3n) + N_s - N_t](p_1^2 - p_3),\end{aligned}$$

where N_s is the number of pairs of points for which the $k - NN$ relation is symmetric, that is, pairs that are $k - NN$s of each other and $N_t = \sum_{i=1}^{n} M_i(M_i - 1)$, and where M_i is the number of points for which point i is a $k - NN$.

Diggle [14] has suggested an alternative based on comparing the k function of the cases with that of the controls. His approach essentially uses circles of the same geographic size, whereas the Cuzick–Edwards approach uses circles of approximately equal population. The choice of approach depends on the type of alternative envisaged. Cuzick & Edwards [11] have also considered tests based on the number of cases encountered before k controls. When $k = 1$, this is similar to the runs test sometimes used to look for clustering in one dimension.

Space–Time Clustering Methods

When events are thought to be closely related to exposures both in time and distance, such as in

epidemics of disease associated with contagious infectious agents, then tests based on space–time clustering are most appropriate. Such tests are self-normalizing in the sense that any overall nonhomogeneity in the time course of the events or their spatial distribution is automatically accounted for. This has great advantages in terms of automatically cancelling out seasonal effects of nonhomogeneous population distributions, but, of course, limits the ability of the test to detect alternatives that vary both in time and space. Thus, a point source of events or a change that affected the entire geographic region under consideration would not be detected. Thus, these tests are appropriate for infectious diseases with short incubation times, but Chen et al. [8] have shown they have low power for the type of clustering expected in adult cancer or other chronic diseases where the **latent period** between exposure and disease is long.

The simplest space–time tests partition space and time separately and then perform a chi-square test for independence on the associated two-way **contingency table** in which spatial cells are rows and temporal cells are columns. However, more interest has been generated by the work of Knox [28, 29], in which distances and times are computed between all pairs of points and tests are developed to determine whether events that are close spatially are also close in time. By partitioning distances and time intervals, these data can be summarized in a two-way table, but the induced **correlations** arising from considering pairs of points means that the **chi-square distribution** is invalid for assessing independence. Knox only considered a **two by two table** formally by dichotomizing time and spatial pairs as close or distant in each variable. One problem with Knox's approach is the arbitrary dichotomy on the close and distant pairs. Related tests have been proposed by Pinkel & Nefzger [45], Barton & David [1] and Mantel [34]. Mantel [34] considered a more general approach giving weights to distances that decrease as the distance increases. Knox's tests is then a special case in which the weight changes from one to zero, once the cut-off is exceeded. Mantel's test can be written in the very general form:

$$T_{\mathrm{M}} = \sum \sum_{i \neq j} X_{ij} Y_{ij},$$

where $X_{ij} = a(i, j)$ is a score for the pair of spatial variables and $Y_{ij} = b(i, j)$ is a score for the pair of temporal variables. Under the assumption that the spatial variables are unrelated to the temporal variables, the permutational distribution of T_{M} can be simulated or approximated. For large samples, the permutational mean and variance can be computed and asymptotic normality assumed, although conditions for this are not clearly known [23]. Even the computation of the permutational variance can be quite involved [34].

Coarsening at Random

Incomplete Data

Incomplete data often occur in biostatistical contexts. Typical examples include **censoring** in **survival analysis**, dropout in longitudinal studies (*see* **Nonignorable Dropout in Longitudinal Studies**), and missing values in multivariate data sets (*see* **Missing Data**). Generally, this can be modeled by replacing the incomplete observation by the subset of the sample space that is known to contain the observation one had wished to make. For instance, right censoring gives rise to half-lines from the censoring time to infinity. Observations where incompleteness is represented by subsets of the sample space in this way are called *coarsened*. Typically, the subsets are stochastic – for instance, determined by a stochastic censoring time – and the criteria for ignoring this randomness have been useful, particularly in the context of missing data and right censoring. In the general model, these criteria go under the name of *coarsening at random*.

Coarsening at random was introduced as a generalization of missing at random by Heitjan and Rubin [3]. Heitjan [2] gives several biostatistical examples and an application to data from the Stanford Heart **Transplantation** Program. Nielsen [6] discusses how to analyze survival data with coarsely observed covariates.

The Coarsening Model

Let X be a random variable we intend to observe but only observe incompletely. Instead we observe a subset, Y, of the sample space, $\mathcal{X}$; Y represents what is observed about X – in particular, $X \in Y$ – but may depend on further randomness. This is modeled by an auxiliary random variable, G, such that Y is a (nonrandom) function of (X, G), that is, $Y = Y(X, G)$, say. Often, G is incompletely observed as well – for instance, a censoring time is not observed unless the survival time is censored – and this is modeled by a subset, H, of the sample space, $\mathcal{Z}$, of G. Thus, the incomplete observation of X is represented by a subset $T = Y \times H$ of the product, $\mathcal{X} \times \mathcal{Z}$, of the sample spaces. This subset should represent all that is known about the intended observation, X, and the coarsening variable, G. Therefore, T contains exactly those elements, (x, g) of $\mathcal{X} \times \mathcal{Z}$ that are mapped to T; that is, $\{(x, g) \in \mathcal{X} \times \mathcal{Z} : T(x, g) = T\}$. Typically, there is a natural choice of the *coarsening variable*, G; otherwise G is just the observed subset, Y.

A slightly more general model is discussed by Nielsen [5] and Gill et al. [1].

Example

(1) Let X be a survival time and G, a censoring time. We observe the smaller of these two, $T^* = X \wedge G$ and which one is the smallest. Such data are called right censored. Here,

$$T(X, G) = \begin{cases} \{X\} \times [X; \infty] & \text{if } T^* = X \\ ]G; \infty[\times \{G\} & \text{if } T^* = G \end{cases}. \tag{1}$$

(2) Let X denote age, which is reported rounded either to the nearest month ($G = 0$) or the nearest year ($G = 1$). Such data are called heaped. Let T^* be the age reported, that is,

$$T^*(X, G) = \begin{cases} \dfrac{\lfloor 12X + 6 \rfloor}{12} & \text{if } G = 0 \\ \left\lfloor X + \frac{1}{2} \right\rfloor & \text{if } G = 1 \end{cases}, \tag{2}$$

where $\lfloor x \rfloor$ is the largest integer not greater than x. Then

$$T(X, G) = \begin{cases} [T^* - \frac{1}{24}; T^* + \frac{1}{24}[\times \{0\} & \text{if } G = 0 \\ [T^* - \frac{1}{2}; T^* + \frac{1}{2}[\times \{1\} & \text{if } G = 1 \end{cases}. \tag{3}$$

Let f_θ be the density of the distribution of X and let the conditional distribution of G given $X = x$ have density $h_\gamma(g|x)$. All densities – probability density functions or probability mass functions – here and in what follows are densities with respect to probability measures. A density with respect to a probability measure is obtained from an ordinary density by dividing it with a fixed density. The reference measure is then the probability measure given by the fixed density; see [4] for a discussion.

The conditional density of T given $X = x$ is then $k_\gamma(t|x) = E_x[h_\gamma(G|x)|T(x, \cdot) = t]$; here, the expectation is with respect to the reference measure of the

distribution of G given $X = x$; this may depend on x. The unconditional density of T is given by

$$\begin{aligned}\varphi_{\theta,\gamma}(t) &= E[f_\theta(X)h_\gamma(G|X)|T = t] \\ &= E[f_\theta(X)k_\gamma(T|X)|T = t], \end{aligned} \quad (4)$$

where the expectation is with respect to the reference measure of the joint distribution of (X, G).

Let $P_{\theta,\gamma}$ be the distribution of (X, G) defined above. A statistical model is obtained when (θ, γ) varies in a space, $\Theta \times \Upsilon$.

Coarsening at Random

Three different concepts of coarsening at random have been developed.

- A *probability*, $P_{\theta,\gamma}$, is *absolutely coarsened at random* or CAR(ABS) if for each pair (x, x') $P_{\theta,\gamma}\{T \in D|X = x\} = P_{\theta,\gamma}\{T \in D|X = x'\}$ for all sets $D \subseteq \{t = y \times h : x, x' \in y\}$.
- A *statistical model* $(P_{\theta,\gamma})_{(\theta,\gamma)\in\Theta\times\Upsilon}$ is *relatively coarsened at random* or CAR(REL) if for all $\gamma \in \Upsilon$ and all $t = y \times h$, the conditional density $k_\gamma(t|x)$ is constant for $x \in y$.
- An *observation* t is a *random coarsening* of x if for all $\gamma \in \Upsilon$ $k_\gamma(t|x)$ only depends on x through y, that is, is constant for $x \in y$.

Example

(1) Suppose the reference measure, ν, of the distribution of G given $X = x$ in the right-censoring example does not depend on x. Then

$$k_\gamma(t|x) = \begin{cases} \dfrac{P_\gamma([x;\infty])}{\nu([x;\infty])} & \text{if } t = \{x\} \times [x;\infty[\\ h_\gamma(g|x) & \text{if } t =]g;\infty[\times\{g\} \end{cases}. \quad (5)$$

The model is CAR(REL) if this expression is the same for all $x \in y$, that is, if $h_\gamma(g|x)$ does not depend on $x \in]g;\infty[$.

(2) In the heaping example, $k_\gamma(t|x) = h_\gamma(g|x)$, and the model is CAR(REL) if $h_\gamma(g|x)$ only depends on x through what is observed about x. Thus, $h_\gamma(1|x)$ may only depend on the age rounded to the closest year, $\lfloor x + 1/2 \rfloor$, whereas $h_\gamma(0|x)$ may depend on the month as well (subject to the total mass restriction, $h_\gamma(1|x)q_x + h_\gamma(0|x)(1 - q_x) = 1$, where q_x is the mass assigned by the reference measure to the set $\{G = 1\}$ given $X = x$).
The probabilities are CAR(ABS) if $P_\gamma\{G = 1|X = x\} = h_\gamma(1|x)q_x$ only depends on the age rounded to the nearest year. Owing to the total mass restriction also, the probability $P_\gamma\{G = 0|X = x\} = h_\gamma(0|x)(1 - q_x)$ can only depend on age rounded to the nearest year.

If all the probabilities $P_{\theta,\gamma}$ in a model are CAR(ABS), then the statistical model is CAR(REL); the converse is not generally true. However, if the reference measure is a product measure, then the probability $P_{\theta,\gamma}$ is CAR(ABS) if the statistical model is CAR(REL).

If CAR(REL) holds, then the **likelihood** factors

$$L_t(\theta, \gamma) = \varphi_{\theta,\gamma}(t) = E[f_\theta(X)|T = t]k_\gamma(t|x) \quad (6)$$

and the **profile likelihood** of θ is just

$$L_t(\theta) = E[f_\theta(X)|T = t]. \quad (7)$$

If furthermore the probabilities are CAR(ABS), then the profile likelihood simplifies to

$$L_t(\theta) = \begin{cases} f_\theta(x) & \text{if } t = \{x\} \times h \\ \displaystyle\int_y f_\theta(x)d\mu(x) & \text{if } \mu(y) > 0 \end{cases}, \quad (8)$$

where μ is the reference measure of the distribution of X. Notice that (8) does not cover all possible observations t; generally, we have to rely on (7).

Example

(1) In the right-censoring example, the profile likelihood becomes

$$L_t(\theta) = \begin{cases} f_\theta(x) & \text{if } t = \{x\} \times [x;\infty[\\ P_\theta\{X > g\} & \text{if } t =]g;\infty[\times\{g\} \end{cases} \quad (9)$$

if the probabilities are CAR(ABS).

(2) In the heaping example, the likelihood becomes

$$L_t(\theta) = \begin{cases} \displaystyle\int_{[t^*-\frac{1}{24};t^*+\frac{1}{24}[} f_\theta(x)(1 - q_x)\mathrm{d}\mu(x) & \text{if } g = 0 \\ \displaystyle\int_{[t^*-\frac{1}{2};t^*+\frac{1}{2}[} f_\theta(x)q_x\,\mathrm{d}\mu(x) & \text{if } g = 1 \end{cases} \quad (10)$$

where t^* is the observed value of T^*, that is, the observed rounded age, if CAR(REL) holds. If also CAR(ABS) holds, then the q_x and $1 - q_x$ terms disappear.

Ignorability

The concept of coarsening at random is useful because it allows one to discuss when and to what extent incompleteness of observations may be ignored when doing likelihood-based inference. In this section, we will discuss three different kinds of ignorability.

If a statistical model is CAR(REL), the **nuisance parameter**, γ, may be ignored for likelihood-based inference, because of the factorization of the likelihood. **Maximum likelihood** estimation of θ is performed as if the coarsening mechanism, that is, γ, is known.

Example In the heaping example, we see that the profile likelihood of θ is a weighted integral of the density over the observed set y if the model is CAR(REL). Thus, apart from the known weights (q_x and $1 - q_x$), we may ignore the coarsening mechanism when calculating the likelihood.

If the probabilities are CAR(ABS), then the coarsening mechanism can be ignored. The θ-part of the likelihood can be calculated from the marginal model of X treating the mapping $Y(X, G)$ as a function of X alone.

Example In the right-censoring example, if CAR(ABS) holds, the profile likelihood is just the same as if the censoring had been fixed.

It is clear that the second kind of ignorability is stronger than the first. CAR(ABS) implies that we may treat the data as if the coarsening is fixed rather than stochastic. When the model is CAR(REL), we can treat the coarsening as known (but stochastic).

CAR(ABS) will in many applications be a questionable assumption as discussed by Heitjan [2] (for instance, in the case of age heaping). Here the weaker assumption, CAR(REL), may be more reasonable.

For ignorability in a **Bayesian** sense, it suffices that the given observation is coarsened at random and that the parameters θ and γ are a priori independent; this implies that the parameters are a posteriori independent. In particular, the posterior distribution of θ can be calculated without having to calculate the posterior distribution of γ or specifying a **prior distribution** of γ.

Example In the right-censoring example, suppose X is **exponentially distributed** with intensity θ. If the prior distribution of θ is exponential with intensity a, then the posterior distribution given y is

$$\begin{aligned}\pi(\theta, \gamma|y) &\propto L_t(\theta, \gamma) \cdot \pi(\theta, \gamma) \\ &\propto (t^* + a)\exp(-\theta(t^* + a)) \\ &\quad \cdot k_\gamma(t|x)\pi(\gamma) \qquad (11)\end{aligned}$$

where t^* is the observed value of $X \wedge G$, if θ and γ are a priori independent. Thus, the posterior distribution of θ is exponential with intensity $t^* + a$. It should be noted that this result uses that the reference measure is a product measure; without this structure the posterior distribution would involve $E[f_\theta(X)|T = t]$ instead of $\exp(-\theta t^*)$.

SØREN FEODOR NIELSEN

Cochran, William Gemmell

Born: July 15, 1909, in Rutherglen, Scotland.
Died: March 29, 1980, in Orleans, Massachusetts.

William G. Cochran. Reproduced by permission of the Royal Statistical Society

William Cochran was a leading contributor to the British–American school of applied statistics during a period of rapid development of the field across the middle decades of the twentieth century. Coming from a modest family background, he early in life showed academic talents that carried him first to Glasgow University and then to Cambridge University, where he studied mathematics, applied mathematics and statistics. His formal education ended with an M.A. degree from Cambridge because **Frank Yates** made an offer, unusual in the depression year of 1934, for him to join the staff at the Rothamsted Experimental Station, where he carried out major analyses of long-term agricultural experiments, gained much practical experience, and became well known in the field. Responding to an invitation from **George Snedecor** of Iowa State College (now University) at Ames, Cochran emigrated to the US in 1939, carrying with him deep involvement with the extensive improvements in applied statistics then taking place in Britain. The US at the time had relatively little exposure to newer methods and theories, especially those deriving from **R.A. Fisher**. In 1943 and 1944, he worked with the Statistical Research Group at Princeton University, specifically on military problems of naval warfare and bomb efficiency. After the war, he was recruited by **Gertrude Cox** to the newly formed Institute of Statistics in North Carolina, where he organized and headed the graduate program in experimental statistics at North Carolina State College in Raleigh. In 1949, he became chairman of the Department of Biostatistics in the School of Hygiene and Public Health at the Johns Hopkins University, where a shift of his focus from agricultural to medical and biological applications took place. In 1957, Cochran moved to Massachusetts to join the Department of Statistics that Frederick Mosteller had just started at Harvard University, where he remained until his retirement in 1976.

Alongside the teaching and research that were the formal responsibilities of his academic positions, Cochran contributed to many panels, committees, and seminars. He was a leading statistician for nationally and internationally prominent reports on the effects of **radiation** in Hiroshima, the Kinsey Report of human sexual behavior, the **Salk polio vaccine** trials, the pivotal Surgeon General's 1964 Report on **Smoking and Health**, and equality of educational opportunity. He published more than 100 research papers, and important books that became widely used text and reference books through numerous editions, most notably: *Experimental Designs* (with Gertrude Cox) in 1950 (1957, 1992); *Sampling Techniques* in 1953 (1963, 1977), and a substantially revised version of George Snedecor's influential *Statistical Methods* in 1967 (1980, 1989). A posthumous text *Planning and Analysis of Observational Studies* was edited in 1983 by Lincoln Moses and Frederick Mosteller. Cochran's publisher, John Wiley & Sons, put out a thick volume of collected papers in 1982.

Bill Cochran was modest in demeanor, but penetrating and quick in his perceptions and analyses of statistical problems. He was a gifted and much respected teacher and speaker at scientific meetings who could always illustrate theory from a wealth of

applications often drawn from personal experience. Well-known leaders in many areas of statistics are among his 40 or so doctoral students. Above all, he was a distinguished scientist, and was fittingly recognized as such by election to the US National Academy of Sciences in 1974, an honor all too rare among biometricians.

A.P. DEMPSTER

Cochrane Collaboration

For all but the last 100 years, decisions on how to treat patients were almost always based on personal experience, anecdotal case histories, and comparisons between a group of patients who received one treatment with an entirely separate group of patients who did not receive that treatment. These processes, although subject to many biases, are still in use today but ways to minimize these biases are now available, accepted, and more easily adopted. Among these is the use of the randomized trial (*see* **Clinical Trials, Overview**) as a means of providing more reliable estimates of the relative effects of interventions, since the only difference between the patients in the groups being compared in a randomized trial will be that of most interest: namely, the interventions under investigation.

However, in part because of chance variations in the types of patients allocated to the different interventions in the randomized trial, the results of a single trial will rarely be sufficient. Most trials are too small and their results are not sufficiently robust against the effects of chance. In addition, small trials might be too focused on a particular type of patient to provide a result that can be either easily or reliably generalized to future patients. Added to this, the amount of information about health care, including that coming from individual randomized trials, is now overwhelming. Vast amounts of information are now readily available in journals, books, magazines, the media and, especially in recent years, on the Internet. However, people making decisions about health care – including patients, their carers, health care professionals, policy makers, and managers – need high quality information and, unfortunately, much of what is available is of poor quality.

To help identify which forms of health care work, which do not, and which are even harmful, results from similar randomized trials need to be brought together. Trials need to be assessed and those that are good enough can be combined to produce both a more statistically reliable result and one that can be more easily applied in other settings. This combination of trials needs to be done in as reliable a way as possible. It needs to be systematic. A systematic review uses a predefined, explicit methodology. The methods used include steps to minimize bias in all parts of the process: identifying relevant studies, selecting them for inclusion, and collecting and combining their data. Studies should be sought regardless of their results.

A systematic review does not need to contain a statistical synthesis of the results from the included studies. This might be impossible if the designs of the studies are too different for an averaging of their results to be meaningful or if the outcomes measured are not sufficiently similar. If the results of the individual studies are combined to produce an overall statistic, this is usually called a **meta-analysis** (*see* **Meta-analysis of Clinical Trials**). A meta-analysis can also be done without a systematic review, simply by combining the results from more than one trial. However, although such a meta-analysis will have greater mathematical precision than an analysis of any one of the component trials, it will be subject to any biases that arise from the study selection process, and may produce a mathematically precise, but clinically misleading, result.

The Cochrane Collaboration

The Cochrane Collaboration is the largest organization in the world engaged in the production and maintenance of systematic reviews. It has received worldwide support in its efforts to do something about the problems outlined above, by making systematic reviews accessible to people making decisions about health care (`www.cochrane.org`). The Collaboration aims to help people make well-informed decisions by preparing, maintaining, and promoting the accessibility of systematic reviews of the effects of interventions in all areas of health care. These reviews bring together the relevant research findings on a particular topic, synthesize this evidence, and then present them in a standard, structured way. One of their most important attributes is that they are periodically updated to take account of new studies and other new information, to help people be confident that the systematic reviews are sufficiently current to be useful in making decisions about health care.

The Cochrane Collaboration was established in 1993, founded on ideas and ideals that stem from earlier times. In October 1992, Iain Chalmers, Kay Dickersin, and Thomas Chalmers wrote an editorial in the *British Medical Journal* [1] that began with the following quote from the British epidemiologist, Archie **Cochrane**, published in 1972:

> It is surely a great criticism of our profession that we have not organised a critical summary, by specialty or subspecialty, updated periodically, of all relevant randomised controlled trials. [3]

This editorial was published at the time of the opening of the first Cochrane Centre in Oxford, United Kingdom. This Centre, was funded by the National Health Service Research and Development Programme in the United Kingdom "to facilitate and co-ordinate the preparation and maintenance of systematic reviews of randomized controlled trials of healthcare". However, there was a clear need for the work to extend beyond this Centre, the United Kingdom and in some circumstances randomized trials.

A year after the UK Cochrane Centre opened, 77 people from 19 countries gathered at what was to become the first Cochrane Collaboration and established *The Cochrane Collaboration* as an international organization. There have been annual Cochrane Colloquia since then, with the most recent being in Barcelona, Spain, in October 2003, attended by more than 1000 people from 45 countries.

The Cochrane Collaboration is supported by hundreds of organizations from around the world, including health service providers, research funding agencies, departments of health, international organizations, industries, and universities. There are currently more than 10 000 people contributing to the work of The Cochrane Collaboration from over 80 countries, and this involvement continues to grow. The number of people involved has increased by about 20% year on year for each of the five years to 2004. The importance of involving people from low and middle income countries in the work of The Cochrane Collaboration is well recognized. This is reflected by the efforts of the centers based in these countries and the steady increase in the number of people actively involved in the preparation and maintenance of Cochrane reviews, from about 300 in the year 2000 to more than 700 in 2003.

The Cochrane Collaboration has 10 guiding principles:

- Collaboration, by internally and externally fostering good communications, open decision-making and teamwork.
- Building on the enthusiasm of individuals, by involving and supporting people of different skills and backgrounds.
- Avoiding duplication, by good management and coordination to maximize economy of effort.
- Minimizing **bias**, through a variety of approaches such as scientific rigor, ensuring broad participation, and avoiding conflicts of interest.
- Keeping up-to-date, by a commitment to ensure that Cochrane Reviews are maintained through identification and incorporation of new evidence.
- Striving for relevance, by promoting the assessment of health care interventions using outcomes that matter to people making choices in health care.
- Promoting access, by wide dissemination of the outputs of The Cochrane Collaboration, taking advantage of strategic alliances, and by promoting appropriate prices, content, and media to meet the needs of users worldwide.
- Ensuring quality, by being open and responsive to criticism, applying advances in methodology, and developing systems for quality improvement.
- Continuity, by ensuring that responsibility for reviews, editorial processes, and key functions is maintained and renewed.
- Enabling wide participation in the work of The Cochrane Collaboration by reducing barriers to contributing and by encouraging diversity.

The work of preparing and maintaining Cochrane reviews is done by the reviewers, of whom there are more than 4000 in 2004. Very few of these are paid to work on their reviews and the main motivation is a desire to answer reliably a question about the relative effects of interventions for people with particular conditions. The reviewers are supported by 50 Cochrane Collaborative Review Groups, who are responsible for reviews within particular areas of health and collectively providing a home for reviews in all aspects of health care. These Groups organize the refereeing of the drafts for Cochrane reviews, and the protocols that precede them, and the editorial teams in these Groups decide whether or not a Cochrane review should be published. As far as possible, they work with the reviewers to ensure that this happens, and the decision that a Cochrane review will be published depends on its quality not its findings. This is unlike the publication process elsewhere in the health care literature where journals rarely help authors with their reports and where the decision about whether or not a paper

will be published will often be dependent on the importance given to the paper, in the light of its findings.

The Collaborative Reviews Groups are based around the world and some have editorial bases in more than one country. There are also Cochrane Methods Groups, with expertise in relevant areas of methodology; Fields or Networks, with broad areas of interest and expertise spanning the scope of many Review Groups; and a Consumer Network helping to promote the interests of users of health care. The work of these Cochrane entities, and their members, is supported by 12 regional Cochrane Centres: Australasian, Brazilian, Canadian, Chinese, Dutch, German, IberoAmerican, Italian, Nordic, South African, UK and USA. The Cochrane Collaboration Steering Group, containing elected members from the different types of entity, is responsible for setting Collaboration-wide policy and, by working with the entities, the implementation of the Collaboration's strategic plan.

One of the important ways in which activity within The Cochrane Collaboration is supported is the Collaboration's Information Management System (IMS). This was developed initially by Update Software, the original publishing partner of The Cochrane Collaboration, before responsibility was transferred to the Nordic Cochrane Centre in Copenhagen, Denmark where much further development has taken place over the last few years. The IMS comprises the set of software tools used to prepare and maintain Cochrane reviews and to submit these for publication, and also to describe the work of each entity and to manage contact details of their members. For the Collaboration's first decade, the IMS worked mainly as standard software running on local computers, with reviewers sharing their files by disk or email attachment. As the Collaboration grew and the number of reviews and the vital task of keeping these up-to-date got bigger, a better way to share these documents and information was needed. In 2001, a software needs assessment survey was conducted. Nearly, all Cochrane entities and almost 500 individuals responded. The results were influential in planning the new IMS, which is being introduced from 2004 to 2006 and which increases the ability of people in The Cochrane Collaboration to work together by providing a central computer approach to the storage of documents such as the draft versions of Cochrane reviews.

The Collaboration has grown quickly through its first decade. Although there is a great deal of work that remains to be done, much has been accomplished already. Cochrane reviews are published in *The Cochrane Database of Systematic Reviews* (*CDSR*). As of mid-2004, this contains the full text of more than 2000 complete Cochrane reviews, each of which will be kept up-to-date as new evidence and information accumulates. There are a further 1500 published protocols for reviews in progress. These set out how the reviews will be done and provide an explicit description of the methods to be followed. The growth in Cochrane reviews is well illustrated by the following milestones. The first issue of CDSR, at the beginning of 1995, included 36 Cochrane reviews; there were 500 in 1999, 1000 in 2001, and 2000 in April 2004. Hundreds of newly completed reviews and protocols are added each year and a few hundred existing reviews are updated so substantively that they can be considered to be the equivalent of new reviews, and there are currently several hundred Cochrane reviews at earlier stages than the published protocol.

The Cochrane Database of Systematic Reviews is available on the Internet and on CD-ROM as part of *The Cochrane Library*. This is published by John Wiley and Sons Ltd and is available on a subscription basis. The establishment of national contracts means that *The Cochrane Library* is currently free at the point of use to everyone in Australia, Denmark, England, Finland, Ireland, Northern Ireland, Norway, and Wales. More countries are being added to this list each year.

The output of The Cochrane Collaboration also includes the *Cochrane Central Register of Controlled Trials (CENTRAL)*, the *Cochrane Database of Methodology Reviews* and the *Cochrane Methodology Register*. All of these are unique resources. In 1993, when the Collaboration was established, less than 20 000 reports of randomized trials could be found easily in MEDLINE, and one of the main tasks facing the Collaboration was the need to identify and make accessible information on reports of trials that might be suitable for inclusion in Cochrane reviews. It has done this through extensive programs of the hand searching of journals (in which a journal is checked from cover to cover to look for relevant reports) and of electronic searching of bibliographic databases such as MEDLINE and EMBASE. Suitable records are

then added to CENTRAL, with coordination by the US Cochrane Centre in Rhode Island, USA [4, 5]. By 2004, CENTRAL contained records for more than 400 000 reports of randomized (or possibly randomized) trials, many of which are not included in any other electronic database. The Cochrane Database of Methodology Reviews contains the full text for Cochrane methodology reviews, which are systematic reviews of issues relevant to the conduct of reviews of health care interventions or evaluations of health care more generally. Currently (mid-2004), there are 10 full Cochrane methodology reviews and published protocols for 8 more. The Cochrane Methodology Register, to a large extent, provides the raw material for the Cochrane methodology reviews, containing more than 5000 records, for example, records for reports of research, and also for ongoing, unpublished research, into the control of bias in health care evaluation.

Over the next few years, The Cochrane Collaboration will strive to ensure that its work is sustainable. Even with more than 4000 Cochrane reviews already underway, and results available from 2000 of these, there is still a large amount of work to be done. A recent estimate is that approximately 10 000 systematic reviews are needed to cover all health care interventions that have already been investigated in controlled trials, and such reviews would need to be assessed and, if necessary, updated at the rate of 5000 per year. If the growth in The Cochrane Collaboration continues at the pace of the last few years, this target will be reached within the coming 10 years. However, this will require continuing and evolving partnership and collaboration. The Cochrane Collaboration will need to continue to attract and support the wide variety of people who contribute to its work. It will also need to work together with funders and with providers of health care to ensure that the resources needed for the work grow and the output of the work is accessible to people making decisions about health care [2].

MIKE CLARKE

Cochrane Lectures

The legacy of Archie **Cochrane** in **epidemiology**, **clinical trials**, social medicine, and **health services research** is marked by at least two series of annual lectures in the United Kingdom.

The first of these – "The Cochrane Lecture" – was initiated two years after Cochrane's death, by the Society for Social Medicine at its annual meeting in September, a gathering that Cochrane attended regularly. The Cochrane lecturers between 1990 and 2004 have been as follows:

1990	Peter Elwood	"Archie Cochrane"
1991	Donald Acheson	"Health, cities and the future"
1992	Iain Chalmers	"Getting to grips with Archie Cochrane's agenda"
1993	Klim McPherson	"The best and the enemy of the good: assessing the role of patient choice in medical decision making"
1994	Stuart Kilpatrick	"Tuberculosis – yesterday and today"
1995	Kay Dickersin	"Consumer involvement in research"
1996	Alan Williams	"All cost-effective treatments should be free!"
1997	Julian Tudor Hart	"What sorts of evidence do we need for evidence-based medicine"
1998	Ann Oakley	"Social science and the experimenting society"
1999	Richard Lilford	"What use are qualitative data when decisions have to be made?"
2000	Nick Black	"Evidence, policy, and evidence-based policy"
2001	Richard Peto	"Halving premature death"
2002	Catherine Peckham	"Science to policy: HIV and other fetal and childhood infections"
2003	Mildred Blaxter	"Fish in water: social capital and the qualitative researcher"
2004	George Davey Smith	"Randomised by (your) god: robust evidence from an observational study design"

A second annual lecture series – "The Cochrane 'Effectiveness and Efficiency' Anniversary Lecture" – was established to mark the anniversary of Cochrane's seminal Rock Carling lecture, "Effectiveness and Efficiency: random reflections on health services", which he delivered in Edinburgh on March 20, 1972. The Nuffield Provincial Hospitals Trust (which published Cochrane's lecture) provided initial funding support for the lecture series, which was established by Iain Chalmers, under the official aegis of Green College, Oxford, a beneficiary of Cochrane's estate. Cochrane lecturers between 1993 and 2004 have been:

1993	Walter Holland	"Epidemiology, research, and how it can contribute to the development of health policy"
1994	William Silverman	"Effectiveness and efficiency... and subjective choice"
1995	David Sackett	"On the need for evidence-based health care"
1996	Richard Doll	"Cochrane and the benefits of wine"
1997	Peter Elwood	"Cochrane and the benefits of aspirin"
1998	Iain Chalmers	"Lord Rayleigh's injunction"
1999	Chris Silagy	"The challenge of the post-Cochrane agenda: consumers and evidence"
2000	Richard Peto	"Getting large-scale randomized evidence"
2001	Valerie Beral	"The causes of breast cancer"
2002	Rory Collins	"LDL cholesterol: from observational to randomized evidence"
2003	Sarah Lewington	"Doubling the importance of blood pressure: the Prospective Studies Collaboration"

2004	Peter Rothwell	"Effectiveness and efficiency in the prevention of the stroke"

IAIN CHALMERS

Cochrane, Archibald ('Archie') Leman

Born: January 12, 1909, in Galashiels, UK.
Died: June 18, 1988, in Dorset, UK.

Archibald Leman Cochrane (1909–1988) was Director of the **Medical Research Council** (MRC) Epidemiology Unit in Cardiff from 1969 to 1974. Prior to this, from 1960 he had been honorary director of the unit and had also held the David Davies chair of tuberculosis and chest diseases in the Welsh National School of Medicine, later the University of Wales College of Medicine. Amongst the many honors he received and significant posts he occupied, the founding Presidency of the Faculty of Community Medicine from 1971 to 1973 ranks high.

Following the study of natural sciences in Cambridge and psychoanalysis in Vienna, he completed his medical studies in University College London and qualified M.B. in 1938. After service in the Royal Army Medical Corps he studied Public Health in the London School of Hygiene and Tropical Medicine.

Archie's career really began to develop when he spent eighteen months studying the epidemiology of tuberculosis at the Henry Phipps Institute in Philadelphia on a Rockefeller Fellowship. Following this, he worked on coal workers' pneumoconiosis and tuberculosis in the MRC Pneumoconiosis Research Unit in South Wales from 1947 to 1960. There he developed field epidemiology methods and the study of total defined communities (*see* **Population-based Study**), rather than just samples of working men. He became almost obsessional about practical aspects of field epidemiology: the representativeness of population samples; the response rate of subjects selected for study; the completeness of the follow-up in a **cohort study**; and the reproducibility of the measurements made. He became especially concerned about reproducibility in the reading of chest X-rays and he introduced the use of "standard films" to reduce observer error in the grading of pneumoconiosis and other chest lesions (*see* **Observer Reliability and Agreement**). In short, he was acutely concerned with every aspect of research methodology and he himself repeatedly demonstrated the potential of epidemiology as a highly accurate quantitative science. He argued that in its relevance to medical and social problems, epidemiology is second to no other research strategy, and he extended his own work to the study of a wide range of conditions, in addition to pneumoconiosis and tuberculosis, including iron deficiency anemia, arthritis, glaucoma, hypertension, bronchitis, and cardiovascular disease.

Archie's greatest love, however, was for the randomized controlled trial (*see* **Clinical Trials, Overview**). Teaching by **Sir Austin Bradford Hill** led him to comment later that "this innovation ... offered clinical medicine an experimental approach to the validation of its practices and treatments" [4]. Although Archie himself conducted very few trials, his encouragement was seminal in many randomized controlled trials in a wide range of medical situations. One trial of his, however, on the treatment of famine edema in men in a prisoner of war camp in Salonica, will certainly go down in history. This was eventually published under the title "Sickness in Salonica: my first, worst and most successful clinical trial" [3].

Archie saw an especially valuable role for the randomized controlled trial in the evaluation of clinical procedures, and the trials he stimulated on the best place of treatment and the optimum length of stay in hospital led to him being invited to give the Rock Carling lecture in 1970. This was later published as a monograph under the title: *Effectiveness and Efficiency – Random Reflections on Health Services* [1]. The provocative and challenging ideas he developed in this had a widespread international effect in stimulating critical evaluation of all aspects of the National Health Service in the UK, and health services in many other countries (*see* **Health Services Research, Overview**).

Perhaps the contribution of Archie to medical research that has had the widest effect, and is likely to have the most far, and long reaching effects, originated from a challenge he made in 1979:

> It is surely a great criticism of our profession that we have not organised a critical summary, by specialty or subspecialty, adapted periodically, of all relevant randomised controlled trials [2].

Iain Chalmers, with others, took this challenge by Cochrane and turned it into the world-wide ongoing **Cochrane Collaboration**. By early 1997 there were 13 Cochrane Centers across the world which organize the searching of all the medical literature, the identification of randomized controlled trials, the preparation of databases (*see* **Database Systems**), and the preparation, publication and maintenance

of systematic reviews of the effects of health care interventions (*see* **Meta-analysis of Clinical Trials**).

These centers are a most fitting memorial to Cochrane. His inspired vision, together with the enthusiasm and sweat of Chalmers, has almost limitless potential benefit. A further development that has arisen from this initiative – the definition and promotion of **evidence based medicine** – is likely to have a profound and widespread effect on all clinical practice.

P. ELWOOD & C. HUGHES

Cohabitation

Cohabitation has increasingly come to be the term used to describe the marital status of couples who are unmarried sexual partners and share the same household. With the rise in cohabitation, shorthand for "unmarried cohabitation", that has occurred in developed countries, the full extent of coresidential heterosexual partnerships are no longer captured by marriage data. Moreover, the rise in extramarital fertility that has also occurred across developed societies in recent decades is related to developments in cohabitation.

Men and women living together outside marriage is not a new phenomenon. Prior to the 1970s it was largely statistically invisible and probably socially invisible outside the local community or milieu. In some countries there were subgroups that were probably more prone to cohabitation than others: the very poor; those whose marriages had broken up but were unable to obtain a divorce, as there was no such legislation, or it was more stringent than nowadays or it was very expensive to obtain a divorce; certain groups of rural dwellers; and groups ideologically opposed to marriage. The form of cohabitation that came to the fore during the 1960s in Sweden and Denmark, and the 1970s in other Northern and Western European countries, North America, and Australia is new, and could be aptly termed "nubile cohabitation", whereby young people predominantly in their 20s and early 30s live together either as a prelude to, or as an alternative to, marriage. Additionally, with the growth in divorce, "postmarital cohabitation" is also likely to have become more prevalent, with the divorced cohabiting either in preference to, or as a prelude to, remarriage. In many data sources it is difficult to distinguish between "nubile" and "postmarital" cohabitation. The increased prevalence of cohabiting unions lies behind much of the decline in first marriage and remarriage rates that have occurred in recent decades.

To date, data on cohabitation tend to be scarce and generally emanate from surveys which can make any comparative analyses problematic, as sample sizes, coverage, and definitions may vary. Notwithstanding, in developed countries with a **time series** of data it is clear that there have been increases in the proportions of women cohabiting, particularly in their 20s. The peak ages for cohabitation tend to be the early 20s, and cohabitation at older ages, particularly in the 30s, is less common. There is some evidence that cohabiting unions tend to be more fragile and less fertile than marriages. What emerges from existing surveys is that cohabitation is a relatively youthful practice and marriage has not been rejected permanently on a wide scale, as even in Sweden and Denmark, where the practice is more long-standing, the majority of unions amongst women in their 30s are legal marital unions.

KATHLEEN KIERNAN

Coherence Between Time Series

Coherence is a measure of the strength of association between **time series**; it is a time series analog of the standard correlation coefficient. Association between time series is a more complex concept than that between scalar characteristics, since the time series data structure is much richer; for example, the association may include a leading or lagging relationship. Two examples are shown in Figure 1. Figure 1(a) shows daily mortality and SO_2 time series in London during the winter months of 1958, with an obvious question whether the pollution was in any way affecting mortality. The strong peaks toward the end of both series are suggestive of a strong association; see [8] for the data set and a detailed analysis, and [9] for a related work. Figure 1(b) shows traces of a person's respiration and heart-rate variability. Since a normal heart responds to the respiration cycles, while an abnormal heart does not, the correlation analysis of the two time series carries a high diagnostic value as to the state of health of the person's heart; see, for example, [1].

We first define some notations and terminology theoretically, then comment on how the quantities are estimated given some finite-length time series data. Given two stationary time series X_t and Y_t, for $t = 0, \pm 1, \ldots$, the autocovariance functions are given by

$$C_x(m) = \mathrm{cov}(X_t, X_{t+m}), \tag{1}$$

$$C_y(m) = \mathrm{cov}(Y_t, Y_{t+m}), \quad m = 0, \pm 1, \ldots. \tag{2}$$

The association between the two time series may be expressed by the cross-covariance function

$$C_{xy}(m) = \mathrm{cov}(X_t, Y_{t+m}), \quad m = 0, \pm 1, \ldots. \tag{3}$$

The cross-correlation function is defined similarly, so the measure of dependencies between X_t and Y_t is no longer a single number, but a function of lag m, which means that potentially it can carry a lot of information about the dependency between X_t and Y_t.

The spectra and cross-spectra of X_t and Y_t (*see* **Spectral Analysis**) are the Fourier transforms of the above quantities, i.e.

$$f_x(\omega) = \sum_{m=-\infty}^{\infty} C_x(m) \exp(-2\pi i \omega m), \tag{4}$$

$$f_y(\omega) = \sum_{m=-\infty}^{\infty} C_y(m) \exp(-2\pi i \omega m), \tag{5}$$

$$f_{xy}(\omega) = \sum_{m=-\infty}^{\infty} C_{xy}(m) \exp(-2\pi i \omega m). \tag{6}$$

The functions $f_x(\omega)$ and $f_y(\omega)$ are called the spectral density functions of X_t and Y_t, and $f_{xy}(\omega)$ the cross-spectrum between X_t and Y_t (*see* **Multiple Time Series**). Since C_x and C_y are symmetric, $f_x(\omega)$ and $f_y(\omega)$ are real functions, but $f_{xy}(\omega)$ is, in general, a complex function. These frequency-domain objects are, in a mathematical sense, equivalent to their time-domain analogs; however, they carry different

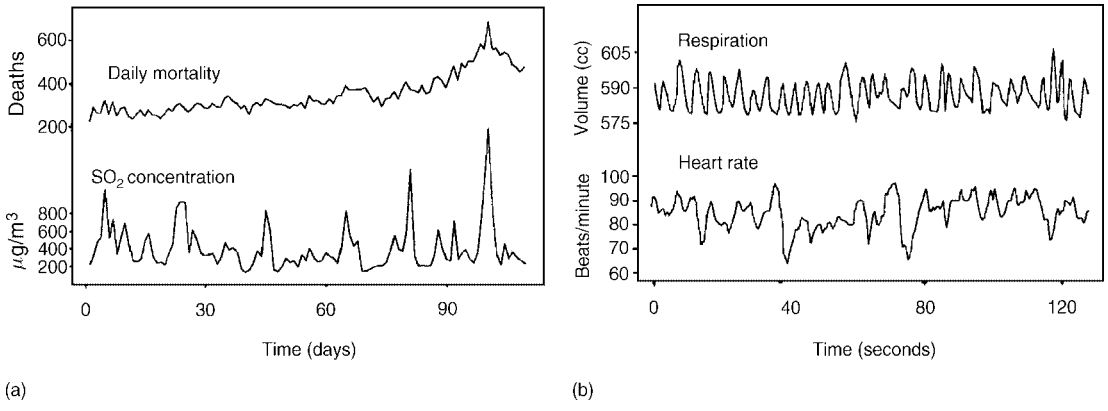

Figure 1 Examples of bivariate time series. (a) Pollution and respiratory mortality in London during winter 1958. (b) Respiration time series in terms of thoracic volume and the heart-rate time series

physical interpretations. To aid this interpretation, define the (squared) coherence as

$$\rho^2(\omega) = \frac{|f_{xy}(\omega)|^2}{f_x(\omega) f_y(\omega)}, \tag{7}$$

and the phase spectrum

$$\phi(\omega) = \tan^{-1}\left\{\frac{\mathrm{Im}[f_{xy}(\omega)]}{\mathrm{Re}[f_{xy}(\omega)]}\right\},$$

where Re $[\cdot]$ and Im $[\cdot]$ are the real and imaginary parts of a complex quantity.

Now the interpretations. It is sometimes natural to think of a time series X_t as a waveform, composed of different frequencies. The spectrum $f_x(\omega)$ is the variance or the power of the component of time series X_t at frequency ω. The coherence $\rho^2(\omega)$ is the proportion of variability of the Y_t component at frequency ω explained by the corresponding X_t component and the $\phi(\omega)$ is the phase shift in the X_t component. The interpretation of $\rho^2(\omega)$ is especially appealing as it corresponds to the usual R^2 interpretation in regression analysis. Let us consider some simple theoretical examples.

Example 1

Let $Y_t = -X_t$; then intuitively $\rho^2(\omega) = 1$, which means that every frequency component of Y_t is totally determined by X_t or there is no noise. (Note the analogy for scalar random variables: if $Y = -X$, then the squared correlation is $\rho^2 = 1$.) It may be shown that $\phi(\omega) = 1/2$, which means that the Y_t components are out of phase by half a cycle from the corresponding X_t components. For a theoretical treatment of this example, see [3, p. 213].

Example 2

Let $Y_t = X_{t-1} + Z_t$, where X_t and Z_t are independent, i.e. Y_t is a delayed version of X_t plus some noise. Let $f_z(\omega)$ be the spectrum of Z_t. Then the coherence between X_t and Y_t is

$$\rho^2(\omega) = \frac{f_x(\omega)}{f_x(\omega) + f_z(\omega)}. \tag{8}$$

(Note the analogy for scalar random variables: if $Y = X + Z$, then the squared correlation is $\rho^2 = \sigma_x^2/(\sigma_x^2 + \sigma_z^2)$.) The interpretation is immediate and useful in general: in frequencies where the noise level is low, i.e. $f_z(\omega)$ is small, the correlation between X_t and Y_t is high, and vice versa. It may be shown that the phase shift is $\phi(\omega) = \omega$. This means that the low-frequency components of X_t and Y_t (for example, the trend or large swings in the series) move in phase, but the faster components are out of phase.

Before we discuss a real data example, we remark that there is a large literature on the spectral estimation based on finite-length time series. Priestley [7] and Brillinger [2] are two main references in the area. An older reference, Jenkins & Watts [4, Chapter 9], gives the techniques and some detailed examples of coherence analysis. The concept of smoothing is central in the nonparametric estimation of the spectra and cross-spectra, where the amount of smoothing is traditionally left subjectively for the user. An objective and automatic smoothing of the spectrum was proposed, for example, in [11] and [6]. Pawitan [5] describes a fully automatic estimation of the cross-spectrum.

Standard statistical packages such as SAS and BMDP have procedures (`PROC SPECTRA` and `BMDP 1T`, respectively) for the traditional estimation of the spectra and cross-spectra, as well as the coherence and phase spectrum (*see* **Software, Biostatistical**). Venables & Ripley [10] show in Chapter 14 some examples of coherence analysis using the S-PLUS statistical language.

Example 3

This example shows the power of coherence analysis using real data on heart-rate variability. The estimates shown in Figure 2 are fully automatic estimates based on the time series in Figure 1(b); see [5] for a detailed description of the estimation technique. The coherence between respiration and heart rate shows that the heart responds to the natural respiration cycle between 0.25–0.5 cycles per second or between 2–4 seconds per cycle. This is expected from a healthy heart and has been shown to be mediated by the parasympathetic nervous system [1]. The phase spectrum indicates that the cardiac response is in phase with respiration if the respiration is slow enough at around 0.25 cycles per second, but is increasingly out of phase with faster respiration due to delay in the cardiac response. We note that none of these phenomena is apparent from the spectral analysis of the individual time series.

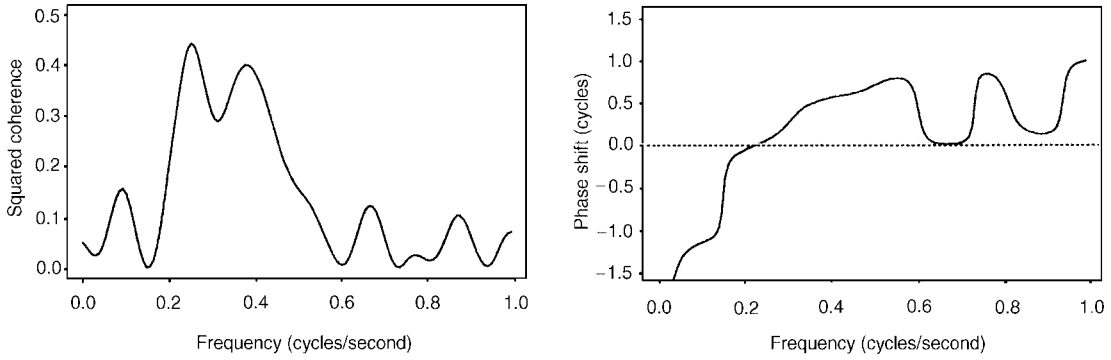

Figure 2 Coherence analysis of heart-rate variability. (a) Heart responds to the respiration cycle at frequencies 0.25–0.5 cycles per second. (b) Cardiac response to slow respiration at around 0.25 cycles per second is almost immediate

YUDI PAWITAN

Cohort Study, Historical

In **cohort study** design, participants are enrolled, often with selection based on one or more exposures of interest, and observed over time for disease incidence or mortality. Cohort studies are further classified by the timing of the enrollment and follow-up in relation to actual calendar time. Cohort studies involving identification of participants and follow-up into the future are termed "prospective cohort studies", while those involving follow-up and events in the past are referred to as "historical cohort studies". Other designations used for historical cohort design include "retrospective cohort study" and "nonconcurrent cohort study". A study may be initiated as an historical cohort study, but subsequently follow-up could be maintained into the future. The study of bladder cancer in British chemical industry workers, conducted by Case et al. [1], represents one of the first comprehensive applications of historical cohort design. Beginning the study in the 1950s, Case et al. traced a group of chemical industry workers employed subsequent to 1920 and showed a clear excess of deaths from bladder cancer, which was attributed to exposures to anilines. The researchers compared the data with expected mortality, on the basis of the experience of males in the general population, over the same time interval. Frost [3] and others had previously applied a similar method in studying infectious diseases.

Historical cohort design can be applied if records are available for the retrospective identification of study participants, the classification of the exposure(s) of interest, and the follow-up of the participants for the relevant outcomes. For example, historical cohort design has been widely applied in investigating the effects of specific occupations and industries (*see* **Occupational Epidemiology**), because of the availability of records appropriate to these purposes. Employment records can be used to identify cohort members and, in some instances, to estimate exposures; follow-up for mortality can be accomplished using pension records and national death registries. In the absence of an internal reference population, comparison has been made in many studies to mortality in the general population. For example, Samet et al. [6] conducted an historical cohort study of lung cancer mortality in underground uranium miners who had worked in the state of New Mexico, USA, using industry and health clinic records to define the cohort. The investigation began in 1978; the records were used to identify men who had worked for at least 12 months in an underground uranium mine in New Mexico by December 31, 1976. Follow-up for mortality was accomplished by using listings of deaths in the state and by matching the study roster against two national databases, the files of the Social Security Administration and the National Death Index. The initial report of study findings involved follow-up through 1985; follow-up has continued.

A variety of approaches may be used to estimate exposures in historical cohort studies of occupational groups, depending on the nature of the exposure(s) and the extent and quality of data available on exposures [2]. The occupation or industry may serve as a surrogate for associated exposures, and job information may be used in a job–exposure matrix to link occupation and industry pairs to specific exposures. General systems have been created for this purpose and the same approach has been tailored to specific occupational groups. If data are available on concentrations of workplace contaminants, it may be possible to calculate estimates of exposure for specific study participants by combining the concentration data with the time spent in jobs involving the exposure. For example, in the study of New Mexico uranium miners, information on concentrations of radon progeny in specific mines was used in combination with data on time spent in the mines to estimate exposures to radon progeny [6].

Historical cohort design has the advantage of rapidity of execution. While the task of conducting an historical cohort study may be formidable, the investigator does not need to wait for follow-up time to accumulate, as in a prospective cohort study. Costs tend to be modest as a result, and many historical cohort studies can be completed in only a few years, depending on the status and complexity of the involved databases.

Historical cohort studies, similar to prospective cohort studies, are subject to limitation by information bias, selection bias (*see* **Selection Bias**; **Bias in Cohort Studies**) and confounding (*see* **Bias in Observational Studies**). The limitations of the design primarily reflect the availability of the relevant historical data to ascertain the cohort participants and to estimate exposures of interest and potential

confounding and modifying factors. Information bias is a particular concern. There is a strong potential for exposure misclassification (*see* **Misclassification Error**) and for bias from uncontrolled confounding. Because databases used to estimate exposures and covariates may be most complete in the more recent years, there is a potential for complex time-dependent exposure misclassification. The design may be further compromised by losses to follow-up and misclassification of the health outcome(s), because of reliance on historical records and death certificate assignment of cause of death. Historical cohort studies of workers involving mortality as the outcome measure are subject to a bias that has been widely termed "the healthy worker effect" [4]. Employed persons tend to be healthier than unemployed persons and consequently fewer deaths than expected are typically observed. The healthy worker effect has been characterized as a form of selection bias [2], although it can also be viewed as a reflection of confounding from uncontrolled differences between employed and unemployed persons. Selection bias could also be introduced in defining a cohort on the basis of incomplete records; for example, the findings of an historical cohort study could be affected by selection bias if records used to define the cohort were more complete in the most recent years of exposure and exposures had declined over the period of eligibility. Furthermore, investigating disease incidence may not be possible using historical cohort design, unless special mechanisms have been put in place to track outcomes of interest, or unless it is possible to match records against an incidence registry for the disease(s) of interest, e.g. a cancer registry.

Historical cohort design may be strengthened by the addition of complementary, nested studies that involve additional collection of data on exposures, confounders, or modifiers from samples of the cohort members. Using case-based sampling methods (*see* **Case–Cohort Study**), more detailed data may be obtained for participants who have developed the outcome of interest and for an appropriate sample of controls. For example, in the study of New Mexico uranium miners, the effect of silicosis (a chronic respiratory disease arising from silica dust exposure) on lung cancer risk was assessed using a nested case-control design [5]. Chest radiographs were interpreted for lung cancer cases ($N = 65$) and for controls ($N = 216$) sampled from a total cohort of 3400 miners.

Historical cohort design has proven to be useful for studying the effects of occupational and other exposures. We may see increasing application of this design as implementation of disease registries expands and large administrative databases developed by health care organizations are used for research on health care outcomes and effectiveness (*see* **Administrative Databases**).

Cohort Study

Cohort studies constitute a central epidemiologic approach to the study of relationships between personal characteristics or exposures and the occurrence of health-related events, and hence to the identification of disease prevention hypotheses and strategies.

Consider a conceptually infinite population of individuals moving forward in time. A cohort study involves sampling a subset of such individuals, and observing the occurrence of events of interest, generically referred to as disease events, over some follow-up period. Such a study may be conducted to estimate the rates of occurrence of the diseases to be ascertained, but most often estimation of relationships between such rates and individual characteristics or exposures is the more fundamental study goal. If cohort study identification precedes the follow-up period, then the study is termed prospective, while a retrospective or historical cohort study involves cohort identification after a conceptual follow-up period (*see* **Cohort Study, Historical**). The subsequent presentation assumes a prospective design.

Other research strategies for studying exposure–disease associations, and for identifying disease prevention strategies, include **case–control studies** and randomized controlled disease **prevention trials**. Compared with case–control studies, cohort studies have the advantages that a wide range of health events can be studied in relation to exposures or characteristics of interest, and that prospectively ascertained exposure data are often of better quality than the retrospectively obtained data that characterize case–control studies. However, a cohort study of a particular association would typically require much greater cost and longer duration than would a corresponding case–control study, particularly if the study disease is rare. Compared with randomized controlled trials, cohort studies have the advantage of allowing the study of a broad range of exposures or characteristics in relation to health outcomes of interest, and typically of much simplified study logistics and reduced cost. Randomized intervention trials can also examine a broad range of exposures and disease associations in an observational manner, but the randomized assessments are necessarily restricted to examining the health consequences of a small number of treatments or interventions. However, disease prevention trials have the major advantage that these comparisons are not confounded (*see* **Confounding**) by pre-randomization disease risk factors, whether or not these are even recognized. The choice among these and other research strategies may depend on the distribution of the exposures in the study population and especially on the ability to measure such exposures reliably, on the knowledge and measurement of confounding factors, on the reliability of outcome ascertainment, and on study costs in relation to the public health potential of study results. These issues will be returned to in the final section of this article.

There are many examples of associations that have been identified or confirmed using cohort study techniques, including that between cigarette smoking and lung cancer (*see* **Smoking and Health**); between blood pressure, blood cholesterol, cigarette smoking, and coronary heart disease; between current use of the original combined oral contraceptives and the risk of various vascular diseases; and between atomic bomb radiation exposure and the risk of leukemia or of various solid tumors, to name a few. In recent years there have also been many examples of the use of cohort study designs to examine the association between exposures that are difficult to measure, or that may have limited within-cohort exposure variability, and the occurrence of disease. Such examples may involve, for example, physical activity, dietary, environmental, or occupational exposures. In these settings cohort studies seem often to yield weak or equivocal results, and multiple cohort studies of the same general association may yield contradictory results. It is important to be able to anticipate the reliability and power of cohort studies, to be aware of strategies for enhancing study power and reliability, and to consider carefully optimal research strategies for assessing specific exposure–disease hypotheses.

This article relies substantially on a recent review of cohort study design issues by the author [66]. The reader is also referred to a number of books and review articles focusing on cohort study methodology, including Kleinbaum et al. [41], Miettinen [52], Kelsey et al. [40], Rothman [80], Breslow & Day [7], Kahn & Sempos [38], Checkoway et al. [16], Willett [101], and Morganstern & Thomas [57].

Basic Cohort Study Elements

Exposure Histories and Disease Rates

A general regression notation can be used to represent the exposures (and characteristics) to be ascertained in a cohort study. Let $z_1(u)^{\mathrm{T}} = [z_{11}(u), z_{12}(u), \ldots]$ denote a set of numerically coded variables that describe an individual's characteristics at "time" u, where, to be specific, u can be defined as time from selection into the cohort, and "T" denotes vector transpose. Let $Z_1(t) = [z_1(u), u < t]$ denote the history of such characteristics at times less than t. Note that the "baseline" exposure data, $Z_1(0)$, may include information that pertains to time periods prior to selection into the cohort. Denote by $\lambda[t; Z_1(t)]$ the population **incidence rate** at time t for a disease of interest, as a function of an individual's preceding **"covariate"** history. A typical cohort study goal is the elucidation of the relationship between aspects of $Z_1(t)$ and the corresponding disease rate $\lambda[t; Z_1(t)]$. As mentioned above, a single cohort study may be used to examine many such covariate–disease associations.

The interpretation of the relationship between $\lambda[t; Z_1(t)]$ and $Z_1(t)$ may well depend on other factors. Let $Z_2(t)$ denote the history up to time t of a set of additional characteristics. If the variates $Z_1(t)$ and $Z_2(t)$ are related among population members at risk for disease at time t, and if the disease rate $\lambda[t; Z_1(t), Z_2(t)]$ depends on $Z_2(t)$, then an observed relationship between $\lambda[t; Z_1(t)]$ and $Z_1(t)$ may be attributable, in whole or in part, to $Z_2(t)$. Hence, toward an interpretation of causality (*see* **Causation**) one can focus instead on the relationship between $Z_1(t)$ and the disease rate function $\lambda[t; Z_1(t), Z_2(t)]$, thereby controlling for the "confounding" influences of Z_2. In principle, a cohort study needs to control for all pertinent confounding factors in order to interpret a relationship between Z_1 and disease risk as causal. It follows that a good deal must be known about the disease process and disease risk factors before an argument of causality can be made reliably. This feature places a special emphasis on the replication of results in various populations, with the idea that unrecognized or unmeasured confounding factors may differ among populations. As noted above, the principal advantage of a randomized disease prevention trial, as compared with a purely observational study, is that the randomization indicator variable $Z_1 = Z_1(0)$, where here $t = 0$ denotes the time of randomization, is unrelated to the histories $Z_2(0)$ of all confounding factors, whether or not such are recognized or measured. See, for example, Rubin [82], Robins [74, 76], and Greenland [27], for a fuller discussion of causal inference criteria and strategies.

The choice as to which factors to include in $Z_2(t)$, for values of t in the cohort follow-up period, can be far from straightforward. For example, factors on a causal pathway between $Z_1(t)$ and disease risk may give rise to "overadjustment" if included in $Z_2(t)$, since one of the mechanisms whereby the history $Z_1(t)$ alters disease risk has been conditioned upon. However, omission of such factors may leave a confounded association, since the relationship between Z_2 and disease risk may not be wholly attributable to the effects of Z_1 on Z_2. See Robins [76] for a detailed discussion of the assumptions and procedures needed to argue causality in such circumstances.

Cohort Selection and Follow-Up

Upon identifying the study diseases of interest and the "covariate" histories $Z(t) = [Z_1(t), Z_2(t)]$ to be ascertained and studied in relation to disease risk, one can turn to the estimation of $\lambda[t; Z(t)]$ based on a cohort of individuals selected from the study population. The basic cohort selection and follow-up requirement for valid estimation of $\lambda[t; Z(t)]$ is that at any $[t, Z(t)]$ a sample that is representative of the population in terms of disease rate be available and under active follow-up for disease occurrence. Hence, conceptually, cohort selection and censoring rates (*see* **Censored Data**) (e.g. loss to follow-up rates) could depend arbitrarily on $[t, Z(t)]$, but selection and follow-up procedures cannot be affected in any manner by knowledge about, or perception of, disease risk at specified $[t, Z(t)]$.

Cohort selection rates typically depend on a variety of pre-enrollment characteristics. Potential study subjects may be excluded if they fail to meet certain conditions, perhaps related to prior health events or to their likelihood of completing all study requirements. Similarly, potential study subjects may choose not to participate in a cohort study for a myriad reasons that may be impossible to quantify. How do such selection factors affect the validity or interpretation of estimates of $\lambda[t; Z(t)]$?

In the presence of selection factors the estimation of $\lambda[t; Z(t)]$ applies not to the original conceptual

population, but to a reduced population satisfying cohort exclusionary and "willingness" criteria. The magnitude of disease rates may well differ between these two populations, particularly if certain health criteria must be met for inclusion, or if study subjects tend to be more or less healthy than the broader population from which they arise. The magnitude of associations between $\lambda[t; Z(t)]$ and elements of $Z(t)$ may be affected by cohort selection, thereby limiting the ability to "generalize" the estimated association to the larger population. In general, issues of bias and **effect modification** can be addressed satisfactorily only if the selection factors are accurately measured and properly incorporated into the disease rate model. The ability to generalize to the larger population additionally requires knowledge about, or estimates of, cohort selection rates as a function of selection factor values (*see* **Validity and Generalizability in Epidemiologic Studies**).

As noted previously, censoring rates at a typical follow-up time t may depend on aspects of $Z(t)$ without biasing the estimation of $\lambda[t; Z(t)]$. Note, however, that elements of $Z(t)$ that relate to censoring then typically need to be included in the disease rate model and analysis in order to avoid bias. For this reason, as well as reasons of overall study **power**, it is important to strive to minimize losses to follow-up in cohort study conduct. Certainly, a dependence of selection or censoring rates on characteristics that may be affected by the exposures of interest can much complicate the interpretation of corresponding estimated relationships with disease risk.

The reader is referred to Miettinen [52] and the texts previously listed, as well as to Greenland [24], Miettinen [53, 54], and Poole [63], for discussion of the definition of the study population, and of the "study base" subset thereof from which a cohort is selected, and to these same sources and Greenland [25], Kalbfleisch & Prentice [39, Chapter 5], and Robins [75] for further discussion of cohort study follow-up bias (*see* **Bias in Cohort Studies**).

Covariate History Ascertainment

In general, valid estimation of $\lambda[t; Z(t)]$ within the subpopulation defined by the selection and follow-up procedures requires the accurate and timely ascertainment of the histories $Z(t)$ during the cohort study follow-up period. As before, let $t = 0$ denote the time of enrollment into the cohort. Then one seeks accurate ascertainment of $Z(t)$ for values of $t \geq 0$ in the follow-up period for each cohort member. Characteristics or exposures prior to cohort enrollment ($t < 0$) may be of considerable interest, but there may be a limited ability to obtain such information retrospectively. Hence, it may sometimes be necessary to restrict the covariate history $Z(0)$ to time-independent factors, or to the current or recent values of time-varying factors (*see* **Time-dependent Covariate**). Reliable measurement tools may not be available, even for current values of exposures of interest, or for corresponding confounding factor histories. Similarly, during cohort follow-up ($t > 0$) reliable means of updating covariate histories may or may not be available, and such updates would typically be practicable only at a few selected time points. Also, some of the measurements of interest to be included in $Z(t)$ may be too expensive to obtain on all cohort members. For example, such measurements may involve biochemical or molecular analysis of blood components, or hand extraction of occupational exposure histories from employer records. Hence, a covariate subsampling plan may be an important element of a cohort study concept and design.

Disease Event Ascertainment

A cohort study will often involve a system for regularly updating disease event information. This may involve asking study subjects to self-report a given set of diagnoses, or to self-report all hospitalizations. Hospital discharge summaries may then be examined for diagnoses of interest with confirmation by other medical and laboratory records. Sometimes disease events of interest will be actively ascertained by taking periodic measurements on all cohort members. For example, electrocardiographic tracings toward coronary heart disease diagnosis or screening breast mammograms toward breast cancer diagnosis may be a part of a basic study protocol. Diagnoses that require considerable judgment may be examined by a committee of experts toward enhancing the standardization and accuracy of disease event diagnoses. In spite of the application of the best practical outcome ascertainment procedures, there will usually be some misclassification (*see* **Misclassification Error**) of whether or not certain disease events have occurred with resulting bias in the estimation of $\lambda[t; Z(t)]$. A dependence of ascertainment rates on factors other

than those included in $Z(t)$ may be able to be accommodated by including such factors as control variables in $Z_2(t)$.

Unbiased ascertainment of the timing of disease events relative to $Z(t)$ is also important for valid inference. For example, if disease screening activities vary with aspects of $Z(t)$, leading to earlier reporting at some covariate values than at others, then biased associations will typically arise. Similarly, differential lags in the reporting of disease events may cause bias unless specifically accommodated in data analysis.

Data Analysis

Suppose now that covariate disease associations of interest have been identified, and that procedures for selecting a cohort and for accurately ascertaining pertinent covariate histories and disease event times have been established. What then can be said about the ability to detect an association between a particular characteristic or exposure and a corresponding disease risk? Typically, a test of association would be formulated in the context of a descriptive statistical model, though in some settings a mechanistic or biologically based model may be available (e.g. Armitage & Doll [2], Whittemore & Keller [99], and Moolgavkar & Knudson [56] (*see* **Multistage Carcinogenesis Models**).

A very useful and flexible descriptive modeling approach formulates the association in terms of relative risk. Specifically, one supposes [18] that

$$\lambda\{t; Z(t)\} = \lambda_0(t) \exp\{z(t)^{\mathrm{T}}\beta\}, \qquad (1)$$

where $z(t)^{\mathrm{T}} = \{z_1(t), \ldots, z_p(t)\}$ is a modeled regression vector formed from $Z(t)$, $\beta^{\mathrm{T}} = (\beta_1, \ldots, \beta_p)$ is a corresponding relative risk parameter to be estimated, and $\lambda_0(\cdot)$ is an unrestricted baseline disease rate (**hazard**) function corresponding to a modeled regression vector $z(t) \equiv 0$. A test of the null hypothesis of no association between, say, $z_1(t)$ and disease risk then corresponds to $\beta_1 = 0$. Estimation and testing can be conducted by applying standard likelihood procedures to the **partial likelihood** function

$$L(\beta) = \prod_{i=1}^{k} \left\{ \exp[z_i(t_i)^{\mathrm{T}}\beta] \Big/ \sum_{l \in R(t_i)} \exp[z_l(t_i)^{\mathrm{T}}\beta] \right\}, \qquad (2)$$

where $t_1, \ldots, t_k$ denotes the disease incidence times in the cohort, $z_i(t_i)$ is the modeled covariate at time t_i for the cohort member diagnosed at t_i, and $R(t_i)$ denotes the set of cohort members being followed for disease occurrence at time t_i. Consideration of the distribution of the score statistics $U_1(0) = \partial \log L(\hat{\beta}_0)/\partial \hat{\beta}_0^{\mathrm{T}}$, where $\hat{\beta}_0$ maximizes $L(\beta)$ subject to $\beta_1 = 0$, makes it clear that the power of the test for $\beta_1 = 0$ depends primarily on the magnitude, β_1, of the regression coefficient, the expected number of disease events, k, during cohort follow-up, and the "spread" of the primary regression variable distribution $[z_{1l}(t); l \in R(t)]$ across the cohort follow-up times. The power will also depend somewhat on the distributions of the other (control) variables included in $z(t)$ and on the sampling variation in $\hat{\beta}_0$. A useful generalization of (1) allows the baseline disease rate function $\lambda_0(\cdot)$ to differ arbitrarily among strata that may be time dependent, typically defined by categorizing the histories $Z_2(t)$. Estimation and testing can then be based on a likelihood function that is simply the product of terms (2) over strata.

Conditions for the avoidance of confounding and other biases in the estimation, of a **relative risk** parameter β_1 are naturally less restrictive than are those for accurate estimation of the entire disease rate process $\lambda[t; Z(t)]$. For example, selection, follow-up, and disease ascertainment rates can depend on factors not included in $Z(t)$ provided such factors are unrelated to $Z_1(t)$, conditional on $[t, Z_2(t)]$, without implying bias in the estimation of β_1, assuming that a relative risk model of the form (1) holds conditional on such factors. There is a considerable epidemiologic literature exploring such issues. In addition to the texts previously cited see, for example, Miettinen & Cook [55], Boivin & Wacholder [5], and Greenland & Robins [29]. Though the use of relative risk, and of closely associated **odds ratios** is ubiquitous in epidemiology, other measures of association, including disease rate difference measures, also have utility and their own criteria for valid estimation. See, for example, the texts previously cited and Greenland [25]. The evolution of the covariate histories $Z(t)$, over time, may also be of substantive interest. For example, the extent to which disease risk factors track over time may have clinical implications, or the extent to which an intermediate outcome in $Z_2(t)$ can explain an exposure disease association may provide insights into disease mechanisms. Joint

analyses of an exposure in relation to two or more disease processes may also be of considerable practical interest.

Subsequent sections expand upon these basic cohort study features.

Study Design

Cohort Study Power

A number of authors have provided a methodology for cohort study sample size and power determination (e.g. Gail [22], Casagrande et al. [15], Fleiss et al. [20], Whittemore [97], Brown & Green [11], Greenland [23], and Self et al. [85]. Breslow & Day [7, Chapter 7] provide a detailed account of this topic, including consideration of the impact of varying the exposure distribution, of confounding factor control, of **matching**, and of nested case–control sampling (*see* **Case–Control Study, Nested**), on study power. See also Whittemore & McMillan [100].

As suggested above, a comprehensive approach to the issue of study power for a particular association would require a range of design assumptions, including assumptions about the exposure distribution and its variation across time, about the magnitude of the regression parameter β_1, and concerning the baseline disease incidence rates. Though such a comprehensive approach may be useful, and flexible power calculation procedures permitting the use of complex assumptions are available (e.g. Self et al. [85]), power calculations for the simple odds ratio special case can provide valuable guidance concerning cohort study power and related design choices. Suppose that a baseline characteristic or exposure of interest is dichotomized into an "exposed" group ($Z_1 = 1$) comprised of the fraction, γ, of the population having a high value of an exposure, and an "unexposed" group ($Z_1 = 0$) comprised of the fraction, $1 - \gamma$, of the population having a comparatively low value. Let p_1 denote the probability that an exposed subject experiences a study disease of interest during a prescribed cohort follow-up period and let p_2 be the corresponding probability for an unexposed subject. Note that p_1 and p_2 can be thought of as average probabilities over the respective distributions of cohort follow-up times and over the exposure distributions within the exposed and unexposed categories. A simple sample size formula, based on the well-known approximate normality of logarithm of the simple odds ratio estimator, indicates that the cohort sample size must be at least

$$n = [p_2(1 - p_2)]^{-1}(\log \lambda)^{-2} Q, \qquad (3)$$

where $\lambda = p_1(1 - p_2)[p_2(1 - p_1)]^{-1}$ is the exposed vs. unexposed odds ratio, and $Q = [\gamma(1 - \gamma)]^{-1}\{W_{\alpha/2} - W_{1-\eta}[\gamma + \lambda^{-1}(1 - p_2 + \lambda p_2)^2(1 - \gamma)]^{1/2}\}^2$, to ensure that a two-sided α-level test (e.g. $\alpha = 0.05$) of the null hypothesis of no exposure effect ($\lambda = 1$) will be rejected with probability (power) η, where $W_{\alpha/2}$ and $W_{1-\eta}$ denote the upper $\alpha/2$ and $1 - \eta$ percentiles of the standard normal distribution, respectively.

Note that Q in Eq. (3) is a rather slowly varying function of λ and p_2 at specified α and η, so that the sample size necessary to achieve a specified power is approximately inversely proportional to $p_2(1 - p_2)$, where p_2 is again the unexposed disease probability, and inversely proportional to $(\log \lambda)^2$, the square of the exposed vs. unexposed log-odds ratio. Hence there is considerable sample size sensitivity to the magnitude of the odds ratio, with an odds ratio of 1.5 requiring about three times the cohort size of an odds ratio of 2.0, and an odds ratio of 1.25 requiring about ten times the sample size of that for an odds ratio of 2.0. The magnitude of the basic disease incidence rates (i.e. p_2) are also of considerable importance in the choice of a cohort size and average follow-up duration. Prentice [66] displayed selected power, η, calculations, developed in planning the cohort study component of the Women's Health Initiative [79, 103] which is currently enrolling 100 000 post-menopausal American women in the age range 50–79, based on (3) for selected cohort sizes, n, odds ratios, λ, and exposure fractions, γ. The power calculations are shown as a function of unexposed average incidence rates and average cohort follow-up duration, the product of which is the unexposed incidence rate p_2.

Measurement error in the modeled regression variable in (1) can involve a substantial loss of power and, except in idealized situations, can invalidate the null hypothesis test. The impact of covariate measurement error on the study design, conduct, and interpretation is one of the least developed, and potentially most important, aspects of cohort study methodology. For example, consider a binary exposure variable subject to misclassification. Suppose also that the misclassification rates do not vary within the exposed and unexposed

groups, according to quantitative exposure levels or other study subject characteristics, and that all necessary confounding variables are included in the analysis and are measured without error. Under this circumstance, misclassification in the binary exposure variable effectively reduces the odds ratio λ in the sample size–power relationship (3). To cite a specific example, suppose that $Z_1 = 1$ denotes values above the median for a specific exposure while $Z_1 = 0$ denotes values below the median, so that $\gamma = 0.5, \lambda = 2.0$, and $p_2 = 0.02$. Suppose that rather than Z_1 one can only measure a variable X_1 which, when dichotomized at its median, gives $p(X_1 = 1|Z_1 = 1) = p(X_1 = 0|Z_1 = 0) = 1 - \Delta$ and $p(X_1 = 1|Z_1 = 0) = p(X_1 = 0|Z_1 = 0) = \Delta$. Suppose that this common misclassification probability takes the value $\Delta = 0.2$. The odds ratio based on the measured dichotomous variate X can then be calculated to be 1.50, so that a 20% exposure misclassification leads in these circumstances to a substantially attenuated odds ratio and requires an increase in cohort sample size by a factor of about 3 to preserve power for the null hypothesis test. See, for example, Walter & Irwig [93] and Holford & Stack [33] for additional discussion of exposure measurement error effects on study design and power. In general, the effects of covariate measurement error may be much more profound than simply relative risk attenuation and loss of power, as will be discussed further below (*see* **Misclassification Error**; **Measurement Error in Survival Analysis**; **Measurement Error in Epidemiologic Studies**).

Study Population

Typically a cohort study will be conceived with a set of motivating hypotheses in mind. The study population may then be selected as one in which such hypotheses and related associations may be able to be efficiently and reliably tested. For example, a range of studies of the health risks following from human exposure to ionizing radiation have been carried out in cohorts of atomic bomb exposed populations in Hiroshima and Nagasaki. A principal "Life Span Study" cohort consists of over 100 000 persons with residence in either city as of 1 October 1950 [4]. Decisions needed to be made concerning the inclusion of such residents who were some distance from the epicenter at the time of bombing or who were "not-in-city" at the time of bombing. The latter group has been variably included in reports from this study. The generalizability of the Life Span Study results is somewhat impacted by selection factors related to survival of the acute exposure and factors related to continuing residence in either of the two cities during the time period 1945–1950, but otherwise appears to be representative of a hypothetical population "like that of Hiroshima and Nagasaki residents" at the time of radiation exposure.

There are several ongoing cohort studies that are motivated in part by hypotheses related to diet and cancer. Recent examples include studies of US nurses (e.g. Willett et al. [102]), studies of women participating in a randomized trial of breast screening to prevent breast cancer mortality (e.g. Howe et al. [34]), studies of Iowa women (e.g. Kushi et al. [43]), and studies of men of Japanese heritage living in Hawaii (e.g. Stemmerman et al. [89]). Such studies appear to be limited (e.g. Prentice et al. [69]) by modest within-population variability in nutrient exposures of interest, substantial exposure measurement error in dietary assessment, and many highly correlated dietary exposure variables. These factors may combine to cast doubt on study reliability. Recent diet and cancer cohort study developments attempt to address such concerns by studying populations having a broader than usual range in dietary habits, by enhancing dietary assessment methodology, and by employing multiple dietary assessment tools in subsets of the cohort. Specifically, recently initiated diet and cancer cohort studies include a study among members of the American Association of Retired Persons with an overrepresentation of persons having estimated fat intake within certain extreme percentiles of the overall fat intake distribution; a multiethnic cohort study taking place in Los Angeles and Hawaii; and a multipopulation cohort study in Europe entitled the European Prospective Investigation into Cancer and Nutrition (e.g. Riboli [73]).

Much valuable information on cardiovascular disease risk factors has arisen in the context of randomized prevention trials, including, for example, cohort studies of persons enrolled in the Multiple Risk Factor Intervention Trial (MRFIT) [58], the Lipid Research Clinic Primary Prevention Trial [49], and the Hypertension Detection and Follow-up Program Trial [35]. Persons screened for possible enrollment in such trials include another potential source

of cohort study enrollees. For example, the approximately 300 000 men screened for possible enrollment in MRFIT, a trial involving about 12 000 randomized men, yielded precise information on the relationship between blood cholesterol and mortality from various diseases (e.g. Jacobs et al. [37]).

In each of the cohort studies mentioned above consideration of inclusion and exclusion criteria is required in interpreting study results, particularly concerning the degree of generalizability of results to a broader source population.

Sample Size and Study Duration

One approach to establishing the size of the cohort is to list motivating hypotheses along with corresponding design assumptions, and to select a cohort size that will yield acceptable power (e.g. >80%) for all, or most, key hypotheses within a practical follow-up period. In fact, cohort studies are often initiated with the hope that active follow-up will continue for some decades, but for scientific and logistic reasons study planning exercises may need to be based on an average follow-up period of, say, 5–10 years. These reasons include funding cycle logistics, the desire of investigators to produce new information in a practicable time period, and a possible reduced relevance of baseline covariate data to disease risk determination beyond a few years of follow-up. Exercises to determine a cohort size should make provisions for the power-influencing factors mentioned previously, particularly exposure measurement error influences.

A more empirical approach to cohort size determination can be based on the consideration of previous cohort study sizes and of the corresponding range of associations tested. Specifically, cohort studies that have yielded much useful information on cardiovascular disease risk factors have often been in the range of 5000 to 20 000 persons, including, for example, the **Framingham Study**, observational studies within the MRFIT study and other coronary heart disease prevention trials, the Adult Health Study of atomic bomb survivors, and the Cardiovascular Health Study. Cohort sizes in the vicinity of 5000 may be adequate for cardiovascular disease studies among older persons, as in the Cardiovascular Health Study [21] that is restricted to persons of age 65 or older, whereas considerably larger cohort sizes may be indicated for studies among younger persons, as in the Royal College of General Practitioners' study of the health effects of oral contraceptive use [81] that enrolled 46 000 younger women.

Most cohort studies of diet and cancer to date have involved sample sizes in the vicinity of 50 000–100 000, including, for example, the Nurses Health Study, the Canadian National Breast Screening study, and the Iowa Women's study. Consideration of range of nutrient intake and likely magnitude of random measurement error in dietary assessment, however, suggests that some pertinent odds ratios following measurement error influences can be hypothesized to be in the range 1.1–1.2 (e.g. Prentice et al. [69], Prentice & Sheppard [70], Prentice [67]). These types of considerations support the recently initiated cohort studies involving larger sample sizes (e.g. 100 000–400 000) in populations having an unusual degree of diversity of dietary habits.

Study Conduct and Analysis

Protocol and Procedures

A cohort study requires a clear, concise protocol that describes study objectives, design choices, performance goals and monitoring and analysis procedures. A detailed manual of procedures, which describes how the goals will be achieved, is necessary to ensure that the protocol is applied in a standardized fashion. Carefully developed data collection and management tools and procedures, with as much automation as practicable, can also enhance study quality. Centralized training of key personnel may be required to ensure that the protocol is understood, and to enhance study subject recruitment and comparability of outcome ascertainment as a function of exposures and confounding factors.

Analysis and reporting procedures should acknowledge the large number of exposure–disease associations that may be examined in a given cohort study, as well as the multiple time points at which hypotheses concerning each such exposure may be tested. In fact, even though such multiple testing considerations are routinely acknowledged in randomized clinical trials, their inclusion in cohort study reporting seems to be uncommon.

Covariate Data Ascertainment and Reliability

The above framework assumes that pertinent covariate histories $Z(t)$ are available for all cohort members

at all times t during the cohort follow-up period. Conceptually, the availability of such data would require baseline covariate data collection to ascertain all pertinent exposures and characteristics prior to enrollment in the cohort study followed by the continuous updating of evolving covariates of interest during cohort follow-up. In practice, however, there may be a limited ability to ascertain retrospectively such covariate information at baseline, unless relevant specimens and materials had fortuitously been collected and stored for other reasons. Furthermore, there will be a limit to the frequency and extent of covariate data updating that can be carried out during covariate follow-up. Such evolving covariate data may be a key to adequate confounding control [76], and may be fundamental to such issues as the estimation of time lags between exposure and disease risk, and estimation of the relationship between covariate change and disease risk more generally.

The fact that the desired covariates may be poorly measured, or completely missing, can be a substantial impediment to the analysis and interpretation of study results. The effects of mismeasured or missing exposure or confounding factor data on relative risk parameter estimation may be much more profound than simple attenuation. In fact, if the measurement error variances are at all large (e.g. more than 10%–20%) relative to the variance of the true regression variables, then it will often be important to undertake additional data collection in the form of validation or calibration substudies, toward accommodating such measurement errors in data analysis. These substudies can also aid in the accommodation of missing covariate data, as it is otherwise necessary to make a missing at random assumption; that is, to assume that missingness rates are independent of the true covariate value, given the accumulated data at earlier time points (*see* **Missing Data in Epidemiologic Studies**).

Validation and Calibration Substudies

In some circumstances it may be possible to design a cohort study to include a validation subsample in which covariate measurements that are essentially without measurement error are taken in a random subset of the cohort. Such measurements may be too expensive or too demanding on study subjects to be practicable for more than a small subset of the cohort. See Greenland [26], Marshall [50], and Spiegelman & Gray [88] for discussion of the role and design of validation substudies (*see* **Validation Study**).

Consistent estimation of the relative risk parameter β is possible by making use of a validation substudy (e.g. Pepe & Fleming [59], Carroll & Wand [14], Lee & Sepanski [46]), though the loss of efficiency arising from substantial measurement errors presumably may be large. The validation sample permits nonparametric estimation of the expectation of $\exp[z(t)^{\mathrm{T}}\beta]$ given the measured covariate and study subject "at risk" status at t, obviating the need for specific measurement error assumptions, and giving rise to estimated likelihood or estimated score procedures for the estimation of β. An alternate data analysis strategy, in the presence of a validation subsample, simply replaces the mismeasured covariate by its estimated conditional expectation, given the accumulated data on the study subject at preceding times. This so-called regression calibration approach is quite convenient, and it performs well in a variety of circumstances even though typically technically inconsistent under (1) and other nonlinear models (e.g. Prentice [64], Rosner et al. [77, 78], Carroll et al. [12], and Wang et al. [94]). If a validation study is possible for some or all important covariates, then the inclusion of a validation sample of appropriate size may be a critically important aspect of cohort study design and conduct.

The regression calibration procedure just mentioned extends fairly readily even if the subsample measure is not the true covariate value but is contaminated by measurement error that is independent of both the routinely available measurement and the true covariate values. See, for example, Greenland & Kleinbaum [28], Kupper [42], Whittemore [98], Rosner et al. [78, 79], Pierce et al. [61], Carroll et al. [13], Armstrong [3], Clayton [17], Thomas et al. [90], and Sepanski et al. [86] for various approaches to cohort data analyses in the presence of calibration subsamples.

Unfortunately, the situation changes dramatically if the subsample measurement error does not satisfy such independence properties. For example, Prentice [67] considers a measurement model for two self-report measures of dietary fat in an attempt to interpret a combined cohort study analysis of dietary fat in relation to breast cancer. One self-report measure, based on food frequency assessment, was available in all cohort study members, while a more detailed measure, based on multiple days of food recording, was available on a small subset of the

cohorts in question. By using food frequency and food record data from the Women's Health Trial feasibility study [36] and allowing the dietary fat measurement errors for the two instruments to be correlated and to depend on an individual's body mass index, Prentice [67] showed that even the strong relative risk relationship between fat and postmenopausal breast cancer suggested by international correlation studies (e.g. Prentice & Sheppard [70] could be projected to be essentially undetectable in a cohort study using a food frequency instrument, regardless of its size. Specifically, relative risks of 1, 1.5, 2.0, 2.7, and 4.0 across fat intake quintiles if measurement errors were absent are reduced to projected values of 1, 1.0, 1.0, 1.1, and 1.1 upon allowing for both random and systematic aspects of dietary fat measurement error. This illustration suggests that covariate measurement errors may be at the root of many controversial associations in epidemiology, and motivates the importance of objective measures of exposure. Biomarker exposure measures may be quite valuable in such contexts even if such measures include considerable noise. For example, in the dietary area, total energy expenditure can be objectively measured over short periods of time using doubly labelled water techniques while protein expenditure can be measured by urinary nitrogen (e.g. Lichtman et al. [47], Heitmann & Lessner [32], Martin et al. [51], Sawaya et al. [84]). Plummer & Clayton [62] use urinary nitrogen data to demonstrate correlated measurement errors among dietary protein self-report measures.

Additional Sampling Strategies

It will often be efficient when conducting a cohort study to assemble the raw materials for covariate history assembly on the entire cohort, but to restrict the processing and analysis of such materials to appropriate subsamples. For example, a random sample, or stratified random sample, of the cohort may be selected, along with all persons experiencing disease events of interest, for covariate data processing. Such a case–cohort approach allows relative risk estimation (e.g. Prentice [65]) based on (2) with $R(t_i)$ consisting of the person developing a disease at t_i (the case) along with all "at risk" members of the selected sample (the subcohort), though (2) no longer has a likelihood function interpretation and specialized variance estimators are required (*see* **Case–Cohort Study**). Alternatively, a case of a specific disease at time t_i may be matched to one or more controls randomly selected from the risk set at t_i, with ordinary likelihood methods applied to (2) except that $R(t_i)$ is replaced by the case and time-matched controls (e.g. Liddell et al. [48], Prentice & Breslow [68]) (*see* **Case–Control Study, Nested**). Recently Samuelson [83] has proposed an alternate analysis of such nested case–control samples that appears to yield meaningful efficiency improvements relative to the standard procedure just described.

The nested case–control sampling approach allows cases and controls to be matched on various study subject characteristics, including time from enrollment into the cohort, as may be important if some covariate measurements (e.g. blood concentrations of selected nutrients) degrade with storage time. Such issues may be accommodated under case–cohort sampling by stratifying the subcohort selection on cohort enrollment data and by analyzing all case and subcohort specimens and materials at a common point in time. In fact, it may be useful to delay subcohort selection to the time of data analysis in order to match subcohort sizes in each stratum to the corresponding numbers of disease events. See Langholz & Thomas [44, 45] and Wacholder [91] for further discussion and comparison of nested case–-control and case–cohort sampling.

A related topic includes a two-stage process in establishing a cohort. A first stage would involve collecting information on the exposures of primary interest, or perhaps collecting fairly crude estimates of such exposures. The second stage would then involve selecting a subset of the stage 1 study subjects that give a desirable exposure distribution for more detailed data collection. The diet and cancer cohort study among members of the American Association of Retired Persons provides an example in which subjects are oversampled for the second stage if their food frequency estimated fat intakes are in certain extreme percentiles. A two-stage sampling approach is also natural for the study of rare exposures. A considerable literature exists on the design and analysis of two-stage sampling schemes, mostly in the context of case–control studies (e.g. White [96], Walker [92], Breslow & Cain [8], Breslow & Zhao [9], Flanders & Greenland [19] (*see* **Case–Control Study, Two-phase**).

Additional Data Analysis Topics

The above discussion assumes that the basic time variable is time from selection into the cohort. This choice is attractive in that relative risk estimation [i.e. each factor in (2)] is then based on comparisons among individuals at the same length of time since cohort entry. Other important time variables, such as study subject age and chronologic time, can be accommodated by regression modeling, or stratification with (2) replaced by a product of like terms over strata. Alternatively, if cohort eligibility criteria or recruitment strategies changed markedly over time, or if covariate data or outcome data ascertainment procedures changed markedly over time, one may prefer to define t to be chronologic time so that relative risk estimates are based on comparisons of measurement taken under common procedures, with age and time since study enrollment controlled by stratification or modeling. In this case a study subject begins contributing to (2) at the time (date) of study enrollment.

If the study is conducted to estimate disease rates, or cumulative disease rates and **absolute risks**, then it may be natural for interpretation to define t to be age, or time from some significant event (e.g. infection with human immunodeficiency virus). Depending on the means of study subject identification such significant event data may only be known to be earlier than a specified time, giving rise to interval censored event time data and a range of interesting statistical estimation issues (e.g. Brookmeyer & Gail [10, Chapter 5]) (*see* **Biased Sampling of Cohorts**).

The fact that multiple outcomes are typically ascertained in a cohort study allows for the possibility of relating an exposure jointly to two or more event rates and, of course, there may be multiple events of a given type during the cohort study follow-up of an individual. The literature includes generalization of (1) to repeat failure times on an individual study subject (e.g. Prentice et al. [72], Andersen et al. [1]), while for single occurrences of multiple types of events one can consider the use of (2) for each failure type in conjunction with a modified variance estimation procedure for the joint estimation of relative risks for several diseases (e.g. Wei et al. [95]). This latter procedure will have acceptable efficiency under most situations of practical interest.

The above presentation assumes that failure times among distinct cohort study members are independent. This assumption may be violated if study subjects share environmental or genetic factors. In fact, in **genetic epidemiology** one may use the relationships among the failure time data of family members in a pedigree cohort study in an attempt to identify the existence (aggregation analysis), inheritance pattern (segregation analysis) and physical location (linkage analysis) of genes that play a role in determining disease risk. Such studies or, more practically, case–control subsamples of population-based family studies, may also be used to study **gene–environment interaction**.

Cohort Study Role

Cohort studies properly play a central role in epidemiologic research. Disease associations that are relatively strong can often be reliably studied using cohort study techniques, especially if there is sufficient knowledge of disease risk factors and exposure correlates to permit comprehensive efforts to control confounding. Relative risk analyses are unlikely to be misleading under these circumstances since residual **confounding** will tend to be small compared with the relative risk trend under study. If the exposures and other covariates of interest can be reliably ascertained retrospectively, then a case–control design may introduce considerable economies relative to a cohort study; in fact, the case–control design is very commonly employed, particularly if the study diseases are rare and good disease registries are available for case ascertainment.

If the relative risk trends to be studied are more modest, then the reliability of the cohort study may be less clear, as uncontrolled confounding, or other biases, may have a salient impact on the estimated associations. If, in addition, the exposures of interest or strong confounding factors or disease outcomes involve measurement errors that are substantial, but of unknown properties, then the cohort study reliability may be poor.

In these circumstances one can turn to an experimental approach, as has been done to study the role of diet in disease in various studies of micronutrient supplementation, and of a low fat eating pattern. Such clinical trials permit a valid test of the intervention applied in relation to a range of diseases without concern about "baseline" confounding,

and without the need for precise dietary assessment. Dietary assessment, in such contexts, enters in a secondary fashion to document that a sufficiently powerful hypothesis test has been conducted, and in attempts to isolate intervention activities responsible for any observed disease risk difference. However, primary disease prevention clinical trials are logistically difficult and expensive, so that only a few can be conducted at any time point, preferably those that are motivated by hypotheses having great public health potential.

The recent movement mentioned above, toward multipopulation cohort studies (e.g. the EPIC study) to enhance exposure heterogeneity seems attractive in the type of circumstances alluded to above. Such a multipopulation cohort can be expected to involve a broadened exposure range, perhaps in a manner that does not increase covariate measurement errors, thereby enhancing both reliability and power. The relative risk information in such a multipopulation study can be partitioned into between-population and within-population components under standard **random effects** modeling assumptions (e.g. Sheppard & Prentice [87]). In fact, it may often happen that much of the retrievable information arises from between-population sources. Also, between-population, but not within-population, relative risk estimates tend to be highly robust to independent mean zero measurement errors in covariates, essentially because such estimates are based on covariate function averages over large numbers of study subjects that are little affected by such errors. Furthermore, the between-population relative risk information may be able to be extracted efficiently by relating covariate history data on modest numbers of persons in each population (e.g. 100–200) to corresponding population disease rates, as may be available from disease registers in each population [71]. These points suggest that studies of relatively modest relative risk trends associated with exposures that are measured with considerable noise may sometimes be efficiently studied using an aggregate data (ecologic) approach that involves covariate surveys in disease populations covered by good quality disease registers. Note, however, that confounding control across heterogeneous populations may pose particular challenges, and that careful data analysis will be required to avoid aggregation and other biases in such a study. See Piantadosi et al. [60], Greenland & Morganstern [30], Brenner et al. [6], and Greenland & Robins [31] for further discussion of these bias issues (*see* **Ecologic Study**; **Ecologic Fallacy**).

Statistical thinking and methodology have come to play an important role in the design, conduct, and analysis of cohort studies. Cox regression and closely related logistic regression methods play a central role in data analysis and reporting, and in related study planning efforts. Cohort sampling techniques are widely used and have enhanced cohort study efficiency. A topic of continuing importance relates to the methodology for measurement error assessment, and to analytic methods to reduce the sensitivity of results to measurement error influences.

ROSS L. PRENTICE

Collapsibility

Consider the $I \times J \times K$ **contingency table** representing the joint distribution of three discrete variables, X, Y, and Z, the $I \times J$ marginal table representing the joint distribution of X and Y, and the set of conditional $I \times J$ subtables (strata) representing the joint distributions of X and Y within levels of Z. A measure of association of X and Y is said to be *strictly collapsible* across Z if it is constant across the conditional subtables *and* this constant value equals the value obtained from the marginal table. Noncollapsibility (violation of collapsibility) is sometimes referred to as **Simpson's paradox** after a celebrated article by Simpson [12], but the same phenomenon had been discussed by earlier authors, including Yule [15]; see also Cohen & Nagel [3]. The term *collapsibility*, however, seems to have arisen later in the work of Bishop and colleagues; see Bishop et al. [1].

Table 1 provides some simple examples. The difference of probabilities that $Y = 1$ (the risk difference) is strictly collapsible. Nonetheless, the ratio of probabilities that $Y = 1$ (the risk ratio) is not strictly collapsible because the risk ratio (*see* **Relative Risk**) varies across the Z strata, and the **odds ratio** is not collapsible because its marginal value does not equal the constant conditional (stratum-specific) value. Thus, collapsibility depends on the chosen measure of **association**.

Now suppose that a measure is not constant across the strata, but that a particular summary of the conditional measures does equal the marginal measure. This summary is then said to be *collapsible* across Z. As an example, in Table 1 the risk ratio standardized to the marginal distribution of Z is

$$\frac{\begin{array}{c}\Pr(Z=1)\Pr(Y=1|X=1,Z=1)\\+\Pr(Z=0)\Pr(Y=1|X=1,Z=0)\end{array}}{\begin{array}{c}\Pr(Z=1)\Pr(Y=1|X=0,Z=1)\\+\Pr(Z=0)\Pr(Y=1|X=0,Z=0)\end{array}}$$
$$= \frac{0.50(0.80)+0.50(0.40)}{0.50(0.60)+0.50(0.20)} = 1.50,$$

equal to marginal (crude) risk ratio. Thus, this measure is collapsible in Table 1. Various tests of collapsibility and strict collapsibility have been developed [4, 7, 14].

The definition of collapsibility also extends to **regression** contexts. Consider a **generalized linear model** for the regression of Y on three regressor vectors $\mathbf{W}$, $\mathbf{X}$, and $\mathbf{Z}$:

$$g[\mathrm{E}(Y|\mathbf{W}=\mathbf{w},\mathbf{X}=\mathbf{x},\mathbf{Z}=\mathbf{z})] = \alpha + \mathbf{w}\boldsymbol{\beta} + \mathbf{x}\boldsymbol{\gamma} + \mathbf{z}\boldsymbol{\delta}.$$

The regression is said to be *collapsible* for $\boldsymbol{\beta}$ over $\mathbf{Z}$ if $\boldsymbol{\beta} = \boldsymbol{\beta}^*$ in the regression omitting $\mathbf{Z}$ [2],

$$g[\mathrm{E}(Y|\mathbf{W}=\mathbf{w},\mathbf{X}=\mathbf{x})] = \alpha^* + \mathbf{w}\boldsymbol{\beta}^* + \mathbf{x}\boldsymbol{\gamma}^*.$$

Thus, if the regression is collapsible for $\boldsymbol{\beta}$ over $\mathbf{Z}$ and $\boldsymbol{\beta}$ is the parameter of interest, then $\mathbf{Z}$ need not be measured to estimate $\boldsymbol{\beta}$. If $\mathbf{Z}$ is measured, however, tests of $\boldsymbol{\beta} = \boldsymbol{\beta}^*$ can be constructed [2, 9].

The preceding definition generalizes the original contingency-table definition to arbitrary variables. However, there is a technical problem with the regression definition: if the first (full) model is correct, then it is unlikely that the second (reduced) regression will follow the given form. If, for example, Y is Bernoulli and g is the logit link function, so that the full regression is first-order **logistic**, the reduced regression will not follow a first-order logistic model except in special cases. One way around this dilemma

Table 1 Examples of collapsibility and noncollapsibility in a three-way distribution

	$Z=1$		$Z=0$		Marginal	
	$X=1$	$X=0$	$X=1$	$X=0$	$X=1$	$X=0$
$Y=1$	0.20	0.15	0.10	0.05	0.30	0.20
$Y=0$	0.05	0.10	0.15	0.20	0.20	0.30
Risks[a]	0.80	0.60	0.40	0.20	0.60	0.40
Risk differences	0.20		0.20		0.20	
Risk ratios	1.33		2.00		1.50	
Odds ratios	2.67		2.67		2.25	

[a]Probabilities of $Y = 1$.

(and the fact that neither of the models is likely to be exactly correct) is to define the model parameters as the asymptotic **means** of the **maximum likelihood** estimators. These means are well defined and interpretable even if the models are not correct [13].

It may be obvious that, if the full model is correct, $\boldsymbol{\delta} = 0$ implies collapsibility for $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ over $\mathbf{Z}$. Suppose, however, that neither $\boldsymbol{\beta}$ nor $\boldsymbol{\delta}$ is zero. In that case, independence of the regressors does not ensure collapsibility for $\boldsymbol{\beta}$ over $\mathbf{Z}$ except when g is the identity or log link [5, 6]; conversely, collapsibility can occur even if the regressors are dependent [14]. Thus, it is not correct to equate collapsibility over $\mathbf{Z}$ with simple independence conditions.

Consider a situation in which the full regression is intended to represent the causal effects of the regressors on Y. One point, overlooked in much of the literature, is that noncollapsibility over $\mathbf{Z}$ (that is, $\boldsymbol{\beta} \neq \boldsymbol{\beta}^*$) does not correspond to **confounding** of effects by $\mathbf{Z}$ unless g is the identity or log link. That is, it is possible for $\boldsymbol{\beta}$ to represent unbiasedly the effect of manipulating $\mathbf{W}$ within levels of $\mathbf{X}$ and $\mathbf{Z}$, and, at the same time, for $\boldsymbol{\beta}^*$ to represent unbiasedly the effect of manipulating $\mathbf{W}$ within levels of $\mathbf{X}$, even though $\boldsymbol{\beta}^* \neq \boldsymbol{\beta}$. Such a divergence is easily shown for logistic models, and points out that noncollapsibility does not always signal a **bias**. In the literature on **random effects** logistic models, the divergence corresponds to the distinction between cluster-specific and population-averaged effects [10]. The cluster-specific model corresponds to the full model in which $\mathbf{Z}$ is an unobserved cluster-specific random variable independent of $\mathbf{W}$ and $\mathbf{X}$, with mean zero and unit variance; $\boldsymbol{\delta}^2$ is then the vector of random-effects variances. For further discussion and an example in which confounding and noncollapsibility diverge, (*see* **Confounding**).

SANDER GREENLAND

Collinearity

Collinearity (or "multicollinearity") refers to a high level of **correlation** within a set of **explanatory variables**. In a **regression** modeling situation, if explanatory variables are highly correlated, then regression coefficient estimates may become unstable and not provide accurate measures of the individual effects of the variables. The estimate of the precision of these coefficient estimates is also affected and therefore confidence intervals and **hypothesis tests** are, likewise, affected.

For the estimation of regression coefficients, the columns of the design matrix (*see* **General Linear Model**) must be linearly independent. At an extreme, if two explanatory variables are perfectly linearly associated (i.e. their correlation is equal to 1), then such collinearity is an example of linearly dependent columns in the design matrix, $\mathbf{X}$. While two parameters require estimation (i.e. the regression coefficients for the two explanatory variables), information is not available in the design matrix to estimate both coefficients uniquely. The two individual effects cannot be distinguished as a result of this collinearity. While collinearity typically does not involve completely linearly related explanatory variables, high levels of correlation can still lead to difficulties in coefficient estimation.

It should be noted that this issue pertains to the relationship among explanatory variables which, ultimately, affects the ability to investigate simultaneously the relationship between the response variable and the explanatory variables. Therefore, the identification of potential collinearity problems is usually addressed by examination of the relationships among explanatory variables.

One simple technique for the identification of collinearity is presented in Kleinbaum et al. [1]. The computation of the variance inflation factor (VIF) is suggested. If there are p explanatory variables, each explanatory variable is, in turn, regarded as an outcome variable in a regression equation that includes the remaining $p-1$ explanatory variables. Then, R_j^2 represents the squared residual correlation obtained using explanatory variable j, $j = 1, \ldots, p$, as the response. The VIF is then defined for each such regression as:

$$\mathrm{VIF}_j = \frac{1}{1 - R_j^2}.$$

If there is a strong relationship between the explanatory variable j and the remaining $p-1$ explanatory variables, then R_j^2 is close to 1 and VIF_j is large. It is suggested, in [1], that values of VIF greater than 10 indicate serious collinearity that will affect coefficient and precision estimation.

Collinearity may also be indicated if coefficient estimates from fitting simple regression models of the response with each explanatory variable are substantially different from coefficient estimates from fitting a **multiple regression** model including all explanatory variables. Similarly, if the order in which certain terms are included in the model seriously affects the coefficient estimates for these terms, then collinearity is indicated. Of course, one of the primary purposes of multivariate regression models is to examine the role of explanatory variables having "adjusted" for other variables in the model so that such behavior is not necessarily a problem. However, serious collinearity problems may prohibit a multivariate model from being fitted at all.

If two or more explanatory variables are highly correlated because they represent measurements of the same general phenomenon (e.g. highest attained level of education and current salary are both aspects of socioeconomic status), then collinearity can be addressed by choosing one variable thought to be the most relevant. This variable would then be included in any models and the remaining, so-called redundant, variables would be excluded. The identification of such redundant variables may be difficult, so, alternately, a new variable that combines information on the correlated variables can be derived. This aggregate variable would be included in models instead of all of the component variables.

It is sometimes helpful, particularly when collinearity is created as a result of including polynomial terms (e.g. $\mathbf{X}$ and $\mathbf{X}^2$ are included in a model together) but also in general, to center the original explanatory variables. This is accomplished by computing new explanatory variables that are the original measurements with the means subtracted. Suppose there are n individuals and p explanatory variables measured on each individual, $X_{ji}, i = 1, \ldots, n$, $j = 1, \ldots, p$. Then the new explanatory variables are $Z_{ji} = X_{ji} - \overline{X}_j$. If a quadratic model is of interest, then one would include the terms Z_{ji} and Z_{ji}^2 in the model. In [1], an example of the effectiveness

of such an approach for correcting collinearity is presented.

When **polynomial regression** is being undertaken, then the further step of orthogonalization (*see* **Orthogonality**) of the explanatory variables is also possible and frequently used in some settings. Orthogonalization of more general sets of explanatory variables is possible but not as widely used.

Combining *P* Values

Empirical investigations typically involve many **hypotheses**. In **clinical trials**, one may test that the medical treatment is efficacious for each of a variety of medical endpoints such as survival, blood pressure, progression of disease, and so on; in **epidemiological** studies, one may test that an environmental toxin is associated with cancer at each of a number of different geographical locations and/or demographic groups.

Combinations of ***P* values** may be considered when the hypotheses are all related to a common question, such as "Does the drug work?" or "Does the environmental toxin cause cancer?"; such methods are called "**meta-analysis**" [4].

Suppose the **null hypotheses** are stated as H_{0i}: {no difference for test i}; and suppose the test statistic is Z_i (*see* **Hypothesis Testing**). The P value is obtained using the distribution of the test statistic Z_i under H_{0i}; assuming a **standard normal** distribution with cumulative probability distribution function $\Phi(.)$, the lower-tailed, upper-tailed, and two-tailed P values are $p_i = \Phi(z_i)$, $p_i = 1 - \Phi(z_i)$, and $p_i = 2(1 - \Phi(|z_i|))$, respectively.

Example: A Clinical Trial

A clinical study of a drug might result in five distinct measurements of **pain**. Upper-tailed (favoring efficacy of drug) P values are $p_1 = 0.078$, $p_2 = 0.091$, $p_3 = 0.213$, $p_4 = 0.121$, and $p_5 = 0.061$, suggesting a clear pattern of beneficial effects, as a P value of 0.50 corresponds to no difference between drug and placebo. However, none meet the standard 0.05 threshold (*see* **Level of a Test**), and the study might therefore be considered nonefficacious. The conclusion that there is no significant efficacy is troublesome from the "common-sense" standpoint, as it seems extremely unlikely that such a consistent pattern of P values could be observed if the drug truly had no effect.

This article addresses the following questions:

1. Can one combine the P values from the various sources to arrive at stronger evidence than is obtained when considering each P value individually?
2. What are the various methods of combining P values?
3. How do the **power** functions of the different methods compare, that is, which combination function should one use?
4. How does one accommodate **correlations** between test statistics and failed distributional assumptions?

Combining *P* Values to Get More Power

Combination of tests is most relevant when the hypotheses are related. For example, if a drug beneficially affects the progression of disease, then one might argue that it should also beneficially affect survival; thus, the hypotheses are related. Similarly, in an epidemiological study, if there were a carcinogenic effect of an environmental toxin in one geographic site, then one would expect that there would be an effect in other sites as well.

Continuing with the epidemiology example, suppose there are two Z-values, each independent, distributed as $N(0,1)$ when there is no effect of environmental toxin on cancer at site i, where $i = 1, 2$. Under the alternatives, the distributions are $N(\delta_i, 1)$, where δ_i is the noncentrality parameter. The 0.05-level test of H_{0i}: $\delta_i = 0$ in favor of H_{0i}: $\delta_i > 0$ rejects when $z_i > 1.645$; the power of the 0.05-level test of H_{0i}: $\delta_i = 0$, for a fixed alternative $\delta_i > 0$, is given by $1 - \Phi(1.645 - \delta_i)$.

One might rather combine the evidence from both regions into a single test using the sum of the Z's; in this case, the hypothesis is H_0: {no effect of environmental toxin at *either* site}. The test rejects H_0 when $(z_1 + z_2) > 1.645 \times 2^{1/2}$, and the power function is $1 - \Phi\{1.645 - (\delta_1 + \delta_2)/2^{1/2}\}$. The combined test has more power than either component test when $0.41\delta_1 < \delta_2 < 2.41\delta_1$. In the case where the hypotheses are related and the study designs comparable, the noncentrality parameters should also be comparable ($\delta_1 \approx \delta_2$), and thus the combined test should be more powerful.

Z-values are simple transformations of the P values, so the test given above is an example of a P value combination statistic $C = \Sigma\Phi^{-1}(1\text{-}p_i)$. This is called the "Liptak" P value combination test; the Liptak test and others are given in the following section.

P Value Combination Tests

One typically assumes that the P values p_i are independent and **uniformly distributed** under their

respective null hypotheses H_{0i}; these assumptions are made throughout this section. P values often are uniformly distributed when the correct distributional forms are used to model the data; for example, when normality, independence, and homoscedasticity (*see* **Scedasticity**) hold. Independence follows when the P values are computed from data values that can be assumed independent.

Under these assumptions, one can provide critical values for the various tests under the combined hypothesis H_0: {H_{01} true *and* H_{02} true *and* ... *and* H_{0k} true}, that is, under $H_0 = \cap H_{0i}$. Combination tests include:

Fisher Combination Test

This test is due to Fisher [3]. The combined test statistic is

$$C_F = -2\Sigma \ln(p_i). \tag{1}$$

C_F is distributed as **Chi-Square** with 2k **degrees of freedom** under H_0; therefore, the α-level test of H_0 rejects when $C_F \geq {\chi^2}_{1-\alpha,2k}$, and the P value of the combined test is $P({\chi^2}_{2k} \geq C_F)$.

In the example with P values 0.078, 0.091, 0.213, 0.121, and 0.061, $C_F = 22.8065$ and ${\chi^2}_{.95,10} = 18.307$; thus, we can reject the combined null at the $\alpha = 0.05$ level, despite the insignificance of every component P value at the 0.05 level. The P value for the combined test is 0.0115.

However, we should note that the assumption of independence is clearly violated in this example, as the multiple pain measurements are correlated, implying that the P values are also correlated. This Fisher combination procedure is therefore not valid; this example is used for illustrative purposes only. The section "Accommodating Nonuniform and/or Dependent P Values" shows how to accommodate **correlation**.

Liptak Combination Test

This test was originated by Liptak [6].

For this procedure, the P values should be one-sided. As shown in the previous section, one may define

$C_L = \Sigma\Phi^{-1}(1 - p_i)$, for upper-tailed P values, or

$C_L = \Sigma\Phi^{-1}(p_i)$, for lower-tailed P values.

C_L is distributed as N(0, k) under H_0; therefore, the α-level test of H_0 rejects when $C_L \geq k^{1/2}\Phi^{-1}(1 - \alpha)$ for upper-tail tests, and when $C_L \leq k^{1/2}\Phi^{-1}(\alpha)$ for lower-tail tests. The P value is either $1 - \Phi(C_L/k^{1/2})$ or $\Phi(C_L/k^{1/2})$ for upper- and lower-tail tests, respectively.

In the example with P values 0.078, 0.091, 0.213, 0.121, and 0.061, $C_L = 6.266$ and $5^{1/2}\Phi^{-1}(1 - .05) = 3.678$; thus, we reject the combined null at the $\alpha = 0.05$ level. The P value for the combined test is 0.0025.

Again, as in the case of the Fisher combination test, this procedure is not valid because these P values are realizations of correlated quantities. Thus, the example given here is for illustrative purposes only. The section "Accommodating Nonuniform and/or Dependent P Values" gives remedies for correlated P values.

Tippett Combination Test

Named after Tippett [13], this test is also known as the "MinP" test, and is the basis for the **Bonferroni** procedure for **multiple comparisons**.

The test statistic is

$$C_T = k \min(p_i). \tag{2}$$

While the distribution of C_T can be obtained easily under the assumptions of uniformity and independence, this test is most commonly used with the Bonferroni inequality; thus, the α-level test of H_0 rejects when $C_T \leq \alpha$. The test is slightly conservative under independence. The P value for the composite test is exactly C_T.

In the example, we have $C_T = 5(0.061) = 0.305$. This is also the P value for the combined test, and it is not statistically significant.

Despite insignificance, this test is valid in the presence of correlation, because of the Bonferroni inequality.

Sidak Combination Test

This test may be attributed to Sidak [11]. The test is very similar to the Tippett test, but is exact, and not conservative, under the assumptions of uniformity and independence.

The test statistic is

$$C_I = 1 - \{1 - \min(p_i)\}^k. \tag{3}$$

The null distribution of C_I is the uniform (0,1) distribution; thus, as with C_T, the α-level test of H_0 rejects when $C_I \leq \alpha$. The P value for the composite test is exactly C_I.

In our example, we have $C_I = 1 - (1 - 0.061)^5 = 0.2700$, which is also the P value of the combined test. This P value is smaller than the Tippett P value, but still insignificant.

This test is also valid in the presence of positive correlation by the Sidak [11] inequality.

Simes' Combination Test

The Sidak and Liptak tests are clearly inferior in that they exclude information in all but one of the P values. The Simes combination test is similar to the Tippett test, but uses information in all of the P values.

Let the ordered P values be $p_{(1)} \leq p_{(2)} \leq \cdots \leq p_{(k)}$. The test statistic is

$$C_S = \min_i \left\{ \frac{kp_{(i)}}{i} \right\}. \tag{4}$$

Since $C_T = kp_{(1)}$, we have $C_S \leq C_T$, and the Simes test is thus uniformly more powerful than the Tippett test. Simes [12] showed that, under independence and uniformity, the distribution of C_S is uniform on (0,1); thus, the α-level test of H_0 rejects when $C_S \leq \alpha$ and the P value for the composite test is exactly C_S.

In the example, $C_S = \min\{5(0.061)/1,\ 5(0.078)/2,\ 5(0.091)/3,\ 5(0.121)/4,\ 5(0.213)/5\} = 0.1513$. This is also the P value for the test, and, while smaller than C_T and C_I, remains insignificant.

This test is valid in the presence of positive correlation by Sarkar's [10] inequality.

Weighted Combinations and other Generalizations

Some hypotheses might be more important than others, in which case weights $w_1, \ldots, w_k$ can be preassigned to the P values. A weighted Fisher combination test statistic can be given by $C_{wF} = -2\ \Sigma w_i \ln(p_i)$, a weighted Liptak test statistic by $C_{wL} = \Sigma w_i \Phi^{-1}(1 - p_i)$, and a weighted Tippett test statistic by $C_{wT} = \min(p_i / w_i)$. Weighted versions of the Tippett test are discussed by Westfall and Krishen [14], and weighted versions of Simes' test are discussed by Benjamini and Hochberg [1]. Another type of combined P value test is the "cutoff" test, which utilizes the ordered P values and may be considered a generalized Simes test [5]. The "truncated product" method has also been proposed recently as a modification of Fisher's combination test, which cures some of its deficiencies [17].

Critical values for generalized combination tests are obtained simply under the assumptions of independence and uniformity; in more complex cases, refer to the section "Accommodating Nonuniform and/or Dependent P Values" below.

Power Comparisons

Assume that the data are, for $i = 1, 2$, $Z_i \sim \mathrm{N}(\delta_i, 1)$, independent, with upper-tailed $\alpha = 0.05$ tests. Power for all procedures is then a function of (δ_1, δ_2).

We can dismiss the Tippett test since it is always less powerful than the Sidak and Simes tests. Further, the Simes test has a very similar power function as the Sidak test; but the Simes test is slightly more powerful than the Sidak test for all cases except $(\delta_1, \delta_2) \in \{\text{very large}, \sim 0+\}$ and $(\delta_1, \delta_2) \in \{\sim 0+, \text{very large}\}$; we thus exclude the Sidak test as well.

Figure 1 shows regions in the positive orthant where each of the methods Fisher, Liptak, and Simes dominate.

Larger Numbers of Tests and Many null effects

Figure 1 shows that the Liptak and Fisher tests are better when the evidence from the two tests is "reinforcing", while the Simes test is better when one effect is large and the other small. While this type of power behavior might suggest that Fisher and Liptak are generally superior in situations where combinations are desired, caution is urged. When the number of tests is larger, with many hypotheses nearly null, or even worse, with one-sided P values in the unanticipated direction, the power of the Liptak and Fisher tests can be much less than that of the Simes, Tippett, and Sidak tests.

Accommodating Nonuniform and/or Dependent *P* Values

In practice, the assumptions of uniformity and independence are not likely to hold. If the P values

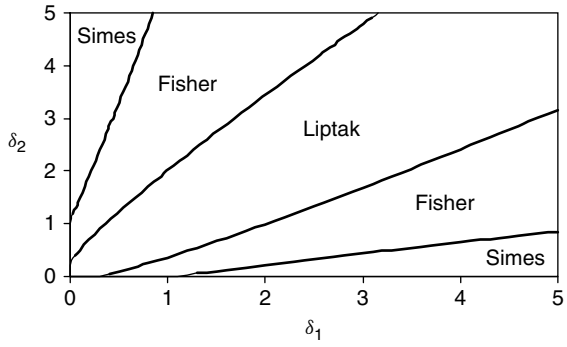

Figure 1 Regions of highest power

are uniformly distributed but dependent, some of the combination tests remain valid. The Tippett combination test is valid, in the sense that the type I error is less than the nominal α in these cases; this follows from the Bonferroni inequality. The Simes combination test has been shown to be conservative as well, under conditions of positive correlation of the P values [10]. However, whereas the Tippett test becomes extremely conservative in cases of highly correlated P values, the Simes test becomes less conservative, and is in fact exact in the case of perfect dependence. The Liptak test can be modified to account for dependence structure; in this case, it is often easier to work directly with the Z statistics rather than the P values; the resulting tests are often called "O'Brien tests" [7].

If the P values are nonuniformly distributed, as typically happens when the distributional assumptions about the data are wrong, it is harder to specify the effects on the combined tests. An exception is the case of discrete (hence nonuniform) **exact** tests, in which case combination tests are often conservative [9, 15].

One can use resampling techniques to obtain more robust, accurate, and in some cases, exact P values for combination tests that fail to satisfy uniformity, dependence, or both. In particular, if the tests come from multivariate data from two groups, and if the global hypothesis refers to equality of the two **multivariate distributions**, one may test the global hypothesis by permutation sampling (*see* **Randomization Tests**) as follows:

(a) Denote the value of the original combination test statistic by C (assume that larger C favor the alternative).

(b) Permute the group labels of the observation vectors, and recompute the combination test statistic from the resulting multivariate data set with permuted group labels. Call the recomputed test statistic C^*.

(c) Repeat (a) to (b) B times, noting whether $C^* \geq C$ for each permuted sample.

The permutation-based P value for the combination tests is then {number of samples for which $C^* \geq C\}/B$. This P value accommodates nonnormality via resampling (nonnormal characteristics of the data are reflected in the sample) and it also accommodates correlations, since the observation vectors remain intact in all permutation samples.

When $B = \infty$, or when the permutations can be enumerated completely, the resulting P value is the exact permutation P value, and the test is called an "exact" test, in the sense of the permutation methods supplied by the software "**StatXact**" [2]. Of course, we cannot take $B = \infty$ in practice, and often the permutations are too numerous to enumerate completely. In these cases, the use of a large B provides good accuracy: If the true P value (as obtained through complete enumeration) is denoted p_C, then the **Monte Carlo** standard error associated with B replications is simply binomial, $\{p_C(1 - p_C)/B\}^{1/2}$. When reporting this standard error, one can substitute the sample-based estimate for p_C.

An entire book is devoted to this subject; see [8] for further discussion and for **algorithms**.

In some cases the permutation approach is not simple, as there may be **covariates**, **survival** functions, and the like, and it may not be clear what should be permuted to represent the combined null hypothesis

H_0. In such cases, **bootstrapping**, either parametric or semiparametric, can help. One needs to model the (usually multivariate) distribution of the data that produced the P values under H_0, and then estimate that distribution under either parametric or semiparametric assumptions. Then one simulates data from the estimated distribution, and computes the resampling-based P value as shown above. Westfall and Young [16, p. 122–3; 214–6] provide examples and further discussion.

Commingling Analysis

A mixture distribution with c components ($c \geq 2$), each with probability density function (pdf) $f_i(x)$, has the pdf f_M given by

$$f_M(x) = \pi_1 f_1(x) + \pi_2 f_2(x) + \cdots + \pi_c f_c(x).$$

The parameters $\pi_i, i = 1, \ldots, c$, are called the mixing proportions, and they satisfy the constraints $\pi_i \geq 0$ and $\pi_1 + \pi_2 + \cdots + \pi_c = 1$. In this article we primarily discuss normal mixtures with two components. That is, $f_M(x)$ is given by

$$f_M(x) = \pi_1 \varphi(x; \mu_1, \sigma^2) + \pi_2 \varphi(x; \mu_2, \sigma^2),$$

where

$$\varphi(x; \mu, \sigma) = \frac{1}{(2\pi)^{1/2}} \exp\left[\frac{-(x-\mu)^2}{2\sigma^2}\right].$$

Everitt & Hand [2] and Titterington et al. [11] have published books on the mixture distribution with extensive examples.

Although the distribution is easy to describe and arises from a simple model, it presents formidable mathematical, computational, and statistical difficulties. **Karl Pearson** [9] was the first to study normal mixtures. He used the **method of moments** to estimate the parameters of each of the components. He pointed out that mixtures of **normal distributions** are hard to distinguish from skewed distributions. For normal components with equal **variances**, the **EM algorithm** [1] is effective for finding the **maximum likelihood** estimates of the parameters. Often, a specific sample has a number of solutions to its maximum likelihood equations, and researchers must take care that they have found the global maximum rather than a local maximum. Finch et al. [4] proposed a random search strategy that has an associated measure of the probability of finding an additional solution.

The most basic problem is to distinguish between a sample from a mixture of two normals and a sample from a single normal. That is, the **null hypothesis** is that a **random sample** was drawn from a normal distribution. The **alternative hypothesis** is that a random sample was drawn from a mixture of two normal distribution with equal variances. The asymptotic distribution of the **likelihood ratio test** is not known because the regularity condition that allows the distribution of the likelihood ratio statistic to be expanded in a series about its parameters does not hold [5]. Otherwise, the asymptotic distribution of the likelihood ratio test would be **chi-square** with two **degrees of freedom**. Thode et al. [10] used **simulation** techniques and found that the convergence rate of the distribution of the likelihood ratio statistic was very slow, if it converged at all. They could not exclude the chi-square distribution with two degrees of freedom as the asymptotic distribution. They reported an approximation to the percentiles of the distribution of the likelihood ratio statistic for finite samples. Very large sample sizes are required to detect a normal mixture with high probability [8]. In a study comparing the likelihood ratio test to other tests of normality, Mendell et al. [7] reported that Fisher's **skewness** test and other tests of symmetry are also powerful tests for detecting mixtures with proportions that are not 50–50 splits.

Maclean et al. [6] suggested the use of a (modified) Box–Cox transformation for this problem to reduce the sensitivity of the test to data from skewed distributions (*see* **Power Transformations**). Their alternative hypothesis is that the random sample was drawn from a mixture of two normals after applying a Box–Cox transformation, and their null hypothesis is that the random sample was drawn from a single normal after applying a possibly different Box–Cox transformation. This procedure reduces, but does not eliminate, the sensitivity of tests for mixtures to data from single skewed distributions.

The normal mixture distribution has great interest in exploratory genetic studies. Researchers interpret evidence of a mixture distribution in the measurement of a biological variable as supportive of the hypothesis that the variable is determined genetically. Commingled distributions have been proposed as a logical extension to the genetic model for metric traits that are either **polygenic** (determined by the additive effect of several genes) or multifactorial (polygenic traits determined by many environmental factors as well). For a polygenic trait (i.e. one determined by a large number of loci, each with small, equal, and additive effects), the distribution of the trait is approximately normal by the **central limit theorem**. Falconer [3] illustrates this in his chapter on continuous variation by deriving the distribution of the **genotype** values for a trait determined by dominant alleles (with gene frequency of

0.5) at each of 24 loci. If a trait is determined by codominant alleles, then the distribution would approximate a normal distribution with even fewer loci involved.

The model for continuous variation resulting from a major gene is a mixture of two or three normal distributions. The expected value for each component is the genotype value. That is, if the trait is determined by a major gene, then there are three major genotypes, A_1A_1, A_1A_2, and A_2A_2. Correspondingly, each genotype has, respectively, the expected values $E(A_1A_1)$, $E(A_1A_2)$, and $E(A_2A_2)$, where $E(A_1A_1) < E(A_2A_2)$. Then, if the allele for high values of the trait is dominant to the allele for low values of the trait, $E(A_1A_2) = E(A_2A_2)$. Similarly, if the allele for high values for the trait is recessive to the allele for a low value for the trait, then $E(A_1A_1) = E(A_1A_2)$. The variation of trait values of individuals who are identical in genotype is due to either minor genes or environmental factors. Thus, if a major gene is involved in the determination of a continuous trait, then there are necessarily two or three components. If there is complete dominance (of either A_1 to A_2 or A_2 to A_1), then there are two components in the distribution. If there is additivity (i.e. $E(A_1A_2) = [E(A_1A_1) + E(A_2A_2)]/2$), incomplete dominance (i.e. $E(A_1A_1) < E(A_1A_2) < E(A_2A_2)$ with $E(A_1A_2) \neq [E(A_1A_1) + E(A_2A_2)]/2$), or overdominance (i.e. $E(A_1A_2) < E(A_1A_1)$ or $E(A_1A_2) > E(A_2A_2)$ at this major locus), then there are necessarily three components. The mixing proportions will correspond to the relative frequencies of the genotypes. Thus, the **power** to detect a mixture distribution will depend on the relative frequencies of the A_1 and A_2 alleles and the differences between the genotype means relative to the variability within groups sharing the same genotype (standardized difference between the genotype means).

Committee of Presidents of Statistical Societies (COPSS)

The Committee of Presidents of Statistical Societies (COPSS) was established in 1963 to address common interests and concerns of North American Statistical Societies. The member societies are the **American Statistical Association** (ASA), the Eastern North American Region (ENAR) of the **International Biometric Society** (IBS), and the Institute of Mathematical Statistics (IMS), the Statistical Society of Canada (SSC), and the Western North American Region (WNAR) of the IBS. COPSS consists of the presidents, past presidents, and presidents-elect of each member society plus a chair and a secretary/treasurer appointed by the committee. The COPSS committee provides a forum for member societies to discuss issues important to statistics.

Historically, COPSS worked on shared problems of the member societies and improved intersociety communication. Many of the initial activities of COPSS were seed activities that later blossomed into programs at member societies. For example, COPSS initiated production of statistical directories. COPSS prepared information for students about statistics and profiles of career statisticians, material that later became the "ASA Careers in Statistics" brochure. COPSS sponsored a lecture series and coordinated the calendar of statistical meetings. COPSS helped to found institutions such as the National Institute of Statistical Sciences (NISS). However, the activity that COPSS is most famous for is that of the COPSS awards.

COPSS began by sponsoring one lectureship and now presents four additional awards. COPSS established the R. A. **Fisher Lectureship** in 1963, to honor the contributions of Sir Ronald Aylmer **Fisher** and the work of a present-day statistician. The Fisher Lectureship recognizes the importance of statistical methods for scientific investigations, and the list of past Fisher lecturers well reflects the prestige that COPSS and its member societies place on this award. The lecture is to be broadly based and is to emphasize aspects of statistics and probability that are closely related to scientific collection and interpretation of data, which are areas in which Fisher made outstanding contributions. The lecture is generally published in one of the COPSS society journals. In 1982, COPSS has added a cash prize and a certificate to the lectureship.

COPSS established the George W. Snedecor Award in 1976. This award honors an individual who is instrumental in the development of statistical theory in biometry. Dr. **Snedecor** was a pioneer in improving the quality of scientific methods concerning the use of statistical methodology. The Snedecor award is for a noteworthy publication in biometry within three years of the date of the award. It is awarded biannually. The presidents' Award, also established in 1976, is presented annually to a young member of the statistical community in recognition of outstanding contributions to the profession of statistics. COPSS defined "young" to mean as not yet having reached his or her 41st birthday during the calendar year of the award. The Elizabeth L. Scott Award, established in 1992, recognizes an individual who exemplifies the contributions of Elizabeth L. Scott's lifelong efforts to further the careers of women in academia. Most recently, COPSS, jointly with the Caucus for Women in Statistics, established the Florence Nightingale David Award in 2001. This award recognizes an individual who exemplifies the contributions of F. N. David. Both the Scott and David awards are presented biannually. All awards have a separate COPSS selection committee. All of the awards have a plaque, certificate, and cash prize. Further information on COPSS can be found at the COPSS website at `www.niss.org/copss/`

SALLIE KELLER-MCNULTY & APARNA V. HUZURBAZAR

Communality

Communality is the proportion of a variable's total variance that is accounted for by the common **factors**. In **factor analysis**, a mathematical model is used to explain the interrelationships of a set of p manifest variables by a smaller number of m underlying latent factors that cannot be observed or measured directly. In common factor analysis, the model relating the measurements on p correlated variables to the m postulated uncorrelated common factors ($m < p$) and p unique factors is

$$\begin{aligned} X_1 &= a_1 A + b_1 B + \cdots + m_1 M + u_1 U_1, \\ X_2 &= a_2 A + b_2 B + \cdots + m_2 M + u_2 U_2, \\ &\vdots \qquad\qquad \vdots \\ X_p &= a_p A + b_p B + \cdots + m_p M + u_p U_p, \end{aligned}$$

where $X_1, X_2, \ldots, X_p$ represent the standardized measurement of the p manifest variables, $A, B, \ldots, M$ represent the standardized scores in the uncorrelated common factors, $a_i, b_i, \ldots, m_i, i = 1, \ldots, p$, are the *common* **factor loadings**, $U_1, U_2, \ldots, U_p$ represent the standardized scores on the p unique factors, and $u_1, u_2, \ldots, u_p$ are the *unique factor loadings*. In the above model the m latent factors and the p unique factors are uncorrelated.

Given that the X_i are standardized and that the latent variables are uncorrelated the variance of X_i is

$$\operatorname{var}(X_i) = 1 = a_i^2 + b_i^2 + \cdots + m_i^2 + u_i^2.$$

The communality h_i^2 is defined as the variance "shared" by the common factors. That is,

$$h_i^2 = a_i^2 + b_i^2 + \cdots + m_i^2,$$

where $i = 1, 2, \ldots, p$. The uniqueness of a variable is u_i^2. It represents the proportion of a variable's variance that does not relate to the common factors.

Communalities can be used in a factor analysis to delineate the dimensions that account for the common variance space. In common factor analysis [1] this is achieved by replacing the unities on the diagonal of the correlation matrix with the communalities. There are various quantities that can be used to estimate the communalities. They include the highest correlation of a variable with the rest of the variables in the set, the average correlation of a variable, the squared multiple correlation of a variable with the others, or the communality of a variable obtained from an initial factor analysis with unities in the diagonal. Among these estimates, the squared multiple **correlation** is the most commonly used estimate for the communality. This squared multiple correlation is the square of the multiple correlation of the regression of X_i on all the other variables. It is the square of the Pearson product moment correlation of a variable, X_i, with $\hat{X}_i$, where $\hat{X}_i$ is the linear multiple regression estimate of X_i on the other $p - 1$ variables. Guttman [2] showed that the squared multiple correlation is a lower bound to its communality and it approaches the true communality as the number of variables increases. However, in the situation where there are a number of highly unreliable variables in the analysis, there may be weak relationships among two or three variables, generating small common factors with no considerable significant loadings. These small "real" common factors and the error factors may jointly account for a substantial proportion of the total variance. Since the squared multiple correlation is based on all the variance which a variable has in common with the others, the *effective* communalities, which are based only on the *salient* factors, may be less than the squared multiple correlations. In this case the effective communalities will be the communalities of interest. A detailed discussion on how to estimate and use these effective communalities in factor analysis can be found in Cureton & D'Agostino [1, Chapter 5].

Because the estimation of communalities introduces a source of error, some factor analyses procedures avoid estimating them and deal solely with the off-diagonal estimates of a correlation to estimate the number of factors (m) and the loadings [3].

HEIDY K. RUSSELL

Communicable Diseases

The epidemiology of communicable diseases typically involves an interplay between the natural history of infective organisms, evolving largely within infected individuals, and their transmission dynamics, governed by direct or indirect contacts between individuals. While most fields of epidemiology comprise a social dimension, for infectious diseases this element enters at the level of mechanism, and is therefore central to our understanding of these diseases. The application of statistics to infectious diseases thus requires both a biological and a sociological (*see* **Social Sciences**) perspective. This dialectic is strikingly illustrated by the epidemiology of the human immunodeficiency virus (HIV) (*see* **AIDS and HIV**), the study of which motivated a large-scale investigation of sexual attitudes and lifestyles [70].

The Scope of Statistics in Infectious Disease Epidemiology

In spite of the distinct characteristics of infectious disease epidemiology, many of the statistical methods most commonly used are entirely standard. Thus, for instance, **observational studies** based on **surveillance** data, and epidemiological investigations using **case–control** or **cohort** designs, employ broadly the same statistical methodology whether the disease involved is measles or cancer. Nevertheless, statistical science has made distinct contributions to many areas of infectious disease epidemiology. The most prominent include catalytic and transmission models (*see* **Infectious Disease Models**), the study of the natural history of infectious disease, the detection of infectiousness, and the statistics of vaccination (*see* **Vaccine Studies**). These are the major topics around which this article is organized. In addition, statistics has played a key role in promoting our understanding of specific infectious diseases, as witnessed by the large statistical literature on the acquired immunodeficiency syndrome (AIDS) [21]. Historically, many statistical techniques which are today widely employed were originally developed in the context of infectious disease epidemiology. Thus John Snow's famous study [110] of cholera and his investigation of an outbreak of cases around the Broad Street pump is an early demonstration of space–time clustering. A more recent example is provided by **Bradford Hill's** pioneering influence on field trials of pertussis vaccines [88], of streptomycin against pulmonary tuberculosis [86], and antihistamines against the common cold [87], which did much to establish the randomized controlled trial (*see* **Clinical Trials, Overview**) as a basic tool in medical research. More broadly, many of the principles governing the transmission of infectious diseases are of a more general nature, as originally alluded to by Ross in his "theory of happenings" [103], and similar models have been applied to such diverse topics as the spread of drug addiction and of scientific ideas [32].

Historical Background

The application of formal mathematical methods to infectious diseases dates back to Daniel Bernoulli's 1760 publication [18] (*see* **Bernoulli Family**) of a mathematical model to evaluate the impact of smallpox on **life expectancy** [31]. Later, **William Farr** [36] sought to describe the course of epidemics by fitting curves to smallpox data, and used this technique to predict the course of an epidemic of rinderpest among cattle [37]. **Brownlee** [22] also pursued this approach, fitting **Pearson distribution** curves to outbreak data on numerous diseases in support of his theory, later disproved, that pathogens decline in infectiousness during the course of an epidemic [50] (*see* **Epidemic Models, Deterministic**).

This early phase of largely empirical investigations was followed by the more analytical work of Hamer [66] and Ross [103], who sought to understand the mechanisms governing disease transmission. Hamer first formulated what was later to be known as the mass action principle, according to which the number of cases in generation $t+1$ is proportional to the numbers of susceptibles and infectives in generation t. Ross developed transmission models for malaria, and formulated the first threshold theorem, on the critical density of mosquitoes required for malaria to remain endemic [49]. The ideas of Hamer and Ross were later elaborated by Kermack & McKendrick [74]. **Chain binomial models** of disease spread may be traced back to En'ko [35], who, as argued by Dietz [29], anticipated the Reed–Frost model (1928) (published as Frost [57]).

The fully stochastic treatment (*see* **Stochastic Processes**) of the chain binomial model is primarily due to **Greenwood** [59].

The pioneering approach of Bernoulli was extended by Muench [91, 92], who investigated the age distribution of susceptibles in a population using survival analytic methods (*see* **Survival Analysis, Overview**). Drawing upon an analogy from chemistry, Muench described his models as catalytic. Dietz [28] clarified the connections between transmission models and catalytic models, and demonstrated how key transmission parameters can be estimated from epidemiological data.

Catalytic Models

The great variety in the ecology and natural history of different infections generally requires different models for different diseases. However, some of the key features of all infectious disease models are captured by the simple case of person-to-person transmission of an infection conferring permanent immunity to those infected. The emphasis here is on endemic diseases that have reached a state of dynamic equilibrium. In this state, the long-term average incidence of infection is broadly constant.

The Basic Relationships

Let the random variable X denote the age at which individuals acquire infection. Let $S(x)$ denote the survivor function (*see* **Survival Analysis, Overview**):

$$S(x) = \Pr\{X > x\}$$

and $\lambda(x)$ the age-specific **hazard rate** of infection. In the context of infectious disease epidemiology, this is often called the force of infection, and depends on a variety of factors, including the rate at which individuals come into contact with one another, and the ease with which the organism is transmitted, given a suitable contact.

Assume, for simplicity, that all individuals in the population die at a fixed age, L, the life expectancy, and that the disease concerned is not fatal. In addition, we allow for the possibility that individuals are protected by maternally acquired immunity from birth to some age, M. These assumptions are broadly applicable to common childhood diseases such as measles, mumps, rubella, and whooping cough in developed countries. For these diseases, $\lambda(x)$ is typically a non-negative unimodal function, formally set to zero for $x \leq M$, and

$$S(x) = \exp\left(-\int_0^x \lambda(u)\,\mathrm{d}u\right).$$

The survivor function equals 1 for $x \leq M$, and hence differs from the probability that an individual of age x is susceptible, which is 0 for $x \leq M$ and $S(x)$ for $x > M$. Let A denote the expectation of X, or average age at infection. The average force of infection acting on susceptibles, $\overline{\lambda}$, is related to A by

$$\overline{\lambda} = \frac{\int_M^L \lambda(x)S(x)\,\mathrm{d}x}{\int_M^L S(x)\,\mathrm{d}x} = \frac{1 - S(L)}{A - M}.$$

For endemic infections, the proportion of the population escaping infection is negligible, and hence $S(L)$ is effectively zero. Thus,

$$\overline{\lambda} \doteq \frac{1}{(A - M)}.$$

It follows that if the average force of infection is reduced, for instance by vaccination, then the average age at infection will rise. Assuming a uniform age distribution, the proportion of the population remaining susceptible is

$$\pi = \int_M^L \frac{S(x)}{L - M}\,\mathrm{d}x = \frac{A - M}{L - M}. \qquad (1)$$

Since the duration of protection by maternal antibodies is usually much less than A, the following approximations hold:

$$\pi \doteq \frac{A}{L} \doteq \frac{1}{\overline{\lambda}L}.$$

So far, the methods described are essentially those of survival analysis, and apply to any event occurring with hazard $\lambda(x)$. We now make the connection with infectious diseases.

An important summary measure of the infectiousness of a disease in a given population is the basic **reproduction number**, R_0. This is the mean number of secondary cases generated by a single infective in a totally susceptible population. It is a parameter of fundamental importance in infectious disease

epidemiology. The higher the value of R_0, the more infectious the disease. However, if the basic reproduction number is equal to or below 1, transmission of the infection cannot be sustained and will eventually die out with probability 1.

R_0 depends on the effective contact rate, β. The term "contact" is taken to mean one of such a nature as to enable transmission of infection to occur. This of course depends on the mode of transmission of each organism. The effective contact rate, β, is defined as follows. Let η denote the rate at which contacts occur in the population, that is, the average number of contact that an individual makes per unit time, and let θ denote the conditional probability of infection, given a contact between an infective and a susceptible. Then the effective contact rate is

$$\beta = \eta\theta.$$

It follows from this definition that

$$R_0 = \beta D,$$

where D is the **mean** duration of the infectious period.

In general, the contact rate, η, and hence β and R_0, vary with age. For simplicity, we assume that the population mixes in a homogeneous fashion, so that η is independent of age. Then β, R_0, and the force of infection are also independent of age. For long-established endemic diseases in dynamic equilibrium, the proportion susceptible fluctuates around the constant value π given by (1). Thus the average number of secondary cases produced by one infective is πR_0. But since the disease is in equilibrium, this must on average equal 1, since otherwise the average proportion susceptible will not remain constant. It follows that

$$\pi R_0 = 1,$$

and hence

$$R_0 = \frac{1}{\pi} \doteq \frac{L}{A} \doteq \lambda L,$$

$$\beta = \frac{1}{\pi D} \doteq \frac{L}{AD} \doteq \frac{\lambda L}{D}. \qquad (2)$$

Thus, in a homogeneously mixing population, the basic reproduction number and the effective contact rate may be estimated from the average age at infection, the life expectancy, and the duration of the infectious period.

These fundamental relationships also have important consequences for the control of infectious diseases. If the proportion of susceptible individuals in the population is reduced by vaccination below the equilibrium level π, then the number of secondary cases produced by each infective will be reduced below 1. Thus the infection will no longer be self-sustaining, and will eventually die out. Assuming that vaccination confers complete protection, and letting V denote the minimum proportion that must be vaccinated for eradication of the infection, we therefore have

$$V = 1 - \pi \doteq 1 - \frac{A}{L} \doteq 1 - (\lambda L)^{-1}.$$

In particular, note that it is not necessary to vaccinate the entire population to eradicate infection. This is the phenomenon of herd immunity: the effect of vaccination is not simply to protect vaccinated individuals, but also to impart indirect protection to unvaccinated susceptibles by impeding the circulation of the infection in the population.

This discussion shows how key epidemiologic parameters, such as the basic reproduction number and the proportion to vaccinate for eradication of infection, may be estimated from observable quantities such as the hazard of infection. Clearly, the assumption of homogeneous mixing is untenable for many populations. More complex versions of the results described above may be derived for age-dependent mixing patterns [3] and [44]. Similarly, the concepts introduced above in the case of person-to-person transmission have direct counterparts for other types of infection. For instance, in the case of helminth infections, the force of infection is the rate at which uninfected individuals acquire parasites, and R_0 is the average number of offspring produced throughout the reproductive life span of a mature parasite that themselves survive to maturity, in the absence of density-dependent constraints on population growth [3].

Estimation of the Force of Infection

As shown above, knowledge of the age-specific force of infection, or infection hazard $\lambda(x)$, is central to control strategies for infectious diseases. In the case of endemic infections conferring long-lasting immunity, with no differential mortality, in unvaccinated

populations, it is most readily estimated from serological surveys, in which a **cross-sectional** sample of the population is tested for the presence or absence of relevant antibodies. Suppose that n_x individuals of age x are tested, with $x > M$, the duration of protection from maternal antibodies. The number r_x who display no evidence of past infection may be regarded as **binomial** $[n_x, S(x)]$, where $S(x)$ is the survivor function. Given a parametric form for the hazard function, the **likelihood** is proportional to

$$\prod_{x=1}^{L} S(x;\beta)^{r_x}[1 - S(x;\beta)]^{n_x - r_x}, \qquad (3)$$

where

$$S(x;\beta) = \exp\left(-\int_0^x \lambda(u;\beta)\,\mathrm{d}u\right).$$

Individuals below age M are excluded from this analysis because they may be protected by maternally acquired antibodies. The decline of maternal protection after birth is of course of interest in its own right, and may be modeled provided sufficient data are available on infants. Note also that in the presence of vaccination, the hazard function can no longer be interpreted as the hazard of infection, but is the combined effect of natural infection and immunization.

For diseases with short **incubation periods**, the force of infection may also be estimated from case reports or routine notification data, provided it is reasonable to assume that these are not subject to age-specific bias in diagnosis or reporting. It is also commonly assumed that the age distribution of the population from which the cases are drawn is **uniform**, at least up to some age x_k above which few infections occur. Let $\mathbf{n} = (n_1, \ldots, n_k)$ denote the numbers of cases in the different age groups, where the subscript i indexes the age range $[x_{i-1}, x_i), i = 1, \ldots, k$. Thus $\mathbf{n}$ is **multinomial** and the likelihood is proportional to

$$\prod_{i=1}^{k}\left[\frac{S(x_{i-1}|\beta) - S(x_i|\beta)}{1 - S(x_k|\beta)}\right]^{n_i}.$$

Parametric models for the force of infection are discussed by Griffiths [62], Grenfell & Anderson [61], and Farrington [38]. Keiding [73] discusses **nonparametric** estimation, with an application to hepatitis A data (*see* **Hepatology**). Alternately, the hazard may be assumed piecewise constant, taking the value λ_j in age group $[x_{j-1}, x_j)$, $j = 1 \ldots k$. This enables **regression** models to be fitted using standard modeling software. Given fixed **covariates z** and letting $t_j(x)$ denote the time spent by an individual of age x in the jth interval, we have

$$\ln[S(x|\beta, \lambda)] = \beta^{\mathrm{T}} z + \sum_{j=1}^{k} \lambda_j t_j(x),$$

and hence the likelihood (3) may be maximized by **generalized linear modeling** with logarithmic link function.

The force of infection is important in its own right, but also in estimating age-dependent contact rates and the basic reproduction number R_0. Statistical methods for estimating the R_0 from serological and other data are described in [19, 30, 44].

The methods described above apply to infections having reached a dynamic equilibrium, in which the age-specific incidence fluctuates around a constant value according to stable epidemic cycles. For emerging infections, such as HIV, the age-specific incidence will initially increase over time. For others, such as hepatitis A, it may decline as contact rates change. The methods described above may be extended to model secular changes in the hazard of infection, using data from sequential seroprevalence surveys in the same population. In this context the hazard $\lambda(x, t)$ depends on both age and time, and the survivor function is

$$S(x, t) = \exp\left(-\int_0^x \lambda(u, t - x + u)\,\mathrm{d}u\right).$$

Ades & Nokes [2] discuss an application to the incidence of toxoplasma infection. In some circumstances data may be available on repeat tests for the same individuals. One example is repeat tests for HIV on attenders at genito-urinary medicine clinics. This sampling scheme gives rise to **interval-censored** data, in which the time of infection is bracketed between the times of the last negative and the first positive tests. Denoting these, respectively, by U and V, where U may be zero (denoting a left-censored observation) and V may be infinite (denoting a right-censored observation), the likelihood is

$$\prod_{i=1}^{n}[S(U_i) - S(V_i)].$$

The estimation method based on case reports can similarly be extended to incorporate secular changes in incidence, provided the incubation period of the disease is short. For diseases with long incubation periods, for example AIDS and the chronic sequelae of hepatitis C infection, symptoms may appear many years after infection, and hence case reports alone provide little information on the date or age of infection. Data on case reports must be combined with information about the incubation period to estimate the incidence function. This is the **back calculation** approach, developed by Brookmeyer & Gail [20] to model the incidence of HIV infection.

For simplicity we ignore age effects. Let $\mu(t)$ denote the rate at which case reports arise, and $F(t)$ denote the distribution function for the incubation period. These are related to the force of infection by the convolution equation

$$\mu(t) = \int_{-\infty}^{t} \lambda(s)S(s)F(t-s)\,\mathrm{d}s.$$

The product $\lambda(s)S(s)$ is sometimes combined into a single term, $\alpha(s)$, denoting the incidence of infection in the population. For uncommon or emerging infections, virtually the entire population is susceptible, hence $\alpha(s)$ and $\lambda(s)$ are practically identical.

Many methods have been proposed to estimate $\lambda(t)$ from this basic equation, given observed case reports and knowledge of the incubation period distribution. A comprehensive account is given in Brookmeyer & Gail [21]. For instance, given a parametric form $\alpha(s;\beta)$ for the incidence curve and assuming that infections arise in a **Poisson process**, then the number of cases, Y_i, arising in time period $[t_{i-1}, t_i)$ is also Poisson with mean

$$\mu_i = \int_{t_{i-1}}^{t_i} \alpha(s;\beta)[F(t_i - s) - F(t_{i-1} - s)]\,\mathrm{d}s,$$

and hence the parameters β may be estimated by maximizing the Poisson log likelihood:

$$\sum_{i=1}^{n} [n_i \ln(\mu_i) - \mu_i - \ln(n_i!)].$$

Transmission Models

Catalytic models describe the age distribution of susceptibles for an endemic infection in dynamic equilibrium. However, they only capture the steady-state characteristics of the infection process, averaged over a long period of time. In particular, they fail to account for epidemic cycles. These constitute one of the most striking features of endemic diseases with short incubation periods, at least those conferring lifelong immunity and not involving a carrier state. In addition, catalytic models cannot be used for infections that have not reached a dynamic equilibrium, such as emerging diseases. By contrast, transmission models, whether deterministic or stochastic, attempt to incorporate the mechanism by which infection is spread in a population.

Dynamic Models for Large Populations

As seen above, the mechanism of disease spread is governed by the effective contact rate, β. This may be expressed more generally as a function $\beta(u, v)$ representing the number of effective contacts per unit time between an individual of age v and individuals of age u. The relationship between the contact rate and the force of infection at age x and at time t depends on the number of infectives in the population at time t. An intuitively appealing, though by no means unique, functional relationship is

$$\lambda(x,t) = \int_0^{\tau} \beta(u,x)Y(u,t)\,\mathrm{d}u,$$

where $Y(x,t)$ is the proportion of infectives of age x in the population at time t.

The basic ideas behind dynamic models may be illustrated using the simple example of a homogeneously mixing population, that is, one in which the contact rate is a constant β. It follows that the force of infection is also independent of age.

The population, of constant size, is divided into proportions $X(t)$ susceptible, $Y(t)$ infective, and $Z(t)$ recovered, who are immune from further infection. Individuals are born into the susceptible class with constant rate μ, and die at the same rate. There is no disease-associated mortality. The model is driven by the mass action principle, according to which the number of new infectives in a small time interval $[t, t+\delta t)$ is proportional to the number of infectives and to the number of susceptibles at time t. The dynamics of this three-stage model, often called a SIR (for susceptible–infectious–recovered) model, may be represented by the following system of differential

equations:

$$\begin{aligned}\dot{X}(t) &= -\beta X(t)Y(t) + \mu - \mu X(t),\\ \dot{Y}(t) &= \beta X(t)Y(t) - \gamma Y(t) - \mu Y(t),\end{aligned} \tag{4}$$

in which the dots represent derivatives with respect to t and γ is the reciprocal of the duration of the infectious period, D. Setting the derivatives to zero and solving for $X(t)$ gives the nontrivial equilibrium proportion susceptible:

$$\pi = \frac{\gamma + \mu}{\beta} \doteq \frac{1}{\beta D},$$

where the approximation is valid provided the duration of infectiousness is much smaller than life expectancy. Note that expression (2) is retrieved only approximately, owing to the different assumptions about the death rate.

Using standard methods for the analysis of small departures from equilibrium, it can be shown that these result in oscillations in the numbers of infectives. When the duration of the infectious period is small compared with the average age at infection, these have period

$$T = 2\pi(AD)^{1/2}. \tag{5}$$

This simple model thus exhibits the well-known phenomenon of epidemic cycles, typical of endemic immunizing infections with short infectious periods and no carrier state.

The second equation in (4) also illustrates the fact that the number of cases only grows if $\beta X(t) - \gamma - \mu > 0$, and hence in an initially susceptible population an epidemic can only occur if

$$R_0 = \frac{\beta}{\gamma + \mu} > 1.$$

Clearly, more sophisticated models can be developed to incorporate a latent period, protection by maternal antibodies, age-dependence, etc. In particular, if an infection has latent period E, D in expression (5) should be replaced by $D + E$. Anderson et al. [4] apply **spectral analysis** to the **time series** of some common childhood infections and show that the epidemic periods broadly correspond to those predicted by the model. More complex modeling techniques, combining time series methods with epidemic modeling, have been described by Finkenstädt & Grenfell [54].

The transmission of infection in a population clearly involves a stochastic component, which is not captured by deterministic models. In small populations, stochastic effects become dominant, and deterministic models are of little use. In particular, they cannot readily account for the phenomenon of extinction, in which the transmission of infection is interrupted.

The stochastic version of (4) may be developed in terms of transition probabilities. Thus, letting $X'(t)$ and $Y'(t)$ denote, respectively, the number (rather than the proportions) of susceptibles and infectives at time t in a population of fixed size N, the corresponding transition probabilities in a short interval $(t, t + \delta t)$ are

$$\begin{aligned}\Pr[X'(t+\delta t) &= X'(t) - 1; Y'(t+\delta t) = Y'(t) + 1]\\ &= N^{-1}\beta X'(t)Y'(t)\delta t,\\ \Pr[X'(t+\delta t) &= X'(t); Y'(t+\delta t) = Y'(t) - 1]\\ &= (\gamma + \mu)Y'(t)\delta t,\\ \Pr[X'(t+\delta t) &= X'(t) + 1; Y'(t+\delta t) = Y'(t)]\\ &= N\mu\delta t,\\ \Pr[X'(t+\delta t) &= X'(t) - 1; Y'(t+\delta t) = Y'(t)]\\ &= \mu X'(t)\delta t.\end{aligned}$$

Unfortunately the solution of such systems is far from straightforward. There is a substantial literature on the properties of general stochastic models, much of it of a highly mathematical nature [5–10, 26] and [112]. In practice, in large populations analytic solutions for the stochastic model become unmanageable. Using **Monte Carlo methods**, Bartlett [9, 10] showed that a minimum population size is required for an infection to remain endemic.

The main purpose of the deterministic and stochastic dynamic models discussed above is to exhibit the qualitative aspects of the spread of infectious disease and to explore threshold phenomena. One important application is in predicting the impact of vaccination strategies. However, for the statistical purposes of hypothesis testing and parameter estimation, different types of stochastic models are used.

Branching Processes

In some cases it is possible to ignore the depletion of susceptibles, for instance during the initial stages

of an epidemic. In these circumstances the spread of infection may be modeled by means of a **branching process** in discrete time [14, 15]. This approach is useful when the emphasis is on parameter **estimation**, rather than **prediction**. In such a model the epidemic begins with the introduction of an initial number of infectives, Y_0, at generation 0. These infect Y_1 individuals, who comprise the next generation of cases. In turn, these infect Y_2 individuals in the next generation of cases, and so on. Suppose that the number of infections directly caused by one individual is a random variable Z with probability distribution $g(z)$, the offspring distribution, and that the numbers of infections caused by two cases from the same generation are independent. Thus, for each i, $Y_i = Z_1 + \cdots + Z_{Y_{i-1}}$, where the Z_j are independent variables with density $g(z)$.

Let μ and σ^2 denote the mean and **variance**, respectively, of the offspring distribution. Thus μ is the expected number of infections caused by one case, and plays the same role as R_0 above. General results on branching processes show that if $\mu \leq 1$, then the process will become extinct with probability one [67]. Inference for branching processes is usually conditional on extinction or nonextinction.

For endemic diseases we proceed conditionally on nonextinction. Generation sizes $Y_0, \ldots, Y_k$ are observed for some value of k. In practice k is usually small, because generations soon become indistinguishable. Also the stock of susceptibles may be depleted, thus rendering the branching process model invalid. Harris [67] proposed the following **nonparametric maximum likelihood** estimator for μ:

$$\hat{\mu} = \frac{\sum_{i=1}^{k} Y_i}{\sum_{i=1}^{k} Y_{i-1}}.$$

The properties of this estimator are discussed by Keiding [72]. Heyde [68] and Dion [33] discuss nonparametric interval estimation (*see* **Estimation, Interval**). Alternatively, a parametric assumption may be made about the offspring distribution $g(z)$. Becker [14] suggests the alternative estimator:

$$\hat{\mu} = \begin{cases} (y_k/y_0)^{1/k}, & \text{if } I_k > 0, \\ 1, & \text{if } y_k = 0. \end{cases}$$

For outbreaks of diseases for which $\mu \leq 1$, it can be shown that if the offspring distribution has a power series distribution, then the total size of the outbreak also has a power series distribution [12], and the total outbreak size is a **sufficient statistic** for μ. The **maximum likelihood** estimate of μ is

$$\hat{\mu} = 1 - \frac{Y_0}{Y_+},$$

where Y_+ is the outbreak size. In particular for **Poisson offspring distributions**, the total number of cases follows the Borel–Tanner distribution and the asymptotic variance of the maximum likelihood estimator of μ is $\mu(1-\mu)/Y_+$.

Heyde [69] discusses a **Bayesian** approach which allows the cases $\mu > 1$ and $\mu \leq 1$ to be treated without distinction. Becker [12, 13, 15] discusses several applications of branching processes to smallpox epidemics. Branching process models have also been proposed for the surveillance of vaccination programs [45].

Chain Binomial Models and Extensions

The branching process offers a simple framework in which to investigate the early stages of epidemics, and outbreaks of nonendemic infections. However, its applicability is limited to situations in which it is reasonable to assume an unlimited pool of susceptibles. In particular, branching processes are unsuitable for the analysis of disease spread within households and small communities. In this context, a more appropriate framework is provided by **chain binomial models**.

Consider a household with n individuals. At generation k there are X_k susceptibles exposed to Y_k infectives. The distribution of the number of cases in the next generation, Y_{k+1}, conditional on X_k and Y_k, is **binomial**:

$$\Pr(Y_{k+1} = z | X_k = x, Y_k = y) = \frac{x!}{z!(x-z)!} p_k^z (1-p_k)^{x-z},$$

where p_k is the probability that a susceptible of generation k will acquire infection from one of the y_k infectives. To parameterize p_k, some assumptions are required. A common assumption due to Reed &

Frost (1928), published as [57], is that contacts with infectives occur independently, so that

$$p_k = 1 - (1 - \pi)^{y_k},$$

where π is the probability of an effective contact between two individuals. In continuous time, the mass action principle as incorporated in (4) coincides with the Reed–Frost model, in which π is replaced by $\beta \cdot \delta t$, where β is the contact rate. An alternate assumption, due to Greenwood [59], is

$$p_k = \begin{cases} \pi, & \text{if } y_k \geq 1, \\ 0, & \text{otherwise.} \end{cases}$$

The Greenwood model may be valid for diseases such as measles, in which infectious material is spread by aerosol. In these circumstances the number of infectives present will have little bearing on the number of susceptibles infected.

In some cases, data may be available on the actual chains of infection within the household, thus enabling the full **likelihood** to be written down. Thus, for one household with x_0 initial susceptibles the likelihood is

$$L = \prod_{i=1}^{m} \Pr(y_i | x_0, y_0, \ldots, y_{i-1}),$$

where m is the total number of generations of cases in the household. For instance, in a household of size three, with one initial infective and two initial susceptibles, the possible chains of infection are {1}, {1, 1}, {1, 1, 1}, {1, 2}. The corresponding probabilities are, respectively, $(1 - \pi)^2$, $2\pi(1 - \pi)^2$, $2\pi^2(1 - \pi)$, π^2. In this case the probabilities are the same under the Reed–Frost and Greenwood assumptions, although this is not generally the case. Bailey [5] contains tables of probabilities for households of up to five.

The parameter π may be estimated by directly maximizing the likelihood L. Alternately it may be maximized using **generalized linear modeling** techniques, since y_{k+1} is conditionally binomial(x_k, p_k). This enables household characteristics to be modeled in a straightforward manner. In the case of the Reed–Frost model, the appropriate link function is the complementary log–log, used with the offset $\ln(y_k)$. Thus, if

$$\ln[-\ln(1 - \pi)] = \alpha + \beta^{\mathrm{T}} x$$

for covariates x, then

$$\ln[-\ln(1 - p_k)] = \ln(y_k) + \alpha + \beta^{\mathrm{T}} x. \qquad (6)$$

The Reed–Frost assumption may also be tested formally, since omission of the offset term $\ln(y_k)$ in (6) corresponds to the Greenwood assumption.

In practice it is exceedingly rare to have such detailed data. In some situations, however, data may be available on the size of outbreaks in households. Assuming that information is also available on the numbers of introductory cases and initial susceptibles, the likelihood of an outbreak of any given size may be obtained by summing the probabilities of all chains with that number of cases. Thus, for instance, in a household of size three with one initial infective and two initial susceptibles, the probability of an outbreak of total size three is $2\pi^2(1 - \pi) + \pi^2 = \pi^2(3 - 2\pi)$.

Bailey [5] discusses some of the problems involved in collecting data on household outbreaks. Bailey [5] and Becker [15] describe **model checking** for the chain binomial model, and extensions to random infectiousness, in which the parameter π may vary between households, for instance according to a **beta distribution**. Becker [15] gives a detailed application of chain binomial methods to the common cold.

The chain binomial models so far considered only seek to model the course of disease within households, and ignore the transmission of infection between households. This latter problem has been discussed by Longini et al. [81] and Longini & Koopman [80]. Suppose that an outbreak in a defined community of households is observed. Infections may be acquired within the household, or from the community, that is, from an individual from a different household. Let π_{c} and π_{h} denote, respectively, the probabilities that a susceptible is infected from the community and from the household during the outbreak. Let p_{is} denote the probability that i of the s initial susceptibles within a given household are infected during the outbreak. Expressions for the p_{is} in terms of π_{c} and π_{h} are obtained recursively using the formula

$$p_{is} = \frac{s!}{i!(s - i)!} p_{ii} (1 - \pi_{\mathrm{c}})^{s-i} (1 - \pi_{\mathrm{h}})^{i(s-i)}.$$

Given a **random sample** of households from the community, the likelihood is the product of the p_{is} over the households in the sample and may be

maximized to estimate the probabilities π_c and π_h. Becker [15], Longini & Koopman [80], and Longini et al. [81] give several applications of this method to data on various respiratory diseases. More complex stochastic models have also been proposed to take account of several levels of mixing, for example, within and between households [7].

Data Augmentation, Martingale and Markov Chain Monte Carlo Methods

Likelihood-based methods for data on infectious disease data can become notoriously cumbersome for even medium-size problems. This is because the infection and disease process is generally only partly observed. For example, in outbreaks of infectious diseases, infection times are rarely observed: only disease onsets are reported.

To remedy this problem, Martingale [15] and data augmentation techniques have been proposed [15–17]. Bayesian estimation methods implemented by Markov chain Monte Carlo are particularly suitable for use with missing data. The methods have been applied to infectious disease data, both to simplify existing likelihood techniques, and to extend them by weakening the assumptions [94–96].

The Natural History of Infectious Diseases

An important area of application of infectious disease statistics is in estimating key parameters describing the natural history of infection. This section describes methods for estimating the incubation, latent, and infectious periods, and the risk and severity of clinical disease following infection.

Estimation of the Incubation Period

The **incubation period** is defined as the interval between acquisition of infection and the appearance of symptoms. A related concept is that of generation time, also called the *serial interval*, which is the time between acquisition and transmission of infection. For many infections, such as measles, mumps, or chickenpox, the two are almost identical. Knowledge of the incubation period and generation time are important for several reasons. First, it enables cases in an epidemic to be classified into generations, thus allowing more detailed investigation of the spread of disease. Secondly, in the investigation of point source outbreaks, for instance involving food contaminated with Salmonella, knowledge of the incubation period is essential to define the time period over which food histories and other risk factor information should be collected. Thirdly, for evolving diseases with long incubation periods, the true incidence of infection can only be determined if the incubation period is known.

For diseases with short incubation periods, the incubation period distribution may be estimated directly using information on the time of exposure. In this way Sartwell [104] found that the incubation periods of many common diseases follow **lognormal distributions**. However, for diseases with long incubation periods, account must be taken of right-truncation: infected individuals who have not yet developed symptoms are not observed (*see* **Truncated Survival Times**). If the incidence of infection varies over time, then ignoring the truncation of the data would produce biased estimates.

Several methods have been proposed for estimating the incubation period in this context. One simple method applicable to grouped data is by linear modeling. Let r_{ij} denote the number of observed cases infected in time period i with incubation period j, where $i = 1, \ldots, k$ and $j = 0, \ldots, k-1$ range over discrete time intervals with $i + j \leq k$, where k denotes the most recent time interval on which data are available. The incubation period distribution is estimated conditionally on the maximum observed interval, $k - 1$. Taking r_{ij} as Poisson with mean μ_{ij}, define the **loglinear model**

$$\log(\mu_{ij}) = h(i) + g(j)$$

for some parametric or nonparametric incidence function $\exp[h(i)]$ and incubation period distribution $\exp[g(j)]$ satisfying $\sum \exp[g(j)] = 1$. This method is described in Zeger et al. [120] and provides a simple way of jointly estimating the incidence function and the (conditional) incubation period distribution.

When data on individuals are available, an alternate method is as follows. Suppose that onsets are observed up to time t_0, resulting in n observations (t_i, s_i), where t_i is the date of onset of symptoms and s_i is the interval between infection and onset of symptoms, that is, the observed incubation period. Letting $\alpha(t)$ denote the incidence of infection at time t and $f(s)$ the density function of the incubation period,

the log likelihood may be written

$$\sum_{i=1}^{n} \ln[\alpha(t_i)] + \sum_{i=1}^{n} \ln[f(s_i)] - \int_{-\infty}^{t_0} \alpha(u) F(t_0 - u)\, \mathrm{d}u, \qquad (7)$$

where $F(s)$ is the distribution function of the incubation period. Suitable parameterizations of $\alpha(t)$ and $f(s)$ may be inserted into (7) and estimates obtained by maximum likelihood. A slightly more general version of this approach was used by Medley et al. [89] to estimate the incubation period of AIDS.

A nonparametric approach has been suggested by Lagakos et al. [78]. In this approach the analysis is undertaken in "reverse time". Right-truncated observations in forward time become left-truncated in reverse time, and can be handled using **nonparametric methods** developed for left-truncated data. Suppose that n observations (t_i, s_i) are made over the time interval $[0, t_0]$, where t_i and s_i denote the same quantities as above. The distribution of the incubation period is estimated conditionally on the maximum observable interval, t_0. Thus, the distribution estimated is

$$F^*(s|t_0) = \frac{F(s)}{F(t_0)}, \quad s \le t_0.$$

Let $v_1, \ldots, v_k$ denote the distinct values of the s_i and define

$$n_j = \sum_{i=1}^{n} 1(s_i = v_j),$$

$$N_j = \sum_{i=1}^{n} 1(s_i \le v_j \le t_0 - t_i),$$

where $1(\cdot)$ is the indicator function. Then in reverse time measured from t_0 to $0, n_j$ is the number of events occurring at reverse time $t_0 - s_j$, and N_j is the number at risk. The nonparametric maximum likelihood estimate of $F^*(s|t_0)$ is then

$$\hat{F}^*(s) = \prod_{v_j \ge s} \left(1 - \frac{n_j}{N_j}\right)$$

for $0 \le s \le v_k$, and 1 for $v_k < s \le t_0$.

All three methods may be used in other contexts, such as estimating the distribution of delays between the onset of disease and reporting or ascertainment.

Estimation of the Latent and Infectious Periods

For some diseases it is possible to identify the end of the infectious period. Thus, for instance, for measles infectiousness is minimal 2 days after the appearance of the rash. For such diseases it is possible to estimate the latency and incubation period from home contact studies, provided the chains of infection within the household are known. The method is described for households of two susceptibles.

For simplicity, assume that the infectious period is of fixed length, μ, and let Z denote the latency period, with probability density function (pdf) $g(z)$. For each case the end of the infectious period is observed, and occurs at time Y. The beginning of the infectious period for each individual is thus $Y - \mu$. Assume also that infectiousness is constant over the infectious period, so that infectious contacts occur in a Poisson process with constant rate β.

The contribution to the likelihood from a household with two co-primary cases infected at the same time with $Y_1 = y_1$, $Y_2 = y_2$, and $y_1 < y_2$, is

$$\int_0^{\infty} g(z) g(z + y_2 - y_1)\, \mathrm{d}z.$$

In the same notation, the contribution to the likelihood of a household in which the primary case infects the remaining susceptible is

$$\beta \int_0^{\mu} g(y_2 - y_1 - z) \exp(-\beta z)\, \mathrm{d}z,$$

while the contribution of a household with a single case with $Y_1 = y_1$ is

$$\exp(-\beta\mu).$$

Letting n_1, n_{11}, and n_2 denote the numbers of households of size two with chains $\{1\}$, $\{1, 1\}$, and $\{2\}$, respectively, the log likelihood is then

$$-n_1\beta\mu + n_{11}\log(\beta) + n_{11}\log\left[\int_0^{\mu} g(y_2 - y_1 - z)\exp(-\beta z)\,\mathrm{d}z\right] + n_2 \log\left[\int_0^{\infty} g(z) g(z + y_2 - y_1)\,\mathrm{d}z\right].$$

Specification of a suitable parametric form $g(\cdot|\gamma)$ then enables the log likelihood to be maximized with respect to β, μ, and γ. This approach can be extended

to households with more than two susceptibles. The assumption of a constant infective period can also be relaxed. These and other extensions are discussed in Bailey [5] and Becker [15]. Becker [15] gives a detailed application of this method to measles data. Likelihood-based methods often rely on strong assumptions. Such assumptions can sometimes be weakened by making use of MCMC methods. O'Neill et al. [94] estimate the latent and infectious periods of measles using such methods.

Severity and Complications of Infectious Diseases

Infection and disease are not synonymous. Some infections are asymptomatic, and most produce a range of symptoms which can vary in severity. The clinical severity of disease may be directly quantified using clinical information. One important such measure is the **case fatality** rate, which is the proportion dying as a result of infection. Alternately, severity may be measured by proxy variables, such as the proportion of cases admitted to hospital, or socioeconomic variables, such as days off work. In most cases disease severity is age-dependent: for instance, for mumps and hepatitis A, severity of disease increases with age. Since the introduction of vaccination increases the average age at infection, vaccination programs can perversely produce an increase in the morbidity attributable to infection [3, 76].

The statistical methods commonly used to investigate risk factors for clinical disease typically involve **survival analysis** and **regression**. One perhaps distinctive application is to the estimation of the mortality attributable to influenza. For example, Serfling [105] applied regression techniques to model the seasonal (*see* **Seasonal Time Series**) and secular trends (*see* **Time Series**) in mortality in selected cities in the US. In influenza epidemic years, large positive residuals are observed, from which an estimate of the **excess mortality** attributable to influenza may be derived.

Some infections, which are otherwise relatively benign, can have devastating consequences on the unborn child. For instance, rubella, toxoplasma, and cytomegalovirus infection in pregnancy can result in congenital abnormalities. The estimation of the number of infections in pregnancy is therefore of critical importance in assessing the value of **screening** and other prevention policies (*see* **Preventive Medicine**). Letting $\lambda(x)$ denote the force of infection at age x, $\eta(x)$ the number of births to women of age x, and τ the duration of pregnancy, the expected number of women infected in pregnancy is

$$\int_0^\infty \eta(z) \int_{z-\tau}^{z} \left[\lambda(x) \exp\left(-\int_0^x \lambda(u)\, du \right) dx \right] dz.$$

The force of infection may be estimated using the methods described above, while information on $\eta(z)$ may be derived from **vital statistics**. This and other methods are discussed by Ades [1].

Some complications have long induction periods. When the incidence of the originating infections varies over time, the estimation of the risk of complications following infection must take account of truncation effects. Similarly, transient effects due to changing incidence of infection may distort the induction period distribution. To see this let $\alpha(t)$ denote the incidence of originating infections, and $f(s)$ denote the pdf of the induction period distribution. Then the observed induction period distribution at time t is

$$f_t^*(s) = \frac{\alpha(t-s) f(s)}{\int_0^\infty \alpha(t-u) f(u)\, du}.$$

Thus, if the incidence is declining over time, the observed distribution of induction times is biased towards longer intervals. These effects are analyzed by Cox & Medley [25] in the context of AIDS. Farrington [39] discusses an application to subacute sclerosing panencephalitis (SSPE) after infection by wild measles virus.

Clustering of Infectious Diseases

One of the distinguishing features of many infectious diseases is their tendency to arise in clusters in space and time (*see* **Clustering**). While *cluster analysis* is a preoccupation common to most areas of epidemiology, in the case of infectious diseases it stems directly from the transmissibility of disease, rather than the influence of shared risk factors. The clearest example of this is the epidemicity of endemic infections, discussed above. Spatial effects can also be important in disease transmission, and may be estimated using suitable statistical methods [79]. This section describes two further areas in which statistical methods have been developed specifically for detecting clusters of infectious diseases.

Detection of an Infectious Etiology

For some diseases, such as leukemia (*see* **Leukemia Clusters**), Hodgkin's disease, and multiple sclerosis, an infectious etiology has been suggested, but still remains unproven. Much effort has been devoted to detecting clustering of cases which might support such a hypothesis. From a statistical point of view, this requires the formulation of a suitable **null hypothesis** reflecting the distribution of cases expected if there was no infectious agent involved, and testing for departures from this hypothesis in a direction suggestive of infection.

There is a large literature on clustering of health events, much of which can be applied to the detection of infectiousness; see, for instance, Mantel [83]. This discussion is limited to some of the methods developed specifically for this purpose.

An early procedure was described by Mathen & Chakraborty [84], who considered the distribution of disease within a community of households. Regarding the total number of cases as fixed, they used as test statistic the total number of households containing at least one case. This idea was developed further by Walter [117] to take account of the actual numbers of cases within each household. Consider a population of n individuals in s households. The ith household comprises n_i individuals, of whom r_i become infected. Conditioning on the total $r = \sum r_i$ cases, the null distribution of r_i is **hypergeometric**. This corresponds to a null hypothesis of no clustering within households. The test statistic, T, is the number of distinct pairs of individuals, both of whom are infected, and both of whom are from the same household:

$$T = \frac{1}{2}\sum_{i=1}^{s} r_i(r_i - 1).$$

Walter [117] gives exact expressions for the null expectation and variance of T. Asymptotically, as $n \to \infty$ and $r/n \to p$, the proportion of the population infected, the null mean and variance of T tend to

$$\mathrm{E}(T) \to np^2(\nu_2 - 1)/2,$$

$$\mathrm{var}(T) \to np^2(1-p)[2p\nu_3 + (\nu_2 - 1)(1-p) - 2p\nu_2^2]/2.$$

where $\nu_2 = s\mathrm{E}(m_i^2)/n$ and $\nu_3 = s\mathrm{E}(m_i^3)/n$. The method may also be extended to the situation where only data on households with one or more infected individuals are collected. Various modifications have been proposed to this test statistic, by Smith & Pike [108] and Fraser [56].

Methods based on the distribution of cases within households are likely to lack **power** when applied to rare diseases. In addition, they do not use information on the times at which cases arise. These shortcomings are addressed by methods to detect space–time interactions. Many methods for detecting space–time clustering have been developed, the first being that of Knox [75]. Suppose that n cases of disease are identified, together with their locations and times of onset. Knox's test statistic is the number of distinct pairs of cases which lived within a distance d and had onsets within a time period t of each other, for fixed values of d and t. Barton & David [11] expressed Knox's statistic in graph-theoretic terms, proximity in space and time being represented by adjacency matrices, and derived the null expectation and variance of Knox's statistic.

Several enhancements of Knox's statistic have been proposed. In its original form it is applicable only to infections with short latent periods. To extend it to diseases with long latent periods, Pike & Smith [99] included information on the infectious and susceptible periods of each case. Evidence of contagion is given by any case being in the "right" place at the "right" time to have caught the disease from some other case. The test statistic measures the total effective contact between distinct pairs of cases, larger values providing evidence of infectiousness.

Pike & Smith [100] extend this approach further by including a control group, and apply the method to Hodgkin's disease. Given n cases of disease, let y_{ij} denote the presence ($y_{ij} = 1$) or absence ($y_{ij} = 0$) of an effective contact from case i to case j, that is, which may have resulted in case i transmitting the disease to case j, for $i, j = 1, \ldots, n$ and $i \neq j$. The test statistic is defined as the total contact between the n cases:

$$T = \sum_i \sum_{j \neq i} y_{ij}.$$

For each case a matched control is selected. The null distribution of T is obtained by calculating the total contact for each of the 2^n random selections of one individual from each of the n case–control pairs. This is most readily derived by **Monte Carlo** simulation. Pike & Smith [100] derive the exact null values of

$E(T)$ and $\text{var}(T)$, and propose a variety of related test statistics for the total numbers of linked patients.

The Detection of Outbreaks

A characteristic shared by many infectious diseases, at least those with short incubation periods, is the rapidity with which they evolve. It follows that if effective control measures are to be introduced, then outbreaks of infectious diseases must be detected in a timely fashion. In this context the emphasis is on the prospective detection of temporal clustering of disease, that is, as data accumulates, rather than the more usual retrospective identification of temporal clusters for epidemiologic analysis. Prospective outbreak detection is therefore necessarily based on incomplete data which are usually subject to delays in reporting, and is further complicated by fluctuations in the historical data series due to seasonal cycles, secular trends, and past outbreaks (*see* **Surveillance of Diseases**).

Several statistical approaches to prospective outbreak detection have been suggested. Cumulative sum statistics have been used to detect the onset of influenza epidemics [115]. **Time series** methods have been suggested for the detection of outbreaks of Salmonella [119]. Nobre & Stroup [93] describe a different approach using exponential smoothing of the time series (*see* **Nonparametric Regression**) to identify the points at which the first derivative of the series departs significantly from zero.

The methods described above involve organism-specific modeling and hence are best suited to monitoring small numbers of data series. For the purposes of routine monitoring of large databases of infectious disease reports, however, **robust** methods are required applicable to a wide variety of organisms. Stroup et al. [114] describe a simple method for routinely detecting aberrations in reports of notifiable diseases in the US. Their method is to compare the current month's reports with the average of those received in comparable baseline periods over previous years. The current month's report is declared aberrant if it lies outside the limits $\hat{\mu} \pm 2\hat{\sigma}$, where $\hat{\mu}$ and $\hat{\sigma}$ are the estimated mean and standard deviation, respectively, of the baseline values.

This approach corrects for seasonal variation, though not for past outbreaks. Also, the method is applicable only for organisms with substantial monthly counts. An algorithm based on **Poisson regression** modeling, applicable to rare as well as frequent organisms, and incorporating an adjustment for past outbreaks, has been described by Farrington et al. [46]. A two-thirds **power transformation** is applied to preserve a roughly constant **false positive** probability for different organism frequencies.

Increasing the availability of good data on geographical locations of the incident cases also make it possible to envisage incorporating a spatial element to the detection process [77, 102].

Vaccination

One of the distinguishing features of infectious disease epidemiology is the ability to prevent disease by vaccination. Vaccination programs are generally acknowledged as among the most effective and cheapest public health measures available. It follows that the statistical issues raised by vaccination are central to the statistics of communicable diseases.

Vaccine Trials

The **clinical trial** is the method of choice for the evaluation of vaccines. (*see* **Vaccine Studies**) Since the 1940s, when the method was first applied systematically to the evaluation of vaccines, a vast body of experience and methodology has developed. This section briefly reviews some of those aspects specific to vaccine trials. More detailed discussions may be found in Smith & Morrow [107] and Farrington & Miller [47].

Vaccine trials broadly fit within the **Phase I**, **Phase II**, and Phase III sequence of trial methodology. Most Phase I and II trials may be regarded as preliminary investigations, laying the groundwork for Phase III protective efficacy trials. However, in some cases Phase II trials take on a different purpose in that they are used to underpin major decisions about vaccination policy. This is the case, for instance, when a vaccine has already undergone a successful evaluation in a Phase III trial, possibly in another country. Additional data are required to support the introduction of the vaccine in a different population, possibly under a different immunization schedule from that used in the Phase III trial. Such Phase II trials may thus be described as confirmatory rather than exploratory.

The primary purpose of a Phase III trial is to assess the protective efficacy of the vaccine in the **target**

population. Phase III trials may be large, especially when the disease concerned is rare. The 1954 field trial of **Salk vaccine** for polio involved 1.8 million children in the US, over 400 000 of whom were randomly assigned to vaccine or placebo and a much larger number enrolled in an open study [55]. Trials on such a gigantic scale are rare, but many nevertheless require sample sizes running into thousands. Vaccine efficacy trials are thus considerable logistic undertakings, and require clear procedures for handling vaccines, including their labeling, storage and transport, and monitoring their condition, for instance using temperature-sensitive devices.

The first stage in designing an efficacy trial is to define the outcome of primary interest (*see* **Outcome Measures in Clinical Trials**). Many vaccines, such as those against pertussis [52] or rotavirus [116], alter the clinical course of the disease. Thus, a vaccine that is effective in preventing clinical disease may have a considerably lower efficacy against milder or asymptomatic infection. Clarity about the purpose of the trial and the intended use of the vaccine is, therefore, essential from the start if confusion resulting from contradictory interpretations of the trial results is to be avoided. In the special circumstances of measles vaccines in developing countries, it has been argued that it is more appropriate to use total mortality from any cause as the primary outcome, rather than measles morbidity, since the effect of vaccination may have nonspecific immunological consequences [64].

These considerations will guide the choice of primary case definitions, which should be chosen with due regard to potential **biases**. Clinical case definitions may lack **specificity**, unless corroborated by laboratory evidence, and hence will bias efficacy towards zero (*see* **Bias Toward the Null**), since the vaccine cannot be expected to protect against infections other than that for which it was developed. However, the use of laboratory methods for confirmation should be validated, since the **sensitivity** of the method may vary between vaccinated and unvaccinated cases. For example, there is some evidence that bacterial isolation rates of *B. pertussis* are lower in vaccinated than unvaccinated cases [113] which would result in an artificially high estimate of vaccine efficacy. As in other studies of vaccine efficacy, special care must be taken to ensure that individuals allocated to the different vaccine groups have the same probability of exposure to infection, for instance by using block randomization within suitably defined units of space and time (*see* **Randomized Treatment Assignment**).

Estimation of Vaccine Efficacy

Vaccine efficacy is defined as the percentage reduction in the attack rate attributable to the vaccine. This may be written:

$$VE = \left(\frac{p_u - p_v}{p_u}\right) \times 100, \tag{8}$$

where p_u and p_v denote, respectively, the risk of infection in unvaccinated and vaccinated individuals over a specified observation period $[0, t]$ (*see* **Attributable Risk**). For notational simplicity, we omit the percentage multiplier and write

$$VE = 1 - \rho,$$

where ρ is the **relative risk** of infection, p_v/p_u. Alternately, one can define vaccine efficacy in terms of the **relative hazard** of infection:

$$VE = 1 - \frac{\lambda_v}{\lambda_u}, \tag{9}$$

where

$$p_u = 1 - \exp(-\lambda_u t), \qquad p_v = 1 - \exp(-\lambda_v t).$$

The two measures do not differ appreciably when $\lambda_u t$ is small.

These measures are used both to quantify vaccine efficacy in clinical trials and to evaluate vaccine effectiveness in the field. The term "effectiveness", rather than "efficacy", is often used to underline the distinction between estimates obtained in controlled experiments and those achieved under field conditions. The latter may be influenced by vaccine storage, variability of vaccination schedules, herd immunity, and other factors not directly attributable to the vaccine's direct biological effect. Henceforth, for reasons of economy, we use the term "efficacy" to cover both biological efficacy and field effectiveness (*see* **Pharmacoepidemiology, Adverse and Beneficial Effects**).

Vaccine efficacy may be estimated directly in a **cohort study** involving vaccinated and unvaccinated individuals. This was the original approach of Greenwood & Yule [60]. Let n_v and n_u denote, respectively,

the numbers of vaccinated and unvaccinated individuals. Suppose that r_v vaccinated and r_u unvaccinated cases arise during a specified observation period. The vaccine efficacy may then be estimated as

$$\widehat{VE} = 1 - \frac{r_v/n_v}{r_u/n_u}.$$

Confidence limits may be derived from those for the estimated relative risk $\hat{\rho} = (r_u/n_u)/(r_v/n_v)$.

Covariate effects may be estimated by modeling the number of cases as **binomial**, using a **generalized linear model** with logarithmic link. Thus, for instance, if each group is stratified according to covariates $\mathbf{x}_i, i = 1, \ldots, k$, then the main effects model for vaccine and covariate effects has the structure:

$$\ln(p_{ui}) = \alpha + \beta^T X_i,$$
$$\ln(p_{vi}) = \alpha - \gamma + \beta^T X_i,$$

and the corrected estimate of vaccine efficacy, allowing for covariate effects, is $\widehat{VE} = 1 - e^{-\hat{\gamma}}$. The effect of the covariates on vaccine efficacy may also be investigated by fitting the relevant **interaction** terms.

A second method for estimating vaccine efficacy is by means of a **case–control study** [106]. A sample of cases is identified along with suitable controls, typically from the same age group and locality. Vaccination histories are obtained for both cases and controls. The **odds ratio** of vaccination in cases and controls is equal to the odds ratio of disease in vaccinated and unvaccinated children. Provided attack rates are low, this approximates the relative risk, so that

$$VE \doteq 1 - \frac{p_v/(1-p_v)}{p_u/(1-p_u)}.$$

The analysis uses standard case control methodology, regression models being fitted with conditional or unconditional **logistic regression** techniques.

A third method for estimating vaccine efficacy, called the *screening method*, is commonly used for routine monitoring purposes, or in circumstances in which only data on cases are available. Suppose that all or a random sample of cases of disease arising over a given period in a defined population are available. Let θ denote the proportion of cases vaccinated, and suppose that the proportion of the population vaccinated, π, is known. The vaccine efficacy is then

$$VE = 1 - \left(\frac{\theta}{1-\theta}\right)\left(\frac{1-\pi}{\pi}\right). \qquad (10)$$

In the screening method, the vaccination coverage, π, is fixed, while θ is estimated.

Stratified analyses (*see* **Stratification**) using the screening method are possible provided suitably stratified vaccine coverage statistics are available. Suppose that cases are observed and classified into m strata, with n_i cases in stratum $i, i = 1, \ldots, m$. Suppose that of the n_i cases in stratum i, r_i, are vaccinated. For each stratum $i = 1, \ldots, m$, let θ_i denote the probability that a case is vaccinated, π_i the population vaccine coverage, and ρ_i the relative risk of disease. Suppose also that k covariates on each stratum are also available, the value of the jth covariate in the ith stratum being denoted by $x_{ij}, j = 1, \ldots, k$. Then, given a linear model for the relative risk,

$$\ln(\rho_i) = \alpha + \sum_{j=1}^{k} \beta_j X_{ij},$$

(10) may be re-expressed for each stratum as

$$\text{logit}(\theta_i) = \text{logit}(\pi_i) + \alpha + \sum_{j=1}^{k} \beta_j X_{ij}. \qquad (11)$$

Assuming that cases of disease arise in a **Poisson process**, r_i is **binomial** (n_i, θ_i). Thus, the model specified by (11) may be fitted as a **generalized linear model** with binomial error and logistic link, with offsets $\text{logit}(\pi_i)$. Clearly, this method depends for its validity on the availability of accurate data on vaccine coverage. Given such data, the method allows vaccine efficacies to be calculated very simply from case reports or notifications. Applications of the method to measles and pertussis vaccine efficacy are given in [42].

Alternatively, if the population vaccine coverage is not known, then it may be estimated from a sample. This approach leads to **case–cohort** designs [90].

In all the methods described above, care must be taken to adjust for potential **confounders**. For instance, both vaccine coverage and incidence of infection may vary with age and location, which may therefore confound vaccine efficacy. In field investigations it is essential to document vaccination

histories, and to ascertain cases independently of vaccination status. These and other methodological issues are discussed in detail in Clarkson & Fine [23], Fine & Clarkson [52], and Orenstein et al. [97].

In estimating vaccine efficacy it is also important to ensure that vaccinated and unvaccinated individuals have the same probability of exposure. In an attempt to control for exposure, vaccine efficacy is sometimes estimated from attack rates in household contacts of infected cases. Some of the methodological issues surrounding such studies are discussed in Fine et al. [53]. Concern about this issue has led to a further measure of vaccine efficacy being proposed, which controls for exposure:

$$VE = 1 - \frac{\theta_v}{\theta_u}, \tag{12}$$

where θ_u and θ_v are, respectively, the transmission probabilities of infection to unvaccinated and vaccinated individuals given contact with a single infective [63].

The various definitions of efficacy given above all represent direct efficacy, that is, they measure the individual benefit gained from vaccination, in a vaccinated population. In addition, the vaccine may confer an indirect benefit through herd immunity, by reducing the circulation of the infection, and hence indirectly protecting unvaccinated individuals. Direct and indirect measures of vaccine efficacy are discussed in [65].

In addition to reducing the susceptibility of those vaccinated, vaccines may also reduce the infectiousness of individuals infected. The estimation of the effect of vaccination on infectiousness is not straightforward, but can be undertaken in the context of household situations [82], or in several populations with different levels of vaccine coverage [27].

Vaccine Models

Two contrasting models of vaccine mechanisms have been suggested [109]. In the first, the so-called "all-or-nothing" model, the vaccine imparts total, long-lasting protection to a proportion of vaccinees, and gives no protection to the remainder. The proportion protected may be estimated unbiasedly as one minus the relative risk of disease, that is, using (8) above. It has been suggested that this model of vaccine protection may apply to live viral vaccines such as measles vaccine. In the second model, sometimes called the "leaky" vaccine model, vaccination does not impart complete protection on any individual, but reduces the hazard of infection by a constant factor. This relative hazard corresponds to $1 - VE$, where the vaccine efficacy is estimated using (9) above. This mechanism might be appropriate for bacterial vaccines, such as whole cell pertussis vaccine. In a randomly mixing population, the vaccine efficacy measure, (12), based on transmission probabilities, has been shown to equal that based on attack rates, (8), for all-or-nothing vaccines, and (9) for leaky vaccines [63].

In practice it is extremely difficult to distinguish between the two vaccine mechanisms, since changes in one or other measure of vaccine efficacy over time can be attributed either to the vaccine mechanism or to waning vaccine efficacy. This confounding of vaccine mechanism and changes in efficacy over time poses particular problems for the evaluation of age-specific efficacy of the vaccine, since a decline in age-specific efficacy may be attributed to the vaccine mechanism, to bias in identifying susceptible individuals, or to waning efficacy of the vaccine. The problem of estimating and interpreting age-specific vaccine efficacy measures is discussed in [41] and [71].

Vaccine Safety Evaluation

Vaccine safety is clearly a critical issue, often generating considerable public interest, particularly in the case of vaccines administered to children on a large scale for preventive purposes. Clinical trials are usually too small to demonstrate the safety of vaccines with respect to rare, but potentially serious, adverse events. Instead, vaccine safety is monitored by surveillance and epidemiologic investigations after the vaccine is in widespread use. Such studies present considerable statistical challenges. For instance, for vaccines administered as part of a routine immunization program, unvaccinated individuals are a selected group which cannot be assumed representative of the population as a whole, and hence should not be included in the control group once high vaccine coverage is achieved [27]. Instead, for acute adverse reactions, such as febrile convulsions following measles or pertussis vaccine, or aseptic meningitis following mumps vaccine, the focus is to detect a clustering of events in the period following vaccination. This is achieved by estimating the relative

rate at which events occur in a specified period following vaccination, compared with the background rate in control time periods, correcting for age effects which may confound the relationship between vaccination and adverse events. Commonly used methods include cohort and case–control studies. In the cohort approach, the analysis is conditional on vaccination times, the time of observation for each individual being divided into "at risk" and "control" periods. In the case–control approach, cases are matched to controls by date of birth and other relevant variables. The date of the reaction in the case is taken as the index date, and exposure in both case and control is defined as vaccination in a specified period prior to the index date. The methodologic issues associated with such studies are discussed in Ray et al. [101] and Fine & Chen [51].

A third method specifically designed for the analysis of acute, transient vaccine reactions combines the economy of the case–control method and the power of the cohort method. This is the case–series method [43]. The method is derived from a cohort model, by conditioning on the total number of events experienced by each individual. Individuals who do not experience any reactions thus make no contribution to the likelihood, and hence only data on cases are required. Thus, suppose that n cases are observed over a defined observation period. For the ith individual, let e_{ijk} denote the time spent in age group j and risk group k. The risk groups are defined in relation to vaccination: for instance, for febrile convulsions after pertussis vaccine, one might use the intervals 0–3 days, 4–7 days, 8–14 days after vaccination as distinct risk groups, all other times being included in the reference control group. The number of adverse events experienced by individual i in age group j and risk group k, r_{ijk}, is assumed Poisson with mean μ_{ijk}. A simple cohort model may be written

$$\ln(\mu_{ijk}) = \ln(e_{ijk}) + \alpha^{\mathrm{T}} x_i + \beta_j + \gamma_k,$$

where x_i are fixed covariates. Conditioning on the total number of events observed for individual i results in the product multinomial likelihood:

$$L = \prod_i \prod_{j,k} \left(\frac{e_{ijk} \exp(\beta_j + \gamma_k)}{\sum_{r,s} e_{irs} \exp(\beta_r + \gamma_s)} \right)^{r_{ijk}},$$

to which individuals with $r_{i..} = 0$ contribute 1, and hence may be ignored. This greatly simplifies the study of adverse events, since only a sample of individuals experiencing an event over a given period is required. This model assumes that events are potentially recurrent. However, for rare nonrecurrent events, such as sudden infant death syndrome (SIDS) or encephalopathy, the method can be applied with little bias. Note that with this approach the effect of fixed covariates on the incidence of adverse events cannot be estimated. However, their effect on the relative incidence of adverse events after vaccine can be estimated by including suitable interaction terms in the model. This method has been shown to be as powerful as the cohort method when vaccine coverage is high [48].

Other Methods

The collection of infectious disease data frequently relies on complex laboratory techniques, such as serological and other assays, electron microscopy, electrophoresis, typing, and other identification methods. Many of these involve statistical techniques, such as statistical taxonomy. A thorough discussion of laboratory methods is beyond the scope of this article. However, the laboratory methods used often also have a direct bearing on the analysis and interpretation of epidemiologic data. This section aims to illustrate this point using two examples.

Prevalence Estimation by Group Testing

In some situations it is necessary, for instance for reasons of economy, to pool samples of material for analysis, and test the combined pool rather than the individual samples. The statistical properties of this approach were originally investigated by Dorfman [34] to reduce the number of tests required to identify cases of syphilis. Today, group testing is often used to test for HIV in large population surveys [21]. In some cases it is possible, and indeed, for diagnostic tests, necessary, to retest the individual components of a positive pool. However, the approach may also be used directly to estimate population prevalence [111]. In this setting the retesting of individual samples is not necessary, and in some cases not possible, as for instance in the study of vertical transmission of yellow fever virus by mosquitoes discussed by Walter et al. [118].

Suppose that n pools have been formed, the ith pool including m_i samples from individuals with a common covariate vector $\mathbf{x}_i$, $i = 1, \ldots, n$. Let $r_i = 1$ if the ith pool is positive, 0 if it is negative. Let π_i be the probability that the ith pool tests positive, and θ_i be the probability that an individual in the ith pool is positive. Thus θ_i is the prevalence in the subpopulation with characteristics $\mathbf{x}_i$. Provided that the individuals within each pool are independent, the pool and population prevalences are related by

$$\pi_i = 1 - (1 - \theta_i)^{m_i}.$$

Thus, if the population prevalences satisfy the linear model

$$\log(-\log(1 - \theta_i)) = \beta^{\mathrm{T}} x_i,$$

with regression parameters β, then the pool prevalences satisfy

$$\log(\pi_i) = \log(m_i) + \beta^{\mathrm{T}} x_i.$$

Thus, the population prevalences and the regression parameters may be estimated by fitting a generalized model with dependent variable r_i, binomial error, complementary log–log link function, and fixed offset $\log(m_i)$. This method is further discussed in [40], with an application to estimating the prevalence of Salmonella contamination in eggs.

The concept of group testing may also be applied to estimating the most probable number (MPN) (*see* **Serial Dilution Assay**) of coliform organisms in water samples, using the multiple fermentation tube method of McCrady [85]. A sample of water from a given source is taken and subdivided, with or without dilution, into subvolumes. These are then incubated in separate tubes, which are examined for evidence of growth, indicating that at least one organism was present in the subvolume. Let n_i denote the number of tubes containing a volume v_i of the original water sample, and r_i the number of positive tubes among these n_i. If coliforms are homogeneously distributed with density λ per unit volume, then r_i is binomial (n_i, π_i), where

$$\log(-\log(1 - \pi_i)) = \log(v_i) + \log(\lambda).$$

Hence the density, λ, and the MPN, λV, where V denotes the original volume of water, may be estimated using a binomial model with a complementary log–log link function and offset $\log(v_i)$.

Mixture Models for Quantitative Assay Data

Laboratory assays are widely used for diagnostic purposes on samples from individual patients. They may also be used in serological surveys to determine immunity levels in a population, and hence to monitor or design vaccination programs. Many commonly used assays, such as enzyme-linked immunosorbent assays (ELISA), give quantitative results. When used for diagnostic purposes, it is necessary to define one or more cutoff values to classify the test results as negative, positive, or equivocal. These cutoff values also determine the diagnostic sensitivity and specificity of the assay. In serological surveys, on the other hand, the aim is not to classify individual test results, but to estimate the age-specific prevalence in the population.

The determination of cutoff values is problematic when there is no objective criterion by which to classify samples as "true" positives or negatives. For common infections, however, this may be achieved by fitting mixture models to data obtained from population-based serological surveys. Furthermore, when used for determining population prevalence, cutoff values are not required using these methods.

Each age group i is assumed to be a mixture of positives (immunes) and negatives (nonimmunes) in the proportions π_i and $1 - \pi_i$, respectively, where π_i is the proportion positive, which may be constrained to increase with age. Assay results in age group i are distributed with density:

$$f(x|\pi_i, \alpha_i, \beta_i) = (1 - \pi_i) g(x|\alpha_i) + \pi_i h(x|\beta_i),$$

where $g(x|\alpha_i)$ and $h(x|\beta_i)$ are the densities of assay results from negative and positive individuals, respectively. For instance, for an ELISA assay, the random variable X may be taken to be the logarithm of the optical density reading, and $g(\cdot)$ and $h(\cdot)$ may be normal with age-dependent means and constant variance. Let $x_0 = -\infty < x_1 < \cdots < x_k = \infty$ subdivide the range of X and suppose that there are n_{ij} values from age group i in interval $[x_{j-1}, x_j)$. The parameters π_i, α_i, and β_i may be estimated by maximizing the product multinomial log likelihood:

$$\sum_i \sum_j n_{ij} \log \left(\int_{x_{j-1}}^{x_j} f(x|\pi_i, \alpha_i, \beta_i)\, \mathrm{d}x \right).$$

Note that the parameters π_i are estimated without the need to specify cutoff values. Appropriate cutoff

values may be derived by examining the **receiver operating characteristic (ROC) curve** using the estimated specificities and sensitivities corresponding to different cutoff values c:

$$\text{spec}_i(c) = \int_{-\infty}^{c} g(x|\hat{\alpha}_i)\,\mathrm{d}x,$$

$$\text{sens}_i(c) = \int_{c}^{\infty} h(x|\hat{\beta}_i)\,\mathrm{d}x.$$

The mixture modeling approach to the determination of cutoff values is discussed in [98] and applied to estimating prevalences in serological surveys by Gay [58], both in relation to parvovirus B19 infection.

Future Challenges

The substantial statistical literature on applications to **AIDS and HIV** demonstrates the vitality of infectious disease statistics. By the beginning of the twenty-first century, smallpox remained the only infectious disease to have been eradicated. The continued toll of infectious disease throughout the world–particularly the increasing impact of **AIDS** in many countries–along with the emergence of new communicable diseases such as **vCJD**, and of resistant forms of diseases like tuberculosis, combine with new concerns over bioterrorism to unfortunately guarantee the continued relevance of infectious disease statistics.

It is perhaps surprising that our understanding of the mechanism of transmission of infectious diseases has not changed fundamentally since the work of the pioneers at the start of the twentieth century. Further work is required on understanding the epidemicity and seasonality of infectious diseases. Work is also needed on the geographic spread of infectious diseases. Though much mathematical modeling and some statistical work has been done in this area (see, for instance, Cliff & Haggett [24]), little data have so far been available. The development of combination vaccines will also bring new challenges, requiring the assessment of new vaccines against old in **equivalence trials** with **multiple comparisons** and **surrogate endpoints**. The potential risks of vaccines are likely to come under ever closer scrutiny, raising the difficult statistical issue of evaluating vaccine safety with respect to adverse events with long induction periods, in highly vaccinated populations.

Community Medicine

Community medicine is a broad medical specialty developed during the twentieth century to cover various aspects of medicine and care in relation to populations (communities) rather than individuals. It embraced the organization and provision of health care throughout a community (or region), including the identification of health problems and needs, and how they were dealt with and met; it involved extensive use of epidemiology, **preventive medicine**, public health, and **health services research**, and more recently, audit and **health economics**. Although still used as a title for some Clinical or Medical School Departments, frequently in conjunction with Family Medicine, Social Medicine, Public Health, or Health Case, sole usage declined towards the end of the twentieth century; it has been replaced by other terms including those noted above.

ANTHONY L. JOHNSON

Co-morbidity

The term "co-morbidity" of two disorders, R and S [1, 3], in its most general sense, indicates only the potential co-occurrence of those disorders in the same unit (e.g. patient, family). Except in those rare cases where the diagnosis of one disorder, say R, explicitly rules out the possibility of the other, S, most disorders are in this sense potentially "co-morbid". There is, however, growing interest in co-morbidity, defined in a more technical sense. In this sense, the co-morbidity of R and S has come to mean some type of nonrandom association between R and S in a population of subjects. There are at least three distinct types of nonrandom such co-morbidity [2], of wide interest in medical research and important to biostatistical issues in research design and analysis.

Clinical Co-morbidity

R and S are said to have "clinical co-morbidity" if the etiology, time course, prognosis, or response to treatment of R is different depending on whether S is or is not present. For example, Feinstein [1, p. 154] points out that a patient's response to treatment of acute pneumococcal pneumonia may be influenced by whether or not the patient has poorly controlled diabetes mellitus or underlying chronic bronchitis at the same time.

This type of co-morbidity is of biostatistical concern in studies of the epidemiology of R, in **clinical trials** assessing the efficacy or effectiveness of treatment of R, and in **health services research** regarding costs related to course, treatment, or prognosis of R. Whether the population of concern in a study in any of these areas should include or exclude subjects with co-morbid S, and if they are included, whether the sample should or should not be stratified on presence or absence of co-morbid S (*see* **Stratification**), makes a major difference to the **power** of statistical **hypothesis testing**, precision of estimating parameters (*see* **Estimation**), and, above all, the clarity of the conclusions.

Epidemiologic Co-morbidity

R and S are said to have "epidemiologic co-morbidity" in a population if the probability of S in a unit with R from that population is different from the probability of S in a unit without R, i.e. the occurrence of R and S in a unit are not independent events. For example, those in a population with depression may be more likely to be alcoholics than those without depression, i.e. there is some correlation between depression and alcoholism.

The most common sources of epidemiologic co-morbidity are shared risk factors. For example, many disorders are more (or less) likely to affect men than women, to affect older subjects than younger, or to affect socially disadvantaged subjects than advantaged ones. Any pair of such disorders is likely to have epidemiologic co-morbidity in a population heterogeneous on those factors, even if, in a subpopulation matched on age, gender, and social class, the two disorders are completely independent. In such a case, the **correlation** between R and S in the heterogeneous population has often been called "pseudocorrelation", since it is a correlation completely explained by a third factor (*see* **Confounding**).

Thus one is likely to find epidemiologic co-morbidity between tobacco and alcohol dependency in the general adult population, a portion of which may arise simply because both tobacco and alcohol abuse is more common among men than among women, and more common in lower socioeconomic status groups than in higher. Within an age–gender matched subpopulation, it may be that tobacco and alcohol use may be independent, that is, not epidemiologically co-morbid. Consequently, the study of epidemiologic co-morbidities can help distinguish those risk factors that might be causal for a disorder from those that are merely markers.

However, epidemiologic co-morbidities may also arise because of "fuzzy" diagnostic boundaries. For example, it is difficult to identify measures of depression and anxiety that are not very highly correlated. When such measures play some role in diagnosing depression and anxiety disorders, one may find epidemiologic co-morbidity between these disorders because the boundaries are so indistinct. What one diagnostician might see as depression, another might classify as anxiety disorder, and vice versa. Consequently, study of epidemiologic co-morbidity also plays a role in the study of diagnostic reliability and validity.

Finally, epidemiologic co-morbidity may arise simply because S is a risk factor for R or vice versa. It may be, for example, that the well-recognized

epidemiologic co-morbidity between depression and alcoholism arises because those suffering depression attempt to self-medicate with alcohol, or because alcoholism induces depression. This is yet another reason why epidemiologic co-morbidity is an important issue in assessing risk factors and identifying possible causal factors in epidemiologic studies.

Familial Co-morbidity

Both clinical and epidemiologic co-morbidity typically tend to refer to co-occurrences of the two disorders in the same person. In contrast, R and S are said to have "familial co-morbidity" if the prevalence of R in the relatives of probands matched on R (either all have R or all do not have R) differs depending on whether the proband does or does not have S. For example, in families of probands, none of whom is an alcoholic, the prevalence of alcoholism among relatives of those probands with major depression may be higher that among relatives of those probands without major depression. In this case, the occurrences of R in the relatives of the probands, not in the probands themselves, is at issue. Indeed, it is possible that R and S cannot, by definition, occur in the same person at the same time, but R and S may still have familial co-morbidity. Such familial co-morbidity has become of interest with the growing interest in the identification of genetic linkages between disorders (*see* **Familial Correlations**).

Two disorders, R and S, may have clinical co-morbidity or epidemiologic co-morbidity, or familial co-morbidity, any two or these, or all three. For example, not only is there epidemiologic co-morbidity among tobacco and alcohol dependency, but evidence is growing that it is more difficult to induce smoking cessation among those who are alcohol-dependent than among those not, which would be clinical co-morbidity. There is no reason why two disorders R and S that have epidemiologic co-morbidity must necessarily have clinical co-morbidity, and presence of either of these types of co-morbidity gives no indication of whether familial co-morbidity pertains as well.

Methods of assessing these types of co-morbidity differ completely. To establish clinical co-morbidity, one samples the population having one or both disorders and assesses some parameter related to etiology, course, prognosis, or response to treatment. Those with neither R nor S are irrelevant to the issue. To establish epidemiologic co-morbidity, one samples the general population, including those with neither R nor S, and assesses incidence or prevalence of both. To establish familial co-morbidity, one identifies probands matched on R, some of whom have and others of whom do not have S, and assesses incidence or prevalence of R among their relatives. One either excludes probands with R (if it is decided to match by sampling probands without R) or excludes probands without R (if it is decided to match by sampling probands with R).

The statistical testing and estimation methods to be used in such assessments comprise fundamentally two-group comparisons of all types. For example, to establish clinical co-morbidity, one might compare survival curves to age of onset of S between those with and without R. To establish epidemiologic co-morbidity, one might estimate or test the **odds ratio** between the occurrences of R and S in the population. To establish familial co-morbidity, one might sample m first-degree relatives for each proband without R and count the number of relatives with R, then compare the distribution of these counts between those probands with or without S.

Co-morbidity has been characterized as "the single most important concept for psychiatric research and practice" [3], and its importance has been stressed in other fields of medical research as well. However, it is a relatively new construct. The majority of references to "co-morbidity" in the medical research literature continue to mean co-occurrence of disorders, whether random or not. Studies specifically related to these types of nonrandom co-morbidity remain relatively rare [4].

Comparative Genomic Hybridization

Comparative genomic hybridization (CGH) is a method for directly identifying regions of gains and losses of genomic material in chromosomes. It is accomplished by extracting deoxyribonucleic acid (**DNA**) from both test and reference cells, each labeled with a different colored fluorescent dye (e.g. red and green). A pool of test and reference DNA is hybridized to a set of normal chromosomes. The result is measured as a series of test-to-reference signals from the fluorescent dyes along each chromosome. An excess of test signal in a chromosomal region indicates gain of genomic material in test relative to reference in that region, while an excess of reference signal indicates loss of genomic material in test relative to reference [3, 4].

Since CGH is applied to the entire genome (i.e. all the chromosomes), the data consist of test-to-reference ratios for a large number of distinct chromosomal regions, called loci (*see* **Gene**). These loci can be ordered from the tip of the short arm of chromosome 1 (called 1pter) to the tip of the long arm of chromosome 22 (called 22qter) in humans. Thus, the human genome is characterized by CGH as a series of such ratios, called a profile. These ratios are first standardized by dividing each ratio by the mean (or median) of all the ratios so that the standardized ratios will have mean (or median) equal to 1.0.

Statistical methods are used to identify chromosomal regions where CGH ratios differ significantly from 1.0. Ideally, there will be replicate samples of the same test material that can be used to estimate a standard deviation for each locus along the CGH profile. Naive methods define CGH loss at a locus if the (standardized) mean of the replicate ratios is more than 2 standard deviations (sd) below 1.0 and a gain if the mean is more than 2 sd above 1.0 [2]. Unfortunately, observations from several data sets suggest that ratios vary systematically from 1.0 along the CGH profile so that the naive method is prone to error. When CGH is applied to whole (intact) chromosomes, the recommended procedure is to obtain replicate samples of reference vs. reference as well as replicate samples of test vs. reference so that a *t*-test can be used to determine at which loci DNA is gained or lost [5, 9].

CGH is now being applied to microarrays, where genomic DNA is represented by thousands of small segments [1, 6, 7]. Experiments have shown that when used to define abnormality (i.e. gain or loss) in tumors based on replicate sets of reference vs. reference CGH means and sd, this method does not work because of hybridization-to-hybridization variability, especially variability between tumor and normal samples. Statistical methods for dealing with these large arrays of CGH ratios are currently under development. One method circumvents the problem of defining gains or losses by using two-sample *t*-tests applied to the (standardized) CGH ratios themselves to find loci where CGH ratios differ between chromosomes in two groups of tumors (for example, invasive vs. *in situ*) or between tumor and normal chromosomes. Because of the large numbers of *t*-tests applied (one for each of the thousands of loci) and lack of independence among the different loci, permutation methods are used to define the expected distribution of the *t*-statistics [8].

DAN H. MOORE II

Compartment Models

Compartmental modeling is a well-established paradigm for describing system kinetics in the natural and biomedical sciences. One early use of such modeling began with attempts to analyze data on the distribution and metabolism of tracer-labeled compounds in the 1920s [5]. The field gained great impetus with the widespread availability of radioactive tracers in the late 1940s and early 1950s. Sheppard [13] is credited with the first use of the term "compartment" in 1948 to describe a kinetic entity. He conceptualized physiological systems as "well-stirred" hydrology models, noting that "real compartments may exist whose contents are homogeneous and are separated from one another by real boundaries". Berman and Schoenfeld [2] and others in the 1960s established the basic mathematical properties of the underlying linear compartmental model with constant coefficients. This early and the subsequent development of compartmental modeling is contained in the classic books by Jacquez [6], which also describe many diverse applications of the methodology (see also [4]). A parallel but virtually independent development of compartmental modeling occurred in pharmacokinetics, as outlined in [3], (*see* **Pharmacokinetics and Pharmacodynamics**).

Standard Deterministic Model

The basic structure of a compartmental model in a physiological context is illustrated in the schematic in Figure 1. The following notation is standard for an n-compartment model. Let

1. $X_i(t)$ be the amount of substance in compartment i at time t,
2. $\mathbf{X}(t) = [X_1(t), \ldots, X_n(t)]'$ be the column-vector of amounts at time t,
3. k_{ij}, for $i = 0, 1, \ldots, n; j = 1, \ldots, n; i \neq j$; denote the fractional flow rate to i from j, where 0 represents the system exterior,
4. $k_{jj} = -\sum_{i \neq j} k_{ij}$, denote the total outflow rate from j,
5. $\mathbf{K} = (k_{ij})$, for $i, j > 0$; be the $n \times n$ **matrix** of k_{ij} coefficients,
6. $\lambda_1, \ldots, \lambda_n$ be the **eigenvalues** of $\mathbf{K}$, with $\mathbf{\Lambda}$ as the diagonal matrix of λ_i, and
7. $T_1, \ldots, T_n$ be the corresponding **eigenvectors** of $\mathbf{K}$ with $n \times n$ eigenvector matrix $\mathbf{T} = (T_1, \ldots, T_n)$.

A (linear) compartment model assumes that each derivative, $\dot{X}_i(t)$, is a linear function of the $X_i(t)$. For example, the most general two-compartment model assumes the following:

$$\begin{aligned} \dot{X}_1(t) &= -(k_{01} + k_{21})X_1(t) + k_{12}X_2(t), \\ \text{and} \quad \dot{X}_2(t) &= k_{21}X_1(t) - (k_{02} + k_{12})X_2(t). \end{aligned} \tag{1}$$

Compartment models may be expressed in matrix form as follows:

$$\dot{\mathbf{X}}(t) = \mathbf{K}\mathbf{X}(t). \tag{2}$$

The above vector of differential equations has the following solution:

$$\mathbf{X}(t) = \exp(\mathbf{K}t)\mathbf{X}(0) \tag{3}$$

with the matrix exponential defined as $\exp(\mathbf{K}t) = \mathbf{I} + \sum_{i=1}^{\infty} \mathbf{K}^i t^i / i!$.

Two corollaries are helpful in practical applications. In most natural applications, the system is "open" and at least "weakly connected", so that no compartment is a "sink". Assuming these conditions, and that $\mathbf{K}$ admits a spectral decomposition (*see* **Matrix Algebra**), a sufficient condition for which is distinct λ_i, one can show

(a) the λ_i have negative real parts, and
(b) $\mathbf{X}(t) = \mathbf{T}\exp(\mathbf{\Lambda}t)\mathbf{T}^{-1}\mathbf{X}(0)$,

where $\exp(\mathbf{\Lambda}t)$ is a diagonal matrix with elements $\exp(\lambda_i t)$.

Assuming also that the λ_i are real, as they are for all two-compartment and most three-compartment

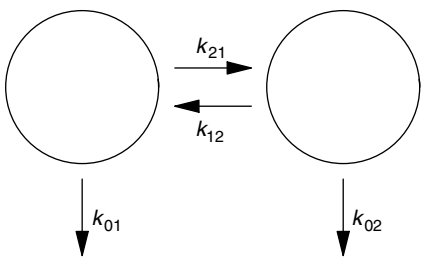

Figure 1 Schematic of general two-compartment model

models, it follows that

$$X_i(t) = \sum_{j=1}^{n} A_{ij} \exp(\lambda_j t), \quad \text{for } i = 1, \ldots, n. \quad (4)$$

In such "sum of exponentials" models, the A_{ij} and λ_j are often called the "macroparameters", and they are usually involved functions of the k_{ij} microparameters. The equivalent solutions based on the k_{ij} parameters are given explicitly for the common two- and three-compartment models in many books, including [4] and [6]. The pharmacokinetic applications share the sum of exponential formulation; however, one notable difference is its reversed order of subscripts in the k_{ij} flow rates.

In practice, often data are concentrations, $C_i(t) = X_i(t)/V_i$, where the V_i are compartment "volumes". In many applications, there are "inputs", leading to a more general matrix model

$$\dot{\mathbf{X}}(t) = \mathbf{K}\mathbf{X}(t) + \mathbf{U},$$
$$\mathbf{Y}(t) = \mathbf{D}\mathbf{X}(t), \quad (5)$$

where $\mathbf{U}$, $\mathbf{Y}(t)$ and $\mathbf{X}(t)$ are vectors of inputs to, outputs from, and amounts in the compartments, respectively, and $\mathbf{K}$ and $\mathbf{D}$ are conformable matrices. These extensions preserve the "sum of exponentials" model. More general formulations, including time-varying $\mathbf{K}(t)$, $\mathbf{U}(t)$, and $\mathbf{D}(t)$ matrices, are considered in general linear systems theory [8].

These models may be fitted to data, using either weighted or unweighted nonlinear **least squares**, to estimate the macro- or microparameters. The underlying theory is described in [1]. Many computer packages are available, including WinSAAM [14] (*see* **Software for Clinical Trials**).

As an illustration, a standard model for calcium kinetics in humans illustrated in Figure 2 has three compartments, namely, plasma (1), soft tissue (2), and bone (3). Weiss et al. [15] describe an experiment in which labeled calcium was introduced as a bolus injection into the plasma compartment of an adult woman, after which the concentration of labeled calcium was observed usually every 8 hours for almost 24 days, as illustrated in Figure 3(a). The fitted concentration-time curve,

$$\mathbf{C}_1(t) = 351.39e^{-5.835t} + 197.20e^{-0.3754t} + 145.31e^{-0.0144t}, \quad (6)$$

fits the data well, and gives estimated rates for $k_{01}, k_{21}, k_{12}, k_{31}$, and k_{13}, respectively, of 0.0652, 2.611, 2.998, 0.389, and 0.162/h, with estimated approximate standard errors of less than 10% for each rate coefficient.

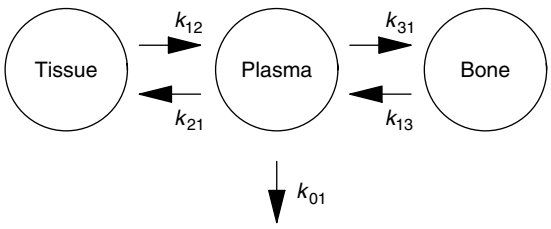

Figure 2 Schematic of standard three-compartment model of calcium clearance

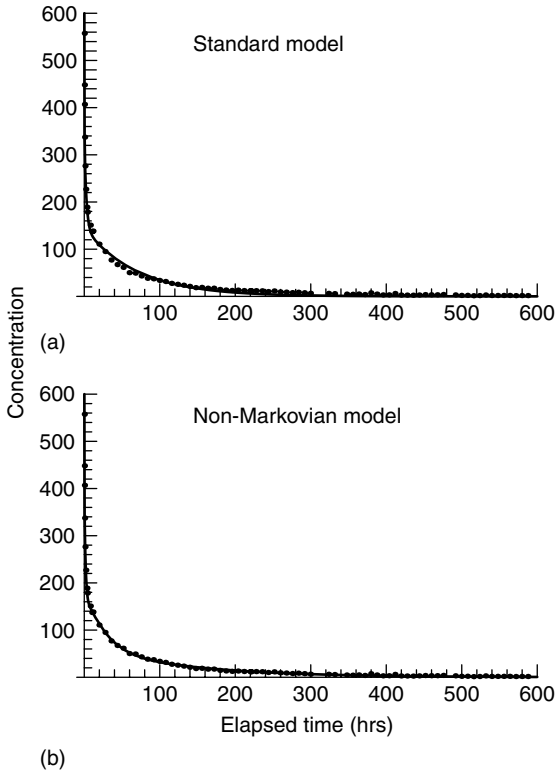

Figure 3 Observed calcium clearance data with fitted curve

An Analogous Stochastic Model

Jacquez [6, p. 235] argues that "In deterministic theory, ... the material in a compartment is treated as a continuum. But matter ... comes in discrete units ... Consequently it is important to develop the theory ... in terms of the probabilities of transfers of unit(s)." A compelling example is modeling the passage of hay particles in ruminants [11]. An analogous stochastic development (*see* **Migration Processes**) requires the following additional notation. Let

8. $P_{ij}(t)$ be the probability that a particle starting in j at time 0, will be in i at time t,
9. $\mathbf{P}(t) = [P_{ij}(t)]$ be an $n \times n$ matrix of probabilities.

Also, let

10. R_{ij} be the retention time during a single visit in j of a particle whose next transfer will be to i,
11. S_{ij} be the total residence time that a particle originating in j will accumulate in i during all of its visits,
12. $\mathbf{E}[S]$ denote the $n \times n$ matrix of mean residence times, with the elements $E[S_{ij}]$.

The key assumptions in the stochastic model are

(a) the conditional probability that, for small Δt, a random particle in j at time t will transfer to i by time $t + \Delta t$ is

$$k_{ij}\,\Delta t,$$

(b) all particles are independent.

The former assumption with the constant conditional flow probability (i.e. **hazard rate**) is equivalent to assuming **exponentially distributed** R_{ij} retention times for all i and j. Under these assumptions, one can show that

$$\mathbf{P}(t) = \exp(\mathbf{K}t), \tag{7}$$

which, under the same regularity conditions as in the deterministic model, implies that each "occupancy" probability function is a sum of exponentials model, that is,

$$P_{ij}(t) = \sum_{\ell} A_{ijl}\,\exp(\lambda_l t) \quad \text{for } i, j = 1, \ldots, n. \tag{8}$$

Thus, this stochastic formulation gives the same sum of exponentials regression model for data.

However, the stochastic model gives additional insight into particle kinetics. The underlying process is **Markovian**, whereupon the matrix of mean residence times (MRT) is

$$\mathbf{E}(S) = -\mathbf{K}^{-1}, \tag{9}$$

with corresponding results available for higher-order moments of the S_{ij} variables, as well as for the number of particle cyclings. As an illustration, the estimated $\mathbf{K}$ matrix for the previous calcium data is

$$\mathbf{K} = \begin{bmatrix} -3.0652 & 2.999 & 0.162 \\ 2.611 & -2.999 & 0 \\ 0.389 & 0 & -0.162 \end{bmatrix}. \tag{10}$$

The first column of $-\mathbf{K}^{-1}$ gives the MRT in the plasma, soft tissue, and bone compartments of a calcium particle introduced into the plasma. The results are 15.34, 13.36, and 36.86 h, respectively, for a total expected residence time in the body of 50.22 h.

Deterministic Model with Time Lags

A generalization of the deterministic model recognizes that transfer of material between compartments may not be instantaneous. Time lags could be introduced, either of fixed size, say τ_{ij}, or more commonly in modeling, of random size with a density function, $h_{ij}(\tau)$. In the latter case, the two-component deterministic model would be

$$\begin{aligned} \dot{X}_1(t) &= k_{11}X_1(t) + k_{12}\int_{-\infty}^{t} X_2(\tau)h_{12}(t-\tau)\mathrm{d}\tau \\ \dot{X}_2(t) &= k_{21}\int_{-\infty}^{t} X_1(\tau)h_{21}(t-\tau)\mathrm{d}\tau + k_{22}X_2(t). \end{aligned} \tag{11}$$

In practice, tractable $h_{ij}(\tau)$ functions are obtained using the "hidden variables" approach, which introduces subsystems of compartments to generate the desired lag distributions. In so doing, "compartmental systems with lags are equivalent to larger compartmental systems without lags" [7], and all of the basic mathematical properties of linear systems are preserved. The procedure is also illustrated in [7].

Analogous Non-Markovian Stochastic Model

The compartment paradigm provides an immediate and tractable stochastic analog of time lags. Neuts [12] shows that any nondegenerate distribution of a positive variable may be represented as a phase-type (PH) distribution. A PH distribution is generated by definition as the time to absorption in a continuous time **Markov chain**, which in turn implies that PH distributions may be generated by stochastic compartmental submodels. Hence, the assumption of an exponentially distributed retention time in a given compartment may be generalized by utilizing an (expanded) compartmental subsystem to generate the desired nonexponential variable. As a simple illustration, setting $k_{01} = k_{12} = 0$ and $k_{21} = k_{02}$ in Figure 1 yields the special case of an Erlang (2) PH distribution of particle retention times.

In practice, any assumed nonexponential variable in the model is approximated to the desired accuracy by utilizing appropriate compartmental submodels, and the resulting larger compartmental systems are fitted to data using standard software. As an illustration, suppose that the previous exponential retention time in the bone compartment, comp 3, is replaced with a PH distribution with four (pseudo)compartments, namely, 3*, 4*, 5*, and 6*, as illustrated in Figure 4. The new flow rates in the submodel are created from the previous two rates, k_{31} and k_{13}, as follows: $k_{3^*1} = k_{4^*3^*} = k_{31} + k_{13}$, $k_{5^*4^*} = k_{6^*5^*} = k_{4^*6^*} = k_{31}$ and $k_{14^*} = k_{13}$. Instead of the previously assumed homogeneous (well-stirred) bone compartment, this expanded model creates a physiologically more realistic short cycle of particles in "soft bone" with possible additional cycles for "hard bone". This yields a natural long-tailed PH distribution without increasing the number of parameters in the model. The estimated parameters k_{01}, k_{21}, k_{12}, k_{31}, and k_{13}, for the expanded six-compartment model are 0.0607, 3.131, 3.735, 0.030, and 0.414 [10]. Some of the eigenvalues of this expanded system with cycling are complex, as expected. The fitted curve,

$$\begin{aligned} C_1(t) = {} & 356.16e^{-7.105t} + 68.50e^{-0.0075t} \\ & + e^{-0.566t}[44.98 \sin b_1 t + 187.85 \cos b_1 t] \\ & + e^{-0.038t}[32.85 \sin b_2 t + 110.26 \cos b_2 t] \end{aligned} \tag{12}$$

with $b_1 = 0.2852$ and $b_2 = 0.0162$, fits the data better as illustrated in Figure 3(b), with an 80% reduction in **mean squared error** (MSE), due to its longer tail. The MRT for the expanded model may be obtained from the negative inverse of the corresponding 6×6 **K** matrix. After summing MRT for the bone submodel, the estimated MRT in the plasma, soft tissue, and bone compartments of a calcium particle introduced into the plasma are 16.47, 13.81, and 69.47 hours, respectively. The latter represents a substantial increase in the MRT from the simple linear model without lags, or correspondingly from the simple Markovian model.

The compartment model construct has also been generalized to include birth and nonlinear rate features, thus broadening its application to broad areas of population biology and other biomedical problems [9]. It is expected that its clear linkage between the mathematical formalism and the underlying biological system, and its ease of application will sustain the widespread use of compartment modeling in practice.

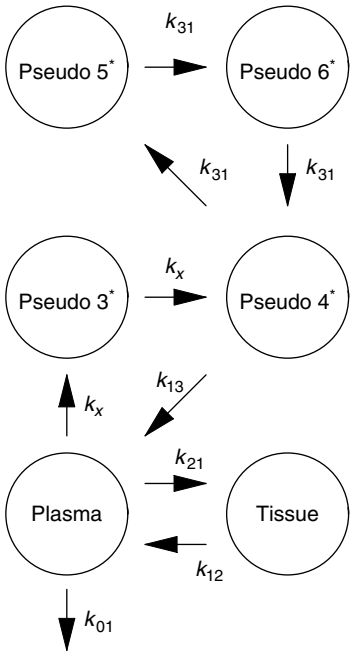

Figure 4 Schematic of non-Markovian model, with four pseudo compartments generating a PH retention time distribution. (Note $k_x = k_{13} + k_{31}$)

Competing Risks

"Competing risks" refers to the study of mortality patterns in a population of individuals, all subject to the same $k \geq 2$ competing risks or **causes of death**. Specifically, the objective is to isolate the effect of a given risk, or a subset of risks, acting on a population. The use of competing risks dates back to 1760 and evolved out of a controversy over smallpox inoculation.

According to Karn [22] and Todhunter [30], smallpox inoculation in the 1700s was administered by applying leeches to the body, a practice that could lead to acute illness and death. Physicians argued whether the benefits of inoculation outweighed the initial risk of death. Daniel **Bernoulli** [9], in a 1760 memoir entitled "Essai d'une nouvelle analyse de la mortalité causée par le petite vérole; et des advantages de l'inoculation pour le prévenir", tried to estimate the expected increase in lifespan (*see* **Life Expectancy**) if smallpox were eliminated. This calculation could then be used to weigh the pros and cons of smallpox inoculation.

Similarly, in the modern treatment of competing risks we are interested in isolating the effect of individual risks. For example, suppose we wish to assess a new treatment for heart disease. In a long-term study of this treatment on a sample of individuals, some will die of causes other than heart disease. The appropriate analysis of this problem must account for the competing effects of death from other causes.

Various methods have been proposed to study the problem of competing risks. For example, Makeham [24] formulated the law of composition of decremental forces and applied it to competing risks theory. A multiple decrement model is a time-continuous **Markov model** with one transient state and k absorbing states. An excellent account of the use of multiple decrement theory to explain competing risks may be found in Chiang [12].

Another approach to modeling competing risks is through the use of latent failure times. This method was first advocated by Sampford [28] who proposed an "accidental death model". In this approach each individual has latent failure times T_1 and T_2, where T_1 corresponds to time of natural death and T_2 to time to accidental death. Sampford assumed that T_1 and T_2 are independent and **normally distributed** and death occurred at time X equal to the minimum of T_1 and T_2. Berkson & Elveback [8] considered a similar model to study the effect of smoking on lung cancer assuming that the latent failure times were independent **exponentially** distributed **random variables**. Moeschberger & David [25] generalized these ideas to k causes of death with general **survival distributions**. Excellent reviews of the theory of competing risks are given by Gail [18, 19], David & Moeschberger [15], and Birnbaum [10].

In this article, latent failure times are used to describe competing risks models. We assume that all individuals in a population are subject to k competing causes of death, $D_1, \ldots, D_k$. For each possible cause of death, D_i, there corresponds a latent failure time, T_i, a positive random variable representing the age at death in the hypothetical situation in which D_i is the only possible cause of death. The joint distribution of the latent failure times is given by the **multivariate survival distribution**

$$H^C(t_1, \ldots, t_k) = P(T_1 > t_1, \ldots, T_k > t_k), \qquad (1)$$

defined for all nonnegative values $t_1, \ldots, t_k$. We use a superscript C to highlight that this is the joint distribution of the complete set of risks acting on the population. The latent failure times are mostly unobservable and serve only as a theoretical construct. In contrast, the observable random variables for each member of a population of individuals are the actual times to death, denoted by the positive random variable X, and the cause of death, Δ, which may take one of the integer values $1, \ldots, k$. The observed time of death, X, is taken to be the minimum of $T_1, \ldots, T_k$, and Δ indexes this cause of death, i.e. $\Delta = i$ if $X = T_i$. For simplicity we assume the joint distribution is absolutely continuous so that Δ is uniquely defined.

The study of competing risks considers the interrelationship of three types of probabilities of death from specific causes. These are:

1. *The crude probability*: the probability of death from a specific cause in the presence of all other risks acting on the population. This is also referred to as **absolute risk**. An example of a crude probability is the answer to the question: What is the chance that a woman will die of breast cancer between ages 40 and 60?
2. *The net probability*: the probability of death if a specific risk is the only risk acting on a population, or conversely, the probability of death if a

specific cause is eliminated from the population. For example, what is the chance of surviving to age 60 if cancer were the only cause of death?

3. *The partial crude probability*: the probability of death from a specific cause when some risks are eliminated from the population. For example, what is the chance that a woman would die from breast cancer between ages 40 and 60 if smallpox were eliminated?

In the next section we define notation and give some fundamental relationships between the three different types of probabilities. Then we consider the issue of **identifiability** of these probabilities and discuss some philosophical issues regarding the study of competing risks in light of nonidentifiability. Finally, we address statistical issues of **estimation** and **hypotheses testing** based on a sample of observable data.

Notation and Relationships

Crude Probability

Crude probability is a way of describing the probability distribution for a specific cause of death in the presence of all causes. Crude probability refers to quantities derived from the probability distribution of the observable random variables, X and Δ, where X is time to death, and $\Delta = 1, \ldots, k$ is cause of death. Two approaches have been used to describe the distribution of X and Δ. The first is through subdistribution functions:

$$F_i^C(x) = \Pr(X \le x, \Delta = i), \quad i = 1, \ldots, k.$$

The function $F_i^C(x)$ denotes the proportion of all individuals who are observed to die from cause D_i at or before time x in the presence of all causes of death. We use the superscript C to denote all causes of death, i.e. $C = \{1, \ldots, k\}$. For example, if D_1 represents death from breast cancer, then the chance that a woman dies from breast cancer between ages 40 and 60 would be equal to $[F_1^C(60) - F_1^C(40)]$. Note that $F_i^C(\infty)$ is the proportion of individuals who will be observed to die from cause D_i, and $\sum_{i=1}^k F_i^C(x) = F^C(x)$ defines the distribution function for death from any cause, i.e. $F^C(x) = \Pr(X \le x)$. We denote the overall survival distribution as $S^C(x) = 1 - F^C(x)$.

Another way to define the distribution of X and Δ is through the use of k cause specific **hazard rate** functions given by

$$\lambda_i^C(x) = \lim_{h \to 0} \left[\frac{\Pr(x \le X < x + h, \Delta = i | X \ge x)}{h} \right], \quad i = 1 \ldots, k.$$

The ith cause-specific hazard is the rate of death at time x from cause i among individuals who are still alive at time x. Calculus yields the following relationships:

$$\lambda_i^C(x) = \frac{\mathrm{d}F_i^C(x)}{\mathrm{d}x} \Big/ S^C(x),$$

$$\lambda^C(x) = \sum_{i=1}^k \lambda_i^C(x) = \frac{\mathrm{d}F^C(x)}{\mathrm{d}x} \Big/ S^C(x), \tag{2}$$

$$S^C(x) = \exp[-\Lambda^C(x)]; \qquad \Lambda^C(x) = \int_0^x \lambda^C(u)\,\mathrm{d}u,$$

$$F_i^C(x) = \int_0^x \exp[-\Lambda^C(u)]\lambda_i^C(u)\,\mathrm{d}u.$$

Note that $\Lambda^C(x)$ is defined as the **cumulative hazard** function of death from any cause and is the sum of the individual cause-specific integrated hazards. The relationship given in (2) illustrates that there is a one-to-one relationship between subdistribution functions and cause-specific hazard functions.

The crude probability distributions may be derived from the joint distribution of the latent failure times as follows. Because $X = \min(T_1, \ldots, T_k)$, it follows that $S^C(x) = H^C(x, \ldots, x)$; hence, it is straightforward to show that

$$\frac{\mathrm{d}F_i^C(x)}{\mathrm{d}x} = -\frac{\partial H^C(t_1, \ldots, t_k)}{\partial t_i}\bigg|_{t_1 = \cdots = t_k = x}.$$

Using (2), the cause-specific hazard function is given by

$$\lambda_i^C(x) = \frac{-\dfrac{\partial H^C(t_1, \ldots, t_k)}{\partial t_i}\Big|_{t_1 = \cdots = t_k = x}}{H^C(x, \ldots, x)}. \tag{3}$$

This relationship was derived by Gail [18] and Tsiatis [31].

Cause-specific hazard functions and cause-specific subdistribution functions may also be defined for a subset of risks. We use italicized capital letters to

index a subset of the risks $1, \ldots, k$; for example, J may be used to denote such a subset of risks. The complement of J is equal to $C - J$ and is denoted by $\overline{J}$. The subdistribution function for failing from any of the causes in J is given by

$$F_J^C(x) = \Pr(X \leq x, \Delta \in J) = \sum_{i \in J} F_i^C(x),$$

and the cause-specific hazard of failing from any of the causes in J is

$$\lambda_J^C(x) = \lim_{h \to 0} \left[\frac{\Pr(x \leq X < x + h, \Delta \in J | X \geq x)}{h} \right] = \sum_{i \in J} \lambda_i^C(x).$$

The Net Probability

The net probability is the probability distribution of time to death if only one cause of death acted on a population. If we are interested in the net probability distribution from cause D_i, then this would be the **marginal probability** distribution of the latent failure time, T_i, given by

$$S_i^i(x) = \Pr(T_i > x) = H^C(t_1, \ldots, t_k) | t_i = x, \quad t_j = 0, j \neq i.$$

We use superscript i to highlight the fact that we consider only the case where D_i is acting on a population. For example, if D_1 denotes death from cancer, then the chance of surviving to age 60 if cancer were the only cause of death would be given by S_1^1 (60).

The net distribution may be defined through the net or marginal hazard function for T_i, that is,

$$\lambda_i^i(x) = \lim_{h \to 0} \left[\frac{\Pr(x \leq T_i < x + h | T_i \geq x)}{h} \right].$$

The net hazard function and net survival distribution are related to each other as follows:

$$\lambda_i^i(x) = -\frac{\mathrm{d}S_i^i(x)}{\mathrm{d}x} \Big/ S_i^i(x), \qquad S_i^i(x) = \exp[-\Lambda_i^i(x)], \tag{4}$$

where $\Lambda_i^i(x) = \int_0^x \lambda_i^i(u)\, \mathrm{d}u$.

One of the key results in competing risks theory is for the case where the latent failure times are assumed to be statistically independent, i.e.

$$H^C(t_1, \ldots, t_k) = \prod_{i=1}^{k} S_i^i(t_i).$$

From (1) it is a simple exercise to show that the ith cause-specific hazard function, $\lambda_i^C(x)$, is equal to the ith net-specific hazard function, $\lambda_i^i(x)$. This important fact allows one to use the crude probability distribution of the observables to obtain net probabilities. Specifically, formulas (1) and (2) may be used to show that the net survival distribution is related to the crude subdistribution functions by

$$H_i^i(x) = \exp\left[-\int_0^x \frac{\mathrm{d}F_i^C(u)}{S^C(u)} \right]. \tag{5}$$

Because $F_i^C(u)$ and $S^C(u)$ may be estimated from a sample of observable data, (5) suggests obvious methods for estimating net survival probabilities when the latent failure times are assumed independent, which are described in detail later. Although the crude cause-specific hazard is equal to the net-specific hazard when the latent failure times are independent, the converse is not true. Examples where non-independent latent failure times have cause-specific hazards equal to the net-specific hazards, although mathematically possible, are generally artificial constructs and not important from an applied perspective.

For many applications it may not be reasonable to assume that the latent failure times are independent. In such cases the relationship between net and crude probabilities becomes more complicated. Without additional assumptions, there is a problem of nonidentifiability discussed in greater detail later.

Partial Crude Probability

We now show how to characterize the distribution of probability of death from a subset of causes acting on a population in the hypothetical situation where all other causes of death are eliminated. Similar to crude probabilities, partial crude probabilities may be expressed through partial crude subdistribution functions or partial crude cause-specific hazard functions. Define X^J and Δ^J respectively as the time of death and cause of death in the hypothetical case where individuals are only subject to the causes of death in J, i.e. the causes $\overline{J}$ are eliminated. In terms of latent failure times, $X^J = \min(T_i, i \in J)$ and $\Delta^J = i$, if

$X^J = T_i,\ i \in J$. The partial crude subdistribution function is given by

$$F_i^J(x) = \Pr(X^J \leq x, \Delta^J = i), \quad i \in J,$$

and the partial crude cause-specific hazard is given by

$$\lambda_i^J(x) = \lim_{h \to 0} \left(\frac{\Pr(x \leq X^J < x + h, \Delta^J = i | X^J \geq x)}{h} \right), \quad i \in J.$$

These definitions may be extended in a natural way to subsets K of J, i.e.

$$F_K^J(x) = \sum_{i \in K} F_i^J(x)$$

and

$$\lambda_K^J(x) = \sum_{i \in K} \lambda_i^J(x).$$

If $J = C$, then partial crude probabilities are the same as crude probabilities, and if $J = i$, so that there is only one cause of death, then partial crude probability is the same as net probability.

Using the same logic as for crude probabilities, we can derive the partial crude cause-specific hazard function from the joint distribution of the latent failure times in a manner similar to that for (3). The partial crude cause-specific hazard is given by

$$\lambda_i^J(x) = \frac{-\left. \dfrac{\partial H^C(t_1, \ldots, t_k)}{\partial t_i} \right|_{t_j = x, j \in J; t_j = 0, j \in \overline{J}}}{H^C(t_1, \ldots, t_k)|_{t_j = x, j \in J; t_j = 0, j \in \overline{J}}}, \quad (6)$$

and the partial crude subdistribution function may be expressed as

$$F_i^J(x) = \int_0^x \exp[-\Lambda_J^J(u)] \lambda_i^J(u)\, \mathrm{d}u, \quad i \in J, \quad (7)$$

where $\Lambda_J^J(u) = \int_0^u \lambda_J^J(v)\, \mathrm{d}v$.

Of particular interest is the case when the latent failure times in the set J are independent of the latent failure times in $\overline{J}$. Comparing (6) with (3) we see that the ith partial crude cause-specific hazard function, $\lambda_i^J(x)$, is equal to the overall crude cause-specific hazard function, $\lambda_i^C(x)$, $i \in J$. This allows us to express the unobservable partial crude probabilities in terms of the observable crude probabilities. So, for example, the partial crude subdistribution function may be expressed in terms of the observable crude subdistribution functions as follows:

$$F_i^J(x) = \int_0^x \exp[-\Lambda_J^C(u)] \lambda_i^C(u)\, \mathrm{d}u, \quad i \in J, \quad (8)$$

where

$$\lambda_i^C(u) = \frac{\mathrm{d}F_i^C(u)}{\mathrm{d}u} \Big/ S^C(u).$$

The above relationships hold whenever the latent failure times in J and $\overline{J}$ are independent. It is not necessary that the failure times within J or $\overline{J}$ be independent.

Issues Regarding the Use and Interpretation of Competing Risks

A major aim in many competing risks studies is the estimation of net survival probabilities. The ability to isolate the effect of one risk acting on a population is intuitively attractive, especially if the focus of a study is to evaluate the effect of an intervention that is targeted at reducing mortality from that specific cause. Of course, net survival probabilities are hypothetical quantities and not directly observable in a population; therefore they must be computed from the available information on the distribution of observables, or what we refer to as *crude probabilities*. Previously, we derived the net survival distribution for a specific risk D_i as a function of the observable crude probabilities under the assumption that the different latent failure times were independent of each other. The independence assumption is critical, because in this case the crude cause-specific hazard function is equal to the net hazard function, which leads to the important relationship given by (5).

In some situations such an assumption of independence may be reasonable. For example, when studying cause of death from a specific disease, it may be reasonable to assume that death from accidental causes is independent of those causes associated with the disease. Of course, there are other scenarios for which the independence assumption is not plausible. It is therefore important to consider the relationship of net probabilities to crude probabilities in the case where the latent failure times are not independent.

As we showed in (3), given any joint distribution of latent failure times, there exists a corresponding set of crude cause-specific hazard functions, or equivalently a set of crude cause-specific subdistribution

functions. Unfortunately, the converse is not true, as there exist many joint distributions, $H^C(t_1, \ldots, t_k)$, that would result in the same set of crude subdistribution functions, $F_i^C(x)$, $i = 1, \ldots k$. These different joint distributions of latent failure times, each resulting in the same set of subdistribution functions, would lead to different net survival probabilities. Consequently we cannot identify net survival probabilities from corresponding crude probabilities. Because crude survival distributions define the observable random variables, we cannot estimate the net survival probabilities from observable data without making additional assumptions that cannot be verified from the observable data. Independence of the latent failure times is one assumption that would resolve the problem of identifiability and permit estimation of net probabilities; however, this assumption can never be verified. This problem of nonidentifiability was pointed out by Cox [13] and Tsiatis [31].

To get a sense of the extent of the nonidentifiability problem, Peterson [26] computed sharp bounds for net survival probabilities as a function of crude subdistribution functions. Specifically, he showed that

$$S^C(x) \leq S_i^i(x) \leq 1 - F_i^C(x).$$

Heuristically, these inequalities may be explained as follows. First, consider the hypothetical case that the causes of death are so highly correlated that an individual dying at time x from any cause other than D_i would have died from cause D_i immediately thereafter. For such a scenario the net survival probability at time x, $S_i^i(x)$, would be equal to the probability of surviving until time x from any cause, $S^C(x) = \Pr(X > x)$. At the other extreme, consider the hypothetical case where an individual who would die from any cause other than D_i would never die from cause D_i. Here, $\Pr(T_i \leq x) = 1 - S_i^i(x)$ would be equal to $F_i^C(x) = \Pr(X \leq x, \Delta = i)$. The upper and lower bounds for net survival probabilities may be quite substantial, as shown by Tsiatis [32].

This creates a philosophical dilemma in competing risks theory. Knowledge of the distribution of observable causes of death does not suffice to determine net survival probabilities. Only if additional assumptions are made on the joint distribution of the latent failure times are we able to identify uniquely the net survival probabilities. Two points of view have been taken in the literature. One is to restrict attention to certain dependency structures on the latent failure times that allow for identification or, at least, restrict to a class of joint distributions where the bounds for the net survival probability are much tighter than the Peterson bounds. This has been the focus of research by Slud & Rubinstein [29], Klein & Moeschberger [23], and Zheng & Klein [33].

Another perspective is as follows. Because nonidentifiability problems can only be handled by making additional assumptions that cannot be verified from the data, perhaps we should only consider making **inference** on the distribution of the observable random variables. That is, the focus should be on estimating cause-specific hazard and subdistribution functions and the comparison of such quantities under a variety of conditions that have practical importance. For example, comparisons may be made among different treatments or varying environmental conditions. This pragmatic point of view suggests that there is no reason to consider hypothetical quantities, such as net survival probabilities, because in fact we will never be in a position to evaluate one cause of death acting in isolation on a population. This point of view was eloquently presented by Prentice et al. [27].

This idea may be modified slightly in the case where a subset of the causes of death that are not of primary interest, denoted by $\overline{J}$, are thought a priori to be independent of the other causes of death, J, that are of interest. For example, certain accidental causes of death may fall into this category when studying treatment of disease. For these problems, inference using partial crude probabilities may be appropriate. We showed before how partial crude probabilities can be defined in terms of the distribution of the observable crude probabilities when causes J are independent of $\overline{J}$.

The Statistical Analysis of Competing Risk Data

Often, the data available for the analysis of competing risks are incomplete or right **censored**. This may be due to the termination of the study before all individuals fail, or to individuals who drop out of the study and subsequently are lost to follow-up. To accommodate this situation we extend the definition of competing risks to include censoring, i.e. we include an additional random variable, T_0, that denotes the latent time to censoring. With this extended definition of competing risks, the observable data are defined by

X^* and Δ^*, where $X^* = \min(T_0, \ldots, T_k)$ and $\Delta^* = i$ if $X^* = T_i$, $i = 0, \ldots, k$. We note that $\Delta^* = 0$ means that the failure time was censored at time X^*.

In a typical competing risks study we observe a sample of data (X_j^*, Δ_j^*, Z_j), $j = 1, \ldots, n$, where for the jth individual, X_j^* denotes the time to failure or censoring, Δ_j^* corresponds to cause of death or censoring, and Z_j corresponds to **covariate(s)** which we may use for modeling the distribution of competing risks. Using this extended notation, the observable data include censoring as a competing risk. We use an asterisk to denote the competing risks model that includes censoring. Therefore, the complete set of observable risks will be denoted by $C^* = 0, \ldots, k$, in contrast to the risks of interest, $C = 1, \ldots, k$, or perhaps some subset, J. In the previous section we denoted the complement of the subset J by $\overline{J} = C - J$; in the extended definition of competing risks we denote the complement of J by $\overline{J}^* = C^* - J$. In what follows it will be assumed that censoring, or risk 0, is independent of the other risks C. Without this assumption, nonidentifiability problems would not allow for **estimation** of the competing risk probabilities of interest regarding causes C.

One Sample Problems

Here we consider the problem of estimating relevant competing risk probabilities from a single sample of data (X_j^*, Δ_j^*), $j = 1, \ldots, n$.

Estimating Cause-Specific Hazard Functions

We showed before that the partial crude cause-specific hazard function is equal to the observable crude cause-specific hazard function whenever the risks in J are independent of the risks in $\overline{J}^*$, i.e.

$$\lambda_i^J(x) = \lambda_i^{C^*}(x). \tag{9}$$

Because censoring, or risk 0, is always assumed independent of the other risks, (9) will follow as long as the risks in J are independent of $\overline{J}$. It is important to note that the crude cause-specific hazard functions discussed in the previous section, $\lambda_i^C(x)$, are actually partial crude cause-specific hazard functions when we include censoring as a competing risk. However, because of (9) applied to $J = C$, $\lambda_i^C(x)$ is equal to the observable $\lambda_i^{C^*}(x)$. In the case when cause of death D_i is independent of the other risks, the net-specific hazard function, $\lambda_i^i(x)$, is equal to $\lambda_i^{C^*}(x)$.

For certain independence assumptions, the cause-specific hazard functions are related to the observable crude cause-specific hazard functions, which by (2) is equal to

$$\lambda_i^{C^*}(x) = \frac{\mathrm{d}F_i^{C^*}(x)}{\mathrm{d}x} \Big/ S^{C^*}(x),$$

where

$$F_i^{C^*}(x) = \Pr(X^* \le x, \Delta^* = i)$$

and

$$S^{C^*}(x) = \Pr(X^* > x).$$

The natural estimate for the crude subdistribution function is the empirical subdistribution function, i.e.

$$\hat{F}_i^{C^*}(x) = n^{-1} \sum_{j=1}^{n} I(X_j^* \le x, \Delta_j^* = i),$$

where $I(\cdot)$ denotes the indicator function. This estimate puts mass $1/n$ at each observed event time from cause i. Similarly,

$$\hat{S}^{C^*}(x) = n^{-1} \sum_{j=1}^{n} I(X_j^* > x)$$

puts mass $1/n$ at each event time.

Because crude cause-specific hazards are functions of the crude subdistribution probabilities, the obvious estimates are obtained by substituting the corresponding functions of the empirical subdistribution probabilities. For example, the estimate of the cumulative cause-specific hazard function is

$$\hat{\Lambda}_i^{C^*}(x) = \int_0^x \frac{\mathrm{d}\hat{F}_i^{C^*}(u)}{\hat{S}^{C^*}(u)} = \sum_{j=1}^{n} \frac{I(X_j^* \le x, \Delta_j^* = i)}{Y(X_j^*)},$$

where $Y(u) = \sum_{j=1}^{n} I(X_j^* > u)$ denotes the number of individuals in the sample who are at risk at time u, i.e. neither died nor were censored. This estimator is the so-called **Nelson–Aalen estimator**; see Aalen [1]. Aalen [2, 3] derived the theoretical **large-sample** properties, including consistency and asymptotic normality, using the theory of **counting processes**.

This estimator of the ith crude cause-specific cumulative hazard is the appropriate estimator for the

partial crude cause-specific cumulative hazard whenever the causes in J are independent of the causes in $\overline{J}^*$, i.e.

$$\hat{\Lambda}_i^{J^*}(x) = \hat{\Lambda}_i^{C^*}(x), \quad i \in J.$$

In the special case where cause i is assumed independent of all other causes, the ith net-specific cumulative hazard function, $\Lambda_i^i(x)$, is estimated by $\hat{\Lambda}_i^{C^*}(x)$. The ith net survival distribution, $S_i^i(x)$, is equal to $\exp[-\Lambda_i^i(x)]$. Therefore, a natural estimator is the exponentiated negative of the Nelson–Aalen estimator. This estimator is

$$\hat{S}_i^i(x) = \exp - \left[\sum_{j=1}^{n} \frac{I(X_j^* \leq x, \Delta_j^* = i)}{Y(X_j^*)} \right].$$

Noting that this is equal to

$$\prod_{j=1}^{n} \exp \left[\frac{-I(X_j^* \leq x, \Delta_j^* = i)}{Y(X_j^*)} \right]$$

and that

$$\exp\left[\frac{-1}{Y(u)}\right] \approx \left[\frac{1-1}{Y(u)}\right],$$

yields the approximation

$$\hat{S}_i^i(x) \approx \prod_{j=1}^{n} \left[\frac{1-1}{Y(X_j^*)} \right]^{I(X_j^* \leq x, \Delta_j^* = i)}.$$

This is the well known **Kaplan–Meier** [21], or product-limit, estimator. The asymptotic equivalence of the exponentiated Nelson–Aalen estimator and the Kaplan–Meier estimator, and the large-sample properties of these estimators, are given by Breslow & Crowley [11].

It is important to note that the Kaplan–Meier estimator, by construction, is a **consistent estimator** of the exponentiated cumulative crude cause-specific hazard function. That this corresponds to an estimator of the net survival distribution follows only when the net hazard function is equal to the crude cause-specific hazard, i.e. when cause i is independent of all the other causes, including censoring. Without this assumption, the Kaplan–Meier estimator of the ith net-specific survival distribution does not estimate any interesting or relevant probability.

If we consider death from any cause, i.e. $\Delta \in C$, then the estimate of the corresponding survival distribution, $S^C(x)$, from a sample of potentially censored data (X_j^*, Δ_j^*), $j = 1, \ldots, n$, follows from applying the same logic:

$$\hat{S}^C(x) = \prod_{j=1}^{n} \left[\frac{1-1}{Y(X_j^*)} \right]^{I(X_j^* \leq x, \Delta_j^* \in C)}.$$

This estimator for the survival distribution from any cause of death in the presence of censoring is the Kaplan–Meier estimator as originally presented in the seminal paper [21] in 1958. Failure is considered a death from any cause, and an incomplete observation is a censored observation. The estimator of the ith net survival function given above is also referred to as a Kaplan–Meier estimator, since it may be derived via the same formula, letting failure be death from cause i and an incomplete observation be death from any cause other than i or censoring.

Estimating Subdistribution Functions

We may use the above results to derive **nonparametric** estimators for crude and partial crude subdistribution functions. Using (2), the ith crude subdistribution function may be expressed as

$$F_i^C(x) = \int_0^x S^C(u)\lambda_i^C(u)\,\mathrm{d}u.$$

Because censoring is independent of the other causes of death, $\lambda_i^C(u) = \lambda_i^{C^*}(u)$. Therefore a natural estimator for the ith subdistribution function is given by

$$\hat{F}_i^C(x) = \int_0^x \hat{S}^C(u) \frac{\mathrm{d}\hat{F}_i^{C^*}(u)}{\hat{S}^{C^*}(u)},$$

where $\hat{S}^C(u)$ is the Kaplan–Meier estimator for the survival distribution of time to death from any cause.

The large-sample statistical properties of this estimator may be derived using the theory of counting processes. Details may be found in Aalen [2, 3], Fleming [16, 17], Benichou & Gail [6], and Andersen et al. [5] when using **cohort** data, and in Benichou & Gail [7] when using **population-based case–control data**.

The Relationship of Competing Risks to Covariates

Often, we are interested in studying the relationship of time to death from one or many causes to other

covariates. For example, we may be interested in the effect of different treatments on reducing the risk of death from specific causes, or we may wish to model the relationship of competing risk probabilities to other **prognostic factors**. These problems are generally posed in terms of hypothesis testing or estimation of **regression** parameters. There is a wide literature on inferential techniques for hypothesis testing and regression modeling for survival problems with censored data. Because of the close relationship between censoring and competing risks, many of the methods developed for analyzing censored survival data may also be applied to competing risks data (*see* **Survival Analysis, Overview**).

Hypothesis Testing

The most widely used methods for testing the **null hypothesis** of no treatment effect among K treatments with censored survival data are the **logrank** or weighted logrank tests. These tests were designed to test the equality of the hazard functions for death among K treatments when the censoring time is independent of time to death within each treatment group. If we study these tests carefully, then we realize that they actually compare the observable cause-specific hazard functions among the different treatment groups. Therefore, we can immediately apply these methods for testing equality of cause-specific hazard functions among different treatments. To be more precise, we denote by $\lambda_{il}^{C^*}(x)$, $l = 1, \ldots, K$, the ith cause-specific hazard function within treatment group l. The weighted logrank tests may then be used to test the null hypothesis that

$$\lambda_{i1}^{C^*}(x) = \cdots = \lambda_{iK}^{C^*}(x), \quad x > 0.$$

The theoretical development for these tests is given by Andersen et al. [4]. This is carried out by letting failure correspond to death from cause i and an incomplete observation to correspond to death from any cause other than i or censoring ($\Delta^* = 0$).

We reiterate the interpretation of this null hypothesis and the results of the logrank test. If we are willing to assume that time to death from cause i is independent of the times to death from other causes as well as time to censoring, within each treatment group $l = 1, \ldots, K$, then the cause-specific hazard function, $\lambda_{il}^{C^*}(x)$, is equal to the net-specific, or marginal, hazard function, $\lambda_{il}^{i}(x)$. Equality of net-specific hazard functions implies equality of net-specific survival probabilities. Therefore, with the assumption of independence, the logrank test is a test of the null hypothesis that the K net-specific survival distributions are equal. This is often the hypothesis of interest.

To illustrate, consider a **clinical trial** of several treatments to reduce breast cancer mortality. Because breast cancer clinical trials generally occur over many years, some patients may die from causes other than breast cancer. Because the treatments were targeted to reduce breast cancer mortality, the investigators are not interested in the effect that treatment may have on other causes of death; rather, they are mainly interested in the effect of the treatments on breast cancer mortality in the absence of causes of death other than breast cancer. This is the classic competing risks problem of comparing net survival distributions. When the logrank test is used, patients not dying from breast cancer are treated as censored observations. As previously discussed, this is an appropriate test for the equality of net survival probabilities when the time to death from other causes is independent of time to death from breast cancer within each treatment group. This assumption may not be true, and in fact cannot be verified with the data because of nonidentifiability problems alluded to above. If this independence assumption is not true, then it is not clear what we are testing when we use the logrank test.

One way around this philosophical dilemma is to consider only tests of observable population parameters. An important observable population parameter is the crude cause-specific hazard function, $\lambda_i^C(x)$. We again emphasize that the population cause-specific hazard function, $\lambda_i^C(x)$, is observable only if there is no additional censoring introduced. With the introduction of censoring, the observable parameter is $\lambda_i^{C^*}(x)$. However, by assumption, the censoring ($\Delta^* = 0$) is independent of the other causes of death, in which case $\lambda_i^C(x) = \lambda_i^{C^*}(x)$.

As we pointed out, the logrank test tests the equality of the cause-specific hazard functions, $\lambda_{il}^{C^*}(x)$, and, with independent censoring, the equality of $\lambda_{il}^{C}(x)$. Therefore, the logrank test would be a valid test of the equality of the breast cancer specific hazard functions among the K treatments. Although this cause-specific hazard function may not be directly related to net-specific breast cancer mortality, if independence does not hold, then it still may be an important comparison. This point of view is given by Prentice et al. [27].

Another observable quantity is the subdistribution function $F_{il}^C(x)$ for cause i within treatment group l. Very little work has been done on deriving tests for the equality of these K-sample subdistribution functions. One exception is a class of tests derived by Gray [20] to test the null hypothesis that

$$F_{il}^C(x) = \cdots = F_{iK}^C(x).$$

Regression Modeling

The most popular framework for modeling the association of censored survival data to prognostic variables is with the **proportional hazards** model of Cox [14] (*see* **Cox Regression Model**). In this model the hazard for death is related to a vector of covariates by

$$\lambda(t|\mathbf{z}) = \lambda_0(t)\exp(\beta^{\mathrm{T}}\mathbf{z}),$$

where $\mathbf{z}$ represents a vector of covariates, and $\lambda(t|\mathbf{z})$ is the hazard rate of death at time t given covariates $\mathbf{z}$. In this model, censoring is assumed to be independent of the failure time, conditional on the covariates. A careful study of the inferential procedure for estimating parameters in the Cox model reveals that this is actually the observable cause-specific hazard of death in the presence of censoring. That this corresponds to the actual net hazard function of death holds only when we add the assumption of independence of censoring time and failure time.

Consequently, this model may also be applied to competing risks data; that is, we may use the same inferential procedures to estimate the parameter β when considering the model

$$\lambda_i^{C^*}(t|\mathbf{z}) = \lambda_{i0}^{C^*}(t)\exp(\beta^{\mathrm{T}}\mathbf{z}).$$

To apply software for the Cox model (*see* **Survival Analysis, Software**), we must define a failure as death from cause i, and an incomplete observation as either death from a cause other than i or censoring. The interpretation of this model and the parameters is the same as discussed above. That is, if we are willing to assume that time to death from cause i is independent of the times to death from other causes and time to censoring, then the observable cause-specific hazard, $\lambda_i^{C^*}(t|\mathbf{z})$, is equal to the net-specific hazard, $\lambda_i^i(t|\mathbf{z})$.

Even if we are unwilling to make this nonidentifiable assumption, the relationship of the observable cause-specific hazard to covariates may be of interest. By assumption, censoring is independent of all other causes of death. This implies that $\lambda_i^C(t|\mathbf{z}) = \lambda_i^{C^*}(t|\mathbf{z})$. Therefore, the results of the Cox regression analysis may be used to estimate the parameters in the model of the cause-specific hazard function, given by

$$\lambda_i^C(t|\mathbf{z}) = \lambda_{i0}^C(t)\exp(\beta^{\mathrm{T}}\mathbf{z}).$$

Using cause-specific hazards thus allows useful interpretation of relevant observable quantities without an additional assumption of independence of the different causes of death.

Complex Diseases

The principal distinction between "simple" monogenic diseases and "complex" genetic diseases is that the latter do not exhibit classic Mendelian patterns of inheritance (*see* **Mendel's Laws**) and characteristically involve multiple **genes** that interact in complex ways with multiple environmental factors [5] (*see* **Gene-environment Interaction**). For instance, asthma and many of the traits associated with asthma exhibit non-Mendelian patterns of inheritance and substantial heterogeneity [6]. The intricacy of the disparate pathogenic mechanisms associated with asthma suggests multiple environmental and genetic determinants, and has led to the definition of asthma as a "complex" phenotype [4].

Other examples of complex human diseases include type 1 and type 2 diabetes, Alzheimer's disease, rheumatoid arthritis, and many cancers and psychiatric disorders. Such diseases tend to be common relative to single-gene disorders, to be chronic conditions that are responsible for significant morbidity and mortality, and to be associated with very substantial economic costs. For example, asthma is the most common chronic childhood disease in developed nations [1], and carries a very substantial direct and indirect economic cost worldwide [8]. As a result of these factors, such diseases have become a major focus of bioscience research in both industry and academia.

Complex diseases tend to involve many difficulties in phenotypic definition and are not generally amenable to investigation using techniques that assume monogenic inheritance. Relative to monogenic disorders, the study of genetically complex diseases presents many additional challenges for **genetic epidemiology**. For instance, classic **segregation analysis** was designed for studies of monogenic diseases and assumes etiologic homogeneity – an assumption unlikely to be met in analyses of complex phenotypes, which are likely to be under the control of multiple environmental and genetic factors. Different genes may segregate in different families, which may in turn be exposed to different environmental factors. The mapping of human susceptibility loci for complex disease is further made difficult by a high population frequency, incomplete **penetrance**, phenocopies (environmentally determined, nongenetic variation in a phenotype that resembles genetically determined variation), **genetic heterogeneity**, and pleiotropy. The substantial genetic heterogeneity that characterizes such diseases is likely to involve both different susceptibility loci and different susceptibility alleles within a locus. Strategies to minimize the effects of genetic heterogeneity in studies of complex diseases have included the use of large pedigrees, genetically isolated populations likely to exhibit **founder effects** (*see* **Inbreeding**), and phenotypically homogeneous subgroups such as early-onset forms of disease [7].

A further characteristic of many complex human diseases is that they are closely associated with one or more "intermediate" phenotypes, e.g. hyperlipidemia in type 2 diabetes [13] and measures of lung function in asthma [16]. Intermediate phenotypes are often quantitative, pathophysiological traits assumed – on the basis of prior clinical, epidemiologic, or laboratory evidence – to be on an etiologic pathway leading to disease. Due to difficulties in phenotype definition and related low statistical power, and the complexity of the interrelationships between clinical disease, intermediate phenotypes and epidemiologic covariates, dichotomous disease affection as an outcome has proven difficult to dissect genetically in many complex diseases. Disease-associated intermediate phenotypes are often themselves highly **heritable**, and power calculations have suggested that testing for **linkage** is significantly enhanced by the use of quantitative traits in preference to a categoric affection phenotype [2, 15]. The use of quantitative intermediate phenotypes also permits selection of subjects in the extremes of the distribution, with increased power to detect linkage [17]. For these reasons, objectively-measured intermediate phenotypes have increasingly become the focus of genetic studies of complex human diseases.

In an attempt to simplify etiologic heterogeneity, many researchers investigating the genetics of complex human disease have turned to inbred animal models [10, 18]. Animals have the advantages of permitting control of both breeding and environmental conditions. Assuming a valid model, these advantages potentially allow complex genetic traits to be more easily dissected using animal models than using human study populations. The extent to which results obtained from experimental animals can be generalized to humans may be problematic, however.

As part of the intense research effort to improve our ability to discover the genetic determinants of complex human disease over the last decade, technologic advances in the laboratory related to sequencing and single nucleotide **polymorphism** (SNP) genotyping have proceeded at a very rapid rate (*see* **Bioinformatics**; **Genetic Markers**). Catalyzed in part by the vast amounts of data generated by the **Human Genome Project** and the SNP genotyping efforts in complex human disease, it has become clear that concomitant statistical advances in the mapping of complex traits will also be required [11, 22, 25] (*see* **Disease-marker Association**; **Linkage Analysis, Model-based**; **Linkage Disequilibrium**). The Human Genome Project and SNP genotyping efforts have caused a broad reexamination of mapping methodologies and study designs in complex human disease [7, 17, 20, 23]. The testing of large numbers of genotypes for association with one or more traits raises important statistical issues regarding the appropriate false positive rate of the tests and the level of statistical significance to be adopted given the multiple testing involved [17, 20]. The required methodologic development in genetic statistics is nontrivial given the complexity of most common human diseases. Some current areas of methodologic development include **haplotype analysis** [9, 22, 25], distance-based mapping measures [3, 19], combined linkage and association analyses [12], techniques for modeling linkage disequilibrium and population history [26] (*see* **Population Genetics**) and **Markov Chain Monte Carlo** based approaches [14].

Genetic approaches to complex diseases offer great potential to improve our understanding of their etiology, but they also offer significant challenges. Despite much progress in defining the genetic basis of diseases such as asthma in the last decade, accompanied by rapid technical progress in sequencing and SNP genotyping technologies (*see* **Sequence Analysis**), further research is required. In particular, genetic localization of most susceptibility loci is still insufficiently precise for the positional cloning of new genes influencing such diseases. Furthermore, there are technical, statistical, ethical, and psychosocial issues that remain unresolved in the investigation of the genetics of complex human diseases. However, a large number of groups are currently active in addressing methodologic problems in genetic statistics, and methodologic progress, together with technologic advances in positional cloning and candidate loci linkage-disequilibrium mapping techniques will likely accelerate our ability to investigate the genetic basis of complex diseases.

Compliance and Survival Analysis

Compliance: Cause and Effect

Today, new treatments must prove their worth in comparative (double blind) randomized clinical trials, the gold standard design for causal inference (*see* **Clinical Trials, Overview**). With noninformatively right-**censored** survival outcomes, a typical robust **intention-to-treat analysis** compares groups as randomized using the popular (weighted) **logrank test**. Accompanying **Kaplan–Meier**, curves describe nonparametrically how survival chances differ between arms. A one-parameter summary of the contrast follows from a **semiparametric** Cox **proportional hazards** (PH) model (*see* **Cox Regression Model**) or **Accelerated Failure-Time Model** [6].

In general, and especially with long-term treatments, patients tend to deviate from their prescribed treatment regime. Varying patterns of observed exposure relative to the assigned are called "compliance (levels)" and recognized as a likely source of variation in treatment effect (*see* **Compliance Assessment in Clinical Trials**). Because deviations from prescribed regimes occur naturally in clinical practice, it is wise to learn about them within the trial context rather than restrict the study population to perfect compliers, an atypical and sometimes small and unobtainable subset of the future patient horizon [12].

Treatments that are stopped or switched or are less dramatic lapses in dosing happen in response to a given assignment. Different exposure patterns between treatment arms therefore point to (perceived) differences following alternative assignments. Studying compliance patterns as an outcome can yield valuable insights [15].

Of course, actual treatment regimes may also influence primary outcomes. From the intent-to-treat perspective, underdosing causes reduced **power** and a requirement for larger samples. Fortunately, the strong **null hypothesis**, where treatment and its assignment have no impact on outcome, is consistently tested irrespective of compliance levels. Under the alternative, we expect, however, different (smaller) intent-to-treat effects than the prescribed regime would create when it materializes. This happens as the treatment group becomes a mix of varying (lower) degrees of exposure [2, 8].

Estimation of the causal effect of actual dose timing becomes challenging, when observed exposure patterns are no longer randomized. (Un)measured patient characteristics and earlier experience may determine exposure levels that become confounded with the natural treatment-free hazard of the patient. The association between compliance which induces treatment exposure levels, and treatment-free hazards is often called a *selection effect* in line with **missing data** terminology. An "as-treated" analysis, such as a PH analysis, with the currently received treatment as a **time-dependent covariate**, compares hazards between differently treated groups at a given time and thus estimates a mix of selection and causal effects [11]. An "on-treatment" analysis censors patients as soon as they go off the assigned treatment and thus generates informative censoring for the same reason. Structural accelerated failure time (SAFT) models and structural PH models have been designed to avoid these biases. We explain their key features and potential through a simple example first.

All-or-nothing Compliance

In randomized studies that evaluate a one-shot treatment, such as surgery [7], vaccination [4], or an invitation to undergo screening [1], all-or-nothing compliance with experimental assignment arises naturally. Let $R_i = 1(0)$ indicate whether individual i, with baseline covariates $\mathbf{X}_i$, gets randomized to the experimental (control) arm. When experimental treatment is not available outside the treatment arm the control arm remains uncontaminated by experimental exposure and its outcomes can serve as reference outcomes for causal inference. Let T_{0i} denote such a potential survival time for individual i following a control trajectory free of experimental exposure. Let T_{1i} and C_i respectively be survival time and compliance following a possible treatment assignment.

R_i operates independently of the vector (T_{0i}, T_{1i}, C_i, $\mathbf{X}_i$) but determines, which components are observed. Observed survival time and exposure are simply denoted T_i, E_i for all. With an uncontaminated control arm, $E_i = C_i R_i$. One goal of causal inference is to estimate how the contrast between potential survival times T_{1i} and T_{0i} varies over the subpopulations determined by different C_i-levels and their induced level of experimental exposure on the treatment arm, E_i.

The sharp null hypothesis assumes it makes no difference what arm one is assigned to and hence:

$$T_{0i} \stackrel{d|\mathbf{X}_i}{=} T_{1i}, \quad (1)$$

where $\stackrel{d|\mathbf{X}_i}{=}$ indicates equality in distribution conditional on $\mathbf{X}_i$.

The most obvious violation of (1) occurs when (some) patients on the experimental arm become exposed and exposure alters survival chances. This is called a direct causal effect of exposure [10]. When an assignment influences survival through mechanisms of action operating independently from exposure levels, we have an indirect effect. Below, we consider a cancer clinical trial [7], where the experimental intervention consists of implanting an arterial device during surgical resection of metastases. A planned implant could lead to an operation scheduled earlier in the day and timing may create its own set of prognostic circumstances. In addition, the news that a planned implant did not happen could be depressing to the patient and diminish survival chances beyond what would have happened on the control arm. Both mechanisms can lead to an indirect (clinical) effect of exposure assignment. Double blind studies are carefully designed to avoid indirect effects, so they satisfy: $T_{0i} \stackrel{\{d|C_i=0,\,\mathbf{X}_i\}}{=} T_{1i}$ and hence, $P(T_{1i} > t|C_i = 0, R_i = 1, \mathbf{X}_i) = P(T_{0i} > t|C_i = 0, R_i = 0, \mathbf{X}_i)$, for all t. The contrast between $P(T_{1i} > t|C_i = e, R_i = 1, \mathbf{X}_i)$ and $P(T_{0i} > t|C_i = e, R_i = 0, \mathbf{X}_i)$ then represents the causal effect of exposure level e. In general, however, this combines direct and indirect effects of assignment in the population with compliance level e.

In what follows, we ignore $\mathbf{X}_i$ for simplicity, but stronger inference can be drawn when assumptions condition on $\mathbf{X}_i$. To estimate $P(T_{0i} > t|C_i = 1, R_i = 1)$, one can solve $P(T_{0i} > t|C_i = 1|R_i = 1)P(C_i = 1, \ R_i = 1) + P(T_{0i} > t|C_i = 0, \ R_i = 1)P(C_i = 0|R_i = 1) = (P(T_{0i} > t|R_i = 1) =)P(T_{0i} > t|R_i = 0)$ after substituting empirical means or (Kaplan–Meier) estimates for the other unknown terms. **Isotonic regression** can turn the pointwise estimates in a monotone survival curve. To evaluate the treatment effect among the exposed, one compares $\hat{P}(T_{1i} > t|C_i = 1, R_i = 1)$ with $\hat{P}(T_{0i} > t|C_i = 1, R_i = 1)$. The selective nature of exposure is seen by contrasting treatment-free survival probabilities for the exposed and nonexposed subpopulations: $\hat{P}(T_{0i} > t|C_i = 1, R_i = 1)$ and $\hat{P}(T_{0i} > t|C_i = 0, R_i = 1)$.

More General Exposure Patterns

A structural model parameterizes the shift in distribution from observed survival time T_i to a reference time, T_{ei} following a specific exposure regime e, in terms of observed (possibly time-dependent) exposures $\mathbf{E}_i$ and covariates $\mathbf{X}_i$. One can thus perform parameter-specific $(\mathbf{E}_i, \mathbf{X}_i)$-dependent back transformations of observed survival times (or distributions). The parameter value that solves estimating equations demanding equality of estimated T_{ei} distributions (conditional on baseline **covariates**) between arms is our point estimate.

The procedure is illustrated in Figure 1 for the SAFT model $T_i \exp\{-\beta_0 E_i\} \stackrel{d|R_i}{=} T_{0i}$ in our trial, where E_i indicates an actual implant of the arterial device. For time-dependent implants $E_i(t)$, we could have used the SAFT model $\int_0^{T_i} \exp(-\beta_0 E_i(u))\,\mathrm{d}u \stackrel{d|R_i}{=} T_{0i}$. For technical points concerning the specific treatment of censored data, we refer the reader to [5, 12]. The left-hand panel shows ITT Kaplan–Meier curves in the standard and intervention arm. In the right-hand panel, the survival curve for the standard arm is compared with KM-curves following the transformations $T_i \exp\{-\beta E_i\}$ with $\beta = -1.5$ and $\beta = -0.36$ on the intervention arm. Reducing treated failure times by the factor $\exp(-1.5)$ overcompensates for the observed harmful treatment effect as survival chances on the intervention arm are now higher than on the standard arm. This is confirmed by the logrank chi-squared value of 9.326, plotted in the middle panel. The survival curve corresponding to the point estimate $\hat{\beta} = -0.36$ ($\exp(\hat{\beta}) = 70\%$) is convincingly close to the observed survival in the standard arm. The middle panel reveals chi-squared values for a range of hypothesized structural parameter values. Those that do not lead to significantly different curves at the 5% level form the 95% **confidence interval** $[-1.07, 0.39]$ for β_0.

Other Structural Modeling Options

One can propose many different maps of the observed into the treatment-specific survival distributions. This may happen on a PH scale [7] or involve time-dependent measures of effect in the SAFT setting [12]. Estimation methods, which rely on the instrument of randomization, protect the α–level (*see* **Hypothesis Testing**) just like the intent-to-treat test,

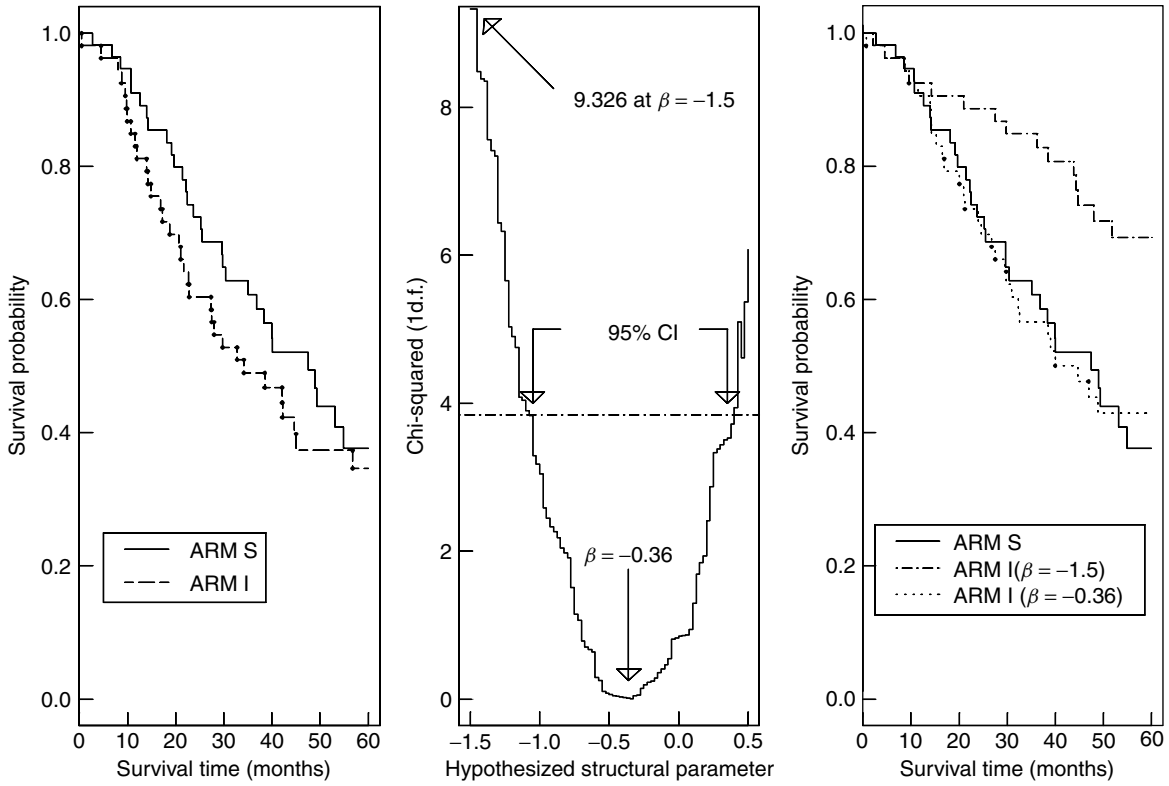

Figure 1 Estimation of structural parameters

but shift the point estimate away from a diluted average. To achieve this, they rely on the postulated structural model, which can sometimes be rejected by the data, but generally not confirmed owing to a lack of observed degrees of freedom. Special care is thus required when interpreting these models and their results. Some diagnostic procedures have been proposed (*see* **Diagnostics**) and forms of **sensitivity analyses** [13, 14].

To explicitly account for measured time-dependent confounders, **structural nested failure-time models** can be used as an alternative, or marginal structural models for T_{ei} as in [3]. The estimation process then relies on the assumption of "no residual confounding", ignores the instrument R_i, and loses its robust protection of the $\alpha-$level.

Structural modeling of failure time distributions has opened a world of practical and theoretical developments for the analysis of compliance and survival time. The field of research is very much alive today. Recent work [9], for instance, proposes to estimate optimal treatment regimes from compliance data. Our brief account can give but a flavor of this wealth.

Compliance Assessment in Clinical Trials

If the results of an **intention-to-treat analysis** in a randomized clinical trial are not statistically significant, then there are several possible explanations. In addition to the obvious explanations of lack of treatment effect and low statistical **power** due to inadequate sample size, treatment differences may be underestimated, and thus statistical power reduced, by poor compliance (sometimes called adherence) to the intervention on the part of the trial participants.

As a simple example, consider a randomized clinical trial in which participants are assigned by randomization to receive active treatment (A) or control (C). We assume that the response to treatment is a binary variable with expected value p_C in the control group and p_A in the active group. The treatment difference is $\delta = p_C - p_A$. If a proportion, π, of the participants assigned to active treatment do not comply with the therapy and we assume that noncompliers respond as control participants, then the observed treatment difference has expected value $\delta^* = p_C - (1-\pi)p_A - \pi p_C = (1-\pi)\delta$. Thus to maintain power, the sample size should be increased by a factor of $1/(1-\pi)^2$ (*see* **Sample Size Determination for Clinical Trials**).

Because poor participant compliance can adversely affect the outcome of a trial, it is important to use methods both to improve and monitor the level of compliance. The methods for improving compliance are largely applications of behavioral methods [4]. However, one widely used method for improving compliance is the use of a placebo run-in (see, for example, [12]). In a placebo run-in, potential participants in a trial are asked to take placebo pills (single masked) (*see* **Blinding or Masking**) for a short period of time. If the participant takes the pills as instructed, then he or she is entered into the trial. However, if the participant does not comply with the instructions on pill taking, then he or she is excluded from the trial. The assumption underlying the placebo run-in is that participants who do not comply in short term run-ins are more likely not to comply to long-term therapy. Two reports [2, 13] have challenged this assumption using either an empirical test or meta-analytic methods.

The most frequently used measure of compliance is the pill count. Participants in a clinical trial are given a specific number of doses of treatment and asked to return unused pills at the time of their next visit to the clinic. A simple calculation determines the proportion of medication unused and, by inference, the amount of medication taken. This measure has obvious problems related to the assumption that the pills not returned have been consumed. For example, a participant may have discarded some pills in anticipation of the clinic visit or pills may have been lost. Thus it is likely that pill counts overestimate compliance [8].

An alternative measure of compliance can be obtained by measuring the level of the agent in body fluids, such as blood or urine. For example, serum and urine measures of zidovudine levels are used in studies of zidovudine in HIV infected patients [10]. In this study, the association between pill count and zidovudine levels was good. This direct measure is superior to pill counts, but the cost of assays may be prohibitive in many settings.

In some lifestyle interventions, such as dietary change, such measures may be the most objective measure available for measuring compliance. Nevertheless, the correlation between the body fluid measure and compliance to the intervention may be low at the individual level, and the measure may be useful only at the group level. An example is the use of serum cholesterol levels to measure compliance with a low-fat dietary intervention.

An alternative to measuring actual blood levels is to add riboflavin to the compound. Urine samples are then collected from participants and the presence of riboflavin in the urine is measured by fluorescence. A major drawback to this method is the possible interaction of the riboflavin with the pharmacological action of the medication. Tests for the possibility of this interaction are too complex and expensive in most cases, rendering the method of little practical utility.

In recent years microprocessors have been used to monitor compliance. The microprocessor is installed in the bottle cap and programmed to record the dates and times of opening of the bottle [3, 5, 7–9]. A similar timing device has been applied in a study using an inhaler for delivery of the drug [1]. The basic assumption for the use of these devices is that the medication is taken at the time the bottle is opened. It is difficult to verify this assumption

in practice, but the method does appear to be more valid than the pill count. These devices have an added advantage over pill counts in that they provide data on compliance with the timing of the medication. Comparison of the electronic measure with pill counts indicates that compliance is estimated to be greater with the pill count than with the electronic devices [3, 11]. The electronic devices have also shown that noncompliance with the timing of doses is a sizable problem [1, 5, 6]. The major drawback to the use of the electronic compliance measures in a large clinical trial is cost.

Composite Estimators

A composite estimator is a weighted combination of two (or more) component estimators. It is important in **sample surveys** because, when appropriate weights are used, its **mean square error** is smaller than that of either component estimator. This decrease in mean square error can be considerable when the two component estimators are independent and their mean square errors are of similar size.

Studies on the use of composite estimators in specific applications often explore different component estimators and different approaches to weighting them in constructing the composite estimator. In a given application, the sample design and available auxiliary data restrict the choice of component estimators and, although, there are a number of approaches to the selection of the composite estimator weight, the mean square error of the resulting composite estimator is often **robust** to modest deviations from the optimum weight.

Early applications of composite estimators appear in the survey sampling literature in conjunction with rotational designs in which some units provide data for more than one time period (see, for example, [18] and [19]). In such situations, two **unbiased** component estimators are available: a standard estimator using data only from the time period of interest, and an estimator that adjusts the estimate for the previous time period forward to the current time using data from units surveyed in both time periods. In these applications, the sample is often designed with a composite estimator in mind.

The majority of the literature on composite estimators addresses a second type of application. When data from a sample survey become available, invariably there is demand for estimates from domains whose sample sizes were not controlled in the design. Generally, these sample sizes are too small to make reliable estimates using standard direct estimators, and indirect estimators are considered. Indirect estimators "borrow strength" through models that link the domain and/or time period of interest to others so that the small sample size in the domain of interest is supplemented by sample observations from other domains and/or times. Although domains defined by geographic boundaries have received, by far, the most attention, these methods are applicable to any arbitrary domain. For example, a synthetic estimator was used to produce selected health statistics for states in an early application of indirect estimators at the US **National Center for Health Statistics** [9, 11]. Its use is justified under a model relating units across domains within poststrata (*see* **Poststratification in Survey Sampling**) that are defined on variables correlated with the one of interest.

A composite estimator was considered in this early application but not implemented because of difficulties in defining a weighting scheme. Further research helped specify weights [15], after which a composite estimator combining the unbiased, high-variance direct estimator with the biased, low-variance indirect estimator was implemented [12]. In this composite estimator, the first component estimator was a standard direct estimator that incorporated observations on the variable of interest only from the state for which the estimate was being made. The second was a synthetic estimator that used observations on the variable of interest from the region comprising the state within poststrata defined by age, race, sex, and other related variables. The weights for the two-component estimators were chosen to minimize the mean square error of the composite estimator and were approximated empirically.

In another early application, the US Bureau of the Census used a composite estimator, composed of a direct sample estimator and an indirect regression estimator (*see* **Ratio and Regression Estimates**), to produce state estimates of median income for four-person families [4]. In yet another application, the US Department of Agriculture used a composite estimator to produce county estimates of livestock inventories, crop production, and acreage planted in selected crops [8]. In addition, a number of other government statistical agencies have considered composite estimators for the production of subnational estimates (see, for example, [1], [3], [10], and [16]).

Theoretical considerations have guided the applications of composite estimators; but, not surprisingly, different theoretical approaches lead to different component estimators and weighting schemes. In the health statistics application described above, the component estimators were treated as given and the problem was approached as a simple one of determining weights to minimize the mean square error of the composite estimator [14].

There are a number of model-based theoretical approaches to the domain estimation problem, in general, and to the derivation of composite estimators,

specifically. One such approach is provided by Royall [13] within the framework of prediction theory, a model-based approach to finite population sampling. **Regression** models relating the variable of interest to auxiliary variables lead to best linear unbiased predictors (*see* **Minimum Variance Unbiased (MVU) Estimator**) of the specified finite population quantity. Models with domain-specific parameters produce direct estimators, whereas models with parameters common across domains produce indirect estimators. In certain models, composite estimators result when a **correlation** among units within poststrata is introduced, with both component estimators and the associated weights specified by the theoretical development.

Whereas the prediction approach uses models at the unit level within domains, nested error linear models (*see* **Multilevel Models**) [5], **Bayes** [17], **empirical Bayes** [2], and hierarchical Bayes [6] methods all incorporate models that are specified at the domain level. These approaches address the problem of estimating, for example, a population mean for each of a number of domains and provide estimators that, under the model, minimize the average squared error over all domains. In fact, such approaches predominate in theoretical investigations of small domain estimation problems (see [7] for a review with discussion).

Computer Algebra

Conventional scientific **computer languages** deal primarily with the manipulation of fixed-length integers and fixed-precision **floating-point** numbers. *Computer Algebra* packages permit one to program using mathematical expressions as well, so that it is straightforward to perform such tasks (*see* **Numerical Analysis**) as:

- arbitrary-precision arithmetic,
- polynomial factorization,
- differentiation of complicated functions,
- integration of wide classes of functions.

This article begins by presenting basic common features, and by listing and giving references for current commercial computer algebra packages. There follow two simple introductory examples of the use of computer algebra in statistical contexts, and then a discussion of some typical constraints and features of computer algebra systems: it is important to be aware of these, since in this area, unrealistic expectations lead all too rapidly to frustration and disappointment. Finally, we list a few representative examples of research uses of computer algebra in statistical science, and conclude with suggestions for further reading.

Basic Common Features of Computer Algebra Systems

What might a computer algebra system have to offer to statistical users? A typical feature list includes:

- a user-interface allowing input and manipulation of mathematical formula, so that one's activity on the computer connects very directly to the underlying mathematics;
- multiple-precision arithmetic (invaluable when one has to check whether a very small value is actually positive or negative!);
- the ability to program the computer algebra system to perform routine tedious formula-manipulation tasks (e.g. computation of the **matrix** of second partial derivatives of a log-**likelihood** function);
- (for most computer algebra packages) integrated graphical and numerical facilities, thus mixing the benefits of computer algebra and more conventional computing (that is to say, based on floating point, rather than symbolic, calculations);
- almost all computer algebra systems are interactive, allowing one to experiment and to explore. This is particularly powerful when combined with numerical and graphical facilities.

Thus, a typical computer algebra system can support all kinds of mathematical calculation, particularly including exact formula-based calculations. This versatility makes computer algebra a most useful resource.

Currently Available Computer Algebra Systems

At the time of writing, commonly used commercial computer algebra systems included *Maple*, *Mathematica*and *REDUCE*. There is little to choose between them in terms of their *basic* computer algebra capabilities, though more advanced users will discover pronounced differences in underlying design philosophies. *Mathematica* and *Maple* both possess hypertext help facilities and have sophisticated "notebook" or "worksheet" front ends, which allow presentation of symbolic, graphical, and numerical results mixed with formatted text in cells in a scrollable display and permit online recalculation and modification of the results. In this as in other features, *REDUCE* takes a minimalist approach (reflecting a design philosophy which emphasizes ease of portability to many platforms).

The first edition of this article also mentioned *AXIOM* and *MACSYMA*. Sadly the innovative *AXIOM* [11] is no longer supported commercially (though readers may care to visit the website

`http://www.aldor.org/`

for the associated compiler `Aldor`). *MACSYMA* [10] is one of the very earliest computer algebra systems, and is still available in a variety of implementations both commercial and noncommercial.

There also exist largely nonprogrammable computer algebra systems such as `Derive` (though this particular system is being continuously enhanced and now offers programming capability), and free computer algebra software such as `CoCoA` (a system for calculations in algebra). However, we limit ourselves here mainly to discussion relating to the commercial systems mentioned above. Table 1 gives references

Introductory Examples

Here are two simple introductory examples, illustrating the use of computer algebra in a broadly statistical context. A different computer algebra package is used for each example, and the meaning of each of the various code fragments is briefly discussed. It should be emphasized that at this level computer algebra packages are largely interchangeable: one could as well use one as the other on such basic problems as these.

The *first example* is an application to probability **generating functions** (pgf). Since pgf's are used to translate basic operations on **random variables** into algebraic operations, they are natural candidates for computer algebra. We use *Mathematica* for this example.

Consider a (hypothetical) animal that hosts N parasites, where $\Pr[N = n] = \lambda^n(1-\lambda)$ for $n = 0, 1, \ldots,$ (and $0 < \lambda < 1$) so N is geometric. Independently each parasite gives birth to M daughter parasites, where $\mathbf{P}[M = m] = \mu^m e^{-\mu}/m!$ for $m = 0, 1, \ldots,$ (and $\mu > 0$) so M is **Poisson**. We know N has pgf $f(s) = (1-\lambda)/(1-\lambda s)$, while M has pgf $g(s) = \exp(-\mu(1-s))$. Then pgf theory tells us the total number T of descendants has pgf $h(s) = f(g(s))$ (*see* **Contagious Distributions**).

We may compute the mean by $\mathbf{E}[T] = h'(1)$, and the probabilities $\mathbf{P}[T = t] = (1/t!)[d^t h(s)/ds^t]_{s=0}$. These operations can be algebraically tedious, but are carried out without much labor if computer algebra is used. Define the functions f, g, h by

```
f[s_] := (1-lambda)/(1-lambda s)
g[s_] := Exp[-mu (1-s)]
h[s_] := f[g[s]]
```

(employing the usefully succinct *Mathematica* notation `f[s_] := ...` for defining a function of `s`), and can then compute the mean by

```
D[h[s],s] /. s->1
```

```
lambda mu
----------
1 - lambda
```

Here `D` carries out the differentiation, and `/.s->1` performs the substitution $s = 1$.

The probabilities can be computed similarly. First define the probability of there being a total of `i` parasites:

```
prob[i_] := Module[{s}, Simplify
       [D[h[s],{s,i}]/(i!) /. s->0] ]
```

This uses *Mathematica*'s `Module` command (because, purely for reasons of programming style, we want `s` to be a local variable here) and `Simplify`, because the output is lengthy enough even when simplified! Note also the iterated derivative form of `D` used here.

For output, we use an iterative `Do` loop and also *Mathematica*'s `TeXForm` facility for producing TEX output:

```
Do[ Print["p_",i," = ",TeXForm
          [prob[i]]], {i, 0, 4}]
```

We present only the last line of output:

$$p_4 = \frac{e^{\mu}\ (-1+\lambda)\ \lambda}{\times \left(e^{3\,\mu} + 11\, e^{2\,\mu}\,\lambda + 11\, e^{\mu}\,\lambda^2 + \lambda^3\right)\ \mu^4} \over 24\,(-e^{\mu}+\lambda)^5}. \quad (1)$$

(Notice that there is still cosmetic work to be done in beautifying this expression; for example, $(-1+\lambda) \to (\lambda - 1)$.)

This last command is easily altered to produce as many probabilities as might be required, and indeed

one can also alter the definitions of $f(s)$, $g(s)$ without difficulty. This demonstrates the flexibility of computer algebra for simple problems involving large quantities of calculation.

The *second example* is an application of computer algebra to the differential equations underlying deterministic **SIR epidemics** (*see* **Epidemic Models, Deterministic**). We use *Maple* for this example.

The underlying differential equations are given by

$$\begin{aligned} \frac{dx}{dt} &= -\alpha x y \\ \frac{dy}{dt} &= \alpha x y - y \\ \frac{dz}{dt} &= y \end{aligned} \tag{2}$$

This is a nonlinear system, so we do not expect to be able to solve it explicitly. However notice that the differential equations for dx/dz and dy/dz are linear, so we may hope to obtain a partial solution using the linear ODE solver `dsolve` of *Maple*. First define the differential equations:

```
SIR :=  diff( x(z), z ) + alpha *
                x(z),
        diff( y(z), z ) - alpha *
                x(z) + 1;
```

We then employ the solver, adding in initial-value conditions and the variables for the differential equation:

```
XYsoln := dsolve( {SIR, x(0) = 1,
        y(0) = n-1}, { x(z),
        y(z) }, 'laplace');
```

where ``laplace'' signifies that the solver `dsolve` is to use the method of Laplace transforms. The result is

```
XYsoln := {y(z) = n - z - exp(-
      alpha z), x(z) = exp(- alpha z)}
```

We can now substitute this back into the equation for dz/dt:

```
Zequation := diff(z(t),t) =
    subs(XYsoln, z = z(t), y(z));
                d
Zequation := ---- z(t) = n - z(t)
                dt
              - exp(-alpha z(t))
```

The resulting ODE cannot be solved for z, but we can obtain a series solution by altering the ``laplace'' directive to ``series'':

```
  Zseries := dsolve( {z(0)=0,
        Zequation }, z(t), 'series');
z(t) = (- 1 + n) t + (- 1/2 alpha +
  1/2 alpha n + 1/2 - 1/2 n) t^2 + O(t^3)
```

Here we have truncated the series to $O(t^3)$ simply to fit the output on the page. Without much further work, one can produce a higher-order series expansion, and use it to further expand the previous solution to x and y. (It is also possible to solve the differential equations numerically within *Maple*, but this leads us too far from our remit.)

Basic Considerations for the Use of Computer Algebra

When choosing which computer algebra system to learn and to use, the dominant consideration should be to find out what system is used by the nearest friendly expert. Readily available expert help is enormously important in getting the most from sophisticated mathematical software. There are differences between systems (further insight on this can be gained by reading some of the critiques and comparisons referenced below), but these are usually of less practical significance than the immediate availability of helpful advice. Note that these systems can all be augmented by writing programs in computer languages specific to the respective systems, and are being actively and vigorously extended by enthusiastic user communities, so that comparison of feature lists is not as relevant as might at first appear.

However, even the casual user, of whatever system, needs to be aware of typical features and constraints of computer algebra computation. Some of these arise out of the very nature of the tasks being performed. For example, the basic unit of computation in a computer algebra system is the representation of a mathematical expression as a list of symbols (for example, $1 + 2x + x^2$ as {+,1,{*,2,x},{^,x,2}}) (for this reason, a common synonym for the term "computer algebra" is *symbolic computation*). These lists can grow to extraordinary lengths in the course of a calculation! (Consider the result of dividing $1 - x^n$ by $1 - x$ when n is some large integer.) This contrasts with conventional scientific

computation, in which the basic unit of computation is a fixed-length bit-sequence representing an integer or floating-point number represented up to machine accuracy. In general computer algebra can be very memory-hungry, and it is strikingly easy to attempt manipulations which in their intermediate stages require huge amounts of memory even if the final result is concise ("intermediate expression swell"). In practice such problems can often be evaded by breaking the task down into more manageable subtasks: success in computer algebra therefore requires persistence and flexibility.

A related problem is that ill-considered computer algebra computation can produce a vast mass of uninformative output, for example, in statistical asymptotics. Of course this is a problem in more conventional computing too, but Hamming's remark "The purpose of computing is insight not numbers" applies with particular force to the practice of computer algebra.

There are other issues: square roots have to be handled with care (since the sign of the root is ambiguous); numerical stability when using numerical interfaces; possible software bugs (computer algebra systems are as prone to bugs as any other large computer program!); some tasks (such as definite integration) do not admit algorithmic solutions and so cannot be implemented in a completely satisfactory way.

Most of the above issues are magnified versions of problems that have to be confronted by anyone undertaking a large calculation: and if they cause more trouble for computer algebra then it is largely because the calculations tend to be larger in scale. In particular, the question of error-free computation is just as pressing for humans as for computer programs! Neither computer algebra nor any other technique can be a replacement for careful thought about a problem.

Examples of Computer Algebra in Statistical Science

To make the case for computer algebra as a useful tool, here is a list of some recent applications drawn from the statistical research literature.

Currie [4] describes the solution of several statistical **maximum likelihood** estimation problems using *Mathematica* in a conceptually simple way (compute the likelihood, then maximize it etc.). As the author points out, this is limited in scope because it makes no use of any special structure which might be present. Nevertheless, two of the statistical problems presented are themselves taken from the recent statistical literature.

This sort of application might equally be carried out using numerical software such as *MATLAB*, except that computer algebra allows one to use the computer to manipulate expressions algebraically (and thus exactly) before committing to floating-point computation. In fact, there are now several examples of symbiotic relationships between computer algebra packages and general purpose numerical analysis software: for example, *MATLAB* can be interfaced to *Maple*.

A more extensive example of *conceptually* simple computer algebra (although possessing formidable technical content) is described by Mannion [16], who uses *REDUCE* to solve a problem in geometric probability posed by Klee, namely, the expected value of the volume of a tetrahedron whose vertices are chosen independently and uniformly at random from within a parent tetrahedron of unit volume.

Use of more sophisticated computer algebra algorithms is discussed in the monograph of Pistone, Riccomagno, and Wynn [17], who consider the use of computational algebra in, for example, issues of **confounding** for statistical models arising in **experimental design**. Let M be a family of **polynomial regression** models $y = p(x) + \varepsilon$ parameterized by $p(x)$, which is the corresponding (multivariate) polynomial in $x = (x_1, \ldots, x_n)$. Statistical identifiability of M corresponds to the question of whether $p(x)$ and $q(x)$ from M agree on all design points x, and this is related in turn to questions of computational algebraic geometry, namely, the theory of Gröbner basis algorithms. Pistone and Wynn discuss the use of the Gröbner basis algorithms in *Maple* and CoCoA in this and other statistical contexts.

Expansions in statistical asymptotics are notorious for leading to lengthy and laborious calculations. Andrews and Stafford [2, 3] describe a cooperating family of *Mathematica* procedures serving as tools to perform such expansions. Collectively the tools provided by Andrews and Stafford provide an environment which the researcher can use to speak statistical asymptotics to the computer.

An example of computer algebra in applied probability is its application to Itô calculus. Recall that Itô calculus allows one to do calculus with **Brownian**

motion instead of smooth functions, thus providing a flexible means of representing diffusions and other continuous random processes. The price to be paid for this flexibility is that the usual fundamental theorem of calculus, namely,

$$\frac{\mathrm{d}}{\mathrm{d}t} f(t) = f'(t) \tag{3}$$

has to be replaced by the celebrated Itô formula, which takes the following form for Brownian motion B:

$$\mathrm{d}\, f(B) = f'(B)\, \mathrm{d}B + \frac{1}{2}\, f''(B)\, \mathrm{d}t \tag{4}$$

This leads to complicated formulae, which has motivated a number of workers to program the resulting structure into a variety of computer algebra packages. The earliest example is to be found in [12], which used a *REDUCE* implementation to solve problems in the statistical theory of **shape**. This implementation can be understood as a formal translation of the underlying algebra of stochastic differentials into the computer algebra package. It has been translated into *Mathematica* [13] and applied to mathematical finance problems, as well as to a number of other research problems.

Further Reading

We have already referred in Table 1 to some books introducing various computer algebra packages. Other valuable literature resources for computer algebra users include a number of critiques and comparisons of computer algebra systems. These are useful not so much at the stage of choosing which computer algebra system to use (as indicated above, this is more likely to be controlled by local availability) but rather after a certain amount of computer algebra experience has been gained. It can then be very helpful to get some insight into the effects of varying design philosophies, which helps one better understand the features and strengths of one's chosen computer algebra system.

Good general introductions to computer algebra are (naturally enough) specific to particular computer algebra systems: [9, 10, 18] and the first parts of [11, 21] all provide very good guidance for beginners using the respective systems.

Fateman has written an excellent critique of *MACSYMA* [6], and also of *Mathematica* [7], which should be required reading for all serious users of computer algebra. Comparisons of various systems are to be found in [8 , 19, 20, 22]. In all these cases, readers should be aware that, for obvious reasons, the computer algebra systems reviewed are usually not the versions currently on market.

Finally, discussion of the basic algorithms employed by computer algebra systems can be found in [1, 5]. This will be useful particularly for workers needing to use advanced features such as Gröbner basis algorithms.

WILFRID S. KENDALL

Computer Architecture and Organization

Introduction

Computer technology has made amazing progress since the first general-purpose electronic computer was created half way through the last century. Today less than a thousand US dollars will purchase a computer that has more performance, more memory, and more communication capabilities than a computer bought in 1980 at a cost of one million US dollars. This improvement is driven both by advances in the technology used to build computers and increasingly by innovations in computer designs harnessing the tremendous capabilities of integrated circuits.

A *computer architecture* refers to those parts of a computer system that are visible to a programmer, whereas a *computer organization* refers to those operational units and the interconnects, not visible to the programmer, that realize the architectural specifications. As a simple example, it is an architectural design issue as to whether or not a computer will have a multiply instruction. It is an organizational issue whether that instruction will be implemented by a special multiply unit or by a mechanism that makes repeated use of the add unit of the system. The distinction is important as one can have machines with the same architecture but different organization. Such machines will typically have different price and performance characteristics but will be able to run the same programs – in which case they are said to be compatible.

The aim here is two-fold: One is to give an overview of modern computer architectures and their organization. The second is to outline programming practices that will lead to efficient use of commonly available computer systems.

Building Blocks of a Typical Computer

A computer is a complex system containing millions of electronic components that can interact in billions of configurations. The key to understanding and describing such a system is to recognize that most complex systems, including the computer, possess a hierarchical structure [11]. With a hierarchical system, we need only deal with one particular level at a time. The behavior at each level depends only on a simplified, abstracted characterization of the system at the next lower level. This model is applicable to both hardware and software design.

At the highest level, we can view the computer as a system consisting of four components: The central processing unit (CPU), main memory, input/output (I/O), and control.

- **Central processing unit (CPU):** This is the "brain" of the computer. Its function is to execute programs by fetching their instructions, examining them, and then executing them. Execution of one instruction typically involves loading of data into main memory or adding two numbers. Distinct components of a CPU are the arithmetic and logical unit (ALU), which performs the computer's data processing functions on integers, floating point unit (FPU), which takes care of computations on real numbers, registers, which provide very fast storage within the CPU, control unit, and CPU internal communication.
- **Memory:** The function of memory units is to store programs and data for retrieval by the CPU. Memory can be classified as primary storage and secondary storage. Primary storage, also known as *Random Access Memory* (RAM), is electronic memory that operates at a relatively high speed but requires a power supply to retain data. Secondary storage, typically magnetic disks, tapes, and optical disks (CDs and DVDs), is mechanical and therefore generally slower. However, it is significantly cheaper and also persistent in the sense that data is retained more or less indefinitely.
- **Input/Output:** Moves data between the computer and its external environment, for example, keyboard, mouse, monitor, printer, networks, or other computers.
- **Control:** Provides for control and communication among CPU, memory, and I/O.

Each of these components constitute complex hierarchies of their own and there may be one or more of each of them in one computer.

Performance

The components described above each have their own set of performance characteristics and achieving

a balanced system in which all components make comparable contributions to the overall performance is a complex and delicate task. An overview of the most important performance issues is given in the following.

CPU Speed and Moore's Law

The speed with which a CPU performs its tasks is normally given as *clock frequency*, these days measured in GHz (gigahertz). The clock defines regular time intervals, *clock cycles*, used to synchronize the various subsystems of the CPU. To execute an instruction, the CPU divides the action to be performed into a series of basic steps such that each step can be completed in one clock cycle. A clock frequency of 1 GHz, therefore, means that the processor can complete one step every nanosecond (10^{-9} s). Be aware, though, that the clock frequency is a measure of the speed of which the processor is capable; the maximal performance will only be realized if the data to be processed are available when needed. For more information on this topic, see below and, for example, [5, p. 16, 329ff] or [13, pp. 39–56].

Gordon Moore [8] observed as early as 1965 that the number of transistors that could be placed onto a single chip was doubling every year – a phenomenon now known as *Moore's law*. To the surprise of many, including Moore, this exponential pace continued year after year into the subsequent decades (after 1970, the number of transistors roughly doubled every 18 months). The consequences of Moore's law are that CPU speeds increase due to the shorter distances between transistors, devices shrink in size, power and cooling requirements are reduced, reliability increases with fewer interchip connections, but the cost of making a single chip remains nearly constant, which, overall, leads to dramatic reductions in the costs of computer circuitry. [12, pp. 31–32].

Caching

Clock rates have roughly doubled every 18 months over the past three decades according to Moore's law. However, while processor power has raced ahead at breakneck speed, other critical components (e.g. memory, disks, communication speeds) of the computer have not kept up. Consequently, there is a constant need for *performance balance*, an adjustment of the computer organization to compensate for the mismatch among the capabilities of the various components. Nowhere is the problem created by such mismatches greater than in the interface between the processor and main memory (RAM).

While the *size* of computer memory has increased according to Moore's law, the typical storage and retrieval *speed* of memory has only increased by about 10% per year [9, p. 243], leading to an increasing gap between the speed with which the CPU can process data, and the speed with which the memory can feed the "monster". Figure 1 illustrates that while clock frequencies have increased from kHz to GHz ranges over the last 30 years, memory access times have only increased from their speeds in 1970 by a factor of approximately 7% per year to a couple of hundred MHz. If memory access fails to keep pace with the processor's demands, the processor will stall in a *wait state* and valuable computational time is lost. For more details, please consult [5, p. 304] or [6, pp. 391, 454–460, 501].

It is technologically possible to make memory that is sufficiently fast to match current clock rates but such memory is very expensive and must be located inside (or very close) to the CPU. This puts a limit on the size of such fast memory. The primary strategy for dealing with this dilemma is to combine a small amount of fast memory (called a *cache* and pronounced "cash") with the relatively slow but large RAM memory.

The basic observation is that memory references made in any short time interval typically use only a

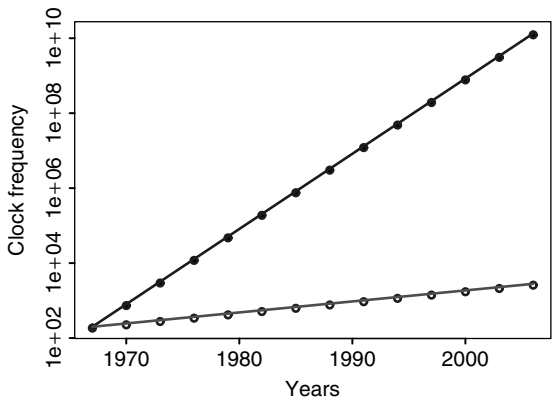

Figure 1 Gap in performance between memory (circles) and CPUs (dots) plotted over time

small fraction of the total memory. This leads to the *locality principle* that is fundamental to all caching systems. When a piece of data is referenced, the data and some of its neighbors are brought from slow memory into the quicker cache so that next time some, or (even better) all, of them are used, they can be accessed quickly.

Design issues such as ensuring that cached data agrees with data in memory, determining optimal cache size, associativity (where in the cache memory blocks can go), whether or not to cache instructions and data separately, are beyond the scope of this treatise. The message for the programmer is that good performance requires respect for the locality principle. It is better to reference elements in an array consecutively rather than in strides greater than one or, even worse, randomly. In addition, one should process a large amount of data block-wise rather than trying to load all of it and then, naively, work from one end to the other. The goal of both strategies is to maximize access to data loaded into the cache before that data gets replaced.

Most operating systems are designed so that data in memory, which is not currently in use, may be temporarily moved to disk in order to free up space. This process, called *swapping*, is necessary for the normal operation of a computer. However, excessive swapping will eventually lead to a phenomenon called *thrashing*, which is an undesirable situation in which the computer spends a large fraction of its time needlessly moving data around. Although thrashing rhymes with "caching", it is extremely detrimental to performance. A good blocking strategy will not only make good use of the memory hierarchy but also help avoid thrashing.

Modern compilers generally scrutinize source code at compile time to ensure that the executable code makes good use of the memory hierarchy. However, it is often necessary to help the compiler in this aspect by observing the locality principle; see for example [6, Chapter 5], [12, p. 41], or [13, p. 65] for thorough discussions of caching.

Memory Hierarchies

> No matter how big the main memory is, it is always too small.
>
> Andrew S Tanenbaum

The caching idea is usually applied at many levels: External cache memory itself is cached in even faster memory inside the CPU, which in turn is cached in registers. Parts of the main memory often serve as disk cache and the disk, in turn, may cache data from a web site or external media such as magnetic tapes. This entire set is known as the memory hierarchy. At the top, we have the CPU registers, which can be accessed at full speed. Next comes the cache memories, internal as well as external to the CPU, which are currently of the order 32 kB to a few megabytes. These cache memories are often referred to as level 1 and level 2 cache, respectively. Main memory is next with sizes ranging from 64 MB to tens of gigabytes. This is followed by magnetic disks and then slower devices such as tapes, CDs, DVDs, floppy disks, and even the whole **internet**. Figure 2 illustrates a conceptualized memory hierarchy.

Achieving Performance

Even though today's computers are capable of performing tasks at unprecedented speeds, there is no guarantee that this will hold true for any individual program. In fact, very few programs utilize the CPU fully and most computers spend their life moving data around rather than processing it. There are a few basic rules and pitfalls that, if observed properly, can increase the performance of a given program dramatically.

- **Make the common case fast:** This is perhaps the most important principle in both hardware and software design. By favoring the frequent event over the infrequent event, overall performance can be greatly improved. An example would be to replace a general solver of linear equations by a faster banded solver in (frequent) cases where equations have a banded structure; see, for example, [6, p. 39] for details.
- **Observe the locality principle:** Work with the cache memory by accessing data consecutively and process large amounts of data block-wise rather than from one end to the other; see for example [6, pp. 432–433] for examples of both strategies.

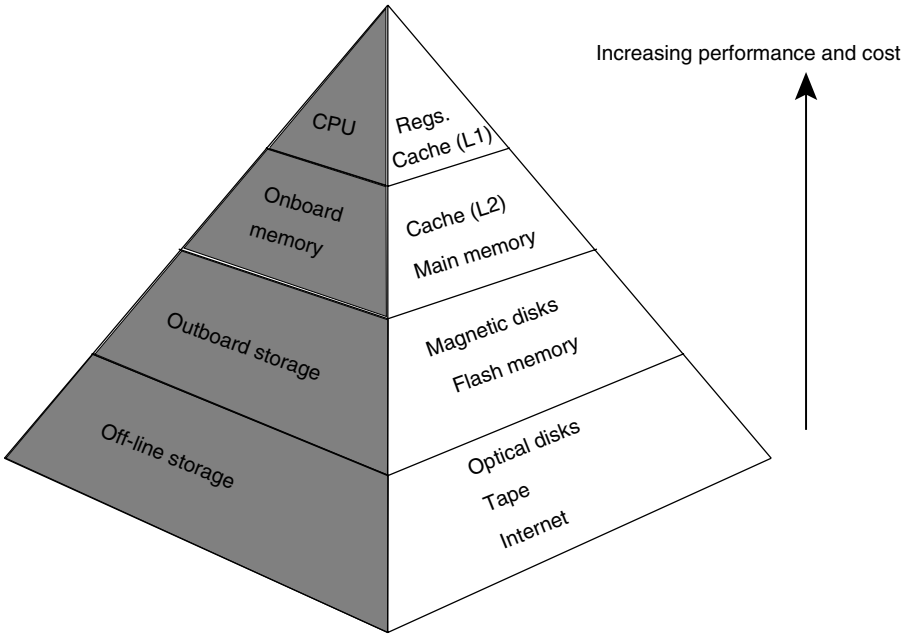

Figure 2 A typical memory hierarchy. Memory media at the top are fast but expensive. Media at the bottom are slow and cheap

Parallel Architectures and Distributed Computing

Increasing clock speeds and making CPUs smarter is one way of achieving greater performance. However, at any given point in time, there is a limit to the performance current technology can achieve for one processor.

An important improvement is to look for concurrency or parallelism where more than one functional unit is employed in order to exceed the performance of one unit. Parallelism comes in two general forms: *Instruction-level parallelism* and *Processor-level parallelism*. In the former, parallelism is exploited within individual instructions to yield more instructions per second out of the machine. In the latter, multiple CPUs work together on the same problem.

Instruction-level Parallelism

To execute a typical instruction, the CPU goes through a number of stages:

1. Fetch the instruction
2. Decode the instruction
3. Fetch the operand
4. Execute the instruction
5. Store the result.

Assuming that each stage can be completed in one clock cycle, the total execution time will take five clock cycles to complete.

Pipelining is a technique whereby multiple instructions are overlapped as in an assembly line. Each stage is carried out by a separate specialized unit operating in *parallel* with other units, although on a different instruction. As an example consider five instructions: During clock cycle 1, Unit A is fetching instruction 1, during cycle 2 Unit A is fetching instruction 2 while Unit B is decoding instruction 1 and so forth. Once the pipeline is full, that is, when the first instruction has been completed, this scheme will complete one instruction for every clock cycle instead of one for every five cycles. Pipelining is a key method for increasing CPU performance [6, p. A-2].

A higher degree of concurrency can be achieved by using multiple pipelines (possibly designed for specific operations such as floating point instructions) to fetch and execute several instructions in

parallel. This is known as *superscalar execution* and can provide execution of more than one instruction per clock cycle. The Pentium family, for example, employs multiple pipelines [13, p. 52]. Of course, the execution must preserve the logical correctness of programs, so extra control hardware and sophisticated compilers are needed.

Vector processors are specialized to operate on long arrays of numbers using pipelining [12, pp. 655–656], [13, pp. 54, 556]. Prominent examples of vector computers are members of the Cray family and the Fujitsu VPP family. Here, the programmer needs to pay special attention to the time taken to "fill up" the pipeline (latency) because it can be significant in the scheme of things. Fortunately, practices similar to those for utilizing caching apply: Operate on long consecutive vectors whenever possible.

Processor-level Parallelism

When multiple CPUs or even multiple computers are combined to solve a task, we talk about processor-level parallelism. Each individual processor may (and typically will) still utilize elements of instruction-level parallelism as described above.

One way of classifying these architectures is according to whether the processors have access to the same memory address space or, alternatively, each CPU has its own memory but communicates with others through a (typically high speed) network. In the former case, we talk about *shared memory machines* or *multiprocessors* while in the latter we talk about *distributed memory machines* or *multicomputers*. Examples of shared memory multiprocessors are the SUN Enterprise, which typically has up to 12 processors sharing a common memory or Pentium PCs with more than one processor. Examples of distributed memory multicomputers are IBM SP2, Compaq Alpha, and all configurations of the *Beowulf* type. The latter comprises a number of off-the-shelf PCs connected with a fast network to form a relatively inexpensive parallel computer; see for example `http://www.beowulf.org` for further details. With shared memory architectures, processors communicate by reading and writing to the same memory, whereas distributed memory architectures rely on explicit communication (often implemented as *message passing*) for interprocessor communication.

Programming shared memory machines is often considered easier than programming distributed memory machines, the reason being that one does not have to worry about where data is located. However, this is somewhat deceptive as *parallel performance* depends strongly on the spatial location of data. The locality principle applies here as well – and in the case of parallel computers, it has to be observed for every processor. Hamacher et al. [5, pp. 648–653] has a worked example of a parallel program written for both paradigms.

Fortunately, the same general guidelines apply to both parallel architectures and the goal is the same, namely, to be able to complete a certain task faster and/or be able to deal with larger problems.

Achieving Parallel Performance

One measure of parallel performance is the *speedup* defined as $S_P = T_1/T_P$, where T_P is the time required to execute a specific task on P processors. The ultimate aim is to be P times faster with P processors, that is $S_P = P$. However, observed speedup is usually less than this ideal and any speedup above $0.75P$ is considered to be good. One must address three critical issues to achieve good speedup:

- **Interprocessor communication:** The amount and the frequency of communications should be kept as low as possible in order to minimize the time processors spend waiting for data. This is the same theme as that of slow memory access preventing full utilization of processors, only much worse in this case due to network speeds being slower than memory speeds. Each communication has a fixed startup time (*latency*), which is independent of the amount of data to be transferred. Frequent transfers of a number of small blocks will, therefore, take longer than transferring all blocks in one bundle. Ensure that interprocessor communications are as infrequent as possible and that processors are busy between transfers; see, for example, [3, p. 23] or [6, p. 546] for details.
- **Data distribution and load-balancing:** The total execution time of a parallel program is determined by that of the slowest processor. If some processors finish much sooner than others, we say that the program is poorly load-balanced. Each processor should get its fair

share of the work load; see, for example, [3, p. 26] for details.

- **Sequential parts of a program:** If half of a program, say, is inherently sequential, the speedup can never exceed 2 no matter how well the remaining half is parallelized. This is a special case of what is known as Amdahl's law. Ensure that all the cost intensive parts are parallelized; see, for example, [3, p. 24], [5, p. 654] or [6, pp. 40, 537] for details.

Consult [10] for a representative example of how to analyze parallel performance.

Examples of Parallel Applications

Of particular interest to the readers are the following examples of the use of parallelism in biostatistics.

- *Parallel Inference Machine* (PIM) is a massively parallel controller designed to execute thousands of control programs concurrently and in real time. Several **bioinformatics** algorithms including *Basic Local Alignment Search Tool* (BLAST) have been implemented on this specialized architecture; see `http://www.paracel.com/faq/faq_algorithm_primer.html`.
- Apple's version of BLAST is developed in collaboration with Genentech and the Stanford University Genetics Department. It takes advantage of algorithmic improvements, advanced memory management and the ability of Apple's Power PC G4 processor to perform multiple operations per clock cycle. This is an example of how performance can be increased by writing and tuning software specifically for a particular computer architecture. However, this often comes at the expense of portability since such software rarely performs well (if at all) on other architectures; see `http://developer.apple.com/hardware/ve/acgresearch.html`.
- Turbogenomic's *Turboblast* delivers BLAST jobs across Beowulf Clusters and other distributed architectures in parallel; see `http://www.turbogenomics.com/products/turboblast_index.html`.

Future Directions

> It is difficult to make predictions, especially about the future.
>
> Robert Storm Petersen

For as long as people have attempted to predict the future of computer architectures, the view has been common, that growth of uniprocessor performance must soon end. Yet as various physical limits were reached, a new technology or approach would emerge yielding continued performance growth according to Moore's law. However, we may at last be approaching a fundamental limitation of silicon and many believe that improvements will slow down over the next 10 to 15 years [6, pp. 528, 648]. In any case, it is almost certain that parallel architectures will play an increasing role in the future, both in the form of tightly knit clusters (such as traditional parallel computers) and in the form of widely distributed networks. One important factor is that the available bandwidth, due to advances of fiber optics, is now growing even faster than Moore's law. This suggests a paradigm shift from a "CPU-centric" view to one where the network itself is central and processors are regarded as peripherals; see [4] or `http://www.gildertech.com`.

A new initiative dubbed *The Grid* promises to fundamentally change the way we think about and use computing. This infrastructure would connect multiple regional and national computing grids creating a universal source of ubiquitous and dependable computing power similar to the electricity and telephone utilities that have existed for almost a century; see [2], `http://www.gridcomputing.com`, or (for a bioinformatics example) `http://www.ncbiogrid.org`.

Other related trends are the emergence of *wireless interconnects* such as Bluetooth (`http://www.bluetooth.com`) and the use of small dedicated (as opposed to general purpose) computers, such as personal organizers, palmtops, fitness/diving/cycling computers, global positioning systems, and so on. Together with grid projects such as Globus, NetSolve, Condor, CUMULVS, WebFlow, they promise to make computing in the future less dependent on local resources and more universally available. For more recent thoughts about the future of computer architectures, see [1], [6, pp. 528, 644–645], or [7].

Computer Languages and Programs

Introduction

Computer languages are artificial languages that enable humans to give instructions to computer systems. Texts written in these languages are called *computer programs* or *code*. To run a program, a *compiler* or *interpreter* (themselves computer programs) must translate the program into *machine code*, which the hardware is able to execute directly. It is possible, but nowadays uncommon, to write programs directly in machine code, or rather in its mnemonic equivalent, *assembly language*.

The history of programming languages has seen the development of languages ever further removed from the machine code level. Not only is assembly language difficult to program but also every variety of computer central processing unit (CPU) has a different code. By contrast, modern high-level languages such as Java [2], Python [16], Matlab [10], and S (*see* **S-PLUS and S**; **R**) [21], are easier to understand; each command represents many lines of code in a lower level language and the code is not dependent on the CPU.

Classifications of Languages

Languages are classified in several different ways, such as by their historical development or computational level, by the sorts of applications for which they are commonly used, by the style of programming that they support, and by how they are translated to the computer's machine code.

Historical and Computational Level Classification

At one time, it was common to speak of "generations" of language development, with machine and assembly language being the first two. At the next level up, the older style of "high-level" languages, such as Fortran and C, were third generation or 3GL languages. In subsequent development beyond such "3GL" languages, any attempt at classification according to language generations breaks down; further development has gone in several different directions. The advances brought by new language developments add to human usability, both by compacting major functions from an earlier generation to a single command in the newer generation and by the use of more powerful conceptualizations. For complex tasks, the reduction in programming time and effort can be spectacular, leading at the same time to programs that are simpler and easier to maintain. Advances may, additionally, be in complexity of data structure, in orientation towards specific applications, in the generation of code from graphical interfaces, in scripting languages, in systems that allow the integration of components that may be written in different languages, in natural language recognition, and in so-called expert systems.

Classification According to Type of Application

C was attractive to programmers because it allowed much of the fine control that is available from assembly language. C^{++} is an extension of C that incorporates more modern language design features (see [2, 8]). C/C^{++} have found extensive use in writing compilers for other languages and in writing operating systems. Java, developed from C^{++}, has quickly gained a key role in **internet** applications. It has well-developed mechanisms for handling computing tasks, including graphics and animation, which involve multiple networked computers (*see* **Computer Architecture and Organization**). For example, the S language [3, 21] that is implemented in S-PLUS and R had in mind, data analysis, graphics (*see* **Graphical Displays**), and related scientific applications (*see* **Software for Clinical Trials**; **Software, Epidemiological**). Mathematica [24] was designed as a language and an environment for handling mathematical tasks, including symbol manipulation. Perl [15] was designed, initially, for use in system administration. It has found wide use in text searching and manipulation.

Programming Style Classification

Perhaps the most insightful classification of languages is by the style of programming that they support. A common distinction is between structured, logical, functional, and object-oriented programming, with modern languages often incorporating elements of all these approaches.

In structured programming, a problem is broken down into a sequence of steps that manipulate the

input data to produce the desired output. The program expresses these as commands to the computer, so that this is an *imperative* approach. The computer then runs this set of commands sequentially from beginning to end. Within this sequence of steps, discrete subtasks are usually identified and written into *procedures*. Hence, this approach is sometimes called *procedural*. Fortran and Algol pioneered this approach in the mid-1950s, and it continues to be in major use today. Languages that are in this tradition include Java, Delphi, Python, C, C^{++}, and Fortran; see [2, 8]. Usually, programs can share procedures that are located separately from the main program in a *library*.

Functional programming takes a different conceptual approach, where instead of executing commands, the program evaluates expressions or functions. Such languages have found wide use in the writing of systems for the text processing that is required for compilers and for the processing of natural languages. Languages that support this style of programming include Lisp and Scheme, which is a dialect of Lisp; see [8] for further details and background. The Emacs editor, which is popular as an interface to statistical systems such as S-PLUS and R, is embedded in a Lisp implementation. Lisp is a mnemonic for "list processing"; all operations are performed by modifying lists.

Prolog implements logical programming. Like functional programming, this is *declarative* rather than imperative, with a program closely resembling a logical proof. Both predicate and propositional logic are included in the language. While mainly used in **artificial intelligence** research, applications have included chemical structure databases (*see* **Chemometrics**) [11].

Object-oriented programming has recently come into prominence. In this approach, models for data are central. A data *object* encapsulates knowledge, both of data *attributes* and of procedures (*methods*) that may be applied to the object. For example, a "distribution" object may have attributes such as the number of data points, and the value of each, and methods to print histograms, estimate density curves, calculate standard deviations, and so on. The Java and C^{++} languages are the best known implementations, while many others, including S, have incorporated object-oriented features.

Excel has its own built-in language that allows its use for quite complex programming tasks. The key idea here is that of a spreadsheet whose entries are progressively modified as calculations proceed. The spreadsheet model is suitable for many simple accounting and data manipulation tasks, but is easily pressed beyond its proper limits for use in tasks for which Python or R or Mathematica would be more appropriate.

Quite different from any of the languages just noted are *markup languages*, of which HTML, XML, and TeX/LaTeX are well-known examples. These are texts that are designed to be "read" by a computer program, which then transforms them in some useful manner. For example, a web browser is a program that, among other functions, translates a file of HTML text into a display showing some portions of the text, while using other portions as instructions for layout, fonts, colors, and so on. The interchange of texts between these different systems can be a challenge [4].

Computer Translation Classification

The method of translating the language from its human readable form to a machine-usable form also varies between languages. There was once a simple choice between *interpreted* and *compiled* languages, with programs in interpreted languages referred to as *scripts*. The general wisdom was that interpreted languages were useful for small quick jobs, and could be quick to develop, but that a compiled language would be best for speed and stability.

When a language is compiled, a program called a compiler scans the human readable *source code*, and translates it into an *object file*, which the machine can execute. A pure interpreter, by contrast, does not preprocess, but scans the script line-by-line, translating into machine code on the fly. This removes many of the possibilities of optimization that a compiler can use, as well as many opportunities for error checking. Pure interpreters still exist in UNIX shell scripting. Compilers, and to some extent, interpreters, are specific to the particular type of machine or CPU. Language features may also be specific to particular types of machines, or to the operating system.

While compiled languages remain more efficient, the increased speed of computers, and access to segments of compiled code for computationally intensive tasks, has made this efficiency less important than earlier. Scripting languages such as Perl and Python [16] are now used for major applications, and

especially for web-based applications. Such scripts can, if necessary, be compiled.

More recently, languages have become hybrids, with both compiled and interpreted implementations or with multipass interpretation where code is translated into an intermediate state. The intermediate state may be virtual machine code – an approach that was pioneered in Smalltalk [8] and best known in Java. In this case, the same code can be used on any system that has its own virtual machine. A closely related approach is used in other languages including Perl and Python, where the intermediate state is a *parse tree* – a representation of the structure of the whole program in a form that is then executed by an interpreter. This is sometimes called "compiling", as parsing is usually a function of compilers. However, because no machine code is generated, this usage is disputed.

Abstract Representations of Problems

A modern view of computer languages is that they support abstract representations of problems in a form adapted to computer implementation. Thus, for the production of a simple form of rhyming dictionary, we may replace "riming" by "gnimir", "timing" by "gnimit", "liver" by "revil", and so on. After sorting, we restore the order in which the letters initially appeared within strings. The use of an abstract representation of an array of words is just as crucial as the procedural abstractions that reverse the order within words and sort words in a lexicographic order. All languages support some level of data abstraction, control abstraction, and procedural abstraction. They may allow entities that combine two or more of these basic forms of abstraction. Further detailed discussion of computer languages from this perspective is beyond the scope of this article.

Nonverbal Communication

Human communication makes extensive use of visual and tactile signals that supplement spoken language. Similarly, the point and click mechanisms of windowing systems supplement rather than replace keyboard or spoken language, and will develop into forms of communication that are richer and more versatile as yet. Visual programming approaches, where a symbolic visual representation describes the computation, can reduce the risk of logical errors in the written code.

Program Design and Implementation

Computer languages are used to construct computer programs. The range of applications is wide – examples are accounting, inventory management, maintenance of patient records, medical and other instrumentation, electronic mailing systems, statistical analysis, and so on. In these and other applications, computer programs may be expected to respond correctly to a huge range of possible inputs.

For simple problems, the writing of a program may be a straightforward use of computer language skills. For large and complex computer programs, program development must be carefully designed and managed. The article on **algorithms** discusses issues that are important for the design of individual components – functions or subroutines – of a computer program. The remainder of this section will comment briefly on software engineering issues that are important for the design and execution of large computer programs.

Steps in a large software engineering project will include: determination of requirements, construction of a specification, design of a computer program, and the writing of code that will implement the design. There should be careful testing at each step. When programs demand the combined efforts of a number of programmers, there must be an effective overall human management.

There have been spectacular failures that emphasize the considerable challenge to software designers and programmers (*see* **Software Reliability**, and [9, 13]). Checks in both hardware and software must ensure that inevitable occasional failure, whether from human error, from an operator error, or from an unanticipated interaction between operator and software, will not have catastrophic consequences.

Program Design Concepts

Key ways to manage complexity, additional to those that we have already described, include the use of encapsulation to hide the information not needed outside of the program module or object, the use of modularity to break programs into separate identifiable components, and the use of hierarchy to impose

a readily intelligible structure on the abstractions used for describing and implementing the program. Additionally, reuse of program modules assists documentation and maintenance, and reduces the burden of testing. Reuse strategies seem to be a particular strength of object-oriented programming.

Until the program is complete, no final check is possible. A prototype, typically an executable program shell from which many individual modules are incomplete or missing, may allow limited early testing. A prototype may be invaluable for helping clarify user requirements and design issues, in checking major aspects of program structure, and as an evolutionary step towards the development of the final product. Efficiency may not be an important consideration at the prototype stage.

Computer Language Use in Statistics

Statisticians have taken an interest in computer language development since its beginnings in the 1950s [5]. Efforts to bring together a code for frequently repeated tasks led to the development of libraries of subroutines or programs. The demand for coherence and uniformity led to the full-fledged package in which a master program handled major aspects of input and output and gave a common interface to the separate routines. Some packages quickly developed abilities for looping, branching, and conditional execution, which match those in, for example, Fortran. They may have added new features as occasion demanded, often without adequate regard to good overall design.

An alternative approach is to begin by developing a statistical language, then using the language to implement statistical analysis abilities. Lisp-Stat [20], which embedded statistical analysis abilities within the Xlisp dialect of Lisp, was an early example of this approach. The language S [3, 21], available commercially as S-PLUS (*see* **S-PLUS and S**) was designed and developed as a language for interactive data analysis and graphics, into which statistical abilities were then embedded. The **R** system [6, 17], which is a free (General Public Licence) implementation of a dialect of the S language, has become a popular environment for developing and testing new statistical methods.

Other languages that have been used by statisticians, and that are now mainly of historical importance, at least for statistical computing, include BASIC and APL [1]. BASIC was adapted to provide an interactive operating, editing, and programming environment on the first generation of microcomputers, beginning in 1975. APL (1962) was characterized by a heavy use of vector and matrix operators, and severe notational complexity. APL and BASIC went some way to providing, in their different ways, demands for an interactive programming environment in which it was easy to move between code development and execution. Much improved responses to these demands are now available.

Data Analysis as Experimental Programming

Statistical analysis problems frequently demand substantial adaptation of the analytical abilities that are immediately available in statistical software systems. Additionally, what emerges from earlier stages of an analysis will typically affect what is done at later stages. Oldford and Peters [14] describe the interactive programming needed for such tasks as experimental programming, a style of programming that S-PLUS and R are specifically designed to support. Depending on what each new computational step reveals and on what follows on from it, it may or may not become part of the final analysis.

The best environments for experimental programming link analysis closely with graphical presentation. Additionally, they automate much of the data and diagnostic testing that humans find tedious. They offer powerful and unified ways of conceptualizing and describing calculations that free the user from the need to worry about the details of implementation. Thus, Nelder and Wedderburn's **generalized linear models** [12] brought a large variety of models together into a common conceptual framework. The GLIM statistical package combined this conceptual framework with the Wilkinson and Rogers syntax [23] for **regression** and **analysis of variance**. The S-PLUS and R systems provide effective and natural object-oriented implementations.

Concepts from object-oriented programming can be important, as in the S language, in simplifying and unifying the description of the computing tasks. Thus, the same print and plot and other commands may be used, with widely differing effects, for a wide variety of objects – analysis of variance objects, linear model objects, and so on.

Experimental programming requires good strategies that will minimize the risk of undetected programming errors, allow retracing of steps, and facilitate documentation of what has been achieved.

Further Reading

Appleby and Vandekopple [2] give an overview of computer languages and computer language concepts. Levenez [8] has links to pages that give a large amount of information on computer languages. For program design and software engineering concepts, see [18]. Wexelblatt [22] is a useful reference for the history of computer languages; see also [8]. The article by Lang [7] (see also [19]) is both a critique of the existing environments for statistical computing and a proposal for the creation of a new generation of tools.

Computer-aided Diagnosis

In the past, a clinician made a diagnosis by supplementing accumulated knowledge with information from written notes, printouts of diagnostic test results, and information from the literature, often obtained by reading medical textbooks and scanning printed versions of *Index Medicus*. Though all the necessary information was contained in this paper trail, a key piece of data could be easily missed. Given the growth in medical knowledge and the large amount of clinical data available, clinicians using paper records find it even more difficult to consider all diagnostic possibilities, particularly with unusual diseases and patient presentations.

Changing technology has created new opportunities for helping the clinician make an accurate diagnosis. Most hospitals and many outpatient practices now use computers for the systematic processing and storage of clinical data, making information retrieval more efficient and accurate. Many medical texts are now available in electronic form, allowing expedient and robust searches of large quantities of material. Also, the availability of MEDLINE, the computerized database from which *Index Medicus* is derived, allows clinicians to cross-reference medical topics from 1966 to the present.

Although these electronic systems allow more efficient retrieval of data, processing the information once it is retrieved usually is still left to the clinician. A clinician traditionally approaches the diagnostic task by compiling available data and developing a list of one or more diagnostic possibilities in a list called a differential diagnosis. Elements of this list are sequentially ruled out on the basis of their appropriateness to the overall clinical scenario. Diagnostic possibilities on this revised list are then tested and ranked to determine appropriate management for a patient.

Over the years, computer aids have evolved to assist with information processing and thus improve the diagnostic process further. The origin of computer-aided diagnostic systems often is credited to Ledley and Lusted [13]. Their 1959 paper described symbolic logic and **probability theory** that led to diagnoses similar to those produced by clinicians' complex reasoning, though probably without reproducing that reasoning exactly. Since then, there have been many refinements of the scope, methods, and capabilities of computer-aided diagnostic systems. In this chapter, we describe these systems and focus on their advantages and limitations and present an overall evaluation of the role of computer-aided diagnosis in clinical practice. The systems are

1. **Algorithms**,
2. **Bayesian** analysis,
3. Belief networks,
4. **Prediction** rules,
5. Rule-based systems,
6. Decision trees,
7. **Artificial intelligence/**Causal reasoning,
8. **Neural networks**.

In addition to these established methods of computer-aided diagnosis, two emerging technologies are being developed and analyzed for their role in computer-aided diagnosis:

9. Microarray technology,
10. Syndromic surveillance.

Algorithms

Algorithmic methods [18] are suitable when a flow chart can be constructed that represents the logic used by a clinician to make a diagnosis. To implement the algorithm, the computer asks the user for information, processes the information, compares the result to the criteria at a branch point in the flow chart, selects a branch, and then moves to the next branch point. This process continues until a terminal branch is reached and a decision can be made. For example, an algorithmic method has been useful for the diagnosis of acid-base disorders [3]. In this situation, the user enters laboratory values, and then answers a series of questions generated by the computer about the patient's clinical condition. When enough information is available, the computer responds with a diagnosis.

Figure 1 shows a simple algorithm to determine the nature of a primary acidosis based solely on laboratory parameters. In this example, the computer would ask the user for the value of the blood pH and the pCO2. The computer then could make diagnostic suggestions, based on the numerical relationship between the pCO2 and the HCO3.

In comparison with other decision aids, algorithmic methods have the advantage of being understood easily by the user. Because the stepwise design

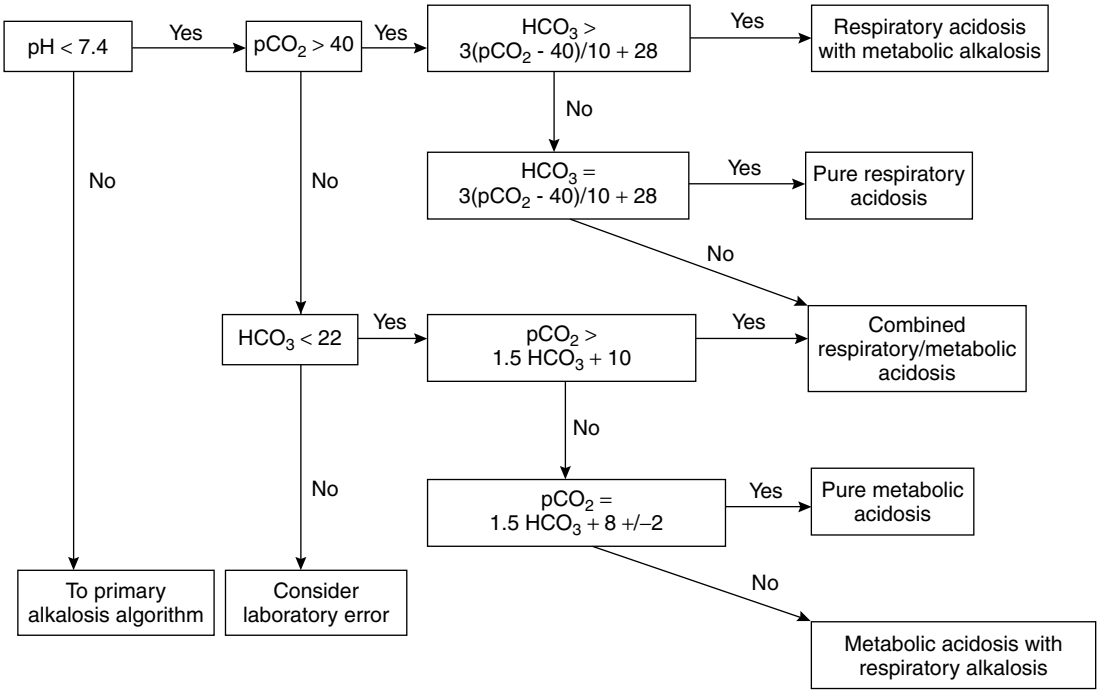

Figure 1 An algorithm for diagnosing classifications of acid disorders. On the basis of the results of laboratory parameters, the algorithm is traversed until an end point is reached. This end point may be a diagnosis, a suggestion to recheck results, or a recommendation to continue traversing a different algorithm

directly follows the clinician's logic, the program's conclusions can be explained so that the clinician can understand easily. Algorithmic methods, however, are not suitable for complex problems. Additionally, clinical diagnoses often involve ambiguous and **missing data**, which cannot be processed by the algorithmic method.

Bayesian Analysis

Bayesian analysis can partially overcome the problems created by missing data and uncertain associations. Instead of requiring a complete data set to provide a definitive conclusion, the Bayesian approach starts with the probability of disease in similar patients, and then uses the conditional probability of a symptom or a test result given the presence of disease to calculate the probability of disease with a symptom or a test result. In this approach, the presence or absence of a clinical finding will not necessarily eliminate a diagnostic possibility from contention, but may change its probability. The mathematical relationship can be expressed as follows:

$$\Pr(D|F) = \frac{\Pr(F|D) \times \Pr(D)}{\Pr(F|D) \times \Pr(D) + \Pr(F|\text{not } D) \times \Pr(\text{not } D)} \quad (1)$$

where $\Pr(D|F)$ is the probability of having disease D given the presence of a set of findings F; $\Pr(D)$ is the prior probability of disease D in the population; $\Pr(F|D)$ is the probability of observing a set of findings F, given the presence of disease D; and $\Pr(F|\text{not } D)$ is the probability of observing a set of findings, F, in a population without disease D (*see* **Bayes' Theorem**).

The calculation is trivial when dealing with a disease having only one finding. If a disease D is associated with many clinically independent findings,

$$P(F|D) = P(f1|D) \times P(f2|D) \times \cdots \times P(Fn|D) \quad (2)$$

where $f1, f2, \ldots, fn$ are individual findings of set F, $P(fi|D)$ is the probability of having finding fi given that a patient is known to have disease D.

There are many successful examples of the Bayesian approach. One involved the diagnosis of patients presenting with acute abdominal pain in which the computer accurately diagnosed 279 out of 304 patients, including 84 out of 85 with appendicitis [9]. The surgeons involved in the study made only 242 correct diagnoses.

There are many limits to the Bayesian approach, however. Most important is the assumption that all signs and symptoms are independent – a feature not typically seen in patient presentations. For instance, both the presence of fever and elevated white blood cell count may be predictors for a bacterial infection. However, the findings of fever and elevated white blood cell count are often associated despite the presence of bacterial infection. These two findings, therefore, are not clinically independent and the Bayesian calculation will be inaccurate. Mathematically, given the assumption of nonindependence of findings $f1$ and $f2$,

$$P(D|F) \neq P(D|f1) \times P(D|f2) \qquad (3)$$

Secondly, the approach assumes that outcomes are mutually exclusive, when in fact, patients can present with multiple disorders. For instance, if the probability of bacterial infection is increased by the presence of an increased white blood cell count, then this probability would be falsely increased by the presence of noninfectious causes of an increased white blood cell count such as leukemia. Thirdly, often the exact **conditional probabilities** are unknown and subjective estimations may decrease accuracy.

Belief Networks

Belief networks [6] were devised to address the Bayesian limitation of conditional nonindependence. The belief network is a lattice in which nodes are used to represent symptoms or diseases, and links among the nodes are structured as a directed graph in which there is a defined association or causal relationship between connected nodes. In this lattice structure, a node representing a disease can "point" to two independent clinical findings caused directly by the disease, which in turn can point to one or more other findings related directly to the first finding and indirectly related to the original disease entity. Conditional probabilities in the direction of the graph, such as the probability of observing a clinical finding given the presence of disease, are presumed known. Bayesian-like logic is then used to create a differential diagnosis by calculating the conditional probabilities of a set of diseases given a set of symptoms or clinical findings. The limitation of belief networks is that they are computationally complex, requiring exponential growth in the number of calculations for each additional node. This limitation, however, is partially mitigated by the use of heuristics and algorithms that can simplify the calculations of some structured networks.

To highlight the difference between a Bayesian approach and a belief network, consider the mathematical relationship between a diagnosis of metastatic cancer and several known findings such as increased total serum calcium, brain tumor, coma, and papilledema. If each of these findings was considered independent of any other finding, the relationship could be diagrammed as in Figure 2.

The probability of having Disease A in the setting of positive findings B through E would be based upon the Bayesian formula with $\Pr(F|A) = \Pr(B|A) \times \Pr(C|A) \times \Pr(D|A) \times \Pr(E|A)$, where F is the set of findings such that $B = T$, $C = T$, $D = T$, $E = T$.

However, medical experience has shown that the presence of coma and papilledema may be related to the presence of a brain tumor, which in turn is related directly to the presence of metastatic cancer; so these findings are not conditionally independent. As a result, coma and papilledema must fall to secondary positions, related directly to brain tumors and indirectly to metastatic cancer. Medical experience also shows that the presence of coma is often related to increased total serum calcium. The belief network structure illustrated in Figure 3 reflects these hierarchical relationships. With this structure, it is possible to calculate the probability of having Disease A with

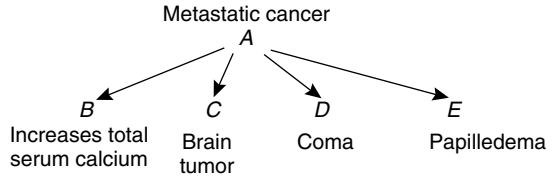

Figure 2 A Bayesian approach to determining the likelihood of metastatic cancer given the presence of associated findings. The structure presumes independence of findings B through E

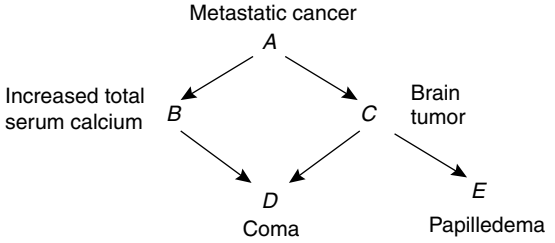

$\Pr(A) = 0.001$

$\Pr(B = T \mid A = T) = 0.3$
$\Pr(B = T \mid A = F) = 0.001$

$\Pr(C = T \mid A = T) = 0.2$
$\Pr(C = T \mid A = F) = 0.00005$

$\Pr(E = T \mid C = T) = 0.4$
$\Pr(E = T \mid C = F) = 0.002$

$\Pr(D = T \mid B = T, C = T) = 0.1$
$\Pr(D = T \mid B = T, C = F) = 0.01$
$\Pr(D = T \mid B = F, C = T) = 0.05$
$\Pr(D = T \mid B = F, C = F) = 0.00001$

Figure 3 A belief network of metastatic cancer with associated clinical findings. In this structure, the disease, metastatic cancer, is related directly to the finding of brain tumor, which, in turn, influences the presence of coma and papilledema. Increased total serum calcium is also related directly to metastatic cancer, and, along with brain tumor, may influence the finding of coma

any combination of associated findings. The calculation is too complex to be illustrated here [6].

Prediction Rules

Despite the mathematical rigor of Bayesian analysis and belief networks, studies have shown that medical experts do not apply this logic. Instead, they often apply prediction rules, which are simple declarative statements of the form "if antecedent then consequent", where the antecedents are one or more patient characteristics and the consequent is the potential diagnosis. Patient characteristics can include demographic characteristics, symptoms, physical examination findings, or laboratory findings. For example, the following prediction rule derives from experience and often is invoked in medicine clinics: "If the patient has a sore throat associated with fever; painful, swollen lymph nodes; tonsillar exudates; and a lack of cough, the diagnosis is more likely streptococcal than viral." Clinicians do not necessarily know how predictive this rule may be, but it is often applied on the basis of the empirical observation that the rule is frequently true.

With the availability of large clinical databases and the diffusion of advanced statistical methods into clinical research, prediction rules are increasingly being created using more sophisticated, mathematically based methods. In these approaches, the statistical analysis identifies which clinical variables are related to the outcome, and then calculates the strength of that relationship. Once this information is known, a rule can be created that contains an added degree of certainty. For example, several analyses of patients with sore throats have been done. These analyses attempted to find a relationship between the empirically observed findings involving patients with sore throats. In one such analysis, **logistic regression** demonstrated that the strength of the relationship between each finding and streptococcal sore throat was about the same [5]. Therefore, the prediction rule specifies counting how many findings are present and then comparing the result with the measured probability of a streptococcal sore throat. If none of the findings is present, the probability of a streptococcal sore throat is 2.5%. The probability of streptococcal sore throat increases when more findings are present: 6.5% with one, 14.8 % with two, 32.0% with three, and 55.7% with all four.

Although this prediction rule was developed with logistic regression, a similar rule for determining the likelihood for a strep throat was developed with **discriminant analysis** [25]. Using this rule, varying point scores are given for the presence and degree of a finding and probabilities are assigned on the basis of the total score. In fact, many other statistical methods that measure the association between variables can be used to develop prediction rules, including such simple methods as **contingency tables** and branching algorithms. Because the relationships among variables are often complex, however, more

complex methods often are appropriate. The more common methods used in clinical medicine are ordinary **least-squares** regression, logistic regression, and discriminant analysis, although recursive partitioning methods (*see* **Tree-structured Statistical Methods**) are becoming increasingly popular, and event-history methods like **Cox regression** are being applied to problems that involve predicting the time to an event, such as death.

Rule-based Systems

Individual prediction rules, both empirically and mathematically derived, have been grouped together in rule-based systems to solve diagnostic dilemmas in a variety of clinical settings [8, 26]. In this approach, the system stores many rules, sometimes several hundred or more, which are processed by a rule interpreter. This interpreter can be designed to work in a top-down fashion in which a disease of interest is tested, by attempting to establish the presence of clinical characteristics known to be linked to the disease by rules in the knowledge base. The top-down approach can be useful if a diagnosis needs to be "ruled-out". For instance, if the computer were considering the diagnosis of streptococcal pharyngitis in a patient with a sore throat, the computer would ask the user if the clinical characteristics associated with streptococcal disease were present. If not, the computer would move on to ask other questions looking for different causes for a sore throat. The advantage to this method is that it may prompt the clinician to find additional information necessary to make a diagnosis. The disadvantage is that it only considers one diagnosis at a time, and a possibly correct diagnosis may be overlooked if the heuristics for identifying that diagnosis are incomplete.

Alternatively, the rule interpreter can work in a bottom-up fashion by accumulating all known patient characteristics and then applying the rules to determine which diseases can be inferred. The bottom-up method is useful because it provides a breadth of diagnostic possibilities, though its main disadvantage is that an incomplete or inaccurate input list of symptoms or patient characteristics may lead to an inaccurate differential diagnosis.

Rule-based systems have several advantages. The rules are modular, declarative statements of medical knowledge that can be used to explain to a user the logic involved in reaching a conclusion. This capability helps the clinician to trust the answer more. However, medical knowledge is not organized into discrete rules, and rule-based systems do not necessarily organize medical knowledge into formats that are intuitive to clinicians. Additionally, the correct application of a rule depends on the clinical context, and specifying all the possible contexts requires an exponential growth in the number of rules. Successful rule-based systems, therefore, encompass limited clinical domains. One such example is MYCIN, which was designed to provide consultative advice on the diagnosis and therapy of infectious disease [8].

Decision Trees

Decision trees constitute still another approach to computer-aided diagnosis. Though decision trees do not provide lists of differential diagnoses, they are used to choose among diagnostic strategies logically and consistently.

Decision trees are structures that rigorously define and link choices and possible outcomes [18]. The tree consists of a linked series of nodes. At the origin is a decision node that reflects the diagnostic choices. Each choice may have one or more intermediate outcomes, which are represented as chance nodes. These nodes may connect to deeper elements of the tree that represent secondary events or further decisions. The branches of the tree end in terminal nodes that represent terminal outcomes and are assigned values, usually based on the clinical importance of the outcome, the cost of the outcome, or the patient's preference for the outcome. Simple calculations based on the probability of each outcome combined with its value determine the expected value of making any given choice. The choice with the highest expected value is preferred over other choices. **Sensitivity analyses** can be performed to determine whether the relationship among expected values changes when inputs are varied over reasonable ranges. In the decision tree shown in Figure 4, the label above each branch describes the action represented by the branch and the label below the branch describes the probability that the action will occur.

A common criticism of decision trees is that many probabilities and values in the trees are not known with certainty. Often, however, the relative ranking of expected values for alternative choices can be shown

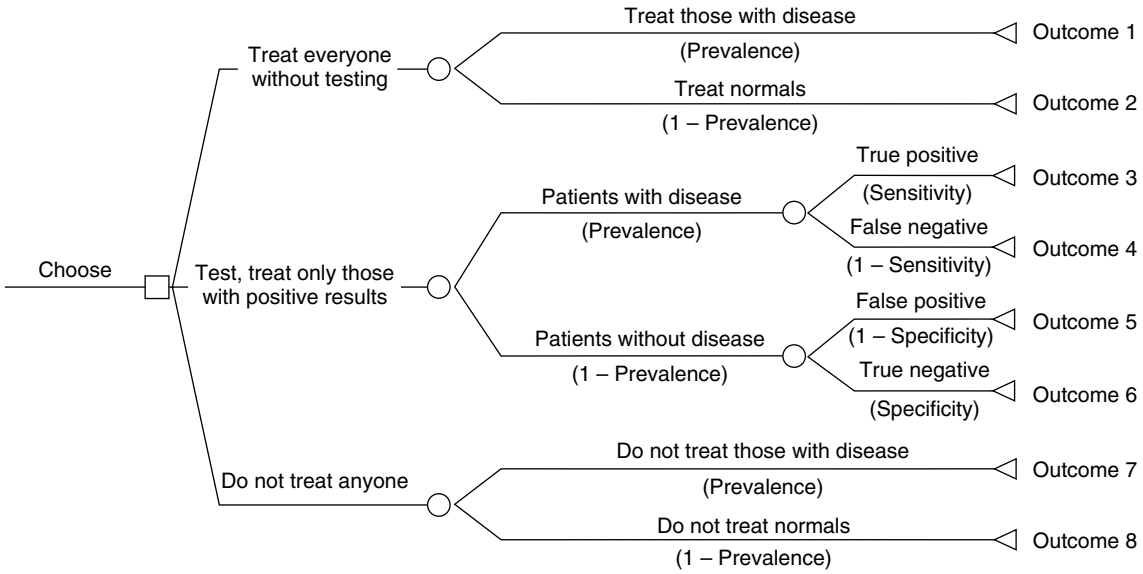

Figure 4 A generalized decision tree for deciding whether to perform a diagnostic test or to give or withhold treatment without testing. The label above each branch describes the action represented by the branch and the label below the branch describes the probability that the action will occur

not to change over a wide range of probabilities and outcome values. Additionally, the construction of a decision tree and its calculation can be time consuming. However, the design process may raise possibilities not considered in a more superficial approach to the diagnostic process and as a result, change a diagnostic approach even without a formal calculation of the decision tree.

Artificial Intelligence/Causal Reasoning

Artificial intelligence (AI) adds a layer of sophistication to computer-assisted diagnosis. These systems not only contain structured sets of rules and mathematical relationships, but they are also programmed with the causal reasoning underlying these associations and many contain mechanisms for self-expansion of the system's knowledge base.

Causal reasoning mimics the thought process of a clinician and is central to the concept of artificial intelligence. Although the algorithmic and prediction-rule approaches depend on quantitative measures, causal reasoning in medicine is mainly qualitative [15, 17]. When deciding blood pressure management, a clinician knows, based on physiological principles, that increases in cardiac contractility cause the blood pressure to increase and that relaxation of blood vessels causes the blood pressure to decrease. The clinician cannot necessarily predict the precise quantities of these values, but can still manage the patient appropriately. However, qualitative reasoning makes it difficult to determine the overall effect of conflicting forces. For example, if cardiac contractility increases and blood vessels relax, the effect on blood pressure will be uncertain.

Causal reasoning can approach a problem from different levels of detail [15, 21]. On a superficial level, interactions can be viewed solely as clinical observations: "The patient has a fever because he has an infection." This explanation may be satisfactory, though other levels of detail are possible if the problem is viewed as a pathophysiological process. For example, "The presence of infection causes white blood cells to release interleukins that stimulate the hypothalamus to raise body temperature." The value of this deeper level of understanding is that it affords a more refined explanation when requested, and it allows use of the rule for other relationships that have a common pathway, for example, other processes that stimulate release of interleukins and result in fever. Though the deep level of understanding allows a more rigorous analysis, separation of the levels

enables the computer to deal with a more manageable set of facts and more closely mimic the manner in which a clinician approaches a problem. For example, though the relationship between insulin and glucose balance can be explained through pathophysiological mechanisms, a clinician can manage diabetes knowing only that administering insulin will lower blood sugar and prevent undesirable complications.

Though artificial intelligence may incorporate recognized statistical methods, the methods in which the formulas are applied require modification to more closely mimic human reasoning. For instance, a strictly Bayesian approach to causal modeling for computer-aided diagnoses can be criticized for its equal weighting of all presenting signs and symptoms. In biologic systems, clinical phenomena such as symptoms and laboratory test results are variably associated with disease. Additionally, our ability to measure these phenomena are inexact. A clinician intuitively considers this variability and uncertainty when making medical decisions. To more closely mimic human reasoning, Bayesian models need to be combined with **multivariate analysis** to take into account the intensity, distribution, and validity of a relationship [4]. Intensity is defined as the expected change in the effect given the cause. For instance, how does the likelihood of a diagnosis change as a laboratory value varies out of the normal range? Distribution refers to the variability of the intensity across patients. Validity is an assigned value reflecting the certainty of relationship. Defining these variables and incorporating them into statistical models is the challenge of artificial intelligence.

The statistical association between a clinical finding and disease entity is only one part of the hierarchy within a causal relationship [16]. The relationship must also have a temporal association. The presence of a historical finding may be significant only if it occurs within the correct interval in relation to the disease. For instance, streptococcal pharyngitis can be a cause of rheumatic fever, but only if the infection occurred a few weeks before the onset of rheumatic fever. Similarly, there must be a functional association. For example, diarrhea may be the functional cause of hypokalemia, but the degree of diarrhea should match the degree of hypokalemia, or else other causes need to be considered.

Incorporation of these mathematical methods into artificial intelligence requires collaboration among diverse disciplines such as psychology, linguistics, and the computer and decision sciences. A true artificial intelligence system would incorporate elements of human reasoning with an automated ability to acquire knowledge and exchange information with its human counterparts naturally. Working examples of artificial intelligence in the medical field have tested each of these features individually, with varying success, but a complete artificial intelligence system has yet to be developed.

Neural Networks

Neural networks are computer programs with features similar to biologic nervous systems. Proponents of neural networks [1, 7, 14] believe other approaches to medical diagnosis can never reflect the complexity of the relationships among symptoms and diseases. Neural networks utilize complex, nonlinear statistical methods to form mathematical relationships between the presence or the absence of clinical findings and the presence or the absence of disease. Paths in the computer representation of a neural network are activated when multiple inputs to nodes reach a certain threshold, causing the node to "fire", analogous to a neuron generating an action potential when a sufficient stimulus is provided. The firing node then stimulates other nodes in the network with a "weight" that is set through a learning process. The neural network "learns" by examining a set of patients with known symptoms and diagnoses. The generated "weights" are not constant and do not apply to a single clinical finding. The mathematical structure formed from this learning set can be applied to a test set of patients whose diagnoses are unknown.

Technically, neural networks are not true artificial intelligence because they lack an underlying causal structure with a deep layer of pathophysiological detail. As a result, a neural network typically cannot explain to clinicians the reasoning that underlies the conclusions the system generates. However, recent developments have enabled extraction of rules from neural networks that can address this limitation within a medical domain [11]. Statisticians have expressed criticism of the mathematical methods that underlie neural networks [19]. For example, there is no equivalent of a **power** calculation to determine how many patients should be included in the learning set. Though intuition would suggest that a larger sample is better, sometimes too large a learning set, with too little variety, imparts an inability to

generalize. However, despite these limitations, neural networks are more accurate than clinicians and other computer diagnostic aids in their prediction of some disease states including myocardial infarction, pulmonary embolism, appendicitis, radiographic analysis, and the analysis of electrocardiograms.

Microarray Technology

While a significant degree of human disease likely has a genetic origin, until recently, techniques to find genetic markers of disease generally have been limited to diseases caused by point mutations of single genes. However, the genetic causes of common diseases such as hypertension, or cancer with its varied clinical presentation and aggressiveness is likely related to the interplay of hundreds or even thousands of genes. Microarray technology is a recent development within molecular biology that has enabled simultaneous analysis of thousands of genes. A microarray is a rectangular grid of small drops (nanoliters) of genetic material that are bound to a solid surface, typically glass. Each spot of genetic material represents a different gene fragment. Since these drops are less than 250 μm in diameter, literally thousands of drops can be present on a glass slide only a few centimeters square. The small scale of these drops, and the mechanism by which the genetic material is "printed" on the slide is analogous to the development of computer microchips in which digital electronic components have been made progressively smaller and now etched into a silicon wafer as a microchip. As a result, these microarray slides are also known as gene chips [22].

In a microarray experiment, genetic material from patients (either DNA, mRNA, or cDNA) is labeled with a fluorescent dye and exposed to the genetic material on the microarray. On spots where the patient's genetic material is complementary to the genetic material on the slide, the patient's genetic material binds to the spot through a process called hybridization. The fluorescent label of the attached genetic material imparts a color change to the spot. Since each spot is so small, and there are thousands of spots to review, computer controlled lasers are used to determine the color change of each spot of the microarray. Genetic material from a patient with a disease and without a disease can be labeled with different colored dyes and exposed to a microarray. Given the genetic similarities of all people, genetic material from both patients will hybridize to many of the same spots on the microarray. However, some spots will only bind the genetic material from the diseased patient, while other spots will bind the material from the unaffected patient. As a result, the presence of a genetic disease can be assessed by observing patterns of colored spots on a microarray slide when the slide is exposed to a patient's genetic material. It is not necessary *a priori* to fully understand the function of the genetic material in each spot of the microarray. Rather, a determination that the pattern of colored spots is similar to that of a diseased individual suggests that a genetic disease is present. When areas of differential coloring are discovered between affected and unaffected individuals, the genetic material associated with those spots can be examined in more detail, thereby helping to focus attention on an area of the genome likely to be associated with disease.

Each microarray experiment generates a large data set with thousands of numbers that represent the degree to which each spot of genetic fragments is complementary to the patient's genetic material. **Cluster analysis** is a common technique used to discover the pattern of coloring that is associated with disease [22]. The computer is provided a training set of data, and it attempts to find patterns of numbers that are differentially associated with disease and nondisease states.

When samples are compared, the distinguishing characteristic does not necessarily have to be the presence or the absence of disease. Microarray analysis can compare genetic samples from patients with the same disease but different levels of aggressiveness or response to treatment. These comparisons might provide a more accurate prognosis or suggest an individualized treatment that is based on the individual's genetic characteristics.

Syndromic Surveillance

For years, technical and administrative systems have been in place, which detect outbreaks of common diseases such as the flu or chicken pox (*see* **Surveillance of Diseases**). In general, these systems have been used to direct resources to areas of need as soon as possible after an outbreak occurs. For example, a growing flu epidemic in a region may help to focus resources on ensuring immunological protection of as-yet-unaffected individuals. These systems

depend on the voluntary reporting of occurrences of symptoms that are consistent with a disease and the submission of patient specimens for more formal analysis. With the acts of bioterrorism of late 2001, it has become increasingly apparent that similar systems need to be implemented that can detect smaller outbreaks of more lethal diseases at an earlier stage when the condition may be more treatable and fewer people have been affected [23]. The difficulty with a practical implementation of such a system is that the early stages of a bioterrorism agent exposure may masquerade as a serious form of a more benign condition such as a "bad" flu or rash. On any given day, a large number of patients present to primary care offices and emergency departments with these symptoms, so it can be difficult to detect the signal of a few patients presenting with symptoms caused by a bioterrorism agent. Syndromic surveillance is the term used to describe the automated data collection and analysis necessary to detect disease caused by bioterrorism agents and changes in the rates of other diseases.

This automated process is currently infeasible in most parts of the country where clinical findings are recorded on paper. However, where electronic medical records exist in ambulatory medical clinics and emergency departments, clinical information systems can transmit instantaneously and automatically a presenting patient's chief complaint, assigned diagnosis, and laboratory information to central processing computers. These central computers integrate data both regionally and nationally. Analysis of this data using spatial cluster detection methods, recursive least squares(RLS) and probabilistic inference techniques may reveal otherwise unrecognized patterns of disease occurrence that could alert public health officials about exposure to a bioterrorism agent [12]. One example of a syndromic surveillance system is the real-time outbreak and disease surveillance (RODS) system that was developed at the University of Pittsburgh and implemented at the 10 emergency departments and 20 acute care facilities comprising the University of Utah Health Sciences Center and Intermountain Health Care during the Winter Olympics in 2002 [10, 24].

Evaluation of Computer Diagnostic Aids

Evaluation of computer-assisted diagnostic systems has been inconsistent. While current studies of neural networks show levels of accuracy in the 90% range, many older studies showed bias in case selection and counted the computer's differential diagnosis as correct even if the true diagnosis was assigned a low probability [20]. A more recent study [2] compared the performance of four differential diagnosis programs chosen for their relatively common use and the breadth of information they covered. In this study, 105 cases were chosen from actual clinic experiences because they were diagnostically challenging and the diagnoses were known with certainty. The clinical findings were entered into the diagnostic programs and the resulting differential diagnoses were analyzed on several objective and subjective scales. Objective measures of success included the presence of the actual diagnosis anywhere on the list of differential diagnoses, the presence of the diagnosis within the top 10 diagnoses, and the mere presence of the diagnosis within the program's knowledge base. Subjective measures of success included the relevance of the top 20 diagnoses, which were defined as diagnoses that were on a clinician's differential diagnosis, but were nonetheless incorrect, and additional diagnoses that were considered relevant, but not included on the clinicians' original differential. The correct diagnosis score, representing the presence of the correct diagnosis anywhere on the list, ranged from 52 to 71%. Only 37 to 44% of correct diagnosis appeared within the top 10 most likely diagnoses. The number of additional diagnoses found by the programs that seemed relevant, but were not, on the clinician's original differential ranged from 1.8 to 2.3.

To make correct and relevant diagnoses, the computer diagnostic aid requires a clinician to be certain of the clinical findings that are entered. These findings may range from answers to simple historical questions to results of invasive and expensive tests. Ideally, all results can be known and the values are accurate. In reality, this is not true. For instance, the differential diagnosis of abdominal pain is quite broad, and a specific diagnosis, such as appendicitis, depends on correctly identifying the presence or absence of presenting signs and symptoms. Signs and symptoms are inherently subjective. Is the patient's pain severe, or does he have a low pain tolerance? Does the patient have a firm abdominal wall, or is there localized tenderness? Are bowel sounds hypoactive, or is this a normal finding for this patient? Even laboratory studies are not definitive. Is the patient's white blood cell count "normal" for the patient despite it being outside

the usual range? The computer diagnostic aid cannot make these distinctions.

Whatever the analytical technique used by a computer diagnostic aid, if a clinician enters the presence of irrelevant signs or symptoms into a diagnostic program, the program cannot rank elements of the extensive differential diagnosis effectively. If important findings are inappropriately omitted, then important diagnoses will be missed.

Lastly, the knowledge base of the system must be considered. Most successful systems encompass a narrow domain of medicine. A complete medical knowledge base must have not only the presenting signs, symptoms, and special study results associated with disease, but also be aware of the complex interrelationships among diseases. The breadth and depth of medicine make this a difficult task even for a seasoned clinician. As with clinicians, the computer-aided diagnostic program can only be as knowledgeable as its knowledge base allows.

These limitations of computer diagnostic decision aids suggest that current technology does not allow them to substitute for expert clinical judgment. Therefore, there is ongoing work to establish appropriate contexts in which these tools can be used. In a general medicine setting, the true diagnosis was not always at the top of the differential diagnosis list, but computer aids identified an average of two relevant diagnoses missed by an expert clinician [2]. This result suggests that sometimes the computer would have motivated a clinician to alter a diagnostic work up strategy, and possibly improve patient outcomes. The value of these diagnostic aids would be different in a subspecialty or general surgery clinic. There is the possibility that they might be most useful in situations where the clinician has less training or experience. For instance, a decision aid could be used by a school nurse when deciding whether a child has a benign condition and can be kept at school or has a more serious condition and should be sent to a doctor's office or an emergency room.

Though there has been much attention directed at comprehensive diagnostic aids, many successful diagnostic aids are used in an appropriately narrow domain. Computers have demonstrated accuracy in EKG interpretation, rheumatologic diagnosis, and the classification of patients with chest pain. Outcomes are presumed to be improved with the use of these tools, though this has not been demonstrated rigorously.

Because they formalize the logic used by clinicians, diagnostic aids can help standardize the practice of medicine. For example, computer-assisted diagnostic aids are being used to develop clinical guidelines and critical care pathways. Also, a clinician using the diagnostic aid may benefit because the aid may suggest an unfamiliar diagnosis and thus redirect the clinician's line of questioning or lead to a special study. The value of this potential benefit is difficult to quantify or evaluate.

The realization of these possibilities and limitations has changed the roles for computer-aided diagnostic systems. The fabled model based on the Greek Oracle in which a computer substituted for the clinical judgment of a clinician has been discarded. Many analysts now believe that a diagnostic system should be supportive, not authoritative. In the future, the appropriate clinical contexts for these systems will be identified. Improvements in technology should enable clinicians to engage these systems more naturally and enable knowledge bases to grow at the same rate as medical knowledge. In this manner, clinicians will retain their central role in the diagnosis and care of patients with the computer diagnostic aid as a resource for difficult diagnostic dilemmas.

Computer-assisted Interviewing

Computer-assisted Interviewing (CAI) is a term that describes the use of a computer to aid the interview process in a survey data collection. The computer generally presents the question text on the screen, along with the allowable response categories, and the interviewer or respondent records the answers directly into the computer. The computer can also be used to undertake various forms of processing at the time of the interview, and it can facilitate electronic data transfer.

CAI is an alternative methodology to traditional paper and pencil interviewing (PAPI), and it has many advantages to offer the researcher over the paper-based approach. The advantages and disadvantages of CAI relative to PAPI are discussed briefly below, with the emphasis on the most commonly occurring situation where interviews are conducted between an interviewer and respondents.

Variations

There are several variations in the way CAI can be administered. The most commonly known form is computer-assisted telephone interviewing (CATI) where the interview is conducted over the **telephone**. CATI is good for shorter, simpler surveys, as it can be more difficult to maintain rapport with the respondent over the telephone and respondent fatigue can occur more quickly [6]. CATI is most commonly conducted in a centralized environment, but there are also significant decentralized applications [2]. Centralized CATI offers certain benefits not available in a decentralized environment, such as automated call scheduling and more timely monitoring capabilities.

Computer-assisted personal interviewing (CAPI) is another variation of CAI. This involves the conduct of face-to-face interviews between the interviewer and respondents. CAPI is good for longer or more complex topics where it is more difficult to maintain respondent cooperation. A distinct advantage of CAPI is that visual aids can be used (e.g. prompt cards), and respondents can complete any associated paperwork (e.g. consent forms). CAPI, by its nature, is usually conducted as a decentralized operation.

A further variation is computer-assisted self-interviewing (CASI) where the respondent completes the survey instrument for him/herself. CASI has numerous applications. One example is in health research where a respondent can sit down at a computer and complete a simple diagnostic questionnaire. Another is in surveys of businesses where the instrument can be emailed or sent on floppy disk for completion. Other less common types of CASI include the use of telephone touchtone or voice recognition software [10]. If CASI is used, it is essential that the instrument provide adequate guides to respondents and that respondents have some basic computer skills.

Advantages

CAI provides greater scope for surveys to deal with issues in depth and to target specific subgroups in the population. This is because the complexity of determining the next relevant question sequence or identifying subgroups can be managed quickly and reliably by the computer program. This is not only an advantage for data quality through such things as lower item **nonresponse**, more consistent response, and so on, but it is also a cost-saving measure, as fewer interviewer errors will need to be corrected in the office. In a large-scale survey operations environment, several CAI surveys can be loaded onto the computer at one time for accurate and efficient enumeration in the field.

CAI enables the researcher to tailor the wording of questions based on information collected earlier in the instrument (e.g. inserting names into relevant questions about family members, using the name of a medication in questions about treatment for a health condition, etc.). This helps make the survey more specific and personalized, and this in turn aids respondent comprehension and rapport [10]. In addition, other information already known about the respondent can be used to assist with the interview (this practice is known as dependent interviewing). This is particularly useful in longitudinal surveys where information gathered in earlier interviews or from other sources (e.g. long-term health conditions, episodes in hospital, etc.) can be used in subsequent interviews. Another example is for monitoring change over time and responding appropriately when change occurs.

Processing time and costs can be reduced significantly with CAI because the data is in an electronic

format as soon as the survey is completed. Data in that format can be transmitted and loaded into the processing system within hours, compared to days or weeks for paper systems, where the forms have to be mailed and the data entered using data entry facilities. CAI also offers the facility of programming simple edits and consistency checks into the instrument, yielding further savings in processing time because some of the checking work is done while the interview is being carried out in the field. Field edits also provide for increased **data quality**, as any data conflicts can be reconciled immediately with the respondent.

Another distinct advantage offered by CAI is the ability to assist the interviewer to code complex responses directly into the computer, rather than recording the answers verbatim and coding them later. A number of alternative coding methods are available, ranging from a simple pick list (shown on the screen) to more sophisticated coding tools that guide the selection of an appropriate code according to prespecified rules and which require only a few letters to be typed. This not only reduces the costs of office coding, it also allows for greater data quality [4, 6]. A good example of this is an item like country of birth, where numerous responses are possible. With a coding tool, the interviewer can code the item in the field while still having access to the respondent, if there is a problem coding a particular response.

CAI also provides some secondary benefits, as the computer can be used for purposes other than just interviewing. For example, the interviewers can be given access to email or news from the office, training, and documentation can be provided electronically, and the computer can be used for other survey tasks such as coding of previously entered data. Sample management and cost monitoring tasks can also be timelier and less onerous in a CAI environment.

Disadvantages

The most obvious disadvantage of CAI relative to PAPI is the initial cost of setting up. There is a large capital investment involved whether you invest in personal computers linked on a network, or individual laptop, or handheld computers (for decentralized interviewing). Indeed, the equipment costs can be so large that despite the many efficiencies of CAI outlined above, CAI can be more expensive than PAPI overall. CAI is most suitable for an environment where the cost of the equipment can be amortized over a number of surveys.

CAI generally requires more time and effort to develop and test the survey instrument and associated field systems prior to the start of fieldwork. Indeed, the total time taken from the start of the survey to the analysis stage is not necessarily any shorter for CAI, especially for one-off surveys. For instance, CAI requires more rigorous **validation** processes to check the instrument [1, 8], as it is most important for the CAI instrument to be error-free (as far as possible) in the field because of the relative inflexibility of CAI for dealing with problems or unusual situations. A good example to illustrate the validation issue is questions with multiple response categories. In a PAPI questionnaire, it is easy to see at a glance that all the response categories are sequenced appropriately. However, in a CAI instrument, it is necessary to check the detailed computer code (a method that can be error prone), or to physically select each possible response category when testing the instrument to ensure that all sequencing is correct. Training for CAI is more complex than for PAPI, as interviewers require basic computer skills in addition to an understanding of the survey instrument. Training may consequently take longer and be more expensive [7]. As an aid to testing interviewer instructions, as well as the effectiveness of CAI instrument layout and design, and the associated field systems, usability testing has gained prominence in recent years. Usability testing focuses on the interviewer's interaction with the survey instrument and CAI systems, and generally involves people being observed in a controlled "laboratory" setting as they use the computer systems. Usability testing is effective in identifying serious and recurring usability problems [5]. As a related training issue, there is also a need to support the CAI technology, both hardware and software, in the field.

Decentralized CAI has the added difficulty of transferring survey instruments to interviewers in the field and the collected responses back to the office. There are several methods available to transfer survey instruments and collected records. One is to make the transfer completely electronic using a fax/modem. With this approach, it is wise to set up an electronic despatch and receipt system to ensure that the collection operations can be suitably managed. Another method is to send floppy disks through the

post. Both these methods (electronic transmission and mailing floppy disks) have security implications for the confidentiality of the survey results. There are good software solutions that make use of passwords and encryption to deal with these security problems, both on the computers and during transmission, but they can add further complexity and costs to a survey. An alternative is to have the interviewers bring the computers to an office to have the information loaded and downloaded, but this method is only really feasible if the interviewers are relatively close to the central location.

The use of computers also introduces occupational health and safety issues for the management of an interviewer work force. With centralized CAI, there are issues of time spent keying, and for field interviewers, there are issues of the size, weight, visibility, and positioning of equipment, which need to be dealt with [10]. Such issues may increase costs and/or restrict the kind of equipment that can be used. These issues may even have an impact on nonresponse (e.g. interviews standing at the doorstep are considerably more difficult to conduct with CAI).

CAI is generally best conducted with software specifically developed for that purpose. There are clearly costs associated with the purchase of the software that must be considered, but software can also have limitations that may restrict the flexibility of the **questionnaire design**. When interviewers first see the computer screen, they should be drawn immediately to the key features needed for successful delivery of questions and accurate recording of responses [3]. To do so requires consistent design, visual discrimination among the different elements (e.g. questions, interviewer's instructions, response categories, navigation tools, etc.), adherence to normal reading behavior (i.e. starting in the upper left-hand corner) and removal of unnecessary information or display features that distract from the task (i.e. clean screen designs with more "white" space). Software should also cater for emerging CAI "best practice" relating to font size and color, line length and spacing, word emphasis, and so on. [3, 9]. The software chosen to write the survey instrument should also ideally be compatible with the survey processing system in order to realize the full benefits of reduced processing costs [6].

An additional disadvantage of CAI software is that it is often unable to produce a suitable paper version of the instrument that includes all the functionality that can be programmed in the software. This can be a particular problem when dealing with people who want to understand the question sequencing and data item derivations.

Related Topics

There are other computer-assisted methodologies used in processing surveys. One is computer-assisted coding (CAC). CAC is similar to an autocoder in a CAI instrument, but it is generally used for more complex coding operations by specialist coders after the main enumeration. Applications for this could include such things as coding of a respondent's medical conditions, medications taken, or possibly their dietary intake.

Another computer-assisted methodology for processing surveys is computer-assisted data input (CADI). CADI is a sophisticated form of data entry whereby on-line edits (e.g. logical and range edits) are applied to the instrument as the data is keyed in. Once the instrument is keyed, the data is internally consistent, thus obviating the need for batch edits checking the internal consistency of forms. Batch edits are only required for checking across forms. Another advantage to CADI is that a CAC can be embedded, thus reducing the costs involved in office coding.

Computer-intensive Methods

One sense of "computer-intensive" statistics is just statistical methodology that makes use of a large amount of computer time. (Examples include the **bootstrap, jackknife,** smoothing, **image analysis**, and many uses of the **EM algorithm**.) However, the term is usually used for methods which go beyond the minimum of calculations needed for an illuminating analysis, for example by replacing analytic approximations by computational ones, or requiring numeric **optimization** or integration over high-dimensional spaces. We introduce the subject by a very simple yet useful example, and then consider some of the areas in which computer-intensive methods are used, to give a flavor of current research.

A Simple Example

Let us examine the idea of a **Monte Carlo** test (see, for example, [60]). Suppose that we have a test statistic T, large values of which indicate a departure from a simple null hypothesis. The traditional analysis is to report *either* the ***P* value** $p = \Pr(T > T_{\text{obs}})$ *or* whether p falls into one of the conventional ranges. However, to compute p we do need to know the distribution of T under the null hypothesis. Traditionally, either T was chosen because its exact distribution was tractable, or some large-sample approximation was used, perhaps a normal distribution.

The Monte Carlo test depends on our being able to **simulate** under the null hypothesis; for each of m replications we generate some artificial data from the null hypothesis and compute the value T_i of the test statistic. One idea is to use the empirical distribution of the T_i as an approximation to the null-hypothesis distribution of T; that is, to compute $\hat{p} = \#\{i : T_i > T_{\text{obs}}\}/m$. However, Monte Carlo tests use a clever variation. If the null hypothesis is true, we have not m but $m + 1$ samples from the null hypothesis, the $T_1, \ldots, T_m$ that we generated plus T itself. A simple counting argument shows that

$$\Pr(T \text{ is amongst the } r \text{ largest}) = \frac{r}{(m+1)}.$$

Thus, we can obtain an *exact* 5% test by taking $r = 1$, $m = 19$ or $r = 5$, $m = 99$ or $r = 25$, $m = 499, \ldots$.

When Monte Carlo tests were first proposed by Barnard [4] in 1963, they would have been rather slow to compute, and needed extensive programming. When the idea was rediscovered in 1975 for some problems in spatial statistics (see [59]), increased computing power had made Monte Carlo tests much more attractive, although the choice of m was still severely limited by computing resources. Eventually good analytic approximations were found for those test statistics under the simpler null hypotheses, but they are hardly ever used, as it has become easy to use the exact Monte Carlo test.

This example has many of the key features of computer-intensive methods: it makes use of a simple calculation repeated many times, it relaxes the distributional assumptions needed for analytical results, and it is in principle exact given an infinite amount of computation. Rather than considering large amounts of data, we consider large amounts of computation, as the ratio of cost of computation to data collection is continually falling.

It is also important that it allows us to avoid asymptotics. Large-sample results are only useful in practice by providing an approximate distribution theory (*see* **Large-sample Theory**). In the spatial-statistics context there are "several ways to infinity" [61]–that is, several possible asymptotic regimes–and it is only possible to find good enough approximations by combining leading terms from all of them. When we consider **neural networks** below, we will see that it is common to increase the complexity of the model with the amount of data to hand, so large-sample results are never appropriate (and in the real world models are always false).

Graphics

A considerable amount of computer power is used to plot or print graphs, and even more is needed for dynamic graphics; for example, to rotate views of data, interactively change the bin size of a histogram, or highlight or identify points (*see* **Graphical Displays**). We now take this for granted (although systems to do this are described later, in the section on Programming Environments). As computer power grows, researchers are exploring ways in which to

compute large numbers of views and let the software arrange the "interesting" ones to show to the user.

The Trellis system (see Becker et al. [7]; this is now part of **S-PLUS** [45]) is based on presenting graphical summaries of many "slices" of the data in a systematic way. Asimov's *grand tour* [3, 18] shows the user a continually rotating series of views (projections) of multidimensional data of real-valued variates, but with four or more variables it is almost impossible for the user to screen the series for interesting views. (See the discussion in [38].) **Projection pursuit** [17, 18, 25, 26, 38, 39, 42, 43] replaces human inspection by optimizing (locally) the "interestingness" of a view. Sometimes the results can be frustrating, but at other times very interesting structures are revealed (see, for example, [64]).

Simulation-Based Approaches

A *reductio ad absurdum* view of statistical methods is that they reduce to either the optimization or the integration of some function, with **Bayesian methods** majoring on integration. For reasonably realistic models the integration is often (extremely) computer-intensive. (Evans & Swartz [23] review analytical as well as Monte Carlo methods to approximate integrals in statistics.)

Simulation provides a very simple way to perform an integration such as $\phi = \mathrm{E}f(X)$. Just generate m examples, $X_1, \ldots, X_m$, from the distribution of X and report the average of $f(X_i)$. It is not usually a good way to find an accurate estimate of ϕ, for the **central limit theorem** (if applicable) suggests that the average error decreases at a rate $1/\sqrt{m}$. For smooth functions in a small number of dimensions, numerical quadrature can do better, and in a moderate number of dimensions it may be better to use nonindependent samples X_i, the so-called quasi-Monte Carlo method [24, 50, 60, 66, 67].

In many statistical applications we do not need to know the integral ϕ at all accurately; in the Monte Carlo test a significance level of 5% is somewhere between, perhaps, 1% and 10%. Thus, in many cases, simulation is a good choice for approximate integration. Remember that a simulation experiment *is* an experiment, and there are a number of techniques [60, 23] to design and analyze it to obtain maximum precision for the computer time spent.

Markov Chain Monte Carlo

The simulation-based methods are of course only easy if we have a simple way to simulate from the assumed model. In highly structured situations we can find that everything depends on everything else. This was first encountered in statistical physics [46] and spatial statistics [30, 59]. Those authors devised iterative algorithms that only used the conditional distributions of small groups of random variables given the rest. As successive samples are not independent but form a **Markov chain** (on a very large state space), these methods are known as MCMC, short for **Markov Chain Monte Carlo**.

The same ideas were taken up for hierarchical Bayesian models by Gelfand & Smith [28, 29] some years later, under the name of Gibbs sampling (precisely the algorithm published in 1977 [59] and 1984 [30], and in the Bayesian context by Pearl [51] in 1987), and the earlier work and many of its lessons have been overlooked. In particular, although the algorithms are guaranteed to converge under mild conditions, that convergence can be far too slow to be useful without clever design, and possibly even then; see [65].

Recent reviews of MCMC from several viewpoints are given in [9], [33], [35], and [75].

Simulated Annealing

Simulation can also be used to do optimization! Most optimization methods can only find a local optimum of a function f on a domain $\mathcal{X}$, and can have great difficulty in combinatorial optimization problems (in which some of the components of $\mathcal{X}$ are categories rather than numbers).

Suppose that we want to minimize f, and we know $f \geq 0$. Consider drawing samples X_i from a distribution over $\mathcal{X}$ with density proportional to $\exp[-f(x)/T]$ for $T > 0$. As we increase T, the distribution becomes more and more concentrated on the region in which $f(x)$ is near its global minimum. Suppose that we run an MCMC simulation and decrease T; we might hope that the sample at time N converges to a global minimum. This idea was suggested by Pincus [55, 56], but was rediscovered and used by Kirkpatrick et al. [41] under the name of

simulated annealing. The idea that the sample might converge proved to be too optimistic in practice (convergence occurs at rate $1/\log N$). Aarts & Korst [1] discuss the theory, and Cantoni [15] provides some useful results on how to vary T if a bounded amount of computing is to be used.

Despite the lack of a convincing theory, simulated annealing has been widely used in large-scale optimization problems. Perhaps the most familiar application in statistics is to the segmentation of noisy images [8, 30, 61].

There are a number of other ways in which to use simulation to approximate maximum likelihood estimates using MCMC; for example, in spatial statistics by Pentinnen [53] and Ripley [61] and in genetics by Geyer [33, 34]).

Relaxing Linearity

One major use of computer-intensive methods has taken place largely outside statistics, in a drive to relax linearity and use much more complex models. In 1993, Ripley [62] wrote about neural networks that

> Their pervasiveness means that they can not be ignored. In one way their success is a warning to statisticians who have worked in a simply-structured linear world for too long.

The extent of nonlinearity which is not just being contemplated, but is being built into consumer hardware, goes far beyond **nonlinear regression** in the sense of, for example, [5].

The most influential developments have been in decision trees (*see* **Computer-aided Diagnosis**) [13, 57, 64], Bayesian networks [2, 27, 36, 37, 49, 52, 64, 68], and neural networks [10, 62–64]. The emphasis in the first and last is on good prediction, and the complexity of the models which are built is normally limited only by the amount of data to hand, even when this is 10^4 or more samples.

Selecting and Combining Models

Another way in which a large amount of computer power has been harnessed is to consider a very large number of models. We should distinguish two uses of statistical models, for *explanation* and for **prediction**. Although statistical training has usually emphasized explanation, that the purpose of the analysis is to discover structure in the data set to hand, in many other fields the emphasis is entirely on prediction. Even in a field such as medical diagnosis (*see* **Decision Analysis in Diagnosis and Treatment Choice**), in which it is helpful to be able to explain the basis of the diagnosis (and this is the aim of work in Bayesian networks), it would be useful to have an accurate diagnosis system without explanation. And for a voice recognition system, to read vehicle license plates, for biometric security checking, and so on, all that is required is accuracy and perhaps speed.

This suggests that for prediction we should either choose a model on the basis of its predictions, or even choose to combine the predictions from several models. The traditional way to proceed was to divide the data into training, validation, and test sets. The training set is used to optimize the parameters in each of the candidate models, the validation set to choose the best one (or combination), and the test set to estimate the performance of the selected prediction method (necessary as the performance on the validation set will be an optimistic measure of future performance)

Rarely will we have enough data to afford separate training, validation, and test sets, and in many problems increasing the size of the training set will result in a significant gain in performance. Enter K-fold **cross-validation**, in which the data set is divided into K sections of roughly equal size, and each section in turn is used as the validation set for the candidate models trained on the rest of the data. When all K fits are done, we have used the whole data set as a validation set, and can choose the best model (or combination). To assess the future performance we also have to take into account the variability of the selection procedure, so we nest the K-fold cross-validation inside a V-fold split into training set and training/validation set. Typically, K and V will be chosen of the order of ten, so each model is fitted of the order of 100 times, and it is not uncommon to entertain 25 models. The procedure rapidly becomes computer-intensive, but only by repeating a simple building block (fit a model on one data set, predict on another) many times. Such procedures can easily be done in parallel, or on separate machines.

The idea of using a weighted average $\Sigma_i w_i f_i(x)$ of the predictions for all the candidate models goes back at least to Stone [71], and arises from Bayesian theory if we believe that one of the models is true,

but do not know which one. In the Bayesian context the weights are the posterior probabilities of the models, the computation of which usually involves a very high-dimensional integration over the parameters (see, for example [54], and [58]). Alternatively, we can use K-fold cross-validation to choose the weights w_i from the performance on the validation sets. Some examples of the use of model averaging in the statistical literature are [21, 31, 32, 44, 48], and [70], but there are many in other fields.

There is no reason why the weights we give to the various models should not vary (slowly) with x, which leads to the idea of regarding the predictions of the candidate models together with x as inputs to some nonlinear function g, so the prediction system becomes

$$g(x, f_i(x), \ldots, f_M(x); \theta)$$

and choosing θ by simultaneous fitting or cross-validation. (In the neural networks literature, variants are known as *stacked generalization* [77] and *hierarchical mixtures of experts* [40].)

Many of the nonlinear procedures such as decision tree induction are rather sensitive to the training set used, and many methods have multiple optima and so are sensitive to the starting values. We can apply the ideas of combining *models* to combining the predictions of the same model fitted on different training sets. Breiman [11, 12] called one procedure *bagging*, which averages the predictions of a model fitted to bootstrapped training sets. We can go further and design subsets of the training data to produce rather different fits to average, a process known as *boosting* [22].

This is a very active area of research, and some of the results of combining simple models have shown very appreciable gains in performance.

Programming Environments

A major attraction of computer-intensive methods is their conceptual simplicity, but most biostatisticians are no keener on computer programming than on deriving asymptotic approximations. The S language (see Becker et al. [6] and Chambers & Hastie [16]) is the preferred working environment of many of the researchers in the field. S is currently marketed exclusively as part of the commercial S-PLUS system [45]. Despite a steep initial learning curve, sophisticated analyses can be performed in S-PLUS very easily [76], and many researchers donate their S software to public archives, notably statlib [47]. The free XLispStat system (see Tierney [74] and also Cook & Weisberg [19], available from statlib [47]) is also popular and has a substantial archive of user-contributed software at UCLA [20]. The package XGobi [14, 17, 18, 72, 73] implements dynamic graphics and projection pursuit, and BUGS [69] is a (currently free) system for using Gibbs sampling for a class of Bayesian methods (*see* **Software, Biostatistical**).

Computerized Therapeutic Decision Support

Introduction

A recent report by the Institute of Medicine examined some of the problems in the United States' health care system and concluded that 44 000 to 98 000 Americans die each year as a result of medical errors [5]. Although some analysts have questioned the accuracy of these numbers, most would agree that more needs to be done to reduce the number of errors. The report's recommendations specifically recognized the potential for error reduction when decision support systems are incorporated into medication-prescribing software and provider order-entry systems. Although this report brought greater attention to the importance of medical errors, we have known for some time that medical errors are a serious problem, and the notion that computer systems can improve the delivery of care and thus reduce errors is not new [9]. Because errors are such a serious problem and decision support systems are so important to their prevention, this chapter focuses on the nature of medical errors and the role of computerized therapeutic decision support in promoting patient safety.

Errors can be defined in two broad categories: errors of execution and errors of planning. Errors of planning occur when an inappropriate plan is selected for a patient. Errors of execution occur when an appropriate plan is carried out incorrectly. Errors of execution can be divided into errors of omission, in which a needed action is not performed, and errors of commission, in which the action performed is the error, either because the wrong action is performed or the correct action is performed incorrectly.

Decision Support

In the broadest sense, "computerized decision support" refers to any assistance that a computer provides when clinicians make decisions about patient care. Thus, any system that presents data in an advantageous way is a form of computerized decision support. For example, a hospital information system can be set up to display a patient's laboratory values at the same time that physicians use the computer to order the patient's medications. This setup might decrease the likelihood that physicians would prescribe a drug that could become toxic in the setting of renal insufficiency because of the prominent display of lab indicators of renal function. Designs that provide this type of assistance to clinicians are valuable, and should be an important part of any clinical system. This chapter, however, focuses on more sophisticated designs. In these designs, the computer system uses more patient information, analyzes the information in complex and sometimes novel ways, and often renders advice specific to the patient and the situation.

These sophisticated decision support systems can be understood best by examining four of their characteristics [2]:

1. Support goal refers to the overall goal of the advice being given.
2. Type of intervention describes how the clinician accesses the advice.
3. Type of knowledge refers to the information being evaluated when the advice is rendered.
4. Method of reasoning refers to the logic used by the system to interpret that knowledge and render advice.

Support Goal

One way to think of the goals of a therapeutic decision support system is to think of the system as either a state-based system or an action-oriented system.

State-based decision support systems attempt to answer the question, "What is true about this patient?" These systems synthesize multiple pieces of information in an attempt to determine diagnosis, prognosis, or specific condition along the continuum of care.

Action-oriented systems attempt to answer the question, "What should be done?" by suggesting a strategy or course of action. For example, a system may take two pieces of data, apply simple logic, and render advice, as follows:

```
IF an angiotensin-converting enzyme
(ACE) inhibitor is prescribed
      AND patient is pregnant
          THEN display
  ''ACE inhibitor is contraindicated in
pregnant patient.
   Consider discontinuing medication.''
```

Action-oriented systems can be extremely useful, especially when they have access to a wide variety of clinical information. They should be a primary focus for dealing with errors of execution when the decision support system operates in conjunction with an electronic medical record or another computer information system.

In practice, the best therapeutic decision support systems combine both of these strategies. These systems first synthesize data from multiple sources to determine the state of the patient and then use their knowledge bases to recommend an action.

Type of Intervention

The type of intervention refers to how much the user is required to do to get a recommendation. In passive systems, the user has to activate the system to get a recommendation. Passive systems often require the user to sit at a computer terminal and respond to questions so that the system can complete its knowledge base before providing a recommendation. These systems are more helpful when clinical management is complicated and requires a small number of difficult decisions, for example, for the selection of an antibiotic in patients with infection [11] and the selection of a chemotherapeutic agent in patients with cancer [4]. Passive systems are more difficult to use and require more clinician time than active forms of decision support.

Semi-active systems provide recommendations without requiring the user to activate the system, and some systems facilitate the action being recommended. For example, a semi-active system might display a reminder message advising against the renewal of an angiotensin converting enzyme ACE inhibitor for a pregnant patient and also provide a convenient way for the physician to discontinue the drug. A semi-active system, however, would never discontinue the medication without the consent of the physician.

Semi-active systems can be divided into reminder systems and alert systems. Alerts can be defined as messages that arise in response to an action. They can be extremely useful in altering errors of commission that might occur while a clinician is using a health care information system. Reminders can be defined as messages that arise spontaneously from an information system or other source. They can be useful for errors of omission where a clinician forgets to perform a needed action. Alerts and reminders can take many forms, in some cases, they would print from an information system at a predetermined time, and in other cases, they would appear on screen while the clinician was interacting with the information system.

Active systems perform actions without any need for direct participation by a clinician. For example, an active system might control a ventilator or a pacemaker. Also, active systems might operate when one action logically follows another. For example, an active system might order a serum drug level automatically when a clinician orders a drug that requires lab monitoring. Active systems promise to reduce errors for activities that require constant monitoring and adjustment, especially when the underlying mechanisms are understood and the need for adjustments are based on well-known parameters. Because medical decision-making (*see* **Decision Analysis in Diagnosis and Treatment Choice**) is so complex and poorly understood, however, active systems are little used.

Some decision support systems combine active, semi-active, and passive elements. Such systems might automatically ask for more information when a clinician orders a test or a patient's status changes and then provide a recommendation. The majority of therapeutic decision support systems, however, are semi-active systems that are used with an electronic medical record or some other type of information system.

Types of Knowledge

Decision support systems require several types of information, or "knowledge", to provide recommendations. One way of categorizing types of knowledge divides them into dynamic facts, static facts, and judgmental knowledge [14]. Dynamic facts change over time. For example, heart rate and blood pressure change rapidly in an intensive care unit and a patient's weight, drug doses, and medication list change more slowly in the outpatient setting. Other dynamic facts reflect changes in patient populations. For example, a decision support system could perform frequent statistical analyses of microbiology data to determine drug resistance patterns and then store the results as a dynamic fact.

Static facts include basic truths about medical care. "E. Coli is a gram-negative rod" is an example of a static fact.

Judgmental knowledge is a combination of formal knowledge about medicine, like the knowledge in textbooks, and experiential knowledge, such as knowing how to perform a procedure. Rules that would be contained in a decision support system typically comprise this type of knowledge. Figure 1 shows how the various types of knowledge might interact in a decision support system. In this case, the electronic medical record stores dynamic facts in the "factual database". The "knowledge base" contains static facts and judgmental knowledge in the form of rules. The "inference engine" determines how the knowledge base and the factual database combine to produce a recommendation.

For example, as the clinician orders new drugs for a patient, the decision support system stores these changes in the factual database as dynamic facts. The inference engine constantly checks dynamic facts to see whether there are related rules in the knowledge base. If the drug "coumadin" is entered into the factual database, the inference engine might identify three related rules.

1. Coumadin is warfarin (anticoagulant) (static fact)
2. IF warfarin AND amiodarone are present on the medication list, THEN display "Amiodarone may increase prothrombin time in patients also receiving warfarin. (priority 5)" (judgmental knowledge)
3. IF warfarin is on the medication list AND the international normalized ratio (INR) of the patient's prothrombin time is greater than 3.5, THEN display "INR is elevated, consider changing the dose of warfarin. (priority 7)" (judgmental knowledge).

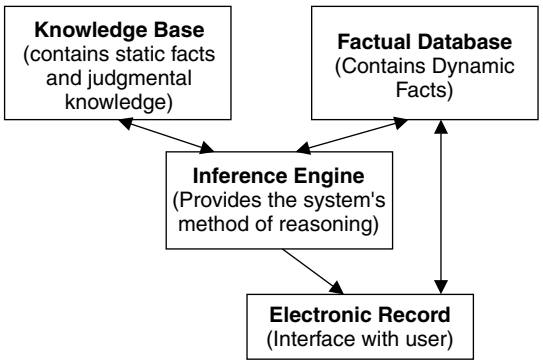

Figure 1 The relationships among components of a typical decision support system

The inference engine runs the rules in sequence and identifies that rule 1 is true but does not require action, rule 2 requires an action with a priority of 5 and rule 3 requires an action with a priority of 7. The inference engine sends a message to the electronic record to display an alert with the text for rule number 3 and a reminder with the text for rule number 2. Since rule 3 has higher priority, it is displayed first in a larger font and rule 2 is displayed second in a smaller font.

Methods of Reasoning

Therapeutic decision support systems can use several methods to process the information contained in their knowledge bases. Although the goal in a therapeutic system is always to recommend an action, the system may first determine the state of the patient in sophisticated ways prior to rendering that advice. For example, **Bayesian** analysis and belief networks can be used to determine a patient's state before the support system makes a recommendation. Most therapeutic decision support systems, however, use rule-based systems (*see* **Computer-aided Diagnosis**). The rules contain the judgmental knowledge that facilitates error reduction and most often take the following form: "IF antecedent THEN consequent." The rules in a therapeutic decision support system are typically run sequentially. The inference engine begins at the top of the list of rules and processes the list until it identifies a relevant rule. Then actions are taken as dictated by the rule. A rule might lead to the evaluation of a new set of rules, or it might initiate some action directed at the clinician, such as a reminder. This rule-based approach is especially useful for preventing errors of execution, because the rules require only a few of the thousands of loosely related bits of knowledge to give advice. For example, the presence of one drug that interacts with another drug is important by itself and does not depend on the other information in the factual database. Because rules work so well, better support systems are distinguished not so much by their rules but by how many rules activate alerts and reminders, which rules are prioritized over others, and whether the factual database is adequate for rule activation.

Evaluation of Therapeutic Decision Support Systems

Increasing use of more comprehensive health care information systems, such as an electronic medical record, has greatly facilitated the use of therapeutic decision support systems. Comprehensive health care information systems tightly integrate computerized advice with the clinician's workflow. Most analysts believe that this integration is critical to having the advice followed.

Drug Dosing and Therapy

Much of the focus for errors in medicine has been on errors in drug dosing and administration. The greatest promise of computer systems may be in decreasing and preventing these types of errors. Several studies have shown that drugs with severe side effects can be more accurately dosed using Bayesian estimates of the drug level following initiation or dose change [3, 13]. Early trials looking at the use of reminders with an electronic order-entry system showed a great deal of promise. In one study, the likelihood of changing the dose of potassium when indicated by abnormal renal function or an elevated potassium level went from 0 to 53%. The health care information systems used in these early studies, however, did not always provide advice at the ideal time and relied instead on paper printouts that were produced and distributed after the clinician had decided about drug dose. Several studies using more sophisticated healthcare information systems have shown that reminder and alert systems improve care by providing recommendations at the point of care. Dosage guidance, alternative medication selection, and prompts for order suggestion have all been shown to be facilitated by reminder systems used with an order-entry system [12]. One study, using a health care information system, compared therapeutic reminders to a "team" approach, which more heavily involved pharmacists and other providers in the drug dosing and administration process [1]. The computerized order-entry system checked for drug allergies, serious drug–drug interactions, and some drug-laboratory interactions. It prevented more than half of the serious medication errors that would otherwise have occurred if there were no intervention at all. Some of this effect was due to decision support and some due to improved legibility and process changes introduced by the order-entry system. No effect over the baseline error rate was seen for the team intervention in this study.

Preventive Care

When a reminder system that focused on preventive care (*see* **Preventive Medicine**) in the inpatient setting was coupled with an order-entry system, no significant differences were found between control physicians and test physicians [10]. When clinicians received reminders, for preventive care in outpatients, that were printed on patient encounter forms, some, but not all, activities increased in frequency [6]. For example, increases were found in fecal occult blood testing (49 to 61%, $p = 0.0007$) and mammography (47 to 54%, $p = 0.036$) but not in pap testing (18 to 21%, $p = 0.2$). The most common reason physicians gave for not performing the study was that it was "not applicable" (22.6%) to the patient because the test had been performed elsewhere (69%) [7], which emphasizes that when preventing errors of omission, the decision support system must have access to all information about a patient to be most effective.

Care Guidelines

Decision support systems for chronic diseases are similar to those for preventive care. One study that examined the use of reminders for performing recommended maintenance studies for patients with diabetes found improvements in foot exams (30 to 55%), urine protein determinations (3.9 to 73.3%), ophthalmologic exams (3 to 19%), and pneumococcal vaccinations (0 to 19.8%) [8].

Conclusion

Computerized therapeutic decision support systems offer tremendous promise in solving the problem of errors in medicine. They seem to function best when they are used in concert with a healthcare information system designed to store patient data in a machine-readable format. In these cases, relatively simple semi-active systems that use a rule-based approach to decrease the likelihood of errors in execution seem to be particularly effective. However, the culture of

medicine is slow to change and these information systems have not been adopted by the vast majority of clinicians and organizations. It will take alignment of financial incentives and a great deal more effort before patients can begin to reap the benefits of this new, decision-making process.

Conception, Models for

The study of human fertility is of enduring interest to demographers who wish to forecast and characterize the dynamics of population change, to reproductive epidemiologists who wish to identify factors that adversely affect human reproduction, and to biologists who wish to improve our understanding of the fundamental processes that underlie human reproduction. The statistical models required necessarily depend on the level of detail available in the data and the scientific purpose of the modeling.

The crudest and most widely available data are on time from marriage to first birth, and time between successive births. Mathematical models for the distribution of such intervals in a population are plentiful in the **demography** literature [8, 19]. Such models account for the heterogeneity across couples in their fertility, sometimes by assuming that the monthly probability of conceiving a clinically recognized pregnancy is a property of the couple that varies across couples according to a beta distribution (*see* **Beta-binomial Distribution**).

In an industrialized society in which contraception and abortion are widely available, fertility is primarily under volitional control and, consequently, the study of such intervals carries little information about the biological capacity to reproduce. Trends, such as increases in the age at a woman's first birth and (consequent) increases in the use of infertility services, largely reflect social forces, and are of greater interest to the demographer than to the reproductive biologist.

A biologically more informative level of detail is provided by studies of the time required to achieve pregnancy in couples not using contraception. The earliest such studies recruited sexually active couples at the time at which they discontinued contraception in order to conceive [10] and followed them up to pregnancy or some maximum follow-up time.

The time-to-event data from such couples can be regarded as discrete failure-time data (*see* **Survival Analysis, Overview**), where "failure" is here a misnomer referring to the occurrence of a recognized pregnancy. While sometimes approximated as smooth for modeling [2, 3], time is discrete in this context, because each menstrual cycle provides a single opportunity to conceive. Consequently, time-to-pregnancy is best measured in integer units based on the number of menstrual cycles from discontinuation of contraception to the achievement of a recognized pregnancy. If reported in units of calendar time, these intervals can be converted to numbers of menstrual cycles, by dividing by the woman's usual cycle length. If all couples had the same constant probability of conceiving per menstrual cycle ("fecundability"), then the distribution of times to pregnancy would be **geometric**.

In practice, however, these intervals are **overdispersed** compared to the geometric, reflecting underlying heterogeneity in fecundability across couples in the population. In the first menstrual cycle at risk, about a third of couples conceive; in the second cycle, about a fourth, and so on. The cycle-specific conception rate continues to decline over time. This is not an effect of time *per se*, but reflects sorting within a heterogeneous population of couples, where the couples with the highest fecundability conceive early and are not present in subsequent **risk sets**. The pattern is not simply due to the presence of a sterile subpopulation, but is evident even among those couples who ultimately do conceive. Following the modeling traditions established in demography, Weinberg & Gladen [11] modeled time-to-pregnancy data according to a beta-geometric, by assuming that each couple has a characteristic fecundability parameter, drawn from a beta distribution.

Parameter estimation is straightforward, because the resulting beta-geometric distribution can be expressed as **generalized linear model**. If p_j denotes the conception rate at cycle j, among couples still at risk, then one can show that

$$\frac{1}{p_j} = c + d(j-1),$$

and hence the maximum likelihood estimates for the beta parameters can be developed using standard software. The parameter, c, is interpretable as the inverse of the mean fecundability across couples, while d depends on the beta variance. One can also allow for a subpopulation of completely sterile couples by means of the **EM algorithm** [4], where the underlying beta distribution for fecundability is now contaminated by a degenerate distribution with mass at fecundability 0 [11]. Thus, relative to this parametric model, one can estimate the prevalence of sterility in a population.

One could also model the underlying heterogeneity distribution nonparametrically, since in general

the cycle-specific conception rates depend in a simple way on the moments of the underlying distribution, as described by Weinberg & Gladen [11]. With a prospective study of cycles up to at most K, the cycle-specific conception rates can be shown to depend on the first K **moments** of the fecundability distribution. Because the number of parameters (moments) to be estimated can be quite large, and the alternative approach is based on a rich family of density functions, the beta-geometric will often be preferred to the nonparametric approach in practice. Also, the natural linear extension of the above generalized linear model allows effects of covariates to be incorporated in the beta-geometric approach.

Because the beta-geometric model does not yield any summary measure of the effect of an exposure that has much intuitive appeal, investigators have turned to other modeling approaches. One can apply the model that Cox suggested for **discrete survival time** data [5], where each cycle's binary outcome is modeled as logit-linear and a cycle-specific baseline serves as the discrete-time analog of the baseline hazard function for continuous failure-time data.

A model that is **loglinear** in covariates can also be fitted [14, 16]. With this model, the effect of a dichotomous exposure is assumed to be multiplicative on each cycle-specific conception probability. The exponentiated coefficient is interpretable as a "fecundability ratio," analogous to a **hazard ratio**, except that it is a ratio of the probability of conception in a cycle for those exposed divided by the probability for those unexposed. Adjustments for **confounding** factors are easily included. Because the outcome here is not rare, the fecundability **odds ratio** estimated in the discrete-time Cox model cannot be seen as an approximation to the fecundability ratio estimated in the loglinear model. The loglinear model can be fitted using standard generalized linear model software, provided that the model incorporates a baseline conception-rate parameter for each cycle number. One complication with using the loglinear model is that the predictive linear function can sometimes exceed zero, implying a probability above 1.0. The logistic formulation is less intuitive to the scientist but avoids this annoying pitfall.

Time to pregnancy can be ascertained either prospectively or retrospectively. In a prospective study, couples are entered either at the time at which they discontinue contraception, or at some point in the middle of their attempt. In the latter case, the left **truncation** must be taken into account by ascertaining the number of months at risk prior to study entry, and delay-entering the couple into the appropriate risk set (cycle number). Thus a couple who have been trying to conceive for six months prior to recruitment into the study would not be credited for their first six failures, but would be entered into their first risk set at cycle seven. Assuming that late entry is not related to fecundability, allowing such couples into the study should produce no bias.

In the retrospective approach, couples are asked about time to pregnancy, based on reconstructing their history of contraceptive use. If every attempt at pregnancy ended in conception, the retrospective design would yield data equivalent to that from a prospective design. In practice, populations include couples with very low or zero fecundability. Such couples contribute to prospective studies but are under-represented in retrospective studies based on achieved conceptions.

Retrospective studies based on a current pregnancy or the most recent pregnancy are also prone to bias in estimating effects of exposures, if the prevalence of those exposures has changed systematically over calendar time (*see* **Bias in Observational Studies**). This is because the couples who required a long time to conceive are reporting exposures that took place long ago, when the opportunity for exposure might have been very different from what it was more recently. Weinberg et al. [13] describe an instance of such bias, where the use of latex gloves by dental assistants was shown (spuriously, we presume) to enhance their fertility. This arose because dental workers wore gloves more often after the AIDS epidemic began, and women who conceived quickly were more likely to have begun their attempt recently, after glove use had become widespread.

A less bias-prone and more detailed approach to studying fertility is provided by a **cohort study** where not only menstrual cycles and pregnancies are recorded, but some marker for the day of ovulation is available for each cycle, together with daily data indicating whether there was unprotected intercourse. Markers for ovulation can be based on hormonal assays of excreted hormones, or on daily records of basal body temperatures. When both intercourse data and a benchmark for ovulation are available, one can ask some interesting questions about reproductive biology. What is the relationship between the timing of intercourse *vis-à-vis* ovulation and the probability

of conception? For how many days in a month is a woman fertile? Do the Y-bearing (boy-producing) sperm and the X-bearing (girl-producing) sperm have similar survival and potency, or is there a relationship between the timing of intercourse and the sex of the baby?

The first extensive data of this sort were described by Barrett & Marshall [1], who studied couples using natural family planning (the rhythm method). Basing the identification of day of ovulation on the rise in basal body temperature that accompanies ovulation, Barrett & Marshall applied a model asserting that the cohorts of sperm introduced to the woman's reproductive tract on different days pose independent **competing risks** (of fertilization) to the ovum. Under this simple independence model, the probability of conception can be written as

$$\Pr[\text{conception in cycle } j \,|\, \text{intercourse pattern}] = 1 - \prod_k (1 - p_k)^{X_{j,k}},$$

where $X_{j,k}$ is an indicator that has a unit value if there was intercourse on day k in cycle j. The indexing specified by k is relative to the day of ovulation, which is usually taken to be day "zero". The parameters p_k are interpretable as the probability that conception would result had there been intercourse only on day k.

Schwartz et al. [7] modified this model in a way that allows for the fact that timing is not everything: a broad constellation of factors must be favorable for conception even to be possible in a given cycle. The ovum must mature properly and be viable, and must be transported through the oviduct; the uterine endometrium must be adequately prepared under hormonal stimulation; the immune system must function properly and not reject the embryonic foreign tissue, and so on. The constellation of such factors is sometimes referred to [15] as "cycle viability," and under the Schwartz et al. model specification, each cycle is either viable or not. Without cycle viability, conception will not occur, regardless of the timing of intercourse. If we denote the probability that the cycle is viable by A, then the model becomes

$$\Pr[\text{conception in cycle } j \,|\, \text{intercourse pattern}] = A \left\{ 1 - \prod_k (1 - p_k)^{X_{j,k}} \right\}.$$

When this model was fitted to data from a cohort study carried out in North Carolina [18], the p_k parameters exceeded zero only over a six-day interval, ending on the estimated day of ovulation [17] and the A parameter was estimated to be 0.37, suggesting that more than half of apparently ovulatory menstrual cycles in healthy women of reproductive age are nonviable.

In fact, as was recognized by Schwartz et al., the A parameter requires a broader interpretation than suggested by "cycle viability". Fertility studies do not detect all conceptions, only those that survive to the point at which the methods applied are capable of recognizing that pregnancy has begun. Studies in which only clinically recognized pregnancies are found in effect include as part of A an additional factor corresponding to the probability that the pregnancy survives up to clinical detectability. Even studies that make use of a very sensitive assay for the pregnancy hormone, hCG, are only detecting conceptions that survived long enough to successfully implant and establish communication with the maternal circulation. While the survival probability is embedded within A and is not statistically identifiable under this model, it is important to recognize that A can incorporate effects of male factors. For example, if husbands are exposed to a mutagen and produce some sperm that are capable of fertilizing a viable ovum but do not produce a viable embryo, then the A parameter would be reduced accordingly.

This means that the models to be discussed that allow the parameters A and p_k to depend on covariates should allow for the possibility that male exposures can affect both A and the p_k. Similarly, female exposures could theoretically affect both A and the p_k. The woman provides the environment in which the sperm must temporarily live before encountering the ovum, so an exposure that renders the female reproductive tract hostile to sperm survival could reduce the p_k, especially for days prior to ovulation. It is also possible that the pattern of intercourse itself could affect A, if certain patterns are associated with aging of the gametes and consequent effects on viability of the conceptus.

Schwartz et al. [7], and later Royston [6], who reanalyzed the same data, allowed for the possibility that A could decline with advancing maternal age. Weinberg et al. [15] developed methods for fitting more complex models, by using the EM algorithm [4] to model cycle viability as an unobservable **Bernoulli**

outcome, whose probability can depend on **covariates** through a generalized linear model.

Parametric models that explicitly estimate parameters related to survival of the sperm and ova have also been proposed [6, 12]. The model developed by Weinberg & Wilcox specifies that the instantaneous probability (hazard) for fertilization at time t (where $t = 0$ at the moment of ovulation), given that the ovum is still viable at t, is proportional to the number of sperm that are still viable at time t. The competing risks for fertilization due to batches of sperm that were introduced on different days are still treated as independent, so that the surviving sperm from the various batches simply commingle. The viable lifetime of individual sperm is assumed to be **exponential**, while ovum survival is taken as fixed. Applying this model to data from the North Carolina study, the mean viable lifetime for sperm was estimated to be 1.4 days, while the ovum appears to survive for less than a day. While it fits the available data very well, this model oversimplifies the underlying biology, because it does not take into account female factors, most notably changes in the cervical mucus that can, depending on the day of the cycle, alternately impede or facilitate the entry of sperm into the upper female reproductive tract.

These variations on the model proposed by Schwartz et al. all have certain doubtful assumptions in common. They assume that sperm introduced on different days present independent risks of fertilization to the ovum. They assume that the time between successive acts of intercourse has no effect on the potency of the second batch of sperm. They assume that the pattern of intercourse has no bearing on the survival-to-detection probability for the embryo, so that embryos formed from relatively aged gametes are not of reduced inherent viability. Finally, they assume that the outcomes for successive menstrual cycles within a couple are independent. Of these, the latter assumption is the most easily demonstrated to be false [22].

Subsequent work has allowed the dependency among successive outcomes from a single couple to be handled by a **generalized estimating equation** (GEE) approach. The estimating equations are taken to be the likelihood equations, so the estimated effects are not modified, but the standard errors are adjusted, usually upward, to properly reflect the dependencies in the data. The extended model now also allows for exposures that may vary from day to day and directly influence the day-specific p_k [20].

The capacity to handle day-specific exposures means that the model can now be used to assess certain direct effects on fertility. One example is in assessment of contraceptive efficacy, where one now would not need to exclude menstrual cycles in which the method being assessed, for example the female condom, was not used for every act of intercourse. Another example is in trying to assess the effect of day-specific characteristics of the cervical mucus on the likelihood of conception.

The heterogeneity among couples is treated as a nuisance by the GEE approach, whereas this variability may be of interest in itself. Accordingly, a subject-specific approach was also developed, in which the cycle viability probability is now taken to be a couple-specific parameter and these are assumed to have been sampled from a beta distribution [22]. The existence of significant heterogeneity in cycle viability among couples demonstrates that the heterogeneity in fecundability long known to demographers is not simply secondary to variation in the frequency and patterns of intercourse, but reflects determinants that are more biologically innate.

The contexts discussed so far have included three levels of detail available in studies of human fertility: that provided by the intervals between marriage and first birth, or between successive births; that provided by studying the number of menstrual cycles from discontinuance of contraception to the onset of a detectable pregnancy; and that provided by daily hormonal assays and intercourse records, allowing the investigator to match up the pattern of intercourse to the time of ovulation itself. An even more refined level of detail is provided by certain clinical protocols used to treat infertile couples.

In *in vitro* fertilization (IVF), the woman's ovaries are hyperstimulated by exogenous hormones to produce many ova at once. When mature, these ova are withdrawn surgically from her ovaries and then fertilized *in vitro*, usually by her husband's sperm. A selection of the resulting embryos is then transferred to her uterus in hopes that pregnancy will ensue. A model closely related to that proposed by Schwartz et al. can be applied to assess the effect of exposures and clinical markers on the likelihood of conception in IVF. The occurrence of conception depends on a susceptibility factor, the receptivity of the uterus to implantation, together with

an aggregation of Bernoulli trials: at least one of the transferred embryos must be viable. The resulting model, an analog of the Schwartz et al. model described above, was proposed by Speirs et al. [9], and more recently reconsidered by Zhou & Weinberg [21].

CLARICE R. WEINBERG

Conception

Any attempt to count the numbers of pregnancies conceived in a population and then use these figures to derive conception rates is bound to be incomplete. Clearly, the pregnancies that end very early before the woman realizes she is pregnant will be missing. Those that end before help is sought from a midwife or doctor are also likely to be left out. Once maternity care has started, documents confirming pregnancy are produced for various official purposes, such as to prove entitlement for maternity benefit payments, but these documents do not usually end up in **vital statistics** systems.

Nevertheless, the idea of trying to count pregnancies directly through a notification system is not a new one. For example in Huddersfield, England, in 1916 a system was introduced by which the doctor or midwife booked by the woman for delivery notified the pregnancy to the Public Health department. By 1934, the proportion of pregnancies notified had reached 77% [1].

The other approach is to estimate the numbers of conceptions indirectly through data collection systems designed to count the outcomes of pregnancy in terms of miscarriage, legal abortion, and registrable birth.

In most countries, the biggest gap is in statistics about miscarriage. Miscarriages once a pregnancy is well established are likely to lead to hospital admission and thus be counted in hospital inpatient statistics. Earlier miscarriages may lead to care outside hospital by general or family practitioners whose work is less likely to appear in national systems. If these miscarriages are reported, then there may be double counting in cases where the woman is subsequently referred to hospital. Most countries have routine data about birth and legal abortion, from which estimates of conceptions can be derived, however. This can be difficult if the records do not include the **gestational age** at which the events occurred.

In England and Wales, estimates are made of the numbers of conceptions leading to either a legal abortion under the 1967 Act or a maternity with one or more registrable live or still births [3]. These estimates are then used to derive age-specific rates per thousand women. Because of the lack of adequate data, pregnancies leading to miscarriages or other outcomes are not included. In Scotland, data about miscarriages in hospital are combined with those about birth and legal abortion to derive estimated teenage conception rates [1].

Gestational age is stated on notifications of abortion, and from 1974–80, the date of the last menstrual period was also included. In deriving the estimated date of conception, it is assumed that the gestational age is determined from the date of the last menstrual period and that, on average, conception takes place 14 days after this. Gestational age is stated on registrations of fetal deaths (*see* **Vital Statistics, Overview**) as stillbirths, and the stated gestational age is used to derive the estimated date of conception.

Gestational age is not recorded on registrations of live births in England and Wales. The date of conception is estimated to have been 38 weeks before the date of birth, on the assumption that the average time between the first day of the last menstrual period and the date of birth is 40 weeks. This can lead to **bias** when tabulating conceptions according to age and other characteristics of the mother, as it assumes that women having preterm births are broadly similar to childbearing women as a whole. This is not the case.

ALISON MACFARLANE

Conditional Probability

Conditional probability has been one of the least understood and most controversial concepts in the history of science. It was introduced by **Thomas Bayes** in 1764, who defined, motivated, and applied this concept much as is done today in post-calculus, but not measure-theoretic, courses in probability theory. For a finite space of possible outcomes, the conditional probability $\Pr(E|F)$ is defined as

$$\Pr(E|F) = \frac{\Pr(E \wedge F)}{\Pr(F)},$$

provided that $\Pr(F) > 0$. (Here "$\wedge$" means "and".) This definition is not arbitrary, but is requisite in both the **Bayesian** and classical frequentist theories of **probability**, in order that such theories do not lead to absurd results.

First consider the classical frequentist approach that stemmed from the work of Jakob Bernoulli (*see* **Bernoulli Family**). In repeated trials, such as arise in games of chance, by the **law of large numbers** it follows that amongst the cases in which the event F occurs, there will be a limiting proportion $\Pr(E|F)$ of cases in which also E occurs, provided that $\Pr(F) > 0$. For a specified event A and sequence of trials on each of which A may or may not occur, define $f_N(A)$ to be the number of times that A occurs in the first N trials. Now suppose that E and $E \wedge F$ are such events, and consider a sequence of independent trials concerning these events, always with the same fixed probability distribution. Then the proportion of times in which the event F occurs amongst the first N trials converges almost surely to its probability $\Pr(F)$, which we assume to be positive (*see* **Convergence in Distribution and in Probability**). The relative frequency of cases in which both E and F occur, amongst those cases in which F occurs, in the first N trials, is

$$\frac{f_N(E \wedge F)}{f_N(F)} = \frac{\left[\dfrac{f_N(E \wedge F)}{N}\right]}{\left[\dfrac{f_N(F)}{N}\right]},$$

with $f_N(F) > 0$ for sufficiently large N. Hence in the frequentist theory, as $N \to \infty$ this relative frequency converges almost certainly to $\Pr(E \wedge F)/\Pr(F)$.

Next, to justify his definition of conditional probability, Bayes had already presented a version of the fundamental coherency argument in terms of a called-off gamble on the event E given F, which was later to be developed in great detail by **de Finetti**. A coherency theorem of de Finetti (Theorem 1 below) proves that unless the value of a called-off gamble is assessed in accord with the conventional $\Pr(E|F)$, a person who bets on all such gambles according to the probability assessments he has asserted can be made a sure loser.

De Finetti's theory of coherence was developed as a consequence of the basic notion that probabilities, if acted upon, should not give rise to certain loss. Any contract concerning an unknown event or variable is called a gamble, so that the taking out of insurance, and indeed investments of any sort, will here be referred to as gambles, without the usual negative connotation for highly speculative activities. A gamble that gives rise to certain loss, no matter what actually occurs, is traditionally called a Dutch book. (More recently, such gambles are discussed in terms of "arbitrage".) To be precise, by a "Dutch book" is here meant a finite collection of gambles and conditional gambles such that no matter how the individual events turn out, whether true or false, one is logically certain to lose a positive amount greater than some $\varepsilon > 0$. The primary result in the theory of coherence is de Finetti's theorem giving necessary and sufficient conditions to avoid a Dutch book. The context for de Finetti's theorem concerns a set of simple gambles and simple conditional gambles. By a simple gamble **G** we mean the following. There exists an event E, which will be verified to be either true (1) or false (0), and the gamble consists in a contract under which if E occurs (or is true) one receives a specified monetary stake S, while if E does not occur (or is false) one receives nothing. We define $\Pr(E)$ to be the price at which a particular person evaluates the worth of this gamble, in the sense that the person would either buy or sell the gamble at the price $\Pr(E) \times S$. If S is positive, and if one is to avoid sure loss, then plainly the gamble has some nonnegative value between 0 and S. It is customary to choose small monetary values for S to aid in the evaluation of $\Pr(E)$, so that one is not overly influenced by considerations that arise when dealing with large sums of money, and which can be dealt with by the theory of **utility**, as for example by F.P. Ramsey [16] and by **L.J. Savage** [19].

Next, a simple conditional gamble concerning the event E given the event F, which is written as (**E**|**F**), is a gamble under which one receives the stake S if both E and F occur, one receives nothing if F but not E occurs, and the gamble is called off if F does not occur. If S is positive then such a gamble has again some nonnegative value, say $p \times S$, which is the price at which one evaluates the worth of the conditional gamble, again in the sense that one would either buy or sell the conditional gamble at this price. It is understood that if F does not occur, then this price is returned. The following theorem, due to de Finetti [4, p. 109], shows that the p obtained in this way for the conditional gamble must be precisely $p = \Pr(E \wedge F)/\Pr(F)$, if sure loss is to be avoided.

Theorem 1. For simple gambles on events $E \wedge F$ and on F, and a simple conditional gamble (**E**|**F**), to avoid a Dutch book it is necessary and sufficient that $\Pr(E \wedge F) = p \times \Pr(F)$, with $0 \leq \Pr(E \wedge F) \leq \Pr(F) \leq 1$. In this case $0 \leq p \leq 1$ whenever $\Pr(F) > 0$.

The proof of this theorem is obtained by considering the payoff for simultaneous bets on each of $E \wedge F$, F, and the conditional gamble (**E**|**F**). The avoidance of a Dutch book is equivalent to the singularity of the matrix that represents the payoff on these three bets as a function of the separate stakes on each bet. It is worth noting that when $\Pr(F) = 0$ the matrix is necessarily singular, and so a conditional probability given an event of probability 0 can be evaluated arbitrarily, without giving rise to sure loss. Thus, in both the de Finetti coherency theory and the classical frequentist theory, standard arguments for the conventional definition of a conditional probability do not apply when the event F has probability 0. When there are only a finite number of possible outcomes, of course, no one takes seriously the possibility that an event of probability 0 might occur. On the other hand, when there are a nonfinite number of possible outcomes, some delicate issues arise for all approaches, which will be discussed below.

Theorem 2 combines related results of de Finetti [4; 5, p. 111] into a single theorem.

Theorem 2. Let $\mathcal{W}$ be a finite space of points w_i, for $i = 1, \ldots, N$. Suppose that a nonnegative function $\Pr(E|F)$ is defined for some pairs of subsets of $\mathcal{W}$ with $F \neq \emptyset$. Suppose further that this function is used to determine prices for conditional gambles, with $\Pr(E|F)$ the price for the conditional gamble (**E**|**F**) with stake unity; and that when $F = \mathcal{W}$, we define $\Pr(E) \equiv \Pr(E|\mathcal{W})$ to be the price for the unconditional gamble on E. Then in order that there be no Dutch book possible on the collection of conditional and unconditional gambles for which prices have already been specified, it is necessary and sufficient that the already specified $\Pr(E|F)$ can be extended to a probability distribution π on $\mathcal{W}$, such that for all E and H with $\pi(H) \neq 0$ we have

$$\Pr(E|H) = \frac{\pi(E \wedge H)}{\pi(H)}.$$

Now let $\mathcal{W}$ be any finite space of outcomes or points. Suppose that one specifies prices for some simple gambles and conditional gambles involving the events of $\mathcal{W}$. Then it follows from the theorem that either one is already subject to a Dutch book based upon these gambles, or else one can extend the original specification to a probability distribution π on all of $\mathcal{W}$. In the latter case, if one uses **Bayes' theorem** to obtain posterior probabilities in any such extension, then the theorem guarantees coherency (the impossibility of a Dutch book) within this framework; conversely, if the original specifications violate Bayes's theorem, in the sense that they are not consistent with *any* Bayesian analysis, one can always be made subject to a Dutch book no matter what the actual outcomes.

In this century, a new understanding of conditional probability arose from the Borel – von Neumann – Wald theory of games and statistical decision functions (*see* **Decision Theory**), which we will refer to as BNW theory. In this context one considers mappings of the data into a space of terminal actions. As will be seen, both the coherency theory of Bayes and de Finetti, as well as the classical frequentist theory of conditional probability, can be expressed in decision-theoretic terms. Since even in logic the interpretation of a conditional statement (such as a counterfactual) is controversial, it is important to provide an operational meaning for conditional probability statements that makes it clear what is gained or lost by various methods for specifying such conditional probabilities. Otherwise, the theory would be largely arbitrary and all assessments would be subject to controversy and doubt. Fortunately, this can be done both simply and forcefully, within the BNW framework, both for conventional decision problems concerning an unknown

parameter, and for prediction problems. In this framework it becomes clear that only decision procedures that are based upon conditional probability cannot be ruled out as objectively defective.

Conditional Probability and Decision Theory

Beginning with the **Neyman–Pearson lemma**, it has been argued that a procedure that has a risk function that can be decreased in some or all components of risk, without increasing other components of risk, is undesirable. For example, in choosing to minimize the type two error probability β of a simple versus simple **hypothesis test**, for a specified type one error probability α, one is implicitly replacing a particular risk function by one that is generally regarded as better in an objective sense. Based upon the theory of games and statistical decision functions, it is shown below that any real-world decision procedure that is not based upon conditional probability is objectively defective in its performance in precisely the same sense as for such type one and two errors.

In decision theory, it is conventional to introduce a space of terminal actions $\mathcal{A}$, a parameter θ, and a loss function $L(\theta, a) \geq 0$, which specifies the loss when action a is taken and θ is the true value of the unknown. A probability model for the data X is specified, which depends only upon the value of θ. If $\mathcal{X}$ is the space of possible data observations, then a pure decision rule d is a mapping from $\mathcal{X}$ into $\mathcal{A}$. A randomized decision rule is a finite mixture of the pure decision rules; for example, $\delta(X) = \sum_{i=1}^{J} [\alpha_j] d_j(X)$ is the randomized decision rule that takes the decision specified by pure decision rule d_j with probability α_j. Pure decision rules are identified with such degenerate probability distributions. The space of randomized decision rules consists of all such finite mixtures of the pure decision rules. The performance of a particular randomized decision rule δ is measured by its risk function

$$R_\delta(\theta) = \mathcal{E}\, L[\theta, \delta(X)],$$

which is the expected loss for δ when θ is the value of the parameter or unknown. The value of $R_\delta(\theta)$ at a particular θ is known as a component of risk for δ.

A procedure is said to be admissible if there is no other available procedure with risk at least as small for all θ and strictly smaller somewhere. A procedure is said to be extended admissible if there is no other decision procedure available that has uniformly smaller risk by some $\varepsilon > 0$. The collection Γ of risk functions for all available randomized decision procedures is known as the risk set, and consists of all mixtures $\sum_{j=1}^{J} \alpha_j R_{d_j}(\theta)$ of the risk functions of the pure decision rules d_j. This set is the convex hull of the risk functions for pure decision rules.

A decision procedure δ is said to be Bayes with respect to a **prior distribution** π for θ if its risk function $R_\delta(\theta)$ is such that

$$\int R_\delta(\theta)\, \pi(\mathrm{d}\theta) \leq \int R_{\delta_1}(\theta)\, \pi(\mathrm{d}\theta)$$

for all other available decision rules δ_1. In other words, a procedure δ is Bayes if for some a priori probability distribution π for θ, no other procedure has smaller expected risk when θ has distribution π. The Bayes risk of a decision procedure δ when π is the a priori distribution is by definition

$$B(\pi, \delta) = \int R_\delta(\theta)\, \pi(\mathrm{d}\theta).$$

The Bayes boundary of the risk set consists of all those risk functions for which no uniform improvement is possible; that is, no improvement by some $\varepsilon > 0$ uniformly in the parameter space.

Next, if a procedure is to be appropriate for real-world applications, in the sense of being implementable on a computer with finite memory, it is necessary that both the data space $\mathcal{X}$ and the action space $\mathcal{A}$ be finite. Even if the original data space were of infinite cardinality, it would be necessary to finitize it in order to put all possible observations into such a computer. Such finitization procedures are of course quite customary, even with integer data, such as time to death as measured to the nearest year, where one puts in an upper bound, for example so that all deaths beyond 200 years are lumped into a single category. Similarly, if time of death is measured in terms of fractions of years, it is customary to round these also, both because no one is seriously interested in measuring such times to death too finely (such as 67.3487532137 years), and also because even if it were possible to do so in a meaningful sense, it would be impossible either to measure or record in a computer too many such decimal points.

In real-world decision problems, the action space must also be finite. No decision maker seriously

contemplates taking more than a finite number of actions. For example, if the problem is to forecast an interest rate a year from now, then real-world forecasts are not given to more than a few decimal points. With regard to the cardinality of the parameter space, in typical real-world problems the parameter too is rounded, and typically loses its meaning beyond a certain known finite number of decimal points. For example, the weight of a whale changes nontrivially whenever the whale spouts, and the height of a person changes during the course of a day. Hence, it is meaningless to define such parameters to too great precision. Only in certain (typically exotic) problems arising in the physical sciences can parameters be taken seriously to many decimal places, and even here the uncertainty principle of quantum mechanics suggests limitations on the ability to measure such parameters.

In the case of a finite data space and a finite parameter space, the conditional probabilities for θ given $X = x$ are well defined, and it is easy to show that the Bayes procedures are those that are equivalent to first updating the initial distribution π to a posterior distribution π^* by using Bayes's theorem, and then choosing a terminal action that minimizes the expected loss with respect to this posterior distribution: see Savage [19, Chapter 3] or DeGroot [7, p. 138]. In the finite case there always exists a pure decision rule δ_π that is a Bayes decision rule for π.

When the parameter space is not finite, there are some technical issues to mention. First, in the original **Kolmogorov** theory, it is conventional to allow only countably additive probability distributions for θ. Such countably additive distributions are necessarily finitely additive, in the sense that the probability of a finite union of disjoint events is the sum of probabilities. However, in recent years it has become understood that the collection of finitely additive distributions, which is a much larger collection, is also of importance. (Indeed, improper prior distributions, such as are widely used by Bayesian statisticians after the fashion of **H. Jeffreys** [12], and implicitly used by some non-Bayesians, can be rigorously interpreted as finitely additive distributions.) By a finitely additive distribution, we mean one in which additivity of probabilities is required to hold for all *finite* unions of disjoint events, but not necessarily for nonfinite unions. If the parameter has only a finite number of values, then finite additivity and countable additivity are equivalent. To say that a procedure is Bayes with respect to a finitely additive probability distribution π means the same as previously, in terms of minimization of expected risk with respect to that distribution, except that now the distributions may be only finitely additive. It is easy to show that the space of all possible finitely additive distributions is equivalent to the space of all nonnegative linear functionals $\pi(f)$ defined on the collection of bounded functions f of the parameter θ. The probability of a subset A of the parameter space is simply the value of the functional π at the indicator of the set A. See Kolmogorov & Fomin [15] for an elegant presentation of the theory of such linear functionals.

The next theorem proves that any procedure that is not based upon conditional probability is objectively defective. This is meant in precisely the same sense as in the Neyman–Pearson lemma, where it is foolish not to minimize the type two error probability for a specified type one error probability. This theorem is a slight strengthening of Theorem 1 of Hill [9] to allow for a possibly infinite parameter space, and the proof is essentially the same. When the parameter space is finite the theorem holds for any loss function whatsoever.

Theorem 3. Suppose that the space of terminal actions $\mathcal{A}$ and the data space $\mathcal{X}$ are finite, with the parameter space arbitrary, and the loss function nonnegative and bounded. Let $\mathcal{D}$ be the class of randomized decision rules of the form $\delta(X) = \sum_{i=1}^{J} [\alpha_j] d_j(X)$. If a decision rule $\delta_0 \in \mathcal{D}$ is not Bayes with respect to some finitely additive a priori distribution, then it can be improved upon, uniformly in the parameter, by an admissible and computable Bayes procedure in $\mathcal{D}$.

The proof of this theorem is obtained by using the fact that under our assumptions any non-Bayes procedure δ_0 can be uniformly improved upon by some other available procedure, say δ_1, not necessarily a Bayes procedure. Now consider the restricted decision problem, in which only decision rules at least as good in risk as δ_1 are considered, and find a Bayes procedure δ_π in this restricted problem for some prior distribution π. Any such Bayes procedure has a risk function less than or equal to that of δ_1 for all θ, and so is uniformly better than δ_0. It is straightforward to show that π can always be chosen so that δ_π is admissible both in the restricted and the original decision problem.

This theorem shows that any real-world non-Bayes procedure can always be improved upon uniformly in the parameter by some positive amount. This is not merely a theoretic possibility, but Theorem 3 suggests a concrete **algorithm** for obtaining such improvements. Indeed, they can be routinely provided by means of existing computational methods for solving **linear programming** problems. The equivalence of the above minimization problem with those arising in linear programming follows from the fact that both problems can be formulated mathematically in terms of the minimization of an inner product of a fixed vector π with a variable vector γ that lies in a known closed convex set. In our problem the vector π is the a priori distribution, while in linear programming problems it is known as the objective function. It should be noted that when the non-Bayes procedure δ_0 is close to the Bayes boundary, then the improvement although uniform is small. On the other hand, many non-Bayes procedures in common use are very remote from the Bayes boundary, and substantial improvement is possible.

The theorem also suggests a new way to resolve issues about subjectivity of Bayes procedures. One can simply take any standard non-Bayes procedure δ_0 and use linear programming to replace it by a uniformly better Bayes procedure. In this way, by restricting the choice to be amongst only those Bayes procedures that are uniformly better than the standard procedure, one can avoid the more subtle and controversial issues concerning comparisons within the full class of Bayes procedures. Of course, the fact that any non-Bayes procedure can be uniformly improved upon by a Bayes procedure makes it clear that one can restrict attention to the class of Bayes procedures, without any loss in so doing. When there is some compelling case for the standard procedure δ_0, then this provides a motivation for giving particular attention to those Bayes procedures that uniformly dominate it, and therefore greatly simplifies the decision problem. Typically there will be several pure Bayes procedures that are uniformly better than δ_0. To choose amongst them, one can either use subjective judgment to select an appropriate a priori distribution π; or alternately use some more objective method to choose amongst the Bayes procedures that are uniformly better than δ_0. For example, one could use a **minimax** procedure in the restricted problem.

It is important to note that many conventional statistical procedures map the data into estimates or tests or predictions, without interpreting such a mapping as being in any sense a conditional procedure, or even as being conditional upon the data. Examples include the product-limit estimator in **survival analysis** (*see* **Kaplan–Meier Estimator**), **proportional hazards** models, the various **bootstraps**, and many other such well-known statistical procedures that are routinely used in the analysis of data. Theorem 3 shows that all such mappings can be assessed with respect to their unconditional performance, and only those procedures which possess the internal consistency properties of procedures derivable from conditional probability distributions are not objectively defective. The theorem even applies to the so-called group decision problem, in which a group must arrive at some decision procedure. No matter how arrived at, if that procedure is not a Bayes procedure based upon conditional probability, then it can be uniformly improved upon by a Bayes decision rule.

Theorem 3 relies upon the existence of a probability model for the data, given the parameter, and also of a **loss function**. When there is no accepted such probability model, then of course everything becomes subjective, and there is essentially no serious role for theory at all. With regard to the loss function, there exist both statistical problems with a generally accepted loss function, and others in which the loss function does not exist or is unknown or is controversial. If there is no loss function at all, then there is really no problem, since anything can be done whatsoever without any punishment for even the most absurd procedures. When a loss function exists but is not entirely known, or alternately when losses or utilities are difficult to assess, it is possible to make use of **robustness** properties of decision procedures. For example, one can obtain an optimal procedure for several different loss functions under consideration, and if these are nearly in agreement then for practical purposes the decision problem is solved.

The Evaluation Game

While it is clear that a decision procedure that can always be uniformly improved upon in risk is not particularly desirable, it is important to point out precisely how the latter leads in practice to poor decisions.

Let θ be a conventional parameter that determines the distribution of a random variable, X, and

let $\delta_i(X)$, $i = 0, 1$, be two decision functions. Suppose that there is a referee who generates couples (θ_j, X_j), on a computer, for $j = 1, \ldots, M$, generating the θ_j in any way whatsoever (not necessarily probabilistically), and then using the specified conditional distribution to generate X_j, given θ_j, with the X_j conditionally independent. Let the referee generate M couples in this way. Assume that the conditional distribution for X_j, given θ_j, is known to all concerned. Consider a statistician or decision-maker who must choose between $\delta_1(X_j)$ and $\delta_0(X_j)$ to **estimate** θ_j using the same decision rule on each of the M occasions. Let $L(\theta_j, \delta_i(X_j))$ be the loss if θ_j is the true value of the parameter and $\delta_i(X_j)$ is used on the jth occasion, $1 \leq j \leq M$. We shall assume that all decision functions are to be mechanically implemented on a computer, without any data analysis or learning from one occasion to another.

Suppose, as in Theorem 3, that δ_1 is uniformly better than δ_0 with $R_{\delta_1}(\theta) \leq R_{\delta_0}(\theta) - \varepsilon$ for all θ with $\varepsilon > 0$. Summing over the M occasions, the actual increment in loss if δ_0 were used on each occasion instead of δ_1, would be $\sum_{j=1}^{M}[L(\theta_j, \delta_0(X_j)) - L(\theta_j, \delta_1(X_j))]$. The conditional expectation of this incremental loss due to use of δ_0, from the perspective of the referee who knows the θ_j, *is then, for any* θ_j *whatsoever*,

$$\begin{aligned} K(\theta_1, \ldots, \theta_M) &= \sum_{j=1}^{M} E_{X_j|\theta_j}\{L[\theta_j, \delta_0(X_j)] \\ &\quad - L[\theta_j, \delta_1(X_j)]\} \\ &= \sum_{j=1}^{M}[R_{\delta_0}(\theta_j) - R_{\delta_1}(\theta_j)] \geq M\varepsilon. \end{aligned}$$

This proves that in repeated usage of δ_0 instead of δ_1 with M large, one typically anticipates enormous extra loss. If, in addition, the referee uses some probability distribution π to generate the θ_j, then

$$\mathcal{E}\, K(\theta_1, \ldots, \theta_M) = M[B(\pi, \delta_0) - B(\pi, \delta_1)],$$

which is M times the difference in Bayes risks for the two procedures. Of course, the best possible decision procedure would be a procedure that is Bayes with respect to the π used by the referee, but even if this is unknown (or does not exist) it is still the case that one can enormously improve upon any specified non-Bayes procedure δ_0 by means of Theorem 3. This is the operational sense in which usage of non-Bayes procedures, that is, those not based upon conditional probability assessments, are objectively defective in performance. This argument also reveals the intimate connection between the fundamental frequentist argument that procedures are to be assessed in terms of long-run performance, and the Bayesian algorithm for obtaining optimal decisions by optimizing conditionally upon the data.

Next, suppose that instead of estimation of an unknown parameter θ, one is using the data X to **predict** another random variable Y. In other words, on the jth occasion one is given X_j and must now predict Y_j. Then the above argument goes through in exactly the same way, with now the usual estimative risk function replaced by the predictive risk function, which is a function of the unknown value of Y. The theory of predictive risk functions is presented in Hill [10]. If the decision function used to predict Y is $\delta(X)$ then the predictive risk function is

$$R_\delta(y) = \mathcal{E}\, L(y, \delta(X)).$$

In other words, the parameter θ is replaced by the true value of Y to be observed. It is assumed that a joint probability distribution has been specified for (X, Y), and $R_\delta(y)$ is the expectation of $L(Y, \delta(X))$, conditional upon $Y = y$.

A particularly important and challenging example, to which Theorem 3 applies, concerns data in a large sparse contingency table, such as is common in medical diagnosis. Suppose that one must put forth a conditional probability that a new patient with symptoms given by $X = x$ has disease y, based upon the data in the table. This is precisely the type of prediction problem just discussed. Many *ad hoc* methods exist for estimating such probabilities. Only those, however, for which there exists a joint distribution for (X, Y) such that the probabilities put forth are truly conditional probabilities based upon that joint distribution, cannot be improved upon uniformly by the algorithm of Theorem 3 (*see* **Decision Analysis in Diagnosis and Treatment Choice**).

The Infinite Case

Kolmogorov [13] put forth a theory of probability in which conditional probabilities were defined as Radon–Nikodym derivates of one bounded signed measure with respect to another. Briefly, let Y be a

random variable with respect to the probability space $(\Omega, \mathcal{A}, P)$ for which the expectation $\mathcal{E}(Y)$ exists, and let $\mathcal{B}$ be a σ-algebra of subsets of Ω such that $\mathcal{B} \subset \mathcal{A}$. Then the signed measure $\mu(B) = \int_B Y \, dP$ defined for $B \in \mathcal{B}$ is absolutely continuous with respect to P. According to the **Radon–Nikodým theorem**, there exists a $\mathcal{B}$-measurable function $f(\omega)$, often written as $f(\omega) = (d\mu/dP)(\omega)$, such that

$$\int_B Y(\omega) \, dP(\omega) = \int_B f(\omega) \, dP(\omega),$$

for all $B \in \mathcal{B}$. Any two such functions $f_i(\omega)$ can differ only on a set in $\mathcal{B}$ of P measure 0, and the conditional expectation of Y given $\mathcal{B}$ is defined to be $\mathcal{E}(Y|\mathcal{B})(\omega) = f(\omega)$ for any such function. Kolmogorov thus attempted to extend the classical concept of conditional probability to the nonfinite case, by requiring that the generalized law of total probability $\mathcal{E}Y = \mathcal{E}\mathcal{E}[Y|X]$ remain true. For Y the indicator of an event, this provides a definition of conditional probability given $\mathcal{B}$. An alternate method to obtain conditional probabilities in the sense of Kolmogorov, more directly related to standard mathematics and expectation, is to use the theory of projections in Hilbert space developed by von Neumann, as for example presented in Rényi [17, p. 262].

The theory of Kolmogorov has proved fruitful in allowing many elegant theorems concerning martingales (*see* **Counting Process Methods in Survival Analysis**) and **Markov processes** to be proved rigorously, in accord with the usual mathematical conventions. On the other hand, this theory is based on a number of idealizations, and in particular rests strongly upon the Axiom of Continuity (or Countable Additivity). Kolmogorov [13, p. 15] states:

> For infinite fields, on the other hand, the Axiom of Continuity, VI, proved to be independent of Axioms I–V. Since the new axiom is essential for infinite fields of probability only, it is almost impossible to elucidate its empirical meaning, as has been done, for example, in the case of Axioms I–V in 2 of the first chapter. For, in describing any observable random process, we can obtain only finite fields of probability. Infinite fields of probability occur only as idealized models of real random processes. *We limit ourselves, arbitrarily, to only those models which satisfy Axiom VI.* [Author's italics.] This limitation has been found expedient in researches of the most diverse sort.

Conditional probability in the sense of Kolmogorov is an extension of the classical concept of Bayes in the sense that the two are in agreement whenever $\mathcal{B}$ is purely atomic, as for countable spaces of outcomes. For it is a standard result that whenever $\mathcal{B}$ is purely atomic with atoms B_i having positive probability, then $(d\mu/dP)(\omega) = \mathcal{E}(Y|B_i)$ for $\omega \in B_i$. See Rényi [17, p. 261]. However, the theory of Kolmogorov also applies to cases in which the underlying space Ω is a finite-dimensional Euclidean space, a Hilbert space, a pseudo-metric space, and even to appropriately defined Borel sets in an abstract space of points. Alternately, this theory can be based upon the Daniell integral, as in Riesz–Sz.-Nagy [18, p. 132], and is then closely related to the theory of nonnegative linear functionals. However, it is not necessarily harmless to generalize the concrete and clear concept of conditional probability in finite spaces to such idealized spaces. Kolmogorov [13, p. 17] puts it well in discussing the Borel field $\mathcal{BF}$:

> Even if the sets (events) A of $\mathcal{F}$ can be interpreted as actual and (perhaps only approximately) observable events, it does not, of course, follow from this that the sets of the extended field $\mathcal{BF}$ reasonably admit of such an interpretation.
>
> Thus there is the possibility that while a field of probability $(\mathcal{F}, P)$ may be regarded as the image (idealized, however) of actual random events, the extended field of probability $(\mathcal{B}, P)$ will still remain merely a mathematical structure.

If one allows the possibility of the realization of an irrational number as the actual outcome of an experiment, with this number obtained by direct measurement, then conditional probability in the sense of Kolmogorov can disagree with the classical concept of both Bayes and the frequentist theory. Of course, no such outcome has ever been observed, or could ever be observed, in finite time, and even such irrational numbers as π and e are at any given time known only up to a finite number of decimal points. Furthermore, the use of transformations such as $\sqrt{x}$ that can lead to irrational numbers does not alter things, since when used operationally by a computer these must be replaced by some finite approximation. If the data space $\mathcal{X}$ consisted of all points in even one of the most simple idealized spaces, the real line, then no real-world observation could ever consist of the exact value of the observation, since it would require infinite time to determine all the decimal points for even a single such measurement. Hence the actual observations upon which one conditions, as in Bayes' theorem, are necessarily very special subsets of $\mathcal{X}$,

such as for example that the observation lies between two rational numbers. Borel, who initiated modern measure theory, was particularly concerned about the misuse of mathematics in connection with real-world data, as for example in Borel [2, Chapters 5–8], and emphasized the importance of approximations in the *evaluation* of real-world probabilities. The theory of Kolmogorov, in the case of even such simple sample spaces as the real line, has no direct relevance for the question of updating of opinions, as in the Bayesian theory, or for decision theory, since the datum x upon which the decision is to be based will always be finitized. Rather, it includes an assumption (countable additivity) which, although useful in proving limit theorems, according to Kolmogorov cannot be justified other than by pragmatic reasons even for this purpose, much less for real-world decision problems.

De Finetti also attempted to extend the classical concept of conditional probability, and proposed a third axiom in de Finetti [6, p. 338] to allow for conditional probability given an event of probability 0. His third axiom states that probability evaluations are to be in accord with the axioms of finitely additive probability theory, even conditional upon an event of probability 0. To obtain conditional probabilities in the general finitely additive setting, Dubins & Savage [8] developed the concept of a finitely additive strategy, under which probability distributions are attached to each history of a process. These specify the probability for the future, given the past of the process, and allow arbitrary observational data, such as irrational numbers or a point in Hilbert space. At this level of generality, it is not necessarily possible to reverse the order of integration, so that a strategy may presume a definite ordering of the observations.

For infinite spaces, the finitely additive theory contains paradoxes of nonconglomerability, a concept due to de Finetti. Nonconglomerability means that for some event A and partition B_t it is the case that $P(A) > \sup_t P(A|B_t)$. In denumerable spaces it is known that countable additivity is equivalent to conglomerability. See Hill & Lane [11] for an elementary proof. Thus the countably additive theory builds in assumptions regarding conditional probability. Kolmogorov, in assuming countable additivity, was implicitly ruling out nonconglomerability, at least in the discrete case. At the present time there is no theory, free of paradoxes, that can seriously deal with the nondenumerable case, as when irrational numbers are taken literally. Borel [3, p. 60, p. 175] gives illuminating discussions of ways in which some mathematicians, unaware of the questions already raised by himself and Poincaré, and later by Kolmogorov; and with limited knowledge of science, have often confused the basic issues when dealing with the nonfinite case. Borel [7, Chapters 2, 3, & 5] discusses the subtle issues that arise in attempting to apply the theory of probability to real-world problems, such as arise in the analysis of mortality tables.

In serious mathematics, an irrational number is viewed as the idealized limit obtained by means of a certain procedure, such as for example the limit of a sequence of partial sums. This point of view can also be taken regarding procedures involving randomness, such as draws from an urn. Prior to the work of Cantor, the realized infinite was regarded as nonsense by most major mathematicians; for example, Gauss and Kronecker. Related viewpoints continued into this century, as represented by Borel. Poincaré, Brouwer, Weyl, and others. Kolmogorov, also a major mathematician who made serious contributions to logic as well as to probability, was concerned with such issues, and his opinions evolved over time. For example, in his book with Fomin, a measure is so defined as not necessarily to be countable additive, and some standard finitely additive measures are studied. The theory of Kolmogorov was elegantly extended by Rényi [17, p. 38] to conditional probability spaces. This extension allows one to deal rigorously with σ-finite measures such as counting measure on a denumerable space, and is a major step toward the finitely additive theory, although Rényi did not choose to make the final extension. There is, however, a clear recognition both by Kolmogorov & Fomin [15, p. 206] and by Rényi [17, p. 60] that generalized functions such as the Dirac delta function are important and legitimate objects for mathematics (and probability) to study. The finitely additive theory can be regarded as the extension of that of Kolmogorov to include such objects.

Kolmogorov [14, p. 1] asserted his continuing belief that

> The frequency concept based on the notion of *limiting frequency* [author's italics] as the number of trials increases to infinity, does not contribute anything to substantiate the applicability of the results of probability theory to real practical problems where we have always to deal with a finite number of trials.

He then proposed a theory of complexity and information based upon admissible algorithms for selecting a subset of a random table, as a possible justification. With a return to the finite case, however, as the critical case for real-world use of probability, the axioms of finitely additive probability (Kolmorogov's axioms I–V) can be strongly motivated, as by himself, or by the coherency theory of de Finetti, or by the BNW theory of statistical decision functions. Consequently, one is led back to the use of conditional probability and Bayes procedures for real-world decision-making. To the extent that nonfinite spaces arise at all in real-world problems, as suggested by Kolmogorov [13, p. 18; 14], it is in giving insight as to approximations that arise when the data space is large but finite, and in providing answers to finite problems by means of methods of analysis available in the infinite case.

Conditionality Principle

The conditionality principle of statistical inference is usually interpreted to mean that inference about $\boldsymbol{\theta}$ in the model $f(\boldsymbol{y};\boldsymbol{\theta})$ should be conditional on any **ancillary statistic** for $\boldsymbol{\theta}$. This principle has caused a great deal of discussion in the literature on the foundations of statistics: for an introduction see [1]. As part of this discussion, examples have been constructed for which there are nonunique ancillary statistics, for which no ancillary statistics exist, and for which there exist ancillary statistics but no maximal ancillary statistic.

From a foundational point of view the conditionality principle entails quite a few difficulties. One of these is Birnbaum's theorem [3], which shows that **sufficiency** and the conditionality principle imply the so-called likelihood principle, which states that inference should be based only on the likelihood function, and not, for example, on the sampling properties of the likelihood function under the model, which would be the usual frequentist approach to likelihood-based inference (*see* **Foundations of Probability**). In fact, the conditionality principle alone entails the likelihood principle, as shown in [5].

Berger & Wolpert [2] is the most comprehensive book treatment of the conditionality principle. It is argued there that the most satisfactory implementation of the likelihood principle is a Bayesian approach to inference. Discussion of other foundational issues arising in conditioning appears in [4]. Recently, McCullagh [6] has considered in detail an unusual (although possibly artificial) class of examples which has more than one ancillary statistic, and in which the conditional inference is quite dependent on the choice of ancillary on which to condition.

Confidence Intervals, Binomial, when no events are observed

The appeal of the *rule of three* to clinicians is in its simplicity and usefulness in safety evaluation of adverse events. Specifically, consider a scenario in which the **probability**, p, of an event (generally an adverse reaction to a drug or clinical procedure) is known, a priori, to be small, and in a study conducted on n patients, no events have occurred. The problem is to find an upper bound for the unknown probability, p. The *rule of three* states that the 95% upper confidence bound for p is approximately $3/n$ (*see* **Confidence Intervals and Sets**).

In the context of safety evaluation in clinical research, in which a clinician has to demonstrate the safety of a new procedure (i.e. show that the probability of an adverse event is lower than some small acceptable probability), the *lower* bound for p is not of practical interest; one is mainly concerned with the *upper* bound on p, since it represents the "worst case scenario", or the largest probability for placing a patient at risk. Thus, the lower bound for p may a priori be taken to equal zero.

Derivation of the Rule of Three

Let the **random variable** X have a **binomial distribution** with parameters n and p. If $X = x$ is the observed number of events in n trials, then the Clopper–Pearson (max-P) upper $100(1-\alpha)\%$ bound for p may be obtained as a solution to

$$\sum_{t=0}^{x} \binom{n}{t} p^t (1-p)^{n-t} = \alpha.$$

When $x = 0$, the expression reduces to $(1-p)^n = \alpha$. Then $P(X = 0|n, p) = (1-p)^n$, and one can obtain the $100(1-\alpha)\%$ upper bound for p by solving $(1-p)^n \leq \alpha$ for p. This yields $p \geq 1 - \alpha^{1/n}$, and by taking $p_u = 1 - \alpha^{1/n}$ for the least upper bound for p, the interval $(0, p_u)$ provides $100(1-\alpha)\%$ coverage for p. Now, $3/n$ appears for the following reason. From the Taylor expansion $\alpha^{1/n} = 1 + \ln(\alpha)/n + [\ln(\alpha)]^2/2n^2 + \cdots$, one obtains, by retaining only the linear portion,

$$1 - \alpha^{1/n} = \frac{-\ln(\alpha)}{n}.$$

For $\alpha = 0.05$, $-\ln(\alpha) = 2.996$, and thus p_u is numerically close to $3/n$.

A similar argument using a **Poisson** random variable, with parameter $\lambda = np$, yields $P(X = 0|np) = \exp(-np) \leq \alpha$, which, after taking the natural log of both sides, produces the least upper bound $p_u = -\ln(\alpha)/n$ which yields $3/n$ as in the binomial case.

The *rule of three* may be derived using the **Bayesian** approach as well. Assume a **Beta**$(1, b)$ **prior** on p, i.e. $\pi(p) = (1-p)^{b-1}/B(1, b)$. Figure 1 presents a sequence of kernels (*see* **Density Estimation**) of Beta$(1, b)$ priors for various values of b. With a Beta$(1, b)$ prior, simple integration yields a posterior credibility interval for p:

$$P(0 < p < p_u | X = 0, b, n) = 1 - (1 - p_u)^{(n+b)} \geq (1-\alpha),$$

which simplifies to

$$p_u \geq 1 - \alpha^{1/(n+b)},$$

and the right-hand side can be approximated via Taylor expansion by

$$\frac{-\ln(\alpha)}{(n+b)}.$$

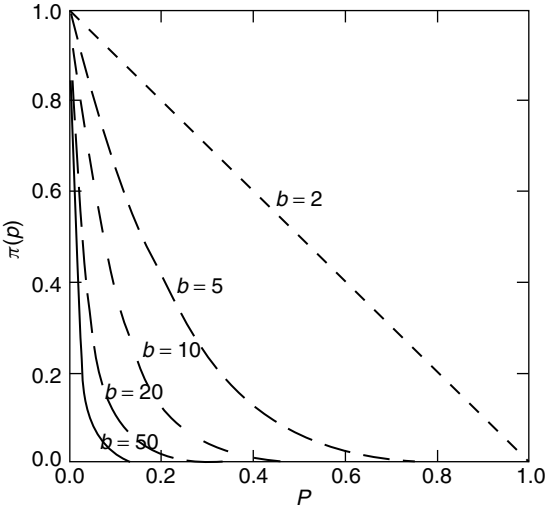

Figure 1 Beta$(1, b)$ prior kernels for various values of b

Table 1 Upper bounds on p when $x = 0$: Poisson (2); exact binomial (3); Rule of Three (4); Bayesian upper bound for uniform (Beta(1, b), $b = 1$); prior (5); improved Rule of Three (6); and Bayesian Rule of Three for $b = 20$ (7)

(1)	(2)	(3)	(4)	(5)	(6)	(7)
n	$-\ln(\alpha)/n$	$1-\alpha^{1/n}$	$3/n$	$1-\alpha^{1/(n-1)}$	$3/(n+1)$	$3/(n+20)$
3	0.99858	0.63160	1.00000	0.52713	0.75000	0.13043
4	0.74893	0.52713	0.75000	0.45072	0.60000	0.12500
5	0.59915	0.45072	0.60000	0.39304	0.50000	0.12000
6	0.49929	0.39304	0.50000	0.34816	0.42857	0.11538
7	0.42796	0.34816	0.42857	0.31234	0.37500	0.11111
8	0.37477	0.31234	0.37500	0.28313	0.33333	0.10714
9	0.33286	0.28313	0.33333	0.25877	0.30000	0.10345
10	0.29957	0.25877	0.30000	0.23840	0.27273	0.10000
20	0.14979	0.13911	0.15000	0.13295	0.14286	0.07500
50	0.05991	0.05816	0.06000	0.05705	0.05882	0.04285
100	0.02996	0.02951	0.03000	0.02923	0.02970	0.02500

This gives us a Bayesian Rule of Three as $3/(n + b)$, with $b \geq 1$. Obviously, for $b = 1$, $3/(n + 1)$ is the largest such upper bound, corresponding to the uniform prior (see Table 1).

If no events occur in k studies of sizes n_1, $n_2, \ldots, n_k$, then one has a more general *rule of three* as $3/(n_1 + n_2 + \cdots + n_k + 1)$, which may be derived using a Bayesian approach.

Confidence Intervals and Sets

A *confidence interval* for a fixed parameter θ, or a *confidence set* for a multidimensional parameter $\boldsymbol{\theta}$, represents a plausible range of values for the parameter(s) that is consistent with the observed data. Specifically, for a single parameter θ, the interval (L, U) is a $100(1-\alpha)\%$ confidence interval for θ if $\Pr(L \leq \theta \leq U) = 1-\alpha$. The quantity $1-\alpha$ is called the *confidence coefficient* or *confidence level*, and is equal to the probability that the random interval (L, U), contains the fixed parameter θ. The confidence limits L and U are constructed from the observed data in such a way that in infinite replications of the study, the proportion of such intervals that contain the parameter θ, or the *coverage probability*, is $1-\alpha$. For an r-dimensional parameter vector $\boldsymbol{\theta}$, the confidence set $\mathbf{I}$ is defined as the r-dimensional space $\mathbf{I} = [\boldsymbol{\theta} : L_j \leq \theta_j \leq U_j,\ j = 1, \ldots, r]$ such that $\Pr(\boldsymbol{\theta} \in \mathbf{I}) = 1-\alpha$.

Confidence intervals need not be symmetric, but could reflect upper or lower bounds for a parameter in a *one-sided confidence interval*, as opposed to the two-sided interval described above. A $100(1-\alpha)\%$ upper one-sided confidence limit or bound U' for θ has the property that $\Pr(U' \geq \theta) = 1-\alpha$. The interval $(-\infty, U')$ is sometimes called a lower one-sided confidence interval. The corresponding lower one-sided bound L' is such that $\Pr(L' \leq \theta) = 1-\alpha$. The definitions of coverage probabilities and confidence coefficients are equally applicable to one-sided limits.

Confidence intervals are often centered around an estimate of the parameter of interest θ, and give an indication of the precision of the estimate. They incorporate the random variation inherent in the data into the estimation procedure. Various methods of constructing confidence intervals are used, depending on the distribution of the data, and the particular parameter of interest (*see* **Estimation, Interval**). The length of the confidence interval, a reflection of the precision of the estimate, is influenced by the sample size, the variability in the data, and the confidence coefficient. The higher the level of confidence, the greater the variability in the data, or the smaller the sample size, the wider is the interval. The tighter the interval, the more certain is the parameter estimation.

The confidence interval is based on frequentist statistical theory in which the parameter θ is considered fixed but unknown, and was developed by Neyman [2, 3]. The alternative **Bayesian** theory considers the parameter θ to be a realization of a random variable Θ, and instead defines a probability distribution for Θ [1]. Probability statements about Θ, conditional on the observed data, are based on the posterior distribution. Upper and lower percentage points of the posterior distribution would correspond to the frequentist confidence interval. For multidimensional parameters, a region of high posterior density would correspond to the confidence set.

NANCY R. COOK

Confidentiality and Computers

Introduction

This updates an article with the same title that appeared in the first edition of EOB.

Confidentiality is defined as "the characteristic of data and information being disclosed only to authorized persons, entities and processes at authorized times and in the authorized manner" [24]. Essentially, confidentiality relates to control over information. Who should have access to information, and under what circumstances?

While confidentiality concerns apply also to paper-based or manual records, the widespread utilization of information technology, and especially the networking of computers (*see* **Computer Architecture and Organization**), has led to new and difficult challenges for maintaining confidentiality and privacy. Confidentiality issues arise both for personal information and for information that is important for the functioning of business and other organizations. Personal information may include facts and figures about ourselves, our lives, our personal work and financial situations, and our medical history. Most people do not however regard information on telephone number or street address as confidential, and are happy for it to be printed in a phone directory, that is, it is placed "in the public domain".

When information is provided to people in trusted positions – doctors, lawyers, researchers, and government officials – there is an expectation that it will be kept secure, used only for the purpose for which it has been collected. Any breach of this trust may compromise future data collection [4].

Social and cultural value systems strongly influence attitudes to privacy and confidentiality. Different societies have different views on where the balance should lie between individual rights and public good.

Privacy and Confidentiality

The confidentiality of personal information is closely aligned with the broader issue of privacy. Gostin et al. [12] suggest that privacy is "the right of an individual to limit access by others to some aspect of the person", while confidentiality is "a form of informational privacy characterized by a special relationship, such as the physician-patient relationship". Privacy protection is about individuals being informed why their information is being collected, having access to their information and having as much say as possible about how their information is used and to whom it may be disclosed [22].

Laws, Standards, Principles, and Practicalities

Rights to privacy and confidentiality, and principles that guide the handling of private information, may be enshrined in law. Public and other bodies who hold data may have their own standards, which interpret and/or supplement legal requirements. Such laws and standards provide a framework for deciding when and under what conditions data can be made available to third parties.

A major impetus to the passing of laws on the privacy of data, in a number of countries, was the *1995 Privacy Directive of the European Union* [11], which applies both to private and to public data. This obliges the EU's member states to ensure that their national legislation is in accordance with the directive, and prevents the exchange of data with nations that do not have "adequate" privacy protections.

A basic principle of most privacy legislation is the protection of the "need to know", or the limiting of access to the minimum required to perform a task. Implicit in this is the need to exclude access for those who have no genuine requirement to access the data. Thus for many (but not all) research uses of medical data, it will be enough to make data available without identifying information, usually with some form of coding or **record linkage** that is unique to the individual. This is not as straightforward as might appear at first glance; thus mechanisms will be required that allow a check on apparent anomalies or suspected errors.

Confidentiality and Computer Systems

Privacy and confidentially measures can work only when the data holder has the will, technical capacity, and moral or legal authority to keep such information secure [8]. To be effective, such measures require the informed cooperation of users. Education thus has an important role.

Stand-alone systems are in principle relatively easy to secure. Broadly, access can be limited to trusted individuals for authorized purposes, and all use can be monitored and logged. It will be possible to attribute any security lapse to one of a small number of known individuals. With smaller systems the same person may have more than one role, that is, general user and system manager. Such a user may be given separate accounts for the separate roles, and be required to access the system with the account that is relevant for the role or task that they are performing at the time.

Networked systems, systems that use wireless connections and (even more) systems that are connected to the **internet**, pose new and difficult security problems. Data collected by the CERTC Coordination Center of Internet security expertise, shows a sharp increase in intrusion incidents between 1999 and 2001 [15]. There may be denials of service, files may be destroyed, damaged, or altered, and the security of data may be compromised.

Current systems may be testing to breaking point current design approaches for networked systems, perhaps inevitable in the rush to create a networked world. The issues are so important that a recently established journal (January 2003), IEEE Security and Privacy, is devoted to them. System design is important, but gives only a first line of defence. System design, however careful and informed, is likely to lag behind technical innovation, for which the crucial test is day to day use.

Planning should therefore include measures that may detect unauthorized intrusion or use of data, should preventative measures fail, and have in place strategies that will respond rapidly and effectively [6, 16, 19, 25]. It should aim to mitigate the potential damage from unauthorized access. An "outsider" who gains access to data, whether by intrusion, from a mix-up, or from an incompletely erased hard drive that has been sent for disposal, will, in general, be unable to do much damage with data that lacks identification information. This emphasizes the importance of the trust that is placed in "insiders", who may be well placed to reconstruct the missing connections.

Security systems that place undue obstacles in the way of legitimate users can be self-defeating. They place obstacles in the way of legitimate use of the data. For medical data, they may compromise the obtaining of information that has strong public health implications. They may make it difficult or impossible to check on apparently anomalous data (*see* **Outliers**). At the same time, unduly onerous systems invite practices that render them partially ineffective. For example, access codes for a supposedly secure system may be made widely available, avoiding the time and complication associated with creating any new access codes.

Preventing and Responding to Incursion

Steps that may reduce the risk of unauthorized access, or to reduce its impact when it does occur, are:

- The use of "secure" software systems, that is, systems that are relatively invulnerable to unauthorized intrusion or to misuse.
- The use of "secure" forms of user identification, and of data transfer (*see* **Sample Surveys in the Health Sciences**).
- The use of a system of permissions that operates on a per file or per directory basis, with access restricted on a "need to access" basis.
- Avoiding or preventing storage of sensitive data on inherently insecure hardware, such as removable devices and laptops.
- Monitoring and logging of access to sensitive data.
- Education of managers and users.
- Regular auditing, checking that physical and system security measures are effective, that users have the correct level of access for their roles, that the rules defined by data providers are being met, and that managers and users understand their roles and responsibilities.
- The use, for sensitive data, of suitable forms of encryption, for data storage as well as for data transmission.
- Use of a system of record linkage that limits the need for access to identification information.
- Storage of identification information separately from the data to which it relates.

It is essential to get expert advice for the setting up of highly secure systems. A threat model, which balances security against the costs and user inconvenience of harsher security implementations, can be helpful [3, 19]. Security breaches such as are documented in Neumann [18, 20] provide data against which any such model can be validated.

Confidentiality, Computers, and Statistical Analysis

In most official statistical agencies, the protection from disclosure of individually identifiable records is guaranteed by legislation. The situation in Australia provides a good example of the issues that this raises. The Census and Statistics Act requires that the Australian Bureau of Statistics does not release statistics "in a manner that is likely to enable the identification of a particular person or organization". This has particular relevance to the release of computer files containing unidentifiable unit records, or microdata. The Australian Statistician [17] has discretionary powers to release unidentifiable individual statistical records, provided a recipient gives a legally binding undertaking that no attempt will be made to identify particular persons or organizations; that the information will be used for statistical purposes only; and that the information will not be disclosed to any other person or organizations. Other conditions may also be imposed.

The Australian Statistician is advised by a panel that assesses all proposals, to ensure that the data are unlikely to enable unit identification. The panel takes into account the level of detail in each record and the extent of disclosure avoidance techniques (e.g. releasing values not as collected but as classes, and randomly perturbing values by some small number). In this way, confidentiality provisions are satisfied while permitting legitimate demands for secondary data analysis, although users sometimes express concern that such techniques significantly reduce the value of the data that are released.

At times, statistical tables can also threaten confidentiality. For example, when a large enterprise dominates an industry, publishing information about that industry could be commercially sensitive. Similarly, detailed or multidimensional tables could contain information about individuals living in small communities. Possible ways to modify tables so that confidentiality is protected include:

a. Perturbing the table, to change the values of the data, for example, randomly rounding the values.
b. Grouping categories together (aggregating). Adding columns or rows together where there are small or confidential numbers, reduces the risk that it will be possible to infer confidential information.
c. Deleting values, or cell suppression. The value in a cell from the table may be suppressed. In order to avoid the value being calculated from subtotals/marginal totals, it is necessary to take other steps as well, usually deleting another set of cell values. Deleting these other cells is known as secondary or complementary cell suppression.

There is an extensive literature that discusses these issues [9, 26, 27, 28].

Confidentiality, Computers, and Epidemiological Research

The quantity and type of health information collected, transmitted, and stored electronically has increased dramatically in recent years. This reflects the widespread use of computers to store health related information systems (*see* **Health Care Utilization Data**), to satisfy accountability requirements and assist quality and continuity of care. Also, the number of procedures and treatments performed has increased and information on lifestyle, **risk factors**, family medical history (*see* **Family History Validation**), health and functional status (*see* **Health Status Instruments, Measurement Properties of**), and genetic data (*see* **Genetic Epidemiology**) are increasingly likely to be recorded. In addition, most countries now maintain registries of **vital statistics**, and registries for particular diseases (*see* **Disease Registers**), for example, **cancer registries**.

In some types of epidemiological research, identification of individuals to the researcher may be unavoidable (*see* **Confidentiality in Epidemiology**). In such cases, the benefits to society must be carefully weighed and justified against privacy principles and against guidelines on the use of identifying information for research purposes. Such guidelines may address the issues of informed consent of subjects (*see* **Medical Ethics and Statistics**), steps to preserve confidentiality, the use of the information obtained only for the purpose for which it was collected, and approval from an institutional ethics committee. Past Australian examples where the public good has outweighed personal privacy principles include epidemiological research into the effects of cigarette **smoking**, use of medical record linkage in research into the side-effects of the oral contraceptive pill, and research into the long-term consequences of chemical

exposures (*see* **Risk Assessment for Environmental Chemicals**) and of war service.

Medical research with human subjects relies heavily both on the trust of patients and on public support for research funding. That trust can be helped by making those whose data are collected aware of their rights, of the intended use of the data, and of potential benefits for medical research. Their attention may be drawn to web sites where they can follow the progress of research. Measures that keep subjects informed may be more important, for the maintenance of public trust, than unduly stringent and onerous privacy guarantees that may impede the use of data for research purposes.

Links on the web site [2] give access to a wide range of information on privacy, confidentiality, and data security, in the United States and internationally. For summary information on selected legal norms that relate to the protection of personal information in health research, with extensive references, see [5]. As examples of requirements, see [5, 7, 13, 14, 21, 22, 23]. See [1] for a set of standards that are intended, in the first place, for medical clinicians. The article [10] has practical advice that is relevant to anyone whose work involves the processing and analysis of data.

Conclusion

Confidentiality has social, cultural, ethical, and legal dimensions. While it is not specific to the use of information on computers, the ability of information systems to store, process, and transmit large amounts of data makes attention to confidentiality in computer systems an issue of major importance. The linking of computer systems via the Internet raises has raised new technical difficulties for the maintaining of security and confidentiality.

Confidentiality in Epidemiology

Respecting **confidentiality** is an important prerequisite in clinical and epidemiologic research. The term *confidentiality* is closely related to informational "privacy" and states the principle of the individual wish and right to decide about the disclosure of personal health data [1, 8]. Based on the Declarations of Helsinki (1964 and 1975) from the World Medical Association, it is a basic right of the patient to be assured that all his medical and personal data are confidential. The health professional who has obtained such data has a primary obligation to respect the confidentiality of the data and to safeguard them against any disclosure. Only in the case of a few well-defined exceptions is disclosure allowed, e.g. prevention of serious risk to public health, order by a court of law in a crime case, and, under certain safeguards, health research (including epidemiologic inquiry) [1, 10] (*see* **Epidemiology as Legal Evidence**).

According to Thompson, the concept of confidentiality refers to three principal values, namely "privacy", "confidence", and "secrecy" [8]. Privacy – and in epidemiology we mean in most cases "informational" privacy – deals with the right of individuals to control their own lives, while confidence is an essential requirement of the doctor–patient relationship. Abuse of the trust of confidence the patient places in his doctor would make the practice of medicine impossible. "Secrecy" can be seen as a complementary factor to individual privacy, but from the perspective of the professional dealing with the question of what the patient is allowed to know about his own records.

Ethical principles may affect research and the way we deal with confidentiality in many ways [2, 10, 11]. First, there is the question of the decision to do or not to do a study. Then the legal framework, including guidelines on how to conduct a study, is important. There is a considerable range of types of legislation to protect individual confidentiality in time and among countries. This perspective deals also with the **data management** and disclosure approaches in balancing the interests of science while respecting confidentiality rules and guidelines [6] (*see* **Ethics of Randomized Trials**).

Ethical Principles

Respect for confidentiality of persons involved in clinical and epidemiologic research has its origins in the fulfillment of relevant ethical principles. In general, four ethical principles can be distinguished [2, 6].

1. *Beneficence*. People in general, and the same is true for epidemiologists, have a moral obligation to do "right", i.e. to benefit individuals and society. The results of a research project should add to the existing knowledge base of medicine in order to make patients better, to prevent health hazards, or to decrease mortality.
2. *Nonmaleficence*. This principle reflects a moral obligation not to do harm to the persons involved in a scientific study. Harm can, under certain circumstances, be justified when the population benefits outweigh the individual harm: e.g. a **Phase I trial** in oncology almost never benefits the patients in the study, but may benefit other patients in the future.
3. *Autonomy*. The principle of autonomy states the moral obligation to respect the right to self-determination. Autonomy is the key principle for respecting confidentiality [1]. The demand for informed consent given by the persons involved in a study reflects the fulfillment of the principle of autonomy.
4. *Justice*. Justice can be considered as the principle of a fair distribution of burdens and benefits between individuals, and between groups in society. This principle may mean equal access to study participation and subsequent benefit (e.g. in **AIDS** trials), as well as equal exposure when certain outcomes are still uncertain (e.g. **post-marketing** studies with new drugs).

A useful approach in applying such principles is the assessment of each ethical principle in the context (or scope) of a specific study. Nilstun & Westrin have proposed to apply these principles from the perspective of each of the parties involved and then to assess the ethical "benefits" and "costs" in the event the study is or is not conducted [6]. This process can be illustrated by an example, in deciding whether to do or not a **pharmacoepidemiologic** study on the risk of hip fracture in patients using benzodiazepines [3]. In this example we may identify two relevant parties, i.e. the persons included in the study and society at

Table 1 The most important possible "benefits" and "costs" when the study is done [3]

	Bene-ficence	Nonmale-ficence	Auto-nomy	Justice
Persons in the study			Costs	
Society at large	Benefit			Benefit

large. In Table 1 a possible outcome of an analysis of the most relevant "benefits" and "costs" is listed concerning the two dimensions of ethical principles and parties involved in the event that the study is conducted. "Benefits" and "costs" are essentially exchanged if the study is not conducted (*see* **Health Economics**).

If the study is done, there are possible "benefits" for society at large because the study strengthened a hypothesis based on earlier findings and its results can guide prescribers in rationing the use of these drugs. There could be potential costs with respect for autonomy by violating the privacy of the patients in the study. Data on prescription drug use had to be linked to cases of hospitalizations for hip fracture without knowing the patient's identity. All this was done with existing data and applying a probabilistic approach in relating different datafiles to the same individual using dates of birth, gender, and physician practice [3]. For society at large, potential "benefits" to the principle of justice can be stated. Justice means a fair contribution to the gain of relevant medical knowledge, obviously within the boundaries of economics and other structural conditions. By "participating" in such a study the population involved took its share in the solidarity of bringing together relevant pieces of clinical and epidemiologic insight.

Legal Framework and Guidelines

There is great international variety in legislation and practice guidelines on protecting violation of confidentiality. Several international professional organizations have developed ethical guidelines and recommendations for epidemiologic studies, including those produced by the **World Health Organization (WHO)**, the Industrial Epidemiology Forum (IEF), the International Epidemiological Association (IEA), and the Council of International Organizations of Medical Sciences (CIOMS), and the guidelines of the International Society for Pharmacoepidemiology (ISPE).

Recently, the greatest attention has been paid to the directives of the European Union [4]. There has been ample expression of public and professional concern against these directives, principally because "privacy" is deemed to be violated even in epidemiologic studies where confidentiality is assured, unless the particular purpose is approved by all individuals [5, 7, 9]. The intent of the European directives is to protect individuals from improper administrative use of personal data, including medical data, although no specific details in this direction were given. The definition of "personal data" is crucial here, because it relates to the question of how much effort is needed to identify an individual person within the format of the data. Apart from many other criteria for and conditions about data confidentiality, "express and written informed consent" and "personal data" are the two basic features of European directives that are most critical.

Record linkage is a key methodology in epidemiology and various techniques (e.g. **Probabilistic matching** and encryption techniques) have been developed to cope with the confidentiality issue [3, 5]. Some privacy advocates, however, continue to argue that written informed consent from all patients would be required to do such linkage studies, even if all the data are processed in a fully anonymous fashion. The creation of unbiased personal histories (including both data on various exposure and outcomes) is a crucial requirement in epidemiology. Record linkage, as was done in the case study on hip fractures, would be virtually impossible if a requirement of full written informed consent were imposed.

Discussion

Protecting confidentiality in the context of scientific inquiry is one of today's paradoxes. The paradox confuses us because it requires us to live simultaneously with opposites. The paradox here is the growing ability and need to apply advanced data systems to investigate health hazards related to various exposures (*see* **Administrative Databases**), and on the other hand the increase of legal control over data collection and procedures to use these data for epidemiologic research. Major progress is being made in automated databases and information technology

to establish effective strategies in the use of data for epidemiologic research. Linking existing data can be an effective and efficient way to study various exposures and population outcomes. However, society is increasingly concerned about violating the privacy of individuals. Ethical controversies on confidentiality may affect and obstruct epidemiologic research in a significant way [4, 9]. On the other hand, ethical principles may be important to support the conduct of research and to guide decision making in this respect.

Westrin & Nilstun have compared the aims and tasks of both epidemiologists and journalists in terms of their responsibility towards the protection of confidentiality [11]. Society seems willing to accept that, in the interests of wider public good, journalism may sometimes invade individuals' privacy and do them harm, but it is not prepared to offer epidemiology an equal measure of tolerance. Confusion still surrounds the question of whether confidentiality can be fundamentally violated by data drawn from personal records. Ethical conflicts between moral principles and methodologic standards affecting epidemiologic research will remain. The future lies in thoughtful weighing of the various "costs" and "benefits" in such conflicts.

HUBERT G. LEUFKENS

Confidentiality

Confidentiality in the context of health and biostatistical research concerns the avoidance of disclosure of sensitive and identifiable information about individual patients to a third party. Confidentiality procedures have been subject to change during recent decades. Patient treatment has increased in complexity, frequently involving both primary health care workers and specialists, often in several hospitals, and more persons thus have a need for access to data on an individual patient, but they may also obtain access to data which are irrelevant for the medical service to be provided. Patient data that were once used almost exclusively by the treating physician are thus often shared with others, including nonmedical persons, to a far greater extent than in the past, particularly for research purposes. This research is generally intended for the benefit of the whole population in identifying causes of disease, evaluating the outcome of treatment, assessing equity in health and in access to treatment services (*see* **Health Services Research, Overview**), etc. The availability and widespread use of computer systems to store, analyze, and transmit large volumes of data, sometimes over public data networks, have radically altered the climate in which patient confidentiality must be maintained (*see* **Administrative Databases**). These changes in the use of confidential data have coincided with heated debate on the **ethics of randomized trials**. Randomized **clinical trials** are essential research tools for identifying optimal future treatments, but they are not always readily understood by the general public. Prospective research such as randomized trials, involving direct recruitment of living patients, requires the informed consent of the patient in many countries today. This consent will usually also set the terms for use of the data.

The ethical issue of confidentiality is more complex where the data subject is not contacted, and may no longer be alive, even if the results of the research do not enable the individual to be identified. This situation arises when data that are collected, for purposes such as routine **surveillance of disease** or **vital statistics**, often under the aegis of government, or for hospital administration or **occupational health**, are collated from available sources and the records for a given individual linked for analysis (*see* **Record Linkage**). The results of such research may provide powerful new insights into trends in the health of the population without any need for individuals to be identified. The possibilities for computerized linkage of data for individuals, even for very large volumes of data, have increased public fears of misuse and of error, and they have stimulated a continuing public debate on ethics and confidentiality in health research (*see* **Confidentiality in Epidemiology**).

What Should be Kept Confidential?

Data given in confidence must clearly be treated as confidential. Health data obtained during the doctor's management of a patient should be regarded as confidential, but may, in the interests of the patient, be transmitted to other physicians involved in the treatment of that patient, and physicians will be expected to observe professional confidentiality. Responses given to an interviewer or written on a form as part of a health survey (*see* **Surveys, Health and Morbidity**) should also be treated as confidential information. Often, a promise of confidentiality is explicitly given to survey respondents to improve the quality and completeness of the information being collected.

The interests of society may override the individual's perceived right to absolute confidentiality when, for instance, the health effects of environmental pollution (*see* **Environmental Epidemiology**), or occupational exposure (*see* **Occupational Epidemiology**) need to be assessed and controlled. Publication and interpretation of the results of such research do not require identification of individuals, whereas it is crucial to the underlying analysis. In such cases, the confidentiality of data about individuals must be observed to the fullest extent possible, and preferably regulated by an independent body. Almost any information may be considered confidential by an individual – such as memberships of unions, income, tax, childbirth, etc. Some obviously identifiable data in the public domain are not considered confidential (e.g. names, addresses, and telephone numbers). Often, however, when joining a union or becoming a member of an organization, the individual may allow use of the data for purposes relevant to their membership.

Who is Entitled to Confidentiality and How is it Preserved?

We are all entitled to confidentiality, to have a space of our own. The problem arises when this space is

of interest to others, in particular to the society in which we have chosen to be members, for example when dealing with public health issues. Confidentiality not only concerns relations with the patient – the data subject – but also the data providers, and it must be preserved in all aspects of data collection, storage, research use, and transmission. Consequently, all persons who have access to personal data must be expected to obey the same constraints with regard to confidentiality (*see* **Data Management and Coordination**). In health, medical confidentiality is part of the professional ethic embodied in the Hippocratic oath, and is set out in most publications on good medical practice. Physicians may lose their license to practice, as may lawyers, if they breach patient–client confidentiality. Other persons such as epidemiologists with access to confidential data should also be subject to such rules. This is not always the case at present [3].

Existing Guidelines on Confidentiality and Security in Manual and Automated Systems

Preservation of confidentiality has been a long-standing tradition in epidemiologic research, in particular in cancer registration (*see* **Disease Registers**), dating back to the 1940s. Automated cancer registration based on electronically available data presents a new challenge, and this also needs to be addressed from the point of view of confidentiality and data security. In principle, security and confidentiality for electronic data collections should follow exactly the same rules and standards as for traditional (manual) registry systems.

Guidelines exist from the International Association of Cancer Registries [2]. These complement international legislation such as the European Union directive "On the Protection of Individuals with Regard to the Processing of Personal Data and the Free Movement of Such Data" [5], recommendations from the Council of Europe, national legislation in the form of data protection acts, and international recommendations on ethics [6, 7].

In manual systems, security depends on dispersion of the data, and the relative difficulty of getting access to data and in linking these with other data. This does not safeguard individual data, which may be disclosed to third parties if the physical security of premises and files is not carefully observed. Coleman et al. [2] list a number of situations where precautions must be taken to avoid accidental breaches of confidentiality by staff, such as use of the telephone and telefax for communicating confidential information, improper disposal of paper records, and insecure transport of data by mail in addition to access control, and so on.

In electronic systems, large volumes of data are gathered in a structured manner, and if confidentiality is not observed, disclosure may concern a much larger number of individuals. It is possible to safeguard electronic systems much better than manual systems, however, not only against unauthorized access, but also by monitoring both authorized access and data in transit between provider and registry (*see* **Confidentiality and Computers**).

It is obvious that if researchers lose the ability to link data on individuals unequivocally, both maintenance of registries such as those on cancer and a great deal of epidemiologic and public health research will be impossible to perform. It is thus incumbent on registries and researchers to preserve the confidentiality of identifiable data in the interest of their own professional activities, irrespective of any official requirements. If confidentiality is breached, years of planning and work on specific research projects may be lost.

The Threat of Breach of Confidentiality

It should also be clear that improper disclosure of data depends on two things – the value of the data, and the number of people who have access to them. Those who see a value in identifiable data are also likely to be those through whom a breach in confidentiality may occur. Registries and researchers may be pressurized to disclose information to parties who believe they have a legal interest in knowing the details – one example being to check if persons with a disease possibly related to occupational asbestos exposure have been reported by the physicians to all relevant bodies [4, 9]. Here, the confidentiality of the data provider and the patient is at stake, competing with the demands of society to ensure that rules and regulations are followed. Another situation is a wish for access from insurance companies, which may provide no benefit to either the individual or society, but rather to the company.

If trust in registries or researchers is lost, there will be an erosion of data quality, inasmuch as sensitive

facts may be suppressed. The value of the registry and the data will drop, and the use for which it was intended may become impossible. It is thus important to have written rules that apply to health researchers using identifiable data, and these must regulate access, specify duties, and impose penalties for any breach, unless this is covered by national legislation.

Practical Means of Preserving Confidentiality

In systems with automated (computerized) data collection from a variety of sources, the number of persons involved with some access to the electronic data increases significantly. It is therefore necessary to control access; to impose passwords and restrictions for various user types; to take further precautions when transmitting, collecting, and analyzing data; and to consider failures in both software and hardware that might corrupt data. Table 1 summarizes the actions that can be taken to preserve confidentiality and data security.

Monitoring Use and Access

Control and monitoring (logging) of access and notification of data subjects and regulatory bodies on access is one basic measure in preserving confidentiality. Even if this does not prevent criminal actions, the fact that access is monitored and that relevant authorities will be notified of any breach of rules should decrease the likelihood of misuse due to carelessness. If misuse occurs, adequate action must be taken. Access to data can also be made user-specific, a mechanism by which only persons with a specific need for knowing the identity of individuals can obtain access to such information – and only for the time period for which this access is needed – whereas access to statistical, tabular, or anonymous person records can be more liberal. In other words, there can be different levels of access and of access control. Users should learn that all access will be monitored and logged.

Anonymous Data File Separation

Various methods have been proposed to safeguard confidentiality. It is relatively easy to make data

Table 1 Actions for preserving confidentiality and data security

Area of concern	Actions
Access control	Passwords Limited access (certain data or certain periods) Access logs – notification (regulatory bodies/data subject)
ID safeguards (data subject and data provider)	Clear rules for authorizing access to identifiable information Making data anonymous – use of keys and file separation Encryption of identifiers Statistical data base (no identifiers) for "public" use
Data use	Monitoring of users and usage
Data security	Transmission – encryption/decryption Stand-alone registry computer system Restricted access from outside – "fire-wall" Dialback methods (combined with encryption) Confidential destruction of used equipment – tapes, hard disks, etc. Test system without real data for development, etc.
Consent	From the data subjects From data subject group representatives (unions, etc.) From institutions (employer, etc.) From ethical committees From data inspection agencies
Legal actions	"Hippocratic oath" or equivalent for all professions Loss of license to practice if violation of confidentiality rules is proven Statutory penalties

anonymous by separating identity information from the data file, and keeping a code detached from the computer system by which the identity of an individual can be linked back to the medical information. This is advisable for research data sets and for PCs in hospitals and clinics where theft of equipment (data on hard disks) poses a major risk for unwarranted breach in confidentiality. Another way of doing this is by means of encryption of the identifying information, with the possibility of subsequent decryption by the researcher holding a secret key or algorithm.

Encryption

Encryption of data is a valuable tool for preserving confidentiality in the communication of data from one place to another. Today, encryption systems exist that allow users to have separate keys for encryption and decryption [1]; the first can be published while the second can be kept secret. Decryption can thus be performed where the necessary precautions for data security are in place, and linkage procedures and quality control can be performed on data with no question about the identity and correctness of linkages.

A cancer registry system based on a complicated system of data encryption has been proposed in Germany [8]. All linkages would be done on encrypted data on the basis of identifying information associated with name and date of birth. Although **false positive** matches were uncommon (<1%), **false negative** matches (duplicates) were higher. Whereas these errors may have little impact on rates and **descriptive epidemiology**, the inability to link cases with absolute reliability for follow-up studies (where more linkages are often involved) is much more serious, since the observed numbers of events may be wrong, and the expected number may also be biased by failure to censor individuals at death, since no link is obtained between data stored at entry and the date of exit (death). It may not be meaningful to conduct registry-based studies in such a setting. It will be of both practical and ethical concern that the researcher cannot control the quality of data, and confidence in the results will be low.

Isolation

Another approach to security is to use technical solutions that make unauthorized access impossible or very difficult. The ultimate solution is the "stand-alone" registry computer system. This may be designed in such a way that the registry still has access to the outside world, whereas external contact with the registry is prohibited by a so-called "firewall" that only allows one-way traffic. Another measure is dialback, where only certain telephone numbers and users (access codes) are allowed a line to the registry, and the request is processed by the registry computer, which dials back the authorized person who requested information or access. Data transmission in such cases can be safeguarded by encryption and decryption, using a common key at both ends.

Confidentiality and data security go hand in hand. Measures need to be taken when implementing new **software** and hardware, where all testing must be performed on test data, not real data. Any electronic media – hard disks, floppy disks, and tapes – must be suitably erased or destroyed if taken out of use. Data discipline is also needed, in the sense that old data are not deleted but changes are appended with dates and a record of who carried out the addition. Precautions must be taken to avoid corruption of data.

Conclusion

Confidentiality must continue to be taken seriously. It should not become prohibitive for research, however, since the results will benefit future generations. We must answer the question "Who are we protecting, and why?" If, in our desire for absolute privacy, we allow unjustifiable concerns for confidentiality to prevent ethical research, we risk protecting the "criminal" rather than our society. Thus we may protect the employer who is exposing employees to carcinogenic substances, or health services that perform poorly, or industries that pollute our environment. We may thus be unable to demonstrate the effect of powerful carcinogens such as tobacco smoking in the future (*see* **Smoking and Health**). We must also balance individual rights with the rights of the society in which we have chosen to live. This balance between the individual's right to privacy and rights of society to uncover hazards is not easy to strike, but if we accept regulation and surveillance by independent bodies, such as democratically elected ethical committees and data protection agencies, we may avoid reintroduction of the Middle Ages in health research. It is often said that those who demand complete confidentiality and privacy are also those who demand control of every

conceivable environmental or occupational hazard to health. Adequate control without prior study is impossible, and such contradictory demands are thus equally impossible to meet. So far, we have not experienced any major breach in confidentiality of identifiable data entrusted to the health research community. Ironically, breaches of confidentiality for criminal records and credit ratings have been widely reported, as have breaches of highly sensitive defense computers. The good record on confidentiality in the domain of health research is due in part to the wide respect for professional ethics, but also to the fact that health researchers are well aware that such a breach could spell the end of much **population-based** research.

HANS H. STORM

Confounder Summary Score

Consider an observational study of the effect of an "exposure" variable X on an outcome variable Y in which multiple **confounders** must be controlled (*see* **Confounding**). Simultaneous **stratification** on all observed confounder combinations may lead to many uninformative strata (i.e. strata in which there is either no variation in the exposure or no variation in the outcome). The usual method of coping with this problem is to estimate exposure effects from coefficients in a **regression** model for the dependence of the outcome on the exposure and confounders. Confounder summary scores are alternatives that use fitted models to define strata.

Parametric modeling raises concerns about the dependence of the resulting effect estimates on the model specification (*see* **Model, Choice of**). In one analysis of the National Halothane Study (NHS), the outcome was regressed on confounders, and the data were then stratified on the fitted values from the regression model [2]. In this manner, the problem of multiple confounders was reduced to stratification on just one variable, the fitted outcome $\hat{Y}$. It was later noted that this scoring procedure produces **biased** effect estimates unless the resulting fitted values are modified by removing the estimated exposure effect [3, 4]. To illustrate these ideas, let X denote the treatment or exposure of interest and let $\mathbf{Z}$ denote the row vector of confounders. The National Halothane procedure involved fitting a model such as

$$g[\mathrm{E}(Y|\mathbf{Z} = \mathbf{z})] = \alpha^* + \mathbf{z}\boldsymbol{\gamma}^*,$$

and then stratifying subjects on their fitted values:

$$\hat{Y} = g^{-1}(\hat{\alpha}^* + \mathbf{z}\hat{\boldsymbol{\gamma}}^*).$$

Miettinen instead fit

$$g[\mathrm{E}(Y|X = x, \mathbf{Z} = \mathbf{z},)] = \alpha + x\beta + \mathbf{z}\gamma.$$

He then stratified subjects on the modified score $g^{-1}(\hat{\alpha} + \mathbf{z}\hat{\boldsymbol{\gamma}})$ (or, equivalently, on $\hat{\alpha} + \mathbf{z}\hat{\boldsymbol{\gamma}}$), the fitted value obtained by deleting the estimated exposure effect $x\hat{\beta}$. The exposure effect $x\hat{\beta}$ is left out of the scoring to ensure that the strata are not defined in part by exposure. The inclusion of exposure when fitting the model also serves this purpose: note that the confounder coefficient, $\boldsymbol{\gamma}^*$, in the model without exposure may carry some of the exposure effects unless X and $\mathbf{Z}$ are independent.

These modified fitted values or linear predictors are an example of *confounder scores*, and the scoring process is called *confounder summarization*. Assuming the fitted model is correct, it has been shown that adjustments using these modified scores could lead to effect estimates unconfounded by $\mathbf{Z}$, but could also overstate significance (i.e. yield downwardly biased ***P* values**) for testing the **null hypothesis** of no exposure effect ($\beta = 0$), whereas the unmodified score used in the original National Halothane approach would generally yield biased estimates of β, but could yield valid significance levels for testing the null [4].

An alternative approach is to control confounding by stratifying on the fitted exposure values obtained by regressing exposure X on the confounders $\mathbf{Z}$. For binary X, Rosenbaum & Rubin [6] termed the resulting fitted values ($\hat{X}$) **propensity scores** and showed that these scores have a number of desirable properties. In particular, Rosenbaum & Rubin showed that, by stratifying on propensity scores, one could obtain valid effect estimates and significance levels from the same model. Scores based on outcome regression are sometimes referred to as *risk scores* or *prognostic scores*, while scores based on exposure regression are sometimes called *exposure scores*. Propensity scores are sometimes referred to as *balancing scores*, reflecting their use in creating strata such that **covariate** distributions are "balanced" across exposure groups.

Apart from propensity scores, confounder summarization methods have seen relatively little use since their initial development. This disuse may be attributable to a number of factors. One problem is that confounder summarization methods are not as insensitive to model **misspecification** as was hoped [1]. As an extreme but transparent example, suppose there is but one confounder, Z, that X given Z has a standard **normal distribution**, that Z has a standard normal marginal distribution, and that the regression of X on Z is

$$\mathrm{E}(X|Z = z) = z^2.$$

If the model fitted for exposure scoring is

$$\mathrm{E}(X|Z = z) = \alpha + \beta z,$$

then the ordinary **least squares** estimate β will have zero expectation and the resulting exposure

scores will stratify subjects randomly, with little confounder control achieved by the stratification. Similarly discouraging examples can be constructed for risk scores.

Of course, careful modeling should detect misspecification as gross as just illustrated. Nonetheless, the example points out that confounder summarization may require as much modeling effort as ordinary analysis. Even more effort may be needed if multiple exposures are studied, for then separate exposure scores must be constructed for each exposure. Thus, in observational studies, there may be no convenience and little **robustness** advantage of confounder summarization over direct model-based estimation. Any robustness advantage may be further diminished when **nonparametric regression** methods can be used to estimate exposure effects.

The interpretation of strata and estimates constructed from confounder scores can also be difficult. While the confounder distributions may be balanced within strata, the strata will usually contain subjects with a heterogeneous mix of confounder profiles, the comparability of which may not be immediately obvious to a clinical reader. When the exposure effect varies across strata, it may be necessary to return to standard methods to identify the source of the variation.

Exposure regression can be used directly as part of a system of models for control of confounding in effect **estimation** [5]. This use, however, is distinct from its use in confounder summarization.

Confounder

As used in epidemiology, a confounder is a factor that is associated with the risk of disease in subjects unexposed to the exposure of interest, that is not affected by exposure or disease, and that is associated with exposure in the source population from which cases arise. For example, the risk of cancer increases with age. To study an exposure that is associated with age, such as cumulative coffee consumption, as a risk factor for cancer, one needs to control for the **confounding** effects of age. Because the confounder is associated both with disease risk and with exposure status, failure to account for the confounder either by appropriate choice of study design, such as a restricted design or a stratified design (*see* **Stratification**), or by analytical adjustments (*see* **Standardization Methods**) can lead to misleading estimates of the relationship between the exposure of interest and the risk of disease (*see* **Confounding**; **Matched Analysis**; **Matching**). However, applying such adjustment methods to a factor that is affected by exposure or disease, such as an intermediate effect of exposure on the pathway leading from exposure to disease (*see* **Causation**) can misleadingly reduce estimates of the strength of **association** between exposure and disease (*see* **Odds Ratio**; **Relative Risk**).

Confounding can be described more fundamentally as a distortion in estimates of **exposure effect** that results when responses from an unexposed **control** population are used to estimate the hypothetical responses that would have been observed in the exposed population had that population been unexposed. In this context, confounders are factors that account for differences between observed control responses and the hypothetical responses in the exposed group that would have been observed had that group been unexposed. A disadvantage of this formulation is that one cannot verify directly that confounding is present, because one does not observe the hypothetical responses of the exposed population had it been unexposed. The criteria for confounding in the previous paragraph, although less fundamental than the definition just given, are at least useful indicators of confounding, although they can be misleading in some situations [1, 2].

MITCHELL H. GAIL

Confounding

The word *confounding* has been used to refer to at least three distinct concepts. In the oldest usage, confounding is a **bias** in estimating causal effects (*see* **Causation**). This bias is sometimes informally described as a mixing of effects of extraneous factors (called **confounders**) with the effect of interest. This usage predominates in nonexperimental research, especially in epidemiology and sociology. In a second and more recent usage, confounding is a synonym for noncollapsibility (*see* **Collapsibility**), although this usage is often limited to situations in which the parameter of interest is a causal effect. In a third usage, originating in the **experimental-design** literature, confounding refers to inseparability of main effects and **interactions** under a particular design. The term *aliasing* is also sometimes used to refer to the latter concept; this usage is common in the **analysis of variance** literature.

The three concepts are closely related and are not always distinguished from one another. In particular, the concepts of confounding as a bias in effect estimation and as noncollapsibility are often treated as identical, although there are many examples in which the two concepts diverge [8, 9, 14]; one is given below.

Confounding as a Bias in Effect Estimation

Confounding

A classic discussion of confounding in which explicit reference is made to "confounded effects" is Mill [15, Chapter X] (although in Chapter III Mill lays out the primary issues and acknowledges Francis Bacon as a forerunner in dealing with them). There, he lists a requirement for an experiment intended to determine causal relations:

> ... none of the circumstances [of the experiment] that we do know shall have effects susceptible of being *confounded with* those of the agents whose properties we wish to study (emphasis added).

It should be noted that, in Mill's time, the word "experiment" referred to an observation in which some circumstances were under the control of the observer, as it still is used in ordinary English, rather than to the notion of a comparative trial. Nonetheless, Mill's requirement suggests that a comparison is to be made between the outcome of his experiment (which is, essentially, an uncontrolled trial) and what we would expect the outcome to be if the agents we wish to study had been absent. If the outcomes is not as one would expect in the absence of the study agents, then his requirement ensures that the unexpected outcome was not brought about by extraneous circumstances. If, however, those circumstances do bring about the unexpected outcome, and that outcome is mistakenly attributed to effects of the study agents, then the mistake is one of confounding (or confusion) of the extraneous effects with the agent effects.

Much of the modern literature follows the same informal conceptualization given by Mill. Terminology is now more specific, with "treatment" used to refer to an agent administered by the investigator and "exposure" often used to denote an unmanipulated agent. The chief development beyond Mill is that the **expectation** for the outcome in the absence of the study exposure is now almost always explicitly derived from observation of a **control** group that is untreated or unexposed. For example, Clayton & Hills [2] state of **observational studies**,

> ... there is always the possibility that an important influence on the outcome ... differs systematically between the comparison [exposed and unexposed] groups. It is then possible [that] part of the apparent effect of exposure is due to these differences, [in which case] the comparison of the exposure groups is said to be *confounded* (emphasis in the original).

In fact, confounding is also possible in randomized experiments (*see* **Clinical Trials, Overview**), owing to systematic improprieties in treatment allocation, administration, and compliance. A further and somewhat controversial point is that confounding (as per Mill's original definition) can also occur in perfect randomized trials due to *random* differences between comparison groups [6, 8].

Various mathematical formalizations of confounding have been proposed. Perhaps the one closest to Mill's concept is based on a formal counterfactual model for causal effects. Suppose our objective is to determine the effect of applying a treatment or exposure x_1 on a parameter μ of population A, relative to applying treatment or exposure x_0. For example, A could be a cohort of breast-cancer patients, treatment x_1 could be a new hormone therapy, x_0 could be a placebo therapy, and the parameter μ could be the 5-year survival probability. The population A

is sometimes called the **target population** or *index population*; the treatment x_1 is sometimes called the *index* treatment; and the treatment x_0 is sometimes called the *control* or *reference* treatment (which is often a standard or placebo treatment).

The counterfactual model assumes that μ will equal μ_{A1} if x_1 is applied, μ_{A0} if x_0 is applied; the causal effect of x_1 relative to x_0 is defined as the change from μ_{A0} to μ_{A1}, which might be measured as $\mu_{A1} - \mu_{A0}$ or μ_{A1}/μ_{A0}. If A is observed under treatment x_1, then μ will equal μ_{A1}, which is observable or estimable, but μ_{A0} will be unobservable. Suppose, however, we expect μ_{A0} to equal μ_{B0}, where μ_{B0} is the value of the outcome μ observed or estimated for a population B that was administered treatment x_0. The latter population is sometimes called the *control* or *reference* population. *Confounding* is said to be present if in fact $\mu_{A0} \neq \mu_{B0}$, for then there must be some difference between populations A and B (other than treatment) that is affecting μ.

If confounding is present, a naive (crude) **association** measure obtained by substituting μ_{B0} for μ_{A0} in an effect measure will not equal the effect measure, and the association measure is said to be *confounded*. For example, if $\mu_{B0} \neq \mu_{A0}$, then $\mu_{A1} - \mu_{B0}$, which measures the *association* of treatments with outcomes *across* the populations, is confounded for $\mu_{A1} - \mu_{A0}$, which measures the *effect* of treatment x_1 on population A. Thus, saying a measure of association such as $\mu_{A1} - \mu_{B0}$ is confounded for a measure of effect such as $\mu_{A1} - \mu_{A0}$ is synonymous with saying the two measures are not equal.

The preceding formalization of confounding gradually emerged through attempts to separate effect measures into a component due to the effect of interest and a component due to extraneous effects [1, 4, 10, 12, 13]. These decompositions will be discussed below.

One noteworthy aspect of the above formalization is that confounding depends on the outcome parameter. For example, suppose populations A and B have a different 5-year survival probability μ under placebo treatment x_0; that is, suppose $\mu_{B0} \neq \mu_{A0}$, so that $\mu_{A1} - \mu_{B0}$ is confounded for the actual effect $\mu_{A1} - \mu_{A0}$ of treatment on 5-year survival. It is then still possible that 10-year survival, ν, under the placebo would be identical in both populations; that is, ν_{A0} could still equal ν_{B0}, so that $\nu_{A1} - \nu_{B0}$ is not confounded for the actual effect of treatment on 10-year survival. (We should generally expect no confounding for 200-year survival, since no treatment is likely to raise the 200-year survival probability of human patients above zero.)

A second noteworthy point is that confounding depends on the target population of **inference**. The preceding example, with A as the target, had different 5-year survivals μ_{A0} and μ_{B0} for A and B under placebo therapy, and hence $\mu_{A1} - \mu_{B0}$ was confounded for the effect $\mu_{A1} - \mu_{A0}$ of treatment on population A. A lawyer or ethicist may also be interested in what effect the treatment x_1 would have had on population B. Writing μ_{B1} for the (unobserved) outcome of B under treatment x_1, this effect on B may be measured by $\mu_{B1} - \mu_{B0}$. Substituting μ_{A1} for the unobserved μ_{B1} yields $\mu_{A1} - \mu_{B0}$. This measure of association is confounded for $\mu_{B1} - \mu_{B0}$ (the effect of treatment x_1 on 5-year survival in population B) if and only if $\mu_{A1} \neq \mu_{B1}$. Thus, the same measure of association, $\mu_{A1} - \mu_{B0}$, may be confounded for the effect of treatment on neither, one, or both of populations A and B.

Confounders

A third noteworthy aspect of the counterfactual formalization of confounding is that it invokes no explicit differences (imbalances) between populations A and B with respect to circumstances or **covariates** that might influence μ [8]. Clearly, if μ_{A0} and μ_{B0} differ, then A and B must differ with respect to factors that influence μ. This observation has led some authors to define confounding as the presence of such covariate differences between the compared populations. Nonetheless, confounding is only a consequence of these covariate differences. In fact, A and B may differ profoundly with respect to covariates that influence μ, and yet confounding may be absent. In other words, a covariate difference between A and B is a necessary but not sufficient condition for confounding. This point will be illustrated below.

Suppose now that populations A and B differ with respect to certain covariates, and that these differences have led to confounding of an association measure for the effect measure of interest. The responsible covariates are then termed *confounders* of the association measure. In the above example, with $\mu_{A1} - \mu_{B0}$ confounded for the effect $\mu_{A1} - \mu_{A0}$, the factors responsible for the confounding (i.e. the factors that led to $\mu_{A0} \neq \mu_{B0}$) are the confounders.

It can be deduced that a variable cannot be a confounder unless it can affect the outcome parameter μ within treatment groups and it is distributed differently among the compared populations (e.g. see Yule [23], who however uses terms such as "fictitious association" rather than confounding). These two necessary conditions are sometimes offered together as a definition of a confounder. Nonetheless, counterexamples show that the two conditions are not sufficient for a variable with more than two levels to be a confounder as defined above; one such counterexample is given in the next section.

Prevention of Confounding

Perhaps the most obvious way to avoid confounding in estimating $\mu_{A1} - \mu_{A0}$ is to obtain a reference population B for which μ_{B0} is known to equal μ_{A0}. Among epidemiologists, such a population is sometimes said to be *comparable to* or *exchangeable with* A with respect to the outcome under the reference treatment. In practice, such a population may be difficult or impossible to find. Thus, an investigator may attempt to construct such a population, or to construct exchangeable index and reference populations. These constructions may be viewed as *design-based* methods for the control of confounding.

Perhaps no approach is more effective for preventing confounding by a known factor than *restriction*. For example, gender imbalances cannot confound a study restricted to women. However, there are several drawbacks: restriction on enough factors can reduce the number of available subjects to unacceptably low levels, and may greatly reduce the generalizability of results as well. **Matching** the treatment populations on confounders overcomes these drawbacks and, if successful, can be as effective as restriction. For example, gender imbalances cannot confound a study in which the compared groups have identical proportions of women. Unfortunately, differential losses to observation may undo the initial covariate balances produced by matching.

Neither restriction nor matching prevents (although it may diminish) imbalances on unrestricted, unmatched, or unmeasured covariates. In contrast, **randomization** offers a means of dealing with confounding by covariates not accounted for by the design. It must be emphasized, however, that this solution is only probabilistic and subject to severe constraints in practice. Randomization is not always feasible, and (as mentioned earlier) many practical problems, such as differential loss and noncompliance, can lead to confounding in comparisons of the groups actually receiving treatments x_1 and x_0. One somewhat controversial solution to noncompliance problems is **intention-to-treat analysis**, which *defines* the comparison groups A and B by treatment assigned rather than treatment received. Confounding may, however, affect even intention-to-treat analyses. For example, the assignments may not always be random, as when **blinding** is insufficient to prevent the treatment providers from protocol violations. And, purely by bad luck, randomization may itself produce allocations with severe covariate imbalances between the groups (and consequent confounding), especially if the study size is small [6, 8, 19]. Block randomization (*see* **Randomized Treatment Assignment**) can help ensure that random imbalances on the **blocking** factors will not occur, but it does not guarantee balance of unblocked factors.

Adjustment for Confounding

Design-based methods are often infeasible or insufficient to prevent confounding. Thus there has been an enormous amount of work devoted to analytic adjustments for confounding. With a few exceptions, these methods are based on observed covariate distributions in the compared populations. Such methods can successfully control confounding only to the extent that enough confounders are adequately measured. Then, too, many methods employ parametric models at some stage, and their success may thus depend on the faithfulness of the model to reality. These issues cannot be covered in depth here, but a few basic points are worth noting.

The simplest and most widely trusted methods of adjustment begin with **stratification** on confounders. A covariate cannot be responsible for confounding within internally homogeneous strata of the covariate. For example, gender imbalances cannot confound observations within a stratum composed solely of women. More generally, comparisons within strata cannot be confounded by a covariate that is constant (homogeneous) within strata. This is so regardless of whether the covariate was used to define the strata. Generalizing this observation to a **regression** context, we find that any covariate with a residual variance of zero conditional on the regressors cannot confound regression estimates of effect (assuming

that the regression model is correct). A broader and more useful observation is that any covariate that is unassociated with treatment conditional on the regressors cannot confound the effect estimates; this insight leads directly to adjustments using a **propensity score**.

Some controversy has existed about adjustment for covariates in randomized trials. Although **Fisher** asserted that randomized comparisons were **unbiased**, he also pointed out that they could be confounded in the sense used here (e.g. see Fisher [6, p. 49]). Fisher's use of the word "unbiased" was unconditional on allocation, and therefore of little guidance for analysis of a given trial. The ancillarity of the allocation naturally leads to conditioning on the observed distribution of any pretreatment covariate that can influence the outcome parameter. Conditional on this distribution, the unadjusted treatment–effect estimate will be biased if the covariate is associated with treatment; this conditional bias can be removed by adjustment for the confounders [8, 18]. Note that the adjusted estimate is also unconditionally unbiased, and thus is a reasonable alternative to the unadjusted estimate even without conditioning.

Measures of Confounding

The parameter estimated by a direct unadjusted comparison of cohorts A and B is $\mu_{A1} - \mu_{A0}$. A number of authors have measured the bias (confounding) of the unadjusted comparison by [10, 12]

$$(\mu_{A1} - \mu_{B0}) - (\mu_{A1} - \mu_{A0}) = \mu_{A0} - \mu_{B0}.$$

When the outcome parameters, μ, are **risks** (probabilities), epidemiologists use instead the analogous ratio

$$\frac{\mu_{A1}/\mu_{B0}}{\mu_{A1}/\mu_{A0}} = \frac{\mu_{A0}}{\mu_{B0}}$$

as a measure of bias [1, 4, 14]; μ_{A0}/μ_{B0} is sometimes called the *confounding risk ratio*. The latter term is somewhat confusing because it is sometimes misunderstood to refer to the effect of a particular confounder on risk. This is not so, although the ratio does reflect the net effect of the differences in the confounder distributions of A and B.

Residual Confounding

Suppose now that adjustment for confounding is done by subdividing the total study population (A + B) into K strata indexed by k. Let μ_{A1k} be the parameter of interest in stratum k of populations A and B under treatment x_0. The effect of treatment x_1 relative to x_0 in stratum k may be defined as $\mu_{A1k} - \mu_{A0k}$ or μ_{A1k}/μ_{A0k}. The confounding that remains in stratum K is called the *residual confounding* in the stratum, and is measured by $\mu_{A0k} - \mu_{B0k}$ or μ_{A1k}/μ_{B0k}.

Like effects, stratum-specific residual confounding may be summarized across the strata in a number of ways, for example by **standardization methods** or by other weighted-averaging methods. As an illustration, suppose we are given a standard distribution $p_1, \ldots, p_K$ for the stratum index k. In ratio terms, the standardized effect of x_1 vs. x_0 on A under this distribution is

$$R_{AA} = \frac{\sum_k p_k \mu_{A1k}}{\sum_k p_k \mu_{A0k}},$$

whereas the standardized ratio comparing A with B is

$$R_{AB} = \frac{\sum_k p_k \mu_{A1k}}{\sum_k p_k \mu_{B0k}}.$$

The overall residual confounding in R_{AB} is thus

$$\frac{R_{AB}}{R_{AA}} = \frac{\sum_k p_k \mu_{A0k}}{\sum_k p_k \mu_{B0k}},$$

which may be recognized as the standardized ratio comparing A and B when both are given treatment x_0, using $p_1, \ldots, p_K$ as the standard distribution.

Regression Formulations

For simplicity, the above presentation has focused on comparing two populations and two treatments. The basic concepts extend immediately to the consideration of multiple populations and treatments. Paired comparisons may be represented using the above formalization without modification. Parametric models for these comparisons then provide a connection to more familiar regression models.

As an illustration, suppose population differences and treatment effects follow the model

$$\mu_k(x) = \alpha_k + x\beta,$$

where the treatment level x may range over a continuum, and k indexes populations. Suppose population k is given treatment x_k, even though it could have been given some other treatment. The absolute effect of x_1 vs. x_2 on μ in population 1 is

$$\mu_1(x_1) - \mu_1(x_2) = (x_1 - x_2)\beta.$$

Substitution of $\mu_2(x_2)$, the value of μ in population 2 under treatment x_2, for $\mu_1(x_2)$ yields

$$\mu_1(x_1) - \mu_2(x_2) = \alpha_1 - \alpha_2 + (x_1 - x_2)\beta,$$

which is biased by the amount

$$\mu_1(x_2) - \mu_2(x_2) = \alpha_1 - \alpha_2.$$

Thus, under this model no confounding will occur if the intercepts α_k equal a constant α across populations, so that $\mu_k(x) = \alpha + \beta x$.

When constant intercepts cannot be assumed and nothing else is known about the intercept magnitudes, it may be possible to represent our uncertainty about α_k via the following mixed-effects model:

$$\mu_k(x) = \alpha + x\beta + \varepsilon_k.$$

Here, α_k has been decomposed into $\alpha + \varepsilon_k$, where ε_k has mean zero, and the confounding in $\mu_1(x_1) - \mu_2(x_2)$ has become an unobserved random variable, $\varepsilon_1 - \varepsilon_2$. **Correlation** of population membership k with x_k leads to a correlation of ε_k with x_k, which in turn leads to bias in estimating β. This bias may be attributed to or interpreted as confounding for β in the regression analysis. Confounders are now covariates that causally "explain" the correlation between ε_k and x_k. In particular, confounders normally reduce the correlation of x_k and ε_k when entered in the model. The converse is false, however: a variable that reduces the correlation of x_k and ε_k when entered need not be a confounder; it may, for example, be a variable affected by both the treatment and the exposure.

Confounding and Noncollapsibility

Much of the statistics literature does not distinguish between the concept of confounding as described above and the concept of noncollapsibility. Nonetheless, the two concepts are distinct: for certain outcome parameters, confounding may occur with or without noncollapsibility and noncollapsibility may occur with or without confounding [8, 9, 14, 17, 20, 22]. Mathematically identical conclusions have been reached by other authors, albeit with different terminology in which noncollapsibility corresponds to "bias" and confounding corresponds to **covariate imbalance** [7, 11].

As an example of no **collapsibility** with no confounding, consider the response distributions under treatments x_1 and x_0 given in Table 1 for a hypothetical index population A, and the response distribution under treatment x_0 given in Table 2 for a hypothetical reference population B. If we take the odds of response as the outcome parameter μ, we get

$$\mu_{A1} = \frac{1460}{540} = 2.70$$

and

$$\mu_{A0} = \mu_{B0} = \frac{1000}{1000} = 1.00.$$

There is thus no confounding of the **odds ratio**: $\mu_{A1}/\mu_{A0} = \mu_{A1}/\mu_{B0} = 2.70/1.00 = 2.70$. Nonetheless, the covariate Z is associated with response and is distributed differently in A and B. Furthermore,

Table 1 Distribution of responses for population A, within strata of Z and ignoring Z, under treatments x_1 and x_0

Subpopulation	Number of responses under x_1	Number of responses under x_0	Subpopulation size
$Z = 1$	200	100	400
$Z = 2$	900	600	1200
$Z = 3$	360	300	400
Totals	1460	1000	2000

Table 2 Distribution of responses for population B, within strata of Z and ignoring Z, under treatment x_0

Subpopulation	Number of responses under x_0	Subpopulation size
$Z = 1$	200	800
$Z = 2$	200	400
$Z = 3$	600	800
Totals	1000	2000

the odds ratio is not collapsible: within levels of Z, the odds ratios comparing A under treatment x_1 with either A or B under x_0 are $(200/200)/(200/600) = (900/300)/(200/200) = (360/40)/(600/200) = 3.00$, a bit higher than the odds ratio of 2.70 obtained when Z is ignored.

The preceding example illustrates a peculiar property of the odds ratio as an effect measure: treatment x_1 (relative to x_0) elevates the odds of response by 170% in population A, yet within each stratum of Z it raises the odds by 200%. When Z is associated with response conditional on treatment but unconditionally unassociated with treatment, the stratum-specific effects on odds ratios will be further from the null than the overall effect if the latter is not null [7]. This phenomenon is often interpreted as a "bias" in the overall odds ratio, but in fact there is no bias if one does not interpret the overall effect as an estimate of the stratum-specific effects.

The example also shows that, when μ is the odds, the "confounding odds ratio" $(\mu_{A1}/\mu_{B0})/(\mu_{A1}/\mu_{A0}) = \mu_{A0}/\mu_{B0}$ may be 1 even when the odds ratio is not collapsible over the confounders. Conversely, we may have $\mu_{A0}/\mu_{B0} \neq 1$ even when the odds ratio is collapsible. More generally, the ratio of crude and stratum-specific odds ratios does not equal μ_{A0}/μ_{B0} except in some special cases. When the odds are low, however, the odds will be close to the corresponding risks, and so the two ratios will approximate one another.

The phenomenon illustrated in the example corresponds to the differences between cluster-specific and population-averaged (marginal) effects in **nonlinear mixed-effects regression** [16]. Specifically, the clusters of correlated outcomes correspond to the strata, the cluster effects correspond to covariate effects, the cluster-specific treatment effects correspond to the stratum-specific log odds ratios, and the population-averaged treatment effect corresponds to the crude log odds ratio.

Results of Gail [7] imply that if the effect measure is the difference or ratio of response proportions, then the above phenomenon – noncollapsibility over Z without confounding by Z – cannot occur, nor can confounding by Z occur without noncollapsibility over Z. More generally, when the effect measure is an expectation over population units, confounding by Z and noncollapsibility over Z are algebraically equivalent. This equivalence may explain why the two concepts are often not distinguished.

Confounding in Experimental Design

Like the bias definition, the third usage of confounding stems from the notion of mixing of effects. However, the effects that are mixed are main (block) effects and interactions (or different interactions) in a linear model, rather than effects in the **nonparametric** sense of a counterfactual model. This definition of confounding differs even more markedly from other definitions in that it refers to an intentional design feature of certain experimental studies, rather than a bias.

The topic of confounded designs is extensive; some classic references are Fisher [6], Cochran & Cox [3], Cox [5], and Scheffé [21]. Confounding can serve to improve efficiency in estimation of certain contrasts and can reduce the number of treatment groups that must be considered. The price paid for these benefits is a loss of **identifiability** of certain parameters, as reflected by aliasing of those parameters.

As a simple example, consider a situation in which we wish to estimate three effects in a single experiment: that of treatments x_1 vs. x_0, y_1 vs. y_0, and z_1 vs. z_0. For example, in a smoking cessation trial these treatments may represent active and placebo versions of the nicotine patch, nicotine gum, and buspirone. With no restrictions on number or size of groups, a fully crossed design would be reasonable. By allocating subjects to each of the $2^3 = 8$ possible treatment combinations, one could estimate all three main effects, all three two-way interactions, and the three-way interaction of the treatments.

Suppose, however, that we were restricted to use of only four treatment groups (e.g. because of cost or complexity considerations). A naive approach would be to use groups of equal size, assigning one group to placebos only (x_0, y_0, z_0) and the remaining three groups to one active treatment each: (x_1, y_0, z_0), (x_0, y_1, z_0), and (x_0, y_0, z_1). Unfortunately, with a fixed number N of subjects available, this design would provide only $N/4$ subjects under each active treatment.

As an alternative, consider the design with four groups of equal size with treatments (x_0, y_0, z_0), (x_1, y_1, z_0), (x_1, y_0, z_1), and (x_0, y_1, z_1). This **fractional factorial design** would provide $N/2$ subjects

under each active treatment, at the cost of confounding main effects and interactions. For example, no linear combination of group means containing the main effect of x_1 vs. x_0 would be free of interactions. If one could assume that all interactions were negligible, however, this design could provide considerably more precise estimates of the main effects than the naive four-group design.

To see these points, consider the following linear model:

$$\mu_{XYZ} = \alpha + \beta_1 X + \beta_2 Y + \beta_3 Z + \gamma_1 XY + \gamma_2 XZ + \gamma_3 YZ + \delta XYZ,$$

where X, Y, and Z equal 1 for x_1, y_1, and z_1, and 0 for x_0, y_0, and z_0, respectively. The group means, in the fractional factorial design are then

$$\mu_{000} = \alpha,$$
$$\mu_{110} = \alpha + \beta_1 + \beta_2 + \gamma_1,$$
$$\mu_{101} = \alpha + \beta_1 + \beta_3 + \gamma_2,$$
$$\mu_{011} = \alpha + \beta_2 + \beta_3 + \gamma_3.$$

Treating the means as observed and the coefficients as unknown, the above system is underidentified. In particular, there is no solution for any main effect β_j in terms of the means μ_{ijk}. Nonetheless, assuming all $\gamma_j = 0$ yields immediate solutions for all the β_j. Additionally assuming a **variance** of σ^2 for each estimated group mean yields that the main-effect estimates under this design would have variances of σ^2, as opposed to $2\sigma^2$ for the main-effect estimates from the naive four-group design of the same size. For example, under the confounded fractional factorial design (assuming no interactions)

$$\hat{\beta}_1 = \frac{\hat{\mu}_{110} + \hat{\mu}_{101} - \hat{\mu}_{000} - \hat{\mu}_{011}}{2},$$

so $\text{var}(\hat{\beta}_1) = 4\sigma^2/4 = \sigma^2$, whereas under the naive design, $\hat{\beta} = \hat{\mu}_{100} - \hat{\mu}_{000}$ so $\text{var}(\hat{\beta}_1) = 2\sigma^2$. Of course, the precision advantage of the confounded design is purchased by the assumption of no interaction, which is not needed by the naive design.

SANDER GREENLAND

Consistent Estimator

Scientists in the fields of medicine and the health sciences frequently collect experimental or observational data to address questions considered to be relevant to the advancement of human health. Examples include **clinical trials** to examine the efficacy of new treatments and epidemiologic studies to better understand the etiology of diseases (*see* **Analytic Epidemiology**). Given that the instruments used for data collection – or the data themselves – are less than perfect, uncertainty is acknowledged in the data analysis stage of scientific inquiry by assuming that the observed data of size n, $\mathbf{Y} = (Y_1, \ldots, Y_n)'$, are generated from a probability (density) function of the form $f(y; \boldsymbol{\theta})$. Here, $\boldsymbol{\theta}$ is a vector of p-dimension, representing parameters characterizing the random mechanism which generated the data. Presumably the parameters $\boldsymbol{\theta}$, or some functions thereof, describe the scientific objectives in a meaningful way. For example, in a clinical trial $\boldsymbol{\theta}$ might characterize the treatment effect for the targeted population (i.e. patients diagnosed with a specific disease). Meanwhile, in an epidemiologic study of the etiology of a disease, $\boldsymbol{\theta}$ might represent the strength of association between a potential risk factor and risk for the disease, often quantified in terms of the **odds ratio**. One goal of data analysis is to learn about the magnitude of $\boldsymbol{\theta}$ from the observed data $\mathbf{Y}$; that is, to *estimate* $\boldsymbol{\theta}$ using $\mathbf{Y}$. **Estimation** is one of several important aspects of statistical **inference**.

An immediate question is how to select a $(p \times 1)$ statistic $\boldsymbol{\delta}(\mathbf{Y})$ to use as an estimator of the unknown value $\boldsymbol{\theta}$. While many criteria for selecting an estimator have been proposed and investigated, one of the most popular is that of **unbiasedness**. Specifically, $\boldsymbol{\delta}(\mathbf{Y})$ is an *unbiased estimator* of $\boldsymbol{\theta}$ if

$$\mathrm{E}(\boldsymbol{\delta}(\mathbf{Y})) = \boldsymbol{\theta}, \tag{1}$$

where the expectation is taken with respect to the true mechanism $f(\cdot; \boldsymbol{\theta})$. A popular interpretation of (1) in nontechnical terms is that if one could repeat the study under the same conditions many times, then $\boldsymbol{\delta}(\mathbf{Y})$, on average, would be equal to the true but unknown $\boldsymbol{\theta}$ value. A further consequence of (1) is that in many cases as the sample size grows, the value of $\boldsymbol{\delta}(\mathbf{Y})$ will grow closer and closer to the true parameter value, $\boldsymbol{\theta}$. This property is due to the **law of large numbers**.

The following two problems, however, hamper the wide utility of unbiasedness as a criterion for selecting estimators of $\boldsymbol{\theta}$. First, unbiasedness is not an invariant property in that, while $\boldsymbol{\delta}(\mathbf{Y})$ is unbiased for $\boldsymbol{\theta}$, it is not true in general that a function $\mathbf{g}(\boldsymbol{\delta}(\mathbf{Y}))$ be unbiased for $\mathbf{g}(\boldsymbol{\theta})$. Secondly, except in the special case of probability models from the **exponential family**, there is very little guidance as to how to obtain unbiased estimators. Indeed, unbiased estimators for $\boldsymbol{\theta}$ may not exist for general probability models.

The **binomial distribution** for independent **binary** observations, which are commonly seen in biomedical research, serves as an excellent example. Suppose for $i = 1, \ldots, n$, that the Y_is are independent and binomially distributed with size one and probability θ. While $\overline{Y} = (Y_1 + \cdots + Y_n)/n$ is known to be unbiased for θ, $\log[\overline{Y}/(1 - \overline{Y})]$ is not unbiased for $\log[\theta/(1 - \theta)]$, the log **odds** of Y_i. Indeed, the expectation of $\log(\overline{Y}/(1 - \overline{Y}))$ does not exist, and no unbiased estimator of $\log[\theta/(1 - \theta)]$, which forms the basis for **logistic regression** models, is known to exist.

Thus, the utility of unbiasedness as a criterion for choosing estimators is limited by the lack of available unbiased estimators. Faced with this situation, statisticians appeal to **large-sample theory** and relax the unbiasedness criterion, while maintaining the requirement that, as the sample size becomes large, the estimator will grow closer and closer to the true $\boldsymbol{\theta}$. Formally, we say that $\boldsymbol{\delta}(\mathbf{Y})$ *converges in probability* to $\boldsymbol{\theta}$ if for any $\varepsilon > 0$,

$$\Pr\{[\boldsymbol{\delta}(\mathbf{Y}) - \boldsymbol{\theta}]'[\boldsymbol{\delta}(\mathbf{Y}) - \boldsymbol{\theta}] > \varepsilon\} \to 0 \quad \text{as } n \to \infty,$$

(*see* **Convergence in Distribution and in Probability**). We define $\boldsymbol{\delta}(\mathbf{Y})$ to be a *consistent estimator* if $\boldsymbol{\delta}(\mathbf{Y}) \to \boldsymbol{\theta}$ in probability as $n \to \infty$. Consistent estimators are desirable for several reasons. First, they are "approximately unbiased" in that, when the sample size is sufficiently large, $\boldsymbol{\delta}(\mathbf{Y})$ will, on average, be close to $\boldsymbol{\theta}$ from the viewpoint of repeated sampling. More importantly, the variability of $\boldsymbol{\delta}(\mathbf{Y})$ *around the true* $\boldsymbol{\theta}$ will vanish as $n \to \infty$. Thirdly, as a result of Slutsky's theorem, consistent estimators are invariant; that is, if $\boldsymbol{\delta}(\mathbf{Y})$ is a consistent estimator of $\boldsymbol{\theta}$, then $\mathbf{g}[\boldsymbol{\delta}(\mathbf{Y})]$ is consistent for $\mathbf{g}(\boldsymbol{\theta})$ as well. Finally, consistency is usually the first step in establishing the asymptotic distribution of an estimator (*see* **Large-sample Theory**). Consistency is further attractive as a criterion because consistent estimators are available in a wide variety of problems.

Returning to the binomial example, the law of large numbers and Slutsky's theorem immediately imply that both $\overline{Y}/n$ and $\log[\overline{Y}/(n-\overline{Y})]$ are consistent estimators of $\boldsymbol{\theta}$ and $\log[\theta/(1-\theta)]$, respectively. Continuing with the binomial example, approximate variances of $\overline{Y}$ and $\log[\overline{Y}/(n-\overline{Y})]$ are, respectively, $\theta(1-\theta)/n$ and $1/(n\theta)+1/[n(1-\theta)]$, decreasing at the rate of n^{-1}. As this example demonstrates, if we accept consistency as a criterion, a variety of estimators are available to the user of statistical methods.

The remaining question is, then: How does one derive consistent estimators for $\boldsymbol{\theta}$? While many estimation methods have been developed in the past century, most of them can be classified into one of the following two types. In the first type, estimators are derived by minimizing with respect to $\boldsymbol{\theta}$ a prespecified objective function of the data $\mathbf{y}$ and parameters $\boldsymbol{\theta}$. Type I methods include as special cases the **maximum likelihood** method, the M-estimation method pioneered by Huber [12] (*see* **Robustness**), and the weighted **least squares** method. The second type of estimators are obtained by simultaneously solving (for $\boldsymbol{\theta}$) p equations containing $\mathbf{y}$ and $\boldsymbol{\theta}$. Examples include the **method of moments**, the **quasi-likelihood** method, and the **estimating functions** method advocated by Godambe [9] and Durbin [6]. One advantage of the first approach is that no differentiability assumption on $\boldsymbol{\theta}$ is required. This is particularly useful when the sampling space depends on $\boldsymbol{\theta}$ [e.g. the **uniform distribution** on $(0,\theta)$] or when the parameter space is discrete. On the other hand, the second approach offers a useful alternative when the probability mechanism generating the data is unclear, and yet the scientific focus is well described by $\boldsymbol{\theta}$. Furthermore, this approach naturally leads to the derivation of the asymptotic distribution of the estimator, an issue addressed elsewhere.

We now discuss briefly how to establish consistency for either type of estimator. The focus is on the basic ideas that are crucial to establishing consistency, and we provide key references for the detailed technical derivations.

Consistency: Type I

This approach aims to find an estimator of $\boldsymbol{\theta}$ by minimizing, with respect to $\boldsymbol{\theta}$, a prespecified objective function $Q_n(\mathbf{y},\boldsymbol{\theta})$ of data $\mathbf{y}=(y_1,\ldots,y_n)'$ and parameter $\boldsymbol{\theta}$. Some familiar examples are given as follows.

Example 1 (Maximum Likelihood Method)

By choosing

$$Q_n(\mathbf{y},\boldsymbol{\theta}) = -\ln f(\mathbf{y};\boldsymbol{\theta}), \tag{2}$$

one has the conventional maximum likelihood estimator (MLE) originated by Fisher [8].

Example 2 (Pseudo Maximum Likelihood Method)

Let $h(\cdot;\theta)$ be a probability (density) function that is specified by the investigator. The idea is to minimize

$$Q_n(\mathbf{y},\boldsymbol{\theta}) = -\ln h(\mathbf{y};\boldsymbol{\theta}), \tag{3}$$

while recognizing that h may not correctly specify the probability mechanism for Y; that is, $h(\mathbf{y};\boldsymbol{\theta}) \neq f(\mathbf{y};\boldsymbol{\theta})$ for some $\mathbf{y}$. This approach was first considered by Huber [13]. The term "pseudo maximum likelihood" was coined in the econometric literature by Gourieroux et al. [10] to emphasize that, due to the complexity of economic phenomena, there is little guarantee that probability models obtained from economic theory are necessarily correct [3]. This concern is a legitimate one in the health sciences as well due to the complexity of bio-psychosocial factors in the human disease process.

Example 3 (M-Estimation)

The MLE for the location parameter under the normality assumption is known to be sensitive to the presence of a small number of **outliers** (**extreme values**) [24]. For example, suppose that interest were on θ, the mean of y. Instead of minimizing $\sum_i (y_i-\theta)^2/2$, which gives rise to $\overline{y}$ as the MLE of θ, Huber [12] proposes to address the problem of such outliers by minimizing

$$Q_n(\mathbf{y},\theta) = \sum_{i=1}^{n} \rho(y_i;\theta),$$

where

$$\rho(y_i,\theta) = \begin{cases} (y_i-\theta)^2/2, & \text{if } |y_i-\theta| \le k, \\ k|y_i-\theta| - k^2/2, & \text{if } |y_i-\theta| > k, \end{cases}$$

and k is a constant pre-specified by the investigator. Many other choices of the function ρ are available and discussed in detail in, for example, Huber [14] and Serfling [23]. Approaches of this kind have

been termed M-estimation and studied extensively, especially in the context of **robust regression** techniques [14].

Example 4 (Weighted Least Squares Method)

The least squares method was invented almost two centuries ago by Legendre [16]. Its purpose is to estimate the regression coefficients θ for the mean of the Y_is conditional on the x_is by minimizing

$$Q_n(\mathbf{y}, \boldsymbol{\theta}) = \sum_{i=1}^{n} (y_i - \mathbf{x}_i' \boldsymbol{\theta})^2, \tag{4}$$

where $\mathbf{x}_i$ is a $p \times 1$ vector of covariates thought to be related to the response variable, $Y_i, i = 1, \ldots, n$. Implicit behind this procedure is the assumption that the x_is and the "error term", $e_i = Y_i - x_i'\theta$, are uncorrelated with each other for the true θ value. In the situation in which the variance varies with $\mathbf{x}_i'\boldsymbol{\theta}$, the mean value of Y_i given x_i, one might modify (4) by minimizing

$$Q_n(\mathbf{y}, \boldsymbol{\theta}) = \sum_{i=1}^{n} \frac{(y_i - \mathbf{x}_i' \boldsymbol{\theta})^2}{V_i(\boldsymbol{\theta})}, \tag{5}$$

where $V_i(\boldsymbol{\theta}) = V(\mathbf{x}_i'\boldsymbol{\theta}) = \mathrm{var}(e_i)$. Consistency of the resulting estimator is very sensitive to this last assumption, since the $\boldsymbol{\theta}$ in $V_i(\boldsymbol{\theta})$ now figures in the objective function.

To demonstrate consistency, let $\hat{\boldsymbol{\theta}}_n \equiv \hat{\boldsymbol{\theta}}_n(\mathbf{y})$ be a statistic which minimizes $Q_n(\mathbf{y}, \boldsymbol{\theta})$ over Θ, the parameter space for $\boldsymbol{\theta}$, and let $\boldsymbol{\theta}_0$ be the true but unknown value of $\boldsymbol{\theta}$. The question is: Can we claim that $\hat{\boldsymbol{\theta}}_n$ is a consistent estimator of $\boldsymbol{\theta}$; that is, that $\hat{\boldsymbol{\theta}}_n \to \boldsymbol{\theta}_0$ in probability? Suppose that Q_n/n converges in probability to $Q_0(\boldsymbol{\theta})$ as $n \to \infty$, where $Q_0(\boldsymbol{\theta})$ is a function determined by the chosen objective function, Q_n, and the true probability model, $f(\cdot; \boldsymbol{\theta}_0)$. Assuming that $Q_0(\boldsymbol{\theta})$ is uniquely minimized by $\boldsymbol{\theta}^*$, intuition (which needs to be made rigorous by additional assumptions and mathematical proofs, of course) suggests that $\hat{\boldsymbol{\theta}}_n$ ought to converge to $\boldsymbol{\theta}^*$ in probability. The claim of consistency is then warranted if $\boldsymbol{\theta}^* = \boldsymbol{\theta}_0$. Can one be sure that $\boldsymbol{\theta}^*$ is indeed equal to $\boldsymbol{\theta}_0$? While there is no simple answer to this question, many sufficient conditions exist to ensure the consistency of $\hat{\boldsymbol{\theta}}_n$ as we will briefly discuss in a few of our example cases.

Example 1 (continued)

In the special case that the Y_is are independent and identically distributed (iid),

$$Q_n(\boldsymbol{\theta}) = -\sum_{i=1}^{n} \ln f_1(y_i; \boldsymbol{\theta}),$$

where $f_1(\cdot; \boldsymbol{\theta})$ is the probability (density) function for a single observation. Then the law of large numbers implies that Q_n/n converges in probability to $Q_0(\boldsymbol{\theta}) = -\mathrm{E}_0[\ln f_1(Y_1; \boldsymbol{\theta})]$ at each θ, where E_0 denotes expectation taken with respect to $f_1(\cdot; \boldsymbol{\theta}_0)$. However, for each $\boldsymbol{\theta} \in \Theta$,

$$\begin{aligned} Q_0(\boldsymbol{\theta}) - Q_0(\boldsymbol{\theta}_0) &= -\mathrm{E}\left[\ln\left(\frac{f_1(Y_1; \boldsymbol{\theta})}{f_1(Y_1; \boldsymbol{\theta}_0)}\right); \boldsymbol{\theta}_0\right] \\ &\geq -\ln \mathrm{E}\left(\frac{f_1(Y_1; \boldsymbol{\theta})}{f_1(Y_1; \boldsymbol{\theta}_0)}; \boldsymbol{\theta}_0\right) = 0, \end{aligned}$$

known as Kullback's inequality. This inequality is strict if $\boldsymbol{\theta} \neq \boldsymbol{\theta}_0$ and if $f(\cdot; \boldsymbol{\theta})$ is identifiable. Therefore, if $f(\cdot; \boldsymbol{\theta})$ is identifiable, then $\boldsymbol{\theta}^* = \boldsymbol{\theta}_0$ and hence $\hat{\boldsymbol{\theta}}_n$ is a consistent estimator of $\boldsymbol{\theta}$. For detailed proof of the consistency of MLE, see, for example, [25, 17], and [5, pp. 256–257].

Example 2 (continued)

In the iid. case, Q_n/n converges to $Q_0(\boldsymbol{\theta}) = -\mathrm{E}_0(\ln h_1(Y_1; \boldsymbol{\theta}))$. Whether $\boldsymbol{\theta}_0$ minimizes $Q_0(\boldsymbol{\theta})$ depends on the probability model specified and its interaction with the true probability model. In the situation in which $\boldsymbol{\theta} = \mathrm{E}(Y_1)$, Gourieroux et al. [10] provide a necessary and sufficient condition for $\boldsymbol{\theta}_0$ to minimize $Q_0(\boldsymbol{\theta})$, namely that $h_1(\cdot; \boldsymbol{\theta})$ take the form of

$$h_1(y_1; \boldsymbol{\theta}) = \exp[a(\boldsymbol{\theta}) y_1 + b(\boldsymbol{\theta}) + c(y_1)],$$

known as a linear exponential family. In this case

$$Q_0(\boldsymbol{\theta}) = -a(\boldsymbol{\theta})\boldsymbol{\theta}_0 - b(\boldsymbol{\theta}) - \mathrm{E}_0[c(Y_1)]$$

is minimized at $\boldsymbol{\theta} \equiv \boldsymbol{\theta}_0$, a simple consequence of Kullback's inequality and the fact that $h_1(\cdot; \boldsymbol{\theta})$ is a probability (density) function.

Example 4 (continued)

Assuming that the x_is are iid, Q_n/n in (5) converges to

$$Q_0(\boldsymbol{\theta}) = \mathrm{E}_{\mathbf{X}_1}\left\{\frac{[\mathbf{X}_1'(\boldsymbol{\theta}_0 - \boldsymbol{\theta})]^2}{V(\mathbf{X}_1'\boldsymbol{\theta})}\right\}$$

$$+ \mathrm{E}_{\mathbf{X}_1}\left[\frac{V(\mathbf{X}_1'\boldsymbol{\theta}_0)}{V(\mathbf{X}_1'\boldsymbol{\theta})}\right].$$

If $\mathrm{var}(Y_i|x_i) = V(\mathbf{x}_i'\boldsymbol{\theta})$ is independent of $\boldsymbol{\theta}$ as in (4), then it is obvious that $\boldsymbol{\theta}_0$ minimizes $Q_0(\boldsymbol{\theta})$ and hence the consistency of $\hat{\boldsymbol{\theta}}_n$ which minimizes the weighted least squares in (4) is established. This is not true, in general, if $V(\cdot)$ does depend on $\boldsymbol{\theta}$. Consider a special case that x_i is dichotomous (1 or 0) with $\lambda = \Pr(X_i = 1)$, so that

$$\mathrm{E}(Y_i|x_i) = \theta_1 + \theta_2 x_i.$$

Furthermore, let $\mathrm{var}(Y_i|x_i) = \mathrm{E}^2(Y_i|x_i)$. It is easy to see that

$$Q_0(\theta) = \lambda\frac{(\theta_{01}+\theta_{02})^2 + (\theta_{01}-\theta_1+\theta_{02}-\theta_2)^2}{(\theta_1+\theta_2)^2} + (1-\lambda)\frac{\theta_{01}^2 + (\theta_{01}-\theta_1)^2}{\theta_1^2},$$

and that $Q_0(\theta)$ is minimized at

$$(\theta_1^*, \theta_2^*) = (2\theta_{01}, 2\theta_{02}).$$

Consistency: Type II

An alternative way of obtaining estimators is by solving an equation

$$\mathbf{g}_n(\mathbf{y};\boldsymbol{\theta}) = \sum_{i=1}^{n}\mathbf{g}(y_i;\boldsymbol{\theta}) = 0, \qquad (6)$$

where $\mathbf{g}_n$, a $(p \times 1)$ vector-valued function, is called an *estimating function* for $\boldsymbol{\theta}$. The MLE may be viewed as a special case if $f(\mathbf{y};\boldsymbol{\theta})$ is first-order differentiable, in which case $\mathbf{g}_n(\mathbf{y};\boldsymbol{\theta}) = \partial \ln f(\mathbf{y};\boldsymbol{\theta})/\partial\boldsymbol{\theta}$, known as the score function for $\boldsymbol{\theta}$ (*see* **Likelihood**). The utility of the estimating function approach, however, is that it provides a sensible alternative to the MLE when the available substantive knowledge is insufficient to formulate a model $f(\mathbf{y};\boldsymbol{\theta})$ for the probability mechanism or, to a lesser extent, when the model $f(\mathbf{y};\boldsymbol{\theta})$ is too complicated to compute.

Example 5

The **quasi-likelihood** method proposed by Wedderburn [26] offers an excellent example. Here, $\boldsymbol{\theta}$ characterizes the relationship between y_i and covariates $\mathbf{x}_i$ through

$$\mu_i(\boldsymbol{\theta}) = \mathrm{E}(Y_i|\mathbf{x}_i) = h^{-1}(\mathbf{x}_i'\boldsymbol{\theta}),$$

where the one-to-one continuous function $h(\cdot)$ is known as the "link" function (*see* **Generalized Linear Model**). The contribution to g_n in (6) from the ith observation is

$$\mathbf{g}(y_i, \mathbf{x}_i;\boldsymbol{\theta}) = \left(\frac{\partial\mu_i}{\partial\theta}\right)' V_i^{-1}(\boldsymbol{\theta})(y_i - \mu_i(\boldsymbol{\theta})), \qquad (7)$$

which depends only on the first two conditional moments of y_i, namely $E(Y_i|\mathbf{x}_i) = \mu_i(\boldsymbol{\theta})$ and $\mathrm{var}(Y_i|\mathbf{x}_i) = V_i(\boldsymbol{\theta})$, where $V_i(\boldsymbol{\theta}) = V(\mu_i(\boldsymbol{\theta}))$.

Note that the expectation of $\mathbf{g}$ in (7) is zero so long as the true probability model $f(\cdot;\boldsymbol{\theta})$ has $\mu_i(\boldsymbol{\theta})$ as the mean for Y_i, and this is true even if $V_i(\boldsymbol{\theta})$ is misspecified. Note also that the score function, $\partial \ln f(\mathbf{y};\boldsymbol{\theta})/\partial\boldsymbol{\theta}$, has zero expectation. This zero expectation property for $\mathbf{g}_n$ is a natural one for the following reason: if the purpose is to find a solution $\hat{\boldsymbol{\theta}}_n$ such that $\mathbf{g}_n(\mathbf{y}, \hat{\boldsymbol{\theta}}_n) = \mathbf{0}$, then it is intuitively desirable that the $\mathbf{g}$s be close to zero, at least in average, at the true $\boldsymbol{\theta}$ value. Similarly to the type I consistent estimators, in the simple case in which the Y_is are iid, the law of large numbers shows that $\overline{\mathbf{g}}_n = \mathbf{g}_n/n$ converges in probability to $\mathbf{g}_0(\boldsymbol{\theta}) = \mathrm{E}_0[\mathbf{g}_1(Y_1;\boldsymbol{\theta})]$ as $n \to \infty$. Following this argument, intuition suggests that $\hat{\boldsymbol{\theta}}_n$ may converge to some $\boldsymbol{\theta}^*$, a solution of $\mathbf{g}_0(\boldsymbol{\theta}) = \mathbf{0}$ and, consequently, $\hat{\boldsymbol{\theta}}_n$ is a consistent estimator of $\boldsymbol{\theta}$ if $\boldsymbol{\theta}^* \equiv \boldsymbol{\theta}_0$. There will generally exist a consistent estimator $\hat{\boldsymbol{\theta}}_n$ if the $\mathbf{g}$s are unbiased (i.e. if $g_0(\theta_0) = 0$) and the following conditions hold:

1. The true parameter $\boldsymbol{\theta}_0$ is an isolated root of $g_0(\boldsymbol{\theta})$ in the sense that there exists an open neighborhood $N \subset \Theta$ containing $\boldsymbol{\theta}_0$ such that $g_0(\boldsymbol{\theta}) \neq 0$ for all $\boldsymbol{\theta} \in N$ except $\boldsymbol{\theta} = \boldsymbol{\theta}_0$.
2. $\mathbf{g}_n(\mathbf{y}, \boldsymbol{\theta})$ is continuous on Θ for all n.
3. $g_0(\boldsymbol{\theta})$ is either continuous or monotone (nonincreasing) on Θ.

In the case where θ is one-dimensional, condition 1 is generally satisfied if $n^{-1}\mathrm{E}_0(-\partial g_n/\partial\theta)$ and $n^{-1}\mathrm{var}_0(g_n)$ converge to positive constants at $\theta = \theta_0$. Condition 3 holds if g_n is continuous in θ and bounded or if g_n is a nonincreasing function of θ, but other sufficient conditions may be available in specific problems or cases in which $g_0(\theta)$ can be computed directly. Under the further condition that g_n is monotone in θ, all solution sequences $\hat{\theta}_n$ will converge to θ_0. Rigorous proofs of the consistency of $\hat{\theta}_n$ based on condition 1 are given in, for example,

[23] and [13]. An alternative approach when g_n is the score function is given by Cramer [4, pp. 501–503].

Example 5 (continued)

The "quasi-score function" defined in (7) generally satisfies the above three conditions if the unconditional (with respect to $\mathbf{X}_1$) **information matrix**

$$\mathrm{E}_{\mathbf{X}_1}\left[\frac{\partial \mu_1}{\partial \boldsymbol{\theta}} V_1^{-1}(\boldsymbol{\theta}) \frac{\partial \mu_1}{\partial \boldsymbol{\theta}}\right]$$

is positive definite for all $\boldsymbol{\theta}$. See detailed derivations for this important special case in [20] and [7].

Example 6 (Mantel–Haenszel Estimator)

Let $y_i = (a_i, b_i, c_i, d_i)$ be the entries from the ith **two-by-two table** stratified according to some arbitrary **confounding** variable, x_i. For example, this sort of data structure could arise in a retrospective **case–control study**, where i indexes a **stratifying** variable for which we want to control. Interest is on the odds ratio describing the association between some exposure of interest and risk for disease, adjusting for varying risk by stratum. In particular, we want to estimate the conditional (on x_i) odds ratio

$$\theta = \frac{\Pr(A_i = a_i|x_i)\Pr(D_i = d_i|x_i)}{\Pr(B_i = b_i|x_i)\Pr(C_i = c_i|x_i)},$$

which measures the strength of association between two dichotomous variables. The **Mantel–Haenszel** estimator [19] is seen as the solution of

$$g_n(\mathbf{y};\theta) = \sum_{i=1}^{n} \frac{1}{N_i}(a_i d_i - \theta b_i c_i) = 0,$$

where $N_i = a_i + b_i + c_i + d_i$ is the number of patients in the ith clinic. Assuming that the X_is are iid and the N_is are constant, one has immediately

$$\mathrm{E}_0[g_1(Y_1, X_1;\theta)] = \frac{1}{N_1}\mathrm{E}_{X_1}\{[\mathrm{E}_0(A_1 D_1|X_1) - \theta \mathrm{E}_0(B_1 C_1|X_1)]\},$$

which is linear in θ with negative slope $\mathrm{E}_{x_1,0}(B_1 C_1)/N_1$.

Some Final Remarks

First, in discussing the consistency of type II estimators, we dealt principally with one-dimensional θ. In models with multidimensional parameter, satisfying condition 1 requires more care. In particular, this condition is generally satisfied if $n^{-1}\mathbf{i}_n(\boldsymbol{\theta}) \to \mathbf{i}(\boldsymbol{\theta})$ as $n \to \infty$, where $\mathbf{i}(\boldsymbol{\theta})$ is a positive definite matrix and continuous in $\boldsymbol{\theta}$, and $\mathbf{i}_n(\boldsymbol{\theta})$ is the information in $\mathbf{g}_n$ given by

$$\mathbf{i}_n(\boldsymbol{\theta}_0) = \left[\mathrm{E}\left(-\frac{\partial \mathbf{g}_n}{\partial \boldsymbol{\theta}}\right)\mathrm{var}^{-1}(\mathbf{g}_n)\mathrm{E}\left(-\frac{\partial \mathbf{g}_n}{\partial \boldsymbol{\theta}}\right)'\right]_{\boldsymbol{\theta}=\boldsymbol{\theta}_0}.$$

Secondly, we have dealt principally with the case in which the Y_is are iid and incorporated regression into our framework by considering the data (Y_i, X_i) to be iid random vectors, implicitly assuming that the distribution of the X_is exists, but is left unspecified. Extension to the independent but not identically distributed case, which may be a more natural approach to regression, is established by setting $\mathbf{x} = (x_1, \ldots, x_n)'$ and assuming that the normed conditional information

$$n^{-1}\mathbf{i}_n(\boldsymbol{\theta}_0) = n^{-1}\left[\mathrm{E}\left(-\frac{\partial \mathbf{g}_n}{\partial \boldsymbol{\theta}}|\mathbf{x}\right)\mathrm{var}^{-1}(\mathbf{g}_n|\mathbf{x}) \times \mathrm{E}\left(-\frac{\partial \mathbf{g}_n}{\partial \boldsymbol{\theta}}|\mathbf{x}\right)'\right]_{\boldsymbol{\theta}=\boldsymbol{\theta}_0}.$$

converges to a positive definite matrix.

Thirdly, it is not required that the Y_is be independent, and models with dependent Y_is are common in biomedical research. In many cases, we still have consistency of $\hat{\boldsymbol{\theta}}_n$. Again, the main requirement is that $n^{-1}\mathbf{i}_n(\boldsymbol{\theta}) \to \mathbf{i}(\boldsymbol{\theta})$ as $n \to \infty$, where $\mathbf{i}(\boldsymbol{\theta})$ is a positive definite matrix.

Fourthly, we have assumed throughout that the elements of $\boldsymbol{\theta}$ are the sole parameters necessary to specify the probability model for the data. Very often in practice, one needs additional parameters, $\boldsymbol{\phi}$ say, to completely specify the model, that is $f(\mathbf{y}) = f(\mathbf{y};\boldsymbol{\theta},\boldsymbol{\phi})$, where $\boldsymbol{\phi}$ is a $q \times 1$ vector of additional parameters. For example, the variance of Y_i in (7) is likely to depend on parameters other than $\boldsymbol{\theta}$ which characterizes the first moment of Y_i. Or, in the retrospective study example (Example 6), the parameter of interest characterizes the within-stratum ratio of disease risk between the exposed and unexposed persons, so that we must control for confounding factors

relating to the stratum. The "stratum effect" is represented by the parameter $\boldsymbol{\phi} = (\phi_1, \ldots, \phi_n)'$. Parameters of this kind are called **nuisance parameters**. Although in the particular case of Example 6, due to the elegance of the Mantel–Haenszel estimator, it is possible to formulate the problem independently of $\boldsymbol{\phi}$, in more general problems, the objective function Q_n to be minimized or the estimating function $\mathbf{g}_n$ to be solved, will depend on $\boldsymbol{\phi}$. We distinguish two cases.

In the first, assuming that one can find a well-behaved estimator of $\boldsymbol{\phi}$, $\hat{\boldsymbol{\phi}}$ say, in that

$$\sqrt{n}(\hat{\boldsymbol{\phi}}_n - \boldsymbol{\phi}_0) = O_p(1), \tag{8}$$

no additional complication is introduced, so far as the consistency of $\hat{\boldsymbol{\theta}}_n$ is concerned, by either minimizing $Q_n(\boldsymbol{\theta}, \hat{\boldsymbol{\phi}}_n)$ or solving $\mathbf{g}_n(\mathbf{y}; \boldsymbol{\theta}, \hat{\boldsymbol{\phi}}_n) = 0$. In the second case, however, $\hat{\boldsymbol{\phi}}_n$ exists but does not meet the requirement given in (8). This often occurs when the number of nuisance parameters increases with n and the number of observations that is informative for each nuisance parameter is small even as n increases. In the retrospective study example, each y_i is a two-by-two table, and $q = n$. This is known as the Neyman & Scott [21] problem, and in such cases the maximum likelihood estimator might not be consistent (*see* **Estimating Functions**). Kalbfleisch & Sprott [15] and Basu [2] discuss a variety of likelihood methods to construct consistent estimators in the presence of many nuisance parameters. Andersen [1] provides proof of the consistency of conditional maximum likelihood estimators under the exponential family. Lindsay [18] extends Andersen's work to a broader class of probability models by further developing the concept of a conditional score function, which provides a zero-unbiased estimating function for θ even if ϕ is poorly estimated.

Fifthly, another assumption often made to show consistency is that the true parameter value θ_0 is an interior point of Θ. There are situations in which the parameter values of interest, θ_0, are on the boundary of the parameter space. A typical example is the application of **variance component** models to **pedigree** data in which the contribution from a particular genetic component is expressed in terms of its variance, which is necessarily nonnegative. Here a value of zero variance corresponds to the lack of contribution from this hypothesized component. In many cases, consistency turns out to hold even for θ_0 on the boundary [22].

Sixthly, one concern for the second (estimating function) approach is the issue of multiple roots when solving $\mathbf{g}_n = \mathbf{0}$. This is a potential problem in all but the simplest probability models (e.g. an exponential family with canonical link function). The question as to which root corresponds to a consistent estimator can be addressed in a variety of ways. For example, if a known consistent estimator is available, the root closest to that estimator will also be consistent [17, p. 421]. The flexibility of the estimating function approach often permits construction of a function with a unique root, which would provide such an estimator. This problem is further addressed by Hanfelt & Liang [11], who integrate estimating functions with respect to $\boldsymbol{\theta}$ to obtain an objective function, which is then minimized to select one $\hat{\boldsymbol{\theta}}_n$ among several solutions to $\mathbf{g}_n = \mathbf{0}$.

Finally, the task of parameter estimation allows scientists to learn about the magnitude of the quantities that reflect scientific objectives. The notion of consistency provides a means to evaluate the quality of proposed estimators. However, one should not lose sight of the fact that point estimation is only an intermediate part of statistical analysis. Equally important is to assess the precision of the estimator $\hat{\boldsymbol{\theta}}_n$, an issue not addressed here. The precision, along with the magnitude of $\hat{\boldsymbol{\theta}}_n$, allows one to construct **hypothesis tests** on $\boldsymbol{\theta}$ or to provide a range of plausible values for $\boldsymbol{\theta}$, given the data $\mathbf{Y} = \mathbf{y}$.

CONSORT

A report of a randomized controlled trial (RCT) should convey to the reader, in a transparent manner, why the study was undertaken, and how it was conducted and analyzed. To assess the strengths and limitations of an RCT, the reader needs and deserves to know the quality of its methodology. Despite several decades of educational efforts, RCTs still are not being reported adequately [2, 5, 10].

The Consolidated Standards of Reporting Trials (CONSORT) statement, published in the *Journal of the American Medical Association* in 1996 [1], was developed to try to help rectify this problem. The CONSORT statement was developed by an international group of clinical trialists, statisticians, epidemiologists and biomedical editors. The CONSORT statement is one result of previous efforts made by two independent groups, the Standards of Reporting Trials (SORT) group [9] and the Asilomar Working Group on Recommendations for Reporting of Clinical Trials in the Biomedical Literature [11]. The CONSORT statement consists of two components, a 21-item checklist (Table 1) and a flow diagram (Figure 1). The checklist has six major headings that pertain to the contents of the report of a trial, namely Title, Abstract, Introduction, Methods, Results and Discussion. Within these major headings there are subheadings that pertain to specific items that should be included in any clinical trial manuscript.

These items constitute the key pieces of information necessary for authors to address when reporting

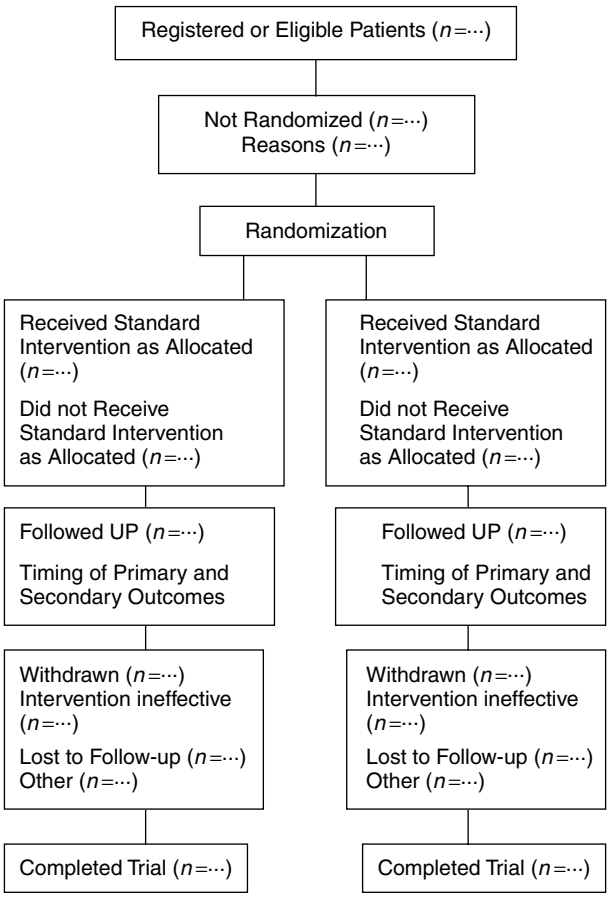

Figure 1 CONSORT flowchart. Reproduced with permission from the *Journal of the American Medical Association*, 1996, Volume 276, 637–665. Copyrighted (1996), American Medical Association

Table 1 CONSORT checklist

Heading	Subheading	Descriptor	Was it reported?	Page no.?
Title		Identify the study as a randomized trial.		
Abstract		Use a structured format.		
Introduction		Identify the study as a randomized trial. Use a structured format. State prospectively defined hypothesis, clinical objectives, and planned subgroup or covariate analyses		
Methods	Protocol	Describe 1. Planned study population, together with inclusion/exclusion criteria. 2. Planned interventions and their timing. 3. Primary and secondary outcome measure(s) and the minimum important difference(s), and indicate how the target sample size was projected. 4. Rationale and methods for statistical analyses, detailing main comparative analyses and whether they were completed on an intention-to-treat basis. 5. Prospectively defined stopping rules (if warranted)		
	Assignment	Describe 1. Unit of randomization (e.g. individual, cluster, geographic). 2. Method used to generate the allocation schedule. 3. Method of allocation concealment and timing of assignment. 4. Method to separate the generator from the executor of assignment.		
	Masking (Blinding)	Describe mechanism (e.g. capsules, tablets); similarity of treatment characteristics (e.g. appearance, taste); allocation schedule control (location of code during trial and when broken); and evidence for successful blinding among participants, person doing intervention, outcome assessors, and data analysts.		
Results	Participant Flow and Follow-up	Provide a trial profile (Figure 1) summarizing participant flow, numbers and timing of randomization assignment, interventions, and measurements for each randomized group.		
	Analysis	State estimated effect of intervention on primary and secondary outcome measures, including a point estimate and measure of precision (confidence interval). State results in absolute numbers when feasible (e.g. 10/20, not 50%). Present summary data and appropriate descriptive and inferential statistics in sufficient detail to permit alternative analyses and replication. Describe prognostic variables by treatment group and any attempt to adjust for them. Describe protocol deviations from the study as planned, together with the reasons.		
Comment		State specific interpretation of study findings, including sources of bias and imprecision (internal validity) and discussion of external validity, including appropriate quantitative measures when possible. State general interpretation of the data in light of the totality of the available evidence.		

the results of an RCT. Their inclusion is based on evidence, whenever possible. For example, authors are asked to report on the methods they used to achieve allocation concealment, possible in every randomized trial. There is growing evidence that inadequately concealed trials, compared with adequately concealed ones, exaggerate the estimates of intervention benefit by 30%–40%, on average [7, 8]. Additional benefits of the checklist (and flow diagram) include facilitating editors, peer reviewers and journal readers to evaluate the internal and external validity of a clinical trial report.

The flow diagram pertains to the process of winnowing down the number of participants from those eligible or screened for a trial to those who ultimately completed the trial and were included in the analysis. The flow diagram pertains particularly to a two-group, parallel design, as stated in the CONSORT statement. Other checklists and flow diagrams have been developed for reporting cluster randomized trials [4] and other designs (see `http://www.consort-statement.org`). The flow diagram, in particular, requests relevant information regarding participants in each of the intervention and control groups who did not receive the regimen for the group to which they were randomized, those who during the course of the trial were discontinued, withdrew, became lost to follow-up, and those who have incomplete information for some other reason.

There is emerging evidence to suggest that the quality of reporting of RCTs, based on the use of the CONSORT statement, compared with not using it, is higher on several dimensions, such as reduced reporting of unclear allocation concealment [6]. Similarly, use of the flow diagram was associated with better overall reporting of RCTs [3].

The CONSORT statement (checklist and flow diagram) is available on the CONSORT website (`www.consort-statement.org`). This site includes information on the growing number of health care journals and biomedical editorial groups, such as the International Council of Medical Journal Editors (ICMJE), who support the use of the CONSORT statement for reporting RCTs.

At this writing the CONSORT statement is undergoing revision. Present plans call for the revised Statement to appear in Spring 2001 along with an extensive explanatory and elaboration document to overcome some of the shortcomings of the original statement, both of which will be available on the above website.

DAVID MOHER

Contagious Distributions

The term "contagion" entered the statistical literature in a paper by Pólya [14] that reexpounded certain ideas previously put forward by Eggenberger & Pólya [3] (*see* **Polya's Urn Model**). During the spread of an infection each new case was considered to release more germs into the atmosphere; the probability of catching the disease was therefore thought to depend on the existing number of cases. Eggenberger & Pólya modeled this via an urn initially containing R red balls (cases) and S black balls (others), where $R + S = N$; balls are drawn one at a time at random from the urn and each drawn ball is immediately replaced together with Δ new balls of the same color. They showed that the probability that, after n draws, r red balls (representing cases of infection) and $n - r = s$ black balls (individuals without the infection) have been drawn is

$$\mathrm{P}_r = \frac{n!}{r!s!}\frac{\rho(\rho+\delta)\cdots[\rho+(r-1)\delta]}{1(1+\delta)\cdots[1+(r-1)\delta]} \times \frac{\sigma(\sigma+\delta)\cdots[\sigma+(s-1)\delta]}{(1+r\delta)[1+(r+1)\delta]\cdots[1+(n-1)\delta}, \quad (1)$$

where $\rho = R/N, \sigma = S/N$, and $\delta = \Delta/N$. In [3] they set $n\rho = h, n\delta = d$, and let $n \to \infty$, with h and d remaining finite, giving the limiting form

$$\mathrm{P}_r = \frac{h(h+d)(h+2d)\cdots[h+(r-1)d]}{r!(1+d)^{(h/d)+r}}, \quad (2)$$

i.e. a **negative binomial distribution**. They fitted this and a **Poisson distribution** to Swiss monthly mortality figures for smallpox over the period 1877 to 1900, as shown in Table 1. The negative binomial distribution fits the data very much better than a Poisson distribution (which is the model for deaths occurring completely at random), supporting their hypothesis of contagion.

The same type of contagion concept, concerning the changing probability of an event during a sequence of events, had arisen previously in a paper by Greenwood & Yule [6]. These authors put forward the "burnt-fingers" hypothesis that after an individual has suffered one accident he/she will have a lower probability of suffering future accidents of the same type (*see* **Accident Proneness**). They obtained a good fit when they applied their model to data on accidents in the manufacture of high-explosive shells.

Neyman [12] had a different concept of contagion. He sought an explanation for the failure of the Poisson distribution to model the distribution of insect larvae in an agricultural field or the distribution of cells in a haemocytometer and observed that such data generally have a long tail and an unexpectedly high variance. He said that such data have a "contagious distribution". The NTA (Neyman's type A) distribution that he fitted can be regarded as arising from a Poisson distribution of clumps (with mean λ), with the number of cells for each clump having independent and identical Poisson distributions (with mean ϕ). It gives a better fit than the Poisson distribution, as shown in Table 2.

Table 1

Number of deaths	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	≥15	Total
Observed number of months	100	39	28	26	13	6	11	5	5	6	1	6	2	2	3	35	288
Negative binomial fit	100.4	36.3	23.5	17.5	13.8	11.3	9.5	8.1	7.0	6.1	5.3	4.7	4.2	3.7	3.3	33.3	288.0
Poisson fit	1.2	6.5	17.8	32.6	44.9	49.4	45.2	35.5	24.5	15.0	8.2	4.1	1.9	0.8	0.3	0.1	288.0

Table 2

Number of cells/square	0	1	2	3	4	≥5	Total
Observed number of squares	213	128	37	18	3	1	400
NTA fit	214.8	121.3	45.7	13.7	3.6	0.9	400.0
Poisson fit	202.2	138.0	47.1	10.7	1.8	0.2	400.0

The expressions for the NTA probabilities are very complicated. The distribution is easier to understand via its probability generating function (pgf) (*see* **Generating Functions**)

$$G_{\mathrm{NTA}}(z) = G[g(z)], \tag{3}$$

where $G(z) = \exp[\lambda(z-1)]$, which is the Poisson pgf for the number of clumps per sample, and $g(z) = \exp[\phi(z-1)]$, the Poisson pgf for the number of larvae per clump.

Many other contagious distributions have been constructed in a similar manner. For example, the Lagrangian Poisson distribution [1] has the pgf

$$G_{\mathrm{LP}}(z) = \exp\{\lambda[t(z)-1]\}, \tag{4}$$

where $t(z)$ is the pgf that is the solution of the equation $t(z) = z\exp\{\psi[t(z)-1]\}$; Consul and his coworkers have fitted this successfully to many types of data including lesions in rabbit lymphoblasts and chromosome aberrations in cultures of human leucocytes. For further examples of such distributions, see Douglas [2] and Johnson et al. [7].

The heterogeneity model considered by Greenwood & Yule [6] in the **accident proneness** context has also been called "contagious". Instead of all individuals in a population having identical Poisson distributions of accidents, the Poisson parameter θ is assumed to vary among individuals. This is a mixture model and θ is the mixing variable. In terms of pgfs we have

$$G_{\mathrm{mixed}}(z) = \int g(z|\theta) f(\theta)\,\mathrm{d}\theta, \tag{5}$$

where $g(z|\theta)$ is a Poisson distribution with parameter θ, $f(\theta)$ is the pdf of the distribution of θ, and integration is over all values of θ. Greenwood & Yule showed that if θ has a **gamma distribution**, then the resultant mixed Poisson distribution is a negative binomial distribution.

The discrete analog of (5) is

$$G_{\mathrm{dmixed}}(z) = \sum_{x=0}^{\infty} g_x(z)\omega_x, \tag{6}$$

were x takes integer values, $g_x(z)$ is a pgf, $\omega_x \geq 0$, and $\sum_{x=0}^{\infty}\omega_x = 1$.

The pgf (3) has the form

$$\begin{aligned} G_{\mathrm{dmixed}}(z) &= \omega_0 + \omega_1 g(z) + \omega_2[g(z)]^2 + \cdots \\ &= G[g(z)], \end{aligned} \tag{7}$$

where $G(z) = \omega_0 + \omega_1 z + \omega_2 z^2 + \cdots$ and $g_x(z) = [g(z)]^x$. It can therefore be regarded as arising from a special kind of mixture of distributions, since $[g(z)]^x$ is itself a pgf when x is an integer (Neyman used this method of expansion when obtaining the NTA probabilities).

Feller [4] referred to the Pólya [14] model as "true contagion" and to the mixture models as "apparent contagion" (in his book, [5, pp. 121–123], he also used the term "spurious contagion"). The "true" and "apparent" terminology is still used. His opinion was that statisticians "speak of contagion (or contagious probability distributions) in a vague and misleading manner".

A major reason for this vagueness is the variety of models that may give rise to a single distribution. Lüders [10] showed that a negative binomial distribution results if $G(z)$ is the pgf of a Poisson distribution and $g(z)$ is the pgf of a logarithmic distribution in (7). The negative binomial distribution therefore arises from all three models discussed above (it is also the outcome of several models unrelated to contagion).

A second instance of a distribution arising from several models is the Hermite distribution. This was first derived by McKendrick [11] via the sum of two correlated Poisson random variables. He fitted it to data on the number of bacteria ingested by phagocytes. Table 3 shows the fit. Kemp & Kemp [9] stated the pgf in the form

$$G_{\mathrm{H}}(z) = \exp\{\lambda[2pq(z-1) + p^2(z^2-1)]\}, \tag{8}$$

and hence showed that the data could also have arisen from a Poisson distribution of phagocytes with each phagocyte containing 0, 1, or 2 bacteria according to a binomial distribution with $n = 2$ (a clustering

Table 3

Number of bacteria/phagocyte	0	1	2	3	≥4	Total
Observed number of phagocytes	269	4	26	0	1	300
Hermite fit (by mle)	269.6	3.7	25.2	0.3	1.2	300.0

model). Alternatively, (8) can be restated as

$$G_{\mathrm{H}}(z) = \mathrm{e}^{-\lambda} + \mathrm{e}^{-\lambda}\lambda(q + pz)^2 + \mathrm{e}^{-\lambda}\lambda^2(q + pz)^4/2! + \mathrm{e}^{-\lambda}\lambda^3(q + pz)^6/3! + \cdots, \quad (9)$$

i.e. as a *mixture* of binomial distributions with exponent parameters taking the values $0, 2, 4, 6, \ldots$.

Another example is the Gegenbauer distribution. Plunkett & Jain [13] obtained this as a gamma mixture of Hermite distributions, giving an "apparent contagion" model. They fitted it to the haemocytometer data quoted above (Table 2) and obtained expected frequencies very similar to those obtained using the NTA distribution. Johnson et al. [7] give a number of other models for the Gegenbauer distribution, including McKendrick's [11] nonhomogeneous birth and death process (*see* **Stochastic Processes**) and Kemp's [8] field observation model involving a Rao damage process.

The multitude of models that may exist for a particular distribution means that it is very much more informative to use the term "contagion model", specifying the model and its form of contagion precisely, than it is to call a particular distribution a "contagious distribution".

Contingency Table

We start by defining a two-way contingency table. Suppose that each of a sample of n individuals is classified according to each of two separate criteria, and each of these criteria can take only a finite number of distinct values. Let us take as an example a study to assess factors associated with women's attitudes toward mammography [6, p. 220]. Each of 309 women has been classified according to:

1. Her "Mammography Experience", which has as its possible values "Never", "Over one year ago", and "Within the past year".
2. Her response to the question "How likely is it that a mammogram could find a new case of breast cancer?", which has as its possible values "Not likely", "Somewhat likely", and "Very likely".

Let the Mammography Experience correspond to the *Rows* of the table and the response to the question about the detection of breast cancer to the *Columns*. Although it happens in this particular example that each of the Rows and Columns has a natural ordering, this is not necessary to the definition of a contingency table. Then the resulting 3×3 *table* of frequencies or counts is, say, (n_{ij}), where:

1. n_{ij} is the number of individuals in Row i and Column j for $i = 1, \ldots, I$ and $j = 1, \ldots, J$.
2. I and J are, respectively, the total numbers of Rows and Columns of the table, here 3, 3. Let n be the total sample size, so that n is the sum of entries of the table; we can then write $n = \sum\sum n_{ij}$.

Note that in our construction of this *cross tabulation* or contingency table, we assume that each individual of the sample of size n is classified into exactly one of the IJ categories of the table, these categories being mutually exclusive and exhaustive. Written less formally, this means that the IJ categories do not overlap in any way, and together they cover all possibilities.

Of course, exactly how the sample is collected for a particular study is of great importance in the subsequent statistical analysis. In classical contingency table analysis, it is assumed that the n individuals form a *random sample* from a population: this means that we assume that each individual is classified independently of the others, and each has the same probability, say p_{ij}, of being classified into row i and column j. Thus $\sum\sum p_{ij} = 1$. Our assumption that we have a random sample has the consequence that the probability distribution of the variable (n_{ij}) is **multinomial**; that is, the frequency function $p[(n_{ij})|p]$ is

$$n! \prod_i \prod_j \left(\frac{p_{ij}^{n_{ij}}}{n_{ij}!} \right),$$

provided that $n_{ij} \geq 0$ and $\sum\sum n_{ij} = n$.

In this case we say that (n_{ij}) is multinomial, with parameters n and (p_{ij}).

To continue with the above example of the attitudes toward mammography data, the results of our survey are shown in Table 1.

These data show a dramatic and self-evident association between rows and columns: in other words, the women's responses to the question about the detection of breast cancer depend strongly on their mammography experience. This can be seen even more clearly by presenting the data from this sample in terms of the *row percentages*. Rounded to the nearest whole number for clarity, these are shown in Table 2.

Presenting the data in this way shows more clearly how the response to the question depends on the mammography experience. Another illuminating way to show this effect would be by using three *bar charts*,

Table 1 Mammography: the counts

	Detection of breast cancer		
Mammography experience	Not likely	Somewhat likely	Very likely
Never	13	77	144
Over one year ago	4	16	54
Within the past year	1	12	91

Table 2 Mammography: the row percentages

	Detection of breast cancer			
Mammography experience	Not likely	Somewhat likely	Very likely	Total
Never	6	33	61	100
Over one year ago	5	22	73	100
Within the past year	1	11	87	100

overlaid on the same graph, with each corresponding to a different row of the table (*see* **Graphical Displays**).

There are several possible analyses we can carry out on this particular table, such as a simple summary in terms of percentages, a graphical summary, or a statistical test of independence which we describe below. None of these analyses can establish whether the association between rows and columns is a *causal* one. This is an inherent limitation of the purely statistical approach. In the current example, the Column variable might be thought of as a **response** to the Row variable, which is an **explanatory** variable or **covariate**. But the simple two-way contingency table cannot directly tell us the mechanism by which the explanatory variable affects the response variable. In any case, in the current example, there could be a mixture of several complex mechanisms which act simultaneously.

The Hypothesis of Independence, H_0, and the Chi-square Test

With the notation introduced above, that

$$p_{ij} = \Pr(\text{Row} = i, \text{Column} = j) \tag{1}$$

for $i = 1, \ldots, I$, $j = 1, \ldots, J$, we see that the hypothesis of independence of rows and columns may be written as

$$H_0 : p_{ij} = p_{i+}p_{+j} \tag{2}$$

for all i, j, where $p_{i+} = \Sigma_j p_{ij}$ is the probability that Row $= i$, and $p_{+j} = \Sigma_i p_{ij}$ is the probability that Column $= j$.

Observe that an equivalent way of writing H_0 is

$$H_0 : \frac{p_{ij}}{p_{i+}} = p_{+j} \tag{3}$$

for all i, j. Now p_{ij}/p_{i+} is the probability that the Column is j, conditional on the Row being i: we write this as $P(\text{Column} = j|\text{Row} = i)$. Thus the hypothesis of independence of rows and columns is equivalent to the statement that the distribution of the variable Column, conditional on the value of the variable Row being i, is the same for all values of i: in this case we say that these conditional distributions are *homogeneous*.

To test the **null hypothesis** of independence H_0, we compute Pearson's chi-square statistic X^2, which is defined as

$$X^2 = \sum\sum \frac{(n_{ij} - e_{ij})^2}{e_{ij}} \tag{4}$$

where e_{ij} are conventionally called the "expected values", and are defined by

$$e_{ij} = \frac{(n_{i+}n_{+j})}{n} \quad \text{for all } i, j, \tag{5}$$

and n_{i+} and n_{+j} are the row and column totals, respectively, defined by $n_{i+} = \Sigma_j n_{ij}$ for all i and $n_{+j} = \Sigma_i n_{ij}$ for all j. (A pedantic but more accurate description of (e_{ij}) is "the **maximum likelihood** estimates of the expected values of (n_{ij}) under H_0".) We know that, under the null hypothesis H_0, the distribution of X^2 is, for large n, approximately χ^2_f, where f, the *degrees of freedom*, are $(I - 1)(J - 1)$. Hence for a significance test of H_0 with approximate significance level α, we reject H_0 if

$$X^2 \geq \chi^2_f(\alpha), \tag{6}$$

the right-hand side being the upper α point of the χ^2_f distribution, which we can find from statistical tables: typically we would take α as 0.01 or 0.05. Thus we have approximately arranged that, for large n, our test gives

$$\Pr(\text{reject } H_0|H_0 \text{ true}) \leq \alpha. \tag{7}$$

This is what we mean by saying that the test is of approximate *size* α.

Chi-square tests are described in depth in another article. The value of the X^2 statistic for the numerical example given above is 24.15, which lies well above 18.47, the 0.001 point of the χ^2_4 distribution. Thus for these data, the null hypothesis of independence of the women's response to the question about the detection of breast cancer and their "Mammography Experiences" is rejected, as our preliminary look at the table suggested would be the case.

From the point of view of scientific enquiry, a statistical significance test is a crude and blunt instrument. If we found that the value of X^2 was significant, we would usually want to investigate in some detail *why* the null hypothesis of independence fails to fit. It is good statistical practice to compare the *adjusted* **residuals**

$$\frac{(n_{ij} - e_{ij})}{[e_{ij}(1 - \hat{p}_{i+})(1 - \hat{p}_{+j})]^{1/2}}, \tag{8}$$

where $\hat{p}_{i+} = (n_{i+}/n)$, $\hat{p}_{+j} = (n_{+j}/n)$, with the standard normal distribution. Thus any residual greater than about 1.5 in absolute value is "interesting", and the corresponding cell (i, j) of the table is special in some way and deserves investigation.

Under the null hypothesis H_0, the **sufficient statistics** for the unknown parameters $((p_{i+}), (p_{+j}))$ are $((n_{i+}), (n_{+j}))$. One consequence of this is that the observed values of these statistics must agree exactly with the corresponding expected values: thus

$$n_{i+} = e_{i+} \text{ for each } i, \text{ and } n_{+j} = e_{+j} \text{ for each } j. \tag{9}$$

This is a special case of a general result for **exponential families**, and we shall see examples of the same result when we consider multiway tables in the final section.

A test statistic which is equivalent to X^2 for large sample size is the *deviance*, conventionally denoted by G^2. It is derived from the ratio of maximized likelihoods (*see* **Likelihood Ratio Tests**). For the example of testing H_0, G^2 is defined by

$$G^2 = 2 \sum \sum n_{ij} \log \left(\frac{n_{ij}}{e_{ij}} \right) \tag{10}$$

and for the numerical example given above G^2 has the value 26.80; recall that the value of X^2 was 24.15.

Both X^2 and G^2 are appropriate test statistics for sampling setups other than the straightforward single multinomial one introduced above. For example, suppose the contingency table (n_{ij}) were collected with the row totals

(n_{i+}) fixed, and

$(n_{ij}|n_{i+})$ independently and multinomially distributed, with

(n_{ij}) multinomial parameters n_{i+}, (θ_{ij}),

where $\sum_j \theta_{ij} = 1$ for each i.

Then the statistics X^2 and G^2 are the appropriate test statistics for testing H: $\theta_{ij} = \phi_j$ for all i, j, for some (unknown) ϕ_j such that $\sum \phi_j = 1$; in other words, the null hypothesis of homogeneity of row distributions.

Yet another way of writing H_0 is

$$H_0 : \log(p_{ij}) = \alpha_i + \beta_j \quad \text{for all } i, j. \tag{11}$$

for some α, β such that $\Sigma p_{ij} = 1$. One reason for writing H_0 in this form is that it enables us to see that it is a *loglinear* hypothesis; that is, the log of the probabilities can be written as a function which is linear in the unknown parameters, which in this case are (α_i), (β_j) (*see* **Loglinear Model**).

Computational Aspects

Contingency table analysis, both by chi-square tests and by small-sample "exact" methods, is easily achieved in many statistical software packages. Usually we can ask for direct computation of the appropriate chi-square statistic, with associated residuals and significance tests. More sophisticated software will allow us to test complex hypotheses of independence by fitting models using one or both of **iterative proportional fitting** (IPF) or **generalized linear modeling** (GLM). IPF may be computationally more efficient than the GLM approach, since in using GLM for contingency table analysis we are ignoring the particular structure of the parameters. For example, in using GLM to test for independence in a two-way contingency table, we use an iterative technique (effectively the *Newton–Raphson*) to solve the maximum likelihood equations when in fact five minutes with a pencil and paper would show us that iteration is unnecessary: there is a closed form solution. But an advantage of the GLM approach is that it is more suited to the problem of choosing the simplest possible model consistent with a given data set. Most statisticians are familiar with the use of GLM in any case, and so this advantage outweighs the possible gain in computational efficiency of IPF. The GLM approach may be rather more forbidding for the less mathematical user, but has definite advantages when we come to consider cross tabulations which are more complex than just the two-way ones. We discuss *multi-way* contingency tables in the last section of this article. Although there are several possible probability distributions available for GLMs, there is no multinomial distribution. This is not a problem, provided that we are fitting a *loglinear* model, such as H_0 as written in its final form above. Thus for testing independence in a two-way contingency table we can use the **Poisson distribution** as a "surrogate" for the multinomial, so that we can compute the appropriate deviance for testing independence for the multinomial model by pretending that (n_{ij}) are

observations on independent Poisson variables. This is a special case of a general result, relating Poisson and multinomial loglinear models.

Quasi-Independence

For some two-way contingency tables with a special structure, it may be obvious that the null hypothesis of independence H_0 cannot possibly be expected to fit, because it is far too "severe". However, a weaker hypothesis which is chosen to represent a version of independence, or **quasi-independence**, may be helpful in the interpretation of the data. For example, Altham [3] discusses the data on initial and final ratings of 121 stroke patients in Table 3, taken from [5].

The rows of the 5×5 table correspond to the patient's state on admission to hospital, and the columns to his state when discharged. These states have possible values A, B, C, D, and E, ranging from A as the least severe to E as the most severe. The resulting contingency table is *triangular*, because the patient's state on being discharged is never worse than his initial state. Because of this constraint, the hypothesis of independence of rows and columns cannot possibly hold. But if we assume that the frequencies (n_{ij}) for $1 \leq j \leq i \leq 5$ come from a multinomial distribution with corresponding parameters (p_{ij}), then it may still be helpful to fit a hypothesis of *quasi-independence* H_{qi}, say:

$$H_{qi} : p_{ij} = \alpha_i \beta_j, \quad \text{for all } j \leq i, \tag{12}$$

for some (α_i), (β_j). This is another loglinear hypothesis, and so may be tested by treating the (n_{ij}) as independent Poisson variables. For the data given here, the deviance for testing H_{qi} has value 9.60, $df = 6$, indicating a reasonable fit. Similar models may be appropriate for the type of "triangular" data arising from **capture–recapture** studies in ecology, where, for example, a bird first ringed in 1975 may be observed in any one of the 10 successive years, but of course a bird first ringed in 1977 could not have appeared in the 1975 count.

Quasi-independence models for square contingency tables (omitting the diagonal entries) are known as "mover–stayer" models in the sociological context. This hypothesis of quasi-independence is one of several models especially suitable for a **square contingency table**; others in this class are models of symmetry, marginal homogeneity, and **quasi-symmetry**.

	35	42	20	16	8	121

Exact Tests of Independence

For tables with small frequencies, the large-sample approximation of the distribution of X^2, or equivalently of the distribution of G^2, to the χ^2 distribution may be doubtful. Most software will give appropriate "warning messages" if the "expected counts" e_{ij} are too small, less than five being a conservative interpretation of "too small" here. In this case the statistician will need to use an exact method (*see* **Exact Inference for Categorical Data**). For a **2 × 2 table**, **Fisher's exact test**, which is based on the **hypergeometric distribution**, is appropriate, and it has been generalized, say, to $I \times J$ tables by using the multivariate hypergeometric distribution: this is the result of conditioning the multinomial distribution on both the row and column frequency totals, under the null hypothesis of independence of rows and columns.

For example, consider the 2×2 contingency table in Table 4.

In carrying out a χ^2 test on this table, we are essentially asking whether the proportion 8/16 is different from the proportion 20/23. The X^2 statistic is 4.67, with corresponding P value $= 0.0307$. But the software warns that the expected counts may be too low for the large-sample approximation to be valid, and it is easy to see that e_{11}, which is $16 \times 11/39$, is 4.5. For the sake of comparison, we do a two-sided Fisher exact test, and find that the corresponding P value is 0.0272. So either

Table 4 Example for Fisher's exact test

8	8
3	20

method would lead us to reject the null hypothesis of independence of rows and columns.

Multiway Contingency Tables

An example of a four-way contingency table is given in Table 5. These data have been slightly adapted for pedagogic purposes from a data set on adolescents supplied by Professor I.J. Goodyer of Cambridge University Developmental Psychiatry. For further discussion of the original data, see [4].

One purpose in collecting such a data set is to find a model which explains how the four variables "Gender", "Depression status", "Behavior", and "Anxiety" are interrelated.

For example, we can see from the two-way marginal Table 6 that the prevalence of depression among girls is 17%, compared with only 8% as the corresponding figure for boys. (The X^2 statistic for this 2×2 table is 4.82, which is significant when referred to χ^2_1.) Similarly, the two-way marginal Table 7, for which the corresponding X^2 statistic is 7.42, suggests that there is a strong positive association between anxiety and behavioral symptoms.

Table 5 2^4 table from psychiatry

	Behavioral symptoms:	No		Yes	
	Anxiety symptoms:	No	Yes	No	Yes
Girls	Depression = no	85	14	10	2
Girls	Depression = yes	8	4	7	4
Boys	Depression = no	107	13	8	3
Boys	Depression = yes	2	3	3	4

Table 6 A pairwise summary from Table 5

	Depression	
	No	Yes
Girls	111	23
Boys	131	12

Table 7 Another pairwise summary from Table 5

		Anxiety symptoms	
		No	Yes
Behavioral symptoms	No	202	34
Behavioral symptoms	Yes	28	13

However, we can see that this piecemeal and *ad hoc* approach to the data analysis is rather unsatisfactory. Looking at the pairwise marginal tables can raise some interesting suggestions, but it may also be misleading because it possibly conceals important features of the data, as we shall see later. Furthermore, even for a four-way contingency table there are six possible pairwise marginal tables to be examined, so that it is clear that for large tables, for example seven-dimensional, we need a more focused modeling strategy.

We return to the above practical example when we have discussed types of independence for multiway contingency in a formal way.

Suppose that the rows, columns, layers, etc. of the multiway table are labeled A, B, C, etc. There are many different sorts of independence between these variables that are possible. This makes analysis of multiway contingency tables interesting and complex. Fortunately, the relationship between the variety of types of independence and loglinear models fits naturally within the GLM framework. We will once again make use of the relationship between the Poisson and the multinomial in the context of loglinear models.

An example with only three variables, say A, B, and C, serves to illustrate the methods used in tables of dimension higher than two. Suppose that A, B, and C correspond, respectively, to the rows, columns, and layers of the three-way table. Let

$$p_{ijk} = \Pr(A = i, B = j, C = k) \quad \text{for } i = 1, \ldots, I, \; j = 1, \ldots, J, k = 1, \ldots, K, \tag{13}$$

so that $\sum p_{ijk} = 1$, and let (n_{ijk}) be the corresponding observed frequencies, assumed to be observations from a multinomial distribution, parameters n, (p_{ijk}).

There are eight different hypotheses corresponding to types of independence between A, B, and C that we now consider. Assume in all of these that the parameters given are such that $\sum p_{ijk} = 1$.

$$\mathrm{H}_0 : p_{ijk} = p_{i++}p_{+j+}p_{++k} \quad \text{for all } i, j, k, \tag{14}$$

thus H_0 corresponds to A, B, and C independent.

$$\mathrm{H}_1 : p_{ijk} = p_{i++}p_{+jk} \quad \text{for all } i, j, k, \tag{15}$$

thus H_1 corresponds to A independent of (B, C).

(Likewise, we could consider the hypothesis B independent of (A, C), and the hypothesis C independent of (A, B).)

$$\mathrm{H}_2 : \frac{p_{ijk}}{p_{i++}} = \left(\frac{p_{ij+}}{p_{i++}}\right)\left(\frac{p_{i+k}}{p_{i++}}\right) \quad \text{for all } i, j, k. \tag{16}$$

Thus H_2 is equivalent to

$$\Pr(B = j, C = k|A = i) = \Pr(B = j|A = i) \times \Pr(C = k|A = i) \quad \text{for all } i, j, k, \tag{17}$$

and so H_2 corresponds to the hypothesis that, for each i, conditional on $A = i$, the variables B and C are independent. In this case we say that B and C are independent, conditional on A. (Likewise, we can define two similar hypotheses by interchanging A, B, and C.)

Independence and conditional independence between variables can be more clearly understood by showing suitable *association graphs* (*see* **Interaction Model**). In this graphical representation of the hypotheses, we represent the variables A, B, and C by the *vertices* of the graph, with links between these vertices representing dependence, and absence of links representing independence. Thus

H_0 corresponds to no links between any of A, B, and C.

H_1 corresponds to a link between B and C only, and A as an isolated point.

H_2 corresponds to a link between A and B, and a link between A and C: thus B and C are linked only through A; see the diagram below.

The theory of association graphs is a useful and elegant one, particularly suitable for displaying and understanding the structure of high-dimensional tables.

Finally, we consider

$$\mathrm{H}_3 : p_{ijk} = \alpha_{jk}\beta_{ik}\gamma_{jk} \quad \text{for all } i, j, k, \text{ for some } \alpha, \beta, \gamma. \tag{18}$$

This hypothesis, which is symmetric in A, B, and C, cannot be given an interpretation in terms of conditional probability (see Figure 1). It corresponds to saying that the *interaction* between any two of the three factors, say A and B, given the level of the third factor, say C, is independent of the level of C. We say that H_3 corresponds to "no three-way interaction" between A, B, and C.

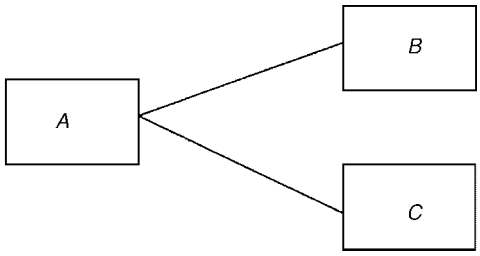

Figure 1 B and C conditionally independent, given A

One way of writing this formally is to say that for each i, j the **odds ratio** describing the dependence between A and B

$$\frac{(p_{ijk}p_{IJk})}{(p_{iJk}p_{Ijk})} \tag{19}$$

is the same for all k.

The eight hypotheses are related to one another as follows: for any given probabilities (p_{ijk}),

H_0 implies H_1, which in turn implies H_3, and

H_0 implies H_2, which in turn implies H_3, and

$\mathrm{H}_1$and H_2 are together equivalent to H_0.

Thus H_0 is the strongest hypothesis and H_3 is the weakest.

All of the eight hypotheses above may be written as loglinear hypotheses and hence tested within the GLM framework with the Poisson distribution and log link function. Since the log is the *canonical link function* for the Poisson distribution, it is the *default* link function for the Poisson in GLM terms.

For example, we may rewrite H_2 as

$$\mathrm{H}_2 : \log(p_{ijk}) = \phi_{ij} + \psi_{ik} \quad \text{for all } i, j, k, \tag{20}$$

for some ϕ, ψ. In the GLM notation for interactions between factors, this corresponds to the model

$$A * B + A * C \text{ or, equivalently, } A * (B + C).$$

We pause to explain briefly the GLM notation for interactions between factors. For example, consider the model

$$A * B + A * C.$$

In the context of loglinear models, this means that we can write $\log(p_{ijk})$ as

$$\log(p_{ijk}) = \mu + \alpha_i + \beta_j + \gamma_k + (\alpha\beta)_{ij} + (\alpha\gamma)_{ik} \tag{21}$$

for all i, j, k. Here the set of parameters $[(\alpha\beta)_{ij}]$ is termed $A.B$, the AB interaction, the set $[(\alpha\gamma)_{ik}]$ the AC interaction, and the sets (α_i), (β_j), (γ_k) are, respectively, the main effects of A, B, and C denoted by A, B, C.

For parameter identifiability in our computations we will need to impose constraints on (α_i), etc. We assume in the numerical examples that follow that the *corner-point* constraints are imposed; thus

$$\alpha_1 = 0, \quad \beta_1 = 0, \quad \gamma_1 = 0, \quad (\alpha\beta)_{1j} = 0, \tag{22}$$

and so on, so that any parameter with a subscript 1 anywhere is set to zero. Different software may impose a different set of constraints: this is always a confusing point for a beginner.

In the same GLM notation, H_0, H_1, and H_3 correspond, respectively, to $A + B + C$, $A + B * C$, and $(B * C + A * B + A * C)$.

For completeness, we will also define the *saturated* model H_s say, which makes no independence statement about A, B, and C:

$$H_s: \log(p_{ijk}) = \rho_{ijk} \text{ for all } i, j, k, \tag{23}$$

for some ρ: in GLM notation this is simply

$$A * B * C.$$

In terms of our association graph, this corresponds to all three links being present between the vertices A, B, and C.

Example

Consider the $2 \times 2 \times 2$ table shown in Table 8.

For example, A might correspond to "agree with a controversial statement" (such as "Women are not inherently better than men at looking after children", B might be the educational level (below or above average), and C might be the gender (men/women).

Table 8 A 2^3 table

	$C = 1$		$C = 2$	
	$A = 1$	$A = 2$	$A = 1$	$A = 2$
$B = 1$	17	23	36	50
$B = 2$	29	14	59	24

As our baseline model, we first fit the saturated model

$$A * B * C.$$

This is bound to give a perfect fit, with deviance and df both zero. So this first step in the model fitting might not appear to be a useful exercise. However, inspection of the resulting *parameter estimates* together with their *standard errors* suggests that the three-factor interaction term, $A.B.C$ can be dropped from the model, since the estimate of $A.B.C$ is -0.197 with se $= 0.561$. So our next step is to fit $(A + B + C) * (A + B + C)$ which gives a deviance of 0.12, with 1 df. Comparison with χ^2_1 shows that this model, which is H_3, is a good fit. Thus there is no three-way interaction between A, B, and C, and so, for example, we can say that the way in which the response to the question A depends on educational level is the same for both men and women.

Again, we compare the parameter estimates with their standard errors, and find that the pairwise interaction $A.C$ is -0.068, with se $= 0.28$. This suggests that $A.C$ should now be dropped from the model, and indeed the resulting model $(A + C) * B$ has deviance 0.18 (2 df). So this model is a good fit. It states that conditional on the educational level, the response to A is independent of the gender.

This model can be rewritten as $A * B + B * C$, and this has the consequence that the *observed and fitted frequencies* for the two-way marginal table $A * B$ must agree exactly, and similarly for the $B * C$ marginal table.

Inspection of the parameter estimates and their standard errors for this model shows that $B.C$ can also be dropped from the model, leading to the model $A * B + C$, which has deviance 0.34 (3 df). But this final step would not make sense if the data were collected with *fixed* totals in the $B.C$ marginal table, since under the model $A * B + C$ we would not necessarily have exact agreement between the observed and fitted frequencies of the $B.C$ table.

The Relationship between Binomial Logistic Regression and Loglinear Models in a Multiway Contingency Table

In a multiway contingency table, it may not be appropriate to treat the variables, say A, B, C, etc. symmetrically. For example, it may be more natural to treat A as a *response* variable, and B, C, etc. as *explanatory* variables.

In particular, if the number of levels of A is two, for example, corresponding to "yes, no", then it may make the analysis easier to interpret if we carry out a binomial logistic regression of A on the factors B, C, etc.

Such an analysis is not essentially different from a loglinear analysis. We can see from the following considerations that there must be certain exact correspondences between the two approaches. To be specific, take the case in which (Y_{ijk}) is multinomial, parameters n, (p_{ijk}) and suppose $i = 1, 2$. Write y_{+jk} as $y_{1jk} + y_{2jk}$. Then $Y_{1jk}|y_{+jk}$ are independent binomial variables, parameters y_{+jk}, θ_{jk}, where

$$\theta_{jk} = \frac{p_{1jk}}{p_{+jk}}. \tag{24}$$

So, for example, the model $A * B + B * C + C * A$ for (p_{ijk}) can be shown to be equivalent to the model for $\text{logit}\,\theta_{jk} = \log[\theta_{jk}/(1 - \theta_{jk})]$,

$$\text{logit}\,\theta_{jk} = \beta_j + \gamma_k. \tag{25}$$

For example, we could use the data from Table 8 above, with A as the response variable, so that we use the binomial proportions 17/40, 29/43, 36/86, and 59/83 as the responses corresponding to the factors (B,C) as (1,1), (2,1), (1,2), and (2,2). In this case it may be seen that the deviance and the fitted frequencies for the logit model $B + C$ are *exactly* the same as those for loglinear model $A * B + B * C + C * A$ with data for the $2 \times 2 \times 2$ and the multinomial model, as above.

We now return to the 2^4 contingency table, Table 5. The simplest model consistent with these data is (gender + anxiety symptoms + behavioral symptoms) * depression. This model has deviance 4.91, with 8 df. For a relatively complex table, a good way to find the simplest reasonable model is to start by fitting the saturated model, and then "step down", discarding the unnecessary parameters, using the **Akaike information criterion** (AIC) as the guide to when to stop the stepping down process.

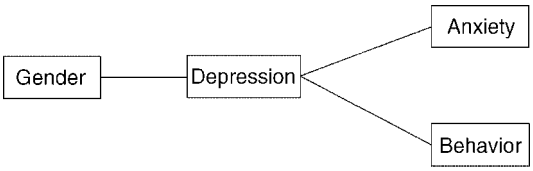

Figure 2 A graphic model for psychiatry data

The final model here shows the key role of depression in explaining the dependence in the four-way table: conditional on the depression status, the two variables anxiety and behavior are independent of each other and are also independent of gender. Its graphical representation is a graph in which the three vertices "gender", "anxiety symptoms", and "behavioral symptoms" are linked to depression, and no other links are present (see Figure 2).

This final model also shows that summarizing the data by certain 2×2 tables, for example by *collapsing* over the variable gender and depression, may be a misleading way to investigate the association between variables. To put this more technically, for the current example with the final model, the two-way marginal table anxiety symptoms × behavioral symptoms is not among the sufficient statistics for the unknown parameters.

The danger in obtaining misleading results by collapsing a contingency table is known as **Simpson's paradox** (also known as *Yule's paradox*).

This brief article has introduced the topic of contingency tables, with particular discussion of types of independence for multiway tables. The reader will have realized that in none of the methods described above is any attention paid to the *order* of the categories of a variable: for example, if A takes as possible values 1, 2, 3, and 4, the above analyses would all remain the same if these levels were renamed as *apples*, *pears*, *oranges*, *bananas*. In this sense our treatment of the variables so far has been entirely *nominal* (*see* **Nominal Data**). This approach may not always be the most sensible one to follow. For example, both of the rows and columns of Table 1 are ordered. We might prefer our analysis to recognize this fact (*see* **Ordered Categorical Data**).

This article represents a brief introduction to the topic of contingency tables, and is not an exhaustive

coverage of the available methods. For more comprehensive coverage, the reader is referred to the two textbooks by Agresti [1, 2].

Continuity Correction

The term "continuity correction" has traditionally referred to an adjustment made when using a continuous probability distribution to approximate a discrete distribution [34]. Statisticians realized early that large-sample approximations to the exact distributions often arising in discrete data settings are poor in small samples and proposed simple adjustments to existing summary statistics in order to provide more reliable inferences. Although the earliest proposals involved corrections of **normal** approximations for making probability statements about **binomial**, **Poisson**, or **negative binomial** random variables [36], continuity corrections have been most prominent in the analysis of **contingency tables**. Recently, modern computing and the availability of exact methods in several software packages [42] have lessened the need for these specific procedures [3] (*see* **Exact Inference for Categorical Data**). However, the term "continuity correction" is also used more generally to refer to any method designed to address the effects on inferential procedures of the discreteness of a small-sample exact distribution (e.g. [21], with reference to the mid-***P* value**). Development of continuity corrections in this broader sense is an active area of statistical research. In this entry, we briefly outline the historical development of the traditional continuity correction in contingency tables and review the performance of continuity corrections in the broader context of small-sample strategies for categorical data.

Hypothesis Testing

The simplest continuity correction involves the normal approximation to a discrete distribution, such as the binomial probability mass function. Consider a binomial random variate X for sample size n and success probability π. The normal approximation to $P(X = x)$ is $P(x - 0.5 \le Z \le x + 0.5)$, where Z is normally distributed with mean and variance matching those from the true $\text{Bin}(n, \pi)$ distribution. The presence of 0.5 in the probability statement constitutes a *continuity correction* in that it accounts for the fact that we use the continuous normal approximation, and not the discrete binomial distribution, to make probability statements about X.

Now consider a **2 × 2 table** with cell frequencies $\{n_{ij}\}$ formed by cross-classifying binary variables X and Y. Denote the marginal row and column totals as $\{n_{i+}\}$ and $\{n_{j+}\}$, respectively, and let n be the total sample size. The well-known chi-squared test of independence uses the Pearson statistic

$$X^2 = \sum_i \sum_j \frac{\left(n_{ij} - m_{ij}\right)^2}{m_{ij}}, \tag{1}$$

where $m_{ij} = n_{i+}n_{+j}/n$ are the fitted values under independence (*see* **Chi-square Tests**). Under the **null hypothesis**, X^2 has a large-sample chi-squared distribution with 1 df. For small samples, Yates [48] proposed the correction

$$X_c^2 = \sum_i \sum_j \frac{\left(|n_{ij} - m_{ij}| - 0.5\right)^2}{m_{ij}} \tag{2}$$

and used the statistic X_c^2 to test the independence of X and Y by comparing it to the same reference chi-squared distribution (*see* **Yates's Continuity Correction**). The continuity correction 0.5 adjusts for using the continuous χ^2 distribution to approximate the exact discrete distribution of X^2 and produces P values that approximate those obtained from **Fisher's exact test**.

Mantel and Haenszel [35] proposed the same correction for testing conditional independence in stratified 2×2 tables (*see* **Stratification**). Let n_{ijk} be the cell counts in stratum k, $k = 1, \ldots, K$, formed by stratifying the relationship of X and Y by a control variable Z, and as above, let subscripted "+" denote marginal summation. These authors considered the exact null product **hypergeometric distribution** of $\{n_{11k}\}$ obtained by treating the observations in different strata as independent and the row and column totals in each stratum as fixed. Specifically, the Mantel–Haenszel statistic is

$$\begin{aligned} M^2 &= \frac{\left(\left|\sum_{k=1}^K n_{11k} - \sum_{k=1}^K m_{11k}\right| - 0.5\right)^2}{\sum_{k=1}^K V(n_{11k})} \\ &= \frac{(|n_{11+} - m_{11+}| - 0.5)^2}{\sum_{k=1}^K V(n_{11k})}, \end{aligned} \tag{3}$$

where

$$m_{11k} = \mathrm{E}(n_{11k}) = \frac{n_{1+k}n_{+1k}}{n_{++k}}$$

and $$V(n_{11k}) = \frac{n_{1+k}n_{2+k}n_{+1k}n_{+2k}}{n_{++k}^2(n_{++k}-1)}$$

are the mean and variance of $\{n_{11k}\}$ based on this exact product hypergeometric distribution under the null hypothesis of conditional independence of X and Y given Z (*see* **Mantel–Haenszel Methods**). Under this null hypothesis, M^2 has approximately a chi-squared distribution with 1 df. Cochran [15] had earlier proposed a closely related statistic but conditioning only on the row totals and without continuity correction. As a result, others (e.g. Landis et al. [32] and Agresti [3]) have labeled (3) the Cochran–Mantel–Haenszel (C-M-H) statistic.

Like the Yates continuity-corrected statistic (2), the C-M-H statistic yields inferences that closely approximate those obtained from the corresponding exact conditional test, which also bases inference on the statistic n_{11+}. As above, assume fixed n_{i+k}. Let π_{ik}, $i = 1, 2$, $k = 1, \ldots, K$, be the probability of a success at level i of X and stratum k of Z. A **logistic regression** model for π_{ik} that specifies a homogeneous log **odds ratio** β across strata is

$$\mathrm{logit}(\pi_{ik}) = \alpha_k + \beta(\mathrm{I}[i = 2]), \tag{4}$$

where $I[\ ]$ is the indicator function. Under this model, the null hypothesis of conditional independence corresponds to $H_0: \beta = 0$, and the **sufficient statistic** for β is n_{11+}. The exact approach bases inference on the distribution of this statistic that is free from the **nuisance parameters** $\{\alpha_k\}$ by conditioning on their sufficient statistics $\{n_{+1k}\}$. The resulting exact joint distribution for the $\{n_{11k}\}$ is the product of the K hypergeometric distributions considered by Mantel and Haenszel, from which one can compute the exact distribution of n_{11+}.

One can now conduct both the C-M-H test and the exact test, as well as compute the corresponding **confidence intervals** for a common odds ratio, using the statistical package **StatXact** [21]. Because exact results are now routinely available in StatXact, there is less of a need for the approximation (3) to the exact result. As a result, StatXact does not report results based on this continuity-corrected version but instead makes a clear distinction between asymptotic and exact tests in this setting by reporting the uncorrected version of (3).

There has been a long running controversy [19, 25, 26] as to the appropriateness of the continuity corrections in (2) and (3). Much of the criticism of these corrections arises from the fact that they lead to tests that approximate exact results, which for small or highly unbalanced samples can yield conservative inferences due to the discreteness of the exact distribution [3, 4]. As a result, the continuity-corrected approximations of the exact tests are also typically conservative. For instance, D'Agostino [22] noted that it is not uncommon for the actual level of a **hypothesis test** with nominal 5% level based on the continuity-corrected Pearson statistic to actually be 1%. Thus, less conservative alternative strategies may be preferable when the exact distribution is highly discrete. For instance, rather than rejecting a null hypothesis based on a preset significance level, Yates [49] and the discussants of his article recommended either (a) simply reporting the P value associated with an exact test or (b) selecting as the type I error rate one of the values having positive probability mass in the discrete P value distribution. For a single 2×2 table, D'Agostino, Chase, and Belanger [23] recommended using either the two-sample t-test or the uncorrected X^2 (*see* **Student's *t* Statistics**). In principle, one can avoid this conservatism by using supplementary **randomization** on the boundary of the **critical region** to construct a uniformly most powerful unbiased (UMPU) α-level test [13, Chapter 8] (*see* **Power**). However, this strategy is unattractive in practice, as two investigators observing the same results can arrive at different conclusions.

Another approach uses the mid-P value [31] to adjust for discreteness. Consider a test statistic T with observed value t_o and an alternative hypothesis such that large values of T reject H_0. The mid-P value is

$$\begin{aligned}\text{mid-}P &= P_0(T > t_o) + \tfrac{1}{2}P_0(T = t_o) \\ &= \text{exact P} - \tfrac{1}{2}P_0(T = t_o),\end{aligned} \tag{5}$$

where P_0 denotes probabilities computed under the null hypothesis. Because this adjustment subtracts one-half of the null probability of an observed response from the ordinary exact P value, mid-P is always less than the ordinary exact P value, leading to a less conservative test. Agresti [3] noted that mid-P behaves more like the P value for a test statistic having a continuous distribution, with the null

distribution of mid-P being more like a **uniform distribution**. For instance, E(mid-P) = 0.5, which is not the case for the ordinary P value based on a discrete distribution. It is in this sense that some consider mid-P a type of continuity correction [21]. Although tests based on mid-P sacrifice precise error control in the sense that the type I error rate is not theoretically guaranteed to be below the nominal level, empirical investigations have shown that in some situations mid-P actually does preserve this nominal level. For instance, Mehta and Walsh [38] reported that mid-P often preserves nominal levels when testing a common odds ratio in stratified 2×2 tables. Overall, for small samples, tests based on mid-P result in actual levels that are on average closer to the nominal levels than those of the corresponding fully exact tests. In addition, this strategy may be applied to any discrete problem for which the exact distribution is obtainable – single binomial proportion, two-sample binomials, paired binomials [27], stratified tables, or more generally small-sample logistic regression [28, 37]. Hwang and Yang [29] have presented additional theoretical arguments for the use of mid-P, and Agresti [2, 3] has recommended the use of the mid-P value as a useful, general strategy for inference in discrete problems.

Several authors have proposed other modifications of the ordinary exact P value that result in less conservative inference. Cohen and Sackrowitz [18] proposed a P value that, like mid-P, adds only a portion of the probability mass $P_0(T = t_o)$ to $P_0(T > t_o)$. In particular, these authors proposed refining the sample space satisfying $T = t_0$ by calculating the null probability of each sample in this set and adding to $P_0(T > t_o)$ only those sample probabilities that are less than or equal to the probability of the observed sample. Similar to the mid-P approach, this alternative strategy results in a test with a smaller P value, and hence greater power, than its exact counterpart. This advantage increases when the distribution of T is highly discrete. Also like mid-P, in theory, this strategy can be applied in a large number of discrete settings. For example, Corcoran, Mehta, and Senchaudhuri [16] used this modified P to test for trend in a $2 \times c$ table with ordered columns (*see* **Trend Test for Counts and Proportions**). The actual level of the test based on this modified P cannot exceed the nominal level for any value of the unknown parameter, by the same reasoning that proves this property of the test based on the ordinary exact P value. Thus, unlike a test based on mid-P, the test based on this modified P retains the strong error control of the exact test.

Interval Estimation

Recently, a large research effort has focused on estimation strategies when the exact distribution of interest is highly discrete. Just as an exact test (without supplementary randomization on the boundary of the critical region) is conservative, confidence intervals based on exact probabilities are conservative in that, for any fixed parameter value, the actual coverage probability can be much larger than the nominal confidence level. This high coverage comes at the price of a loss of precision, in the form of wider than necessary confidence intervals. Several authors have shown that, if one is willing to relax the requirement that the actual confidence level of the interval always be no less than the nominal level, one may construct intervals that, when compared to the exact interval, have coverage probabilities much closer to the nominal confidence level for most parameter values.

For instance, for a single binomial proportion, Agresti and Coull [6] argued that the Clopper–Pearson (1934) "exact" confidence interval for the success probability, based on inverting equal-tailed binomial tests of $H_0: \pi = \pi_0$, is not necessarily optimal in small samples because of this conservatism. Several authors (e.g. [6, 10, 39, 46]) have recommended the score interval as an alternative (*see* **Likelihood**). Let X denote a binomial variate for sample size n, and let $\hat{\pi}$ denote the sample proportion. This score confidence interval, apparently first discussed by Edwin B. Wilson [47], takes the form

$$\frac{\left(\hat{\pi} + \frac{z^2_{\alpha/2}}{2n} \pm z_{\alpha/2}\sqrt{[\hat{\pi}(1-\hat{\pi}) + z^2_{\alpha/2}/4n]/n}\right)}{(1 + z^2_{\alpha/2}/n)}, \tag{6}$$

where z_c denotes the 1-c quantile of the standard normal distribution. Expression (3) results from inverting the approximately normal test that uses the null **standard error**, that is, its endpoints are the π_0 solutions to the equations $(\hat{\pi} - \pi_0)/\sqrt{\pi_0(1-\pi_0)/n} = \pm z_{\alpha/2}$. For a 95% confidence interval, Agresti and Coull [6] also proposed a simple approximation to the score interval that is simple to compute. This approximation

constructs the Wald interval (*see* **Likelihood**)

$$\tilde{\pi} \pm z_{\alpha/2}\sqrt{\frac{\tilde{\pi}(1-\tilde{\pi})}{\tilde{n}}} \tag{7}$$

using a new sample proportion $\tilde{\pi}$ and sample size $\tilde{n}$ formed after adding two successes and two failures to the data. Both of these alternative intervals yield actual confidence levels that are typically much closer to nominal levels than those of the exact Clopper–Pearson interval.

Others have proposed additional strategies for estimation of a binomial proportion. Vollset [46] showed that the interval obtained by inverting the test based on mid-P is less conservative than the exact interval but slightly more conservative than the score interval. This interval may be preferable in situations where the score interval is slightly liberal, namely, when π is near 0 or 1. Brown, Cai, and Das Gupta [10] recommended an interval based on Jeffrey's **prior** in a **Bayesian** setting. Interestingly, this interval approximates the mid-P–corrected Clopper–Pearson interval. Still another effective strategy for reducing conservatism in this setting is inversion of a single two-sided rather than two one-sided tests [4, 7]. That is, let $f(X;\pi)$ be the probability mass function of X given π, and let x be the observed value of X. Sterne [45] showed that the $100 \times (1-\alpha)$ confidence interval for π obtained by inverting a single two-sided test consists of those values of π that satisfy

$$P_\pi\left[f(X;\pi) \le f(x;\pi)\right] > \alpha. \tag{8}$$

That is, the confidence interval consists of inverting a test that uses as a P value the sum of null probabilities less than or equal to that for the observed response. The resulting interval is exact, yet uniformly shorter than the Clopper–Pearson interval. Blyth and Still [9] and Casella [11] refined this approach to satisfy several optimality properties, and Blaker [8] proposed a related exact interval. The Blyth–Still–Casella intervals are available in the latest version of the StatXact software [21].

It is worth noting that Vollset considered continuity-corrected versions of both the score interval (6) and the normal-theory Wald interval [i.e. equation (7) using the original sample proportion $\hat{\pi}$ and sample size n]. Both of these corrected intervals use the normal continuity correction to the binomial observation x mentioned earlier. Vollset noted that the correction does not significantly improve the well-known horrible performance [10] of the Wald interval. However, the continuity-corrected score interval approximates the exact interval, leading to conservative inference. Casella [12] expressed a preference for this corrected score interval in the classroom. Brown, Cai, and Das Gupta [10] explicitly showed the effect of this correction on the score interval by plotting the coverage probabilities and expected lengths of the score intervals with and without the correction. For other general reviews of inference for a single binomial proportion, see Agresti [2, 4], Agresti and Min [7], and Newcombe [39].

Similar patterns hold in other discrete settings. For a review, see Agresti [2, 4, 7]. For the difference between two independent binomial proportions, Nurminen [41] proposed inverting the large-sample score test. Let $\delta = \pi_1 - \pi_2$ denote the difference between two independent proportions. This test for $H_0\colon \delta = \delta_0$ treats the test statistic

$$T = \frac{\hat{\pi}_1 - \hat{\pi}_2 - \delta_0}{\sqrt{\tilde{\pi}_1(1-\tilde{\pi}_1)/n_1 + \tilde{\pi}_2(1-\tilde{\pi}_2)/n_2}}, \tag{9}$$

where $\tilde{\pi}_1$ and $\tilde{\pi}_2$ denote the ML estimates of π_1 and π_2 subject to $\pi_1 - \pi_2 = \delta_0$, as a standard normal random variable. Agresti [4] noted that the score approach yields reasonable coverage probabilities in this context as well. Chan and Zhang [14] proposed an exact test formed by inverting two one-sided tests based on the null probability ordering of (9). Because either π_1 or π_2 is a nuisance parameter, the exact intervals in this setting are unconditional. That is, because the difference $\delta = \pi_1 - \pi_2$ does not correspond to a canonical parameter in an **exponential family** model, it is not possible to obtain a likelihood free of π_1 by conditioning on its sufficient statistic. Instead, the exact approach inverts the test for $H_0\colon \delta = \delta_0$ based on the unconditional P value, $\sup_{\pi_1}\left(P_{\delta=\delta_0,\pi_1}(T \ge t_o)\right)$. Agresti and Min [7] showed that inverting the analogous two-sided score test can lead to shorter intervals, and Agresti and Caffo [5] showed that a simple adjustment that constructs the normal-theory Wald interval after adding a success and a failure to each sample is also effective. Newcombe [40] considered approaches that form intervals by inverting two test statistics, one for each proportion, both with and without continuity corrections. As is the case for a single proportion, these investigations showed that continuity-corrected Wald-type

intervals are too liberal, whereas the continuity-corrected score intervals are quite conservative. Santner and Snell [43] proposed an unconditional exact interval for δ based on the unstandardized statistic $\widehat{\pi}_1 - \widehat{\pi}_2$, although recent results have shown this statistic to be extremely conservative [14, 21]. For related approaches, see [17, 44]. Recent software now reflects the increased number of choices for inference in this setting. For example, StatXact-5 gives the user a choice of constructing the Agresti-Min, the Chan–Zhang, or the Santner–Snell interval for δ, although Cytel notes [21] that the latter conservative interval is included largely for historical reasons.

These general trends also hold when interest focuses on the odds ratio in 2×2 tables. For a single table, Cornfield [20] proposed the exact conditional interval for the odds ratio θ in a single 2×2 table. One obtains this interval by conditioning on the row and column totals of the table and by inverting two one-sided $\alpha/2$ tests for θ based on the resulting exact hypergeometric distribution. Several authors (e.g. [1, 33]) have shown this interval to be highly conservative for small or highly unbalanced samples. Cornfield [20] and Fisher [24] proposed a continuity-corrected approximation to Cornfield's exact interval. This interval, formed by inverting the distribution of the continuity-corrected Pearson chi-squared statistic (2) after conditioning on the observed row and column totals, is the continuity-corrected score interval in this case. As expected, this strategy is also conservative, as it once again approximates the exact interval [1, 33]. Agresti [1] noted that the interval obtained by inverting the uncorrected score interval yields much shorter intervals, while producing coverage probabilities at or near nominal levels. Less work exists for the stratified 2×2 setting, although Kim and Agresti [30] proposed an exact confidence interval for a common odds ratio formed by inverting a test based on the modified P value discussed above.

In summary, the traditional continuity corrections of score statistics typically yield results that closely approximate those from the corresponding exact method. As a result, tests and intervals based on these continuity-corrected statistics yield reliably conservative inferences but with actual confidence levels often far above nominal levels. In applications in which maintaining either the type I error rate or nominal confidence level is absolutely necessary, exact methods are preferred to other approaches, and recent advances in computational algorithms make such methods accessible in commercial **software**. Thus, the continuity-corrected score methods are perhaps useful when one is interested in exact inference but does not have access to software with exact capabilities. In this sense, one can obtain a good approximation to an exact result using simple formulas. In situations in which maintaining nominal levels is not as crucial, one can use an alternative method, such as an approach based on the uncorrected score statistic or the mid-P value, that will yield an actual level close to, but not always bounded by, the nominal level.

Contrasts

The objectives of most studies include comparisons among population characteristics (e.g. **means**). Most such comparisons are *contrasts*. Consider a **clinical trial** involving a control and two test treatments, with parameters μ_1, μ_2, and μ_3 the control and test treatment (population) means, respectively. The *pairwise* contrast (*see* **Paired Comparisons**) $\Psi_1 = \mu_2 - \mu_3$ compares the means of the two test treatments, while the contrast $\Psi_2 = (\mu_2 + \mu_3)/2 - \mu_1$ compares the average of the means of the two test treatments with the mean of the control. More generally, collections of contrasts may be formulated to represent research comparisons of interest. For example, certain specialized classes of contrasts determine the main effect and **interaction** sums of squares reported in **analysis of variance** (ANOVA) tables (see below).

Contrasts are formally defined and discussed here using the matrix representation of a linear model (*see* **General Linear Model**), although the concept of a contrast is not limited to experiments analyzed with such models. Let $\mathbf{Y}^{(n\times 1)}$ denote the vector of n observed responses, $\mathbf{X}^{(n\times p)}$ the $(n \times p)$ regression or design matrix of rank $r \le p$, where x_{ij} is the value of the jth independent variable for the ith observation, $i = 1, \ldots, n$, $j = 1, \ldots, p$, and $\beta^{(p\times 1)}$ the parameter vector. The linear model representation is: $\mathbf{Y} = \mathbf{X}\beta + \varepsilon$, where $\varepsilon^{(n\times 1)}$ is the vector of **unbiased** (mean zero) **random errors**. A *contrast* in the parameters $\beta_1, \ldots, \beta_p$ is a linear combination

$$\Psi = \mathbf{c}'\beta = c_1\beta_1 + \cdots + c_p\beta_p \quad \text{subject to}$$
$$c_1 + \cdots + c_p = 0. \tag{1}$$

For the clinical study example above, with $\beta = (\mu_1, \mu_2, \mu_3)'$, $\Psi_1 = \mathbf{c}_1'\beta$ where $\mathbf{c}_1 = (0, 1, -1)'$ and $\Psi_2 = \mathbf{c}_2'\beta$ where $\mathbf{c}_2 = (-1, 0.5, 0.5)'$.

Estimability of Contrasts

A contrast $\Psi = \mathbf{c}'\beta$ is *estimable* if there exists an $(n \times 1)$ vector of constants, $\mathbf{b}$, such that $\mathbf{b}'\mathbf{Y}$ is an *unbiased* estimator of Ψ. Equivalently, Ψ is estimable if there exists a constant vector $\mathbf{a}$ such that $\mathbf{c}' = \mathbf{a}'\mathbf{X}$. An estimable Ψ has a *unique* **least squares** *estimate* $\hat{\Psi} = \mathbf{c}'\hat{\beta}$, where $\hat{\beta}$ is *any* solution to the normal equations $\mathbf{X}'\mathbf{X}\beta = \mathbf{X}'\mathbf{Y}$ [4]. Furthermore, $\hat{\Psi}$ is the Best Linear Unbiased Estimate (BLUE) of Ψ [4] (*see* **Minimum Variance Unbiased (MVU) Estimator**). Note that the preceding estimability results hold whether the variance–**covariance matrix** of ε has the standard "uncorrelated, constant variance" form, $\sigma^2\mathbf{I}_n$, or the more general form $\sigma^2\mathbf{V}$, where $\mathbf{V}$ is a known $(n \times n)$ positive definite matrix, except that in the latter case $\hat{\beta}$ is any solution of $\mathbf{X}'\mathbf{V}^{-1}\mathbf{X}\beta = \mathbf{X}'\mathbf{V}^{-1}\mathbf{Y}$. For the remainder of this discussion, the standard case will be assumed.

Variance of Contrasts

If $\Psi_1 = \mathbf{c}_1'\beta, \ldots, \Psi_q = \mathbf{c}_q'\beta$ are q estimable contrasts, then the $(q \times q)$ variance–covariance matrix of $(\Psi_1, \ldots, \Psi_q)$ is given by

$$\sigma^2\mathbf{C}'(\mathbf{X}'\mathbf{X})^-\mathbf{C}, \tag{2}$$

where the ith column of $\mathbf{C}$ is $\mathbf{c}_i$, $i = 1, \ldots, q$, and $(\mathbf{X}'\mathbf{X})^-$ is the same generalized inverse of the information matrix $\mathbf{X}'\mathbf{X}$ used to produce an estimated parameter vector, $\hat{\beta} = (\mathbf{X}'\mathbf{X})^-\mathbf{X}'\mathbf{Y}$, that solves the normal equations. An estimate of the error variance, σ^2, is usually provided by the **mean square for error**.

Example: Clinical Study

For the clinical study example introduced above, the *means* model is: $Y_{ij} = \mu_i + \varepsilon_{ij}$, $j = 1, \ldots, n_i, i = 1, 2, 3$. With this parameterization, *every* linear combination of the three means is estimable, including all contrasts. With $\hat{\beta} = (\hat{\mu}_1, \hat{\mu}_2, \hat{\mu}_3)'$, where $\hat{\mu}_i = \sum_j Y_{ij}/n_i$, the unique least squares estimator of a contrast $\Psi = \mathbf{c}'\beta$ defined by (1) is $\hat{\Psi} = \sum c_i\hat{\mu}_i$. Since $\mathbf{X}'\mathbf{X}$ has inverse $(\mathbf{X}'\mathbf{X})^{-1} = \text{diag}(n_1^{-1}, n_2^{-1}, n_3^{-1})$, using (2), the variance of $\hat{\Psi}$ is $\text{var}(\hat{\Psi}) = \sigma^2 \sum c_i^2/n_i$.

In the equivalent *effects* model parameterization, $Y_{ij} = \mu + \tau_i + \varepsilon_{ij}$, the individual components of $\beta = (\mu, \tau_1, \tau_2, \tau_3)'$ are not estimable and $\mathbf{X}'\mathbf{X}$ does not have an inverse. However, a contrast in the means, $\Psi = \sum c_i\mu_i$, is (i) estimable and (ii) equal to the *same* contrast in the treatment effects, $\Psi = \sum c_i\tau_i$. The unique least squares estimator of Ψ is $\hat{\Psi} = \sum c_i\hat{\tau}_i$, irrespective of the choice of generalized inverse used to find a solution $\hat{\beta} = (\hat{\mu}, \hat{\tau}_1, \hat{\tau}_2, \hat{\tau}_3)'$ of the normal equations [4]. The variance of $\hat{\Psi}$ is given by (2) and is the same in both the means and effect model parameterizations. See the *SAS/STAT User's*

Guide [2] entry for procedure GLM for solutions corresponding to the generalized inverse of $\mathbf{X}'\mathbf{X}$ obtained with the *set-to-zero* side conditions (*see* **Software, Biostatistical**). In particular, the *only* estimable linear combinations of the effects parameters [i.e. the coefficient of μ in (1) is zero] are contrasts [3]. Furthermore, if Ψ is a contrast in the effects parameters, then the coefficient of μ must be zero.

Main Effect and Interaction Contrasts

The results in the preceding example hold for any one-way treatment structure, $\beta = (\mu_1, \ldots, \mu_p)'$. Contrasts that represent main effect and interaction comparisons are discussed here in the context of the two-way **factorial** treatment structure, where factor A has levels $i = 1, \ldots, I$ and factor B has levels $j = 1, \ldots, J$. There are $n_{ij} > 0$ observations on each *treatment combination* (i.e. no missing cells). Extensions to three or more factors follow accordingly but with increased technical and notational complexity.

The population mean for the (i, j)th treatment combination is μ_{ij}, and is modeled by $\mu_{ij} = \mu + \alpha_i + \beta_j + \gamma_{ij}$ in the corresponding *full* effects model. The linear model is $Y_{ijk} = \mu_{ij} + \varepsilon_{ijk}$, $k = 1, \ldots, n_{ij}$. Any contrast $\Psi = \sum_i \sum_j c_{ij}\mu_{ij}$, $\sum_i \sum_j c_{ij} = 0$, in the means

$$(\mu_{11}, \ldots, \mu_{1J}, \mu_{21}, \ldots, \mu_{2J}, \ldots, \mu_{I1}, \ldots, \mu_{IJ})', \tag{3}$$

is estimable and has the same estimate (and variance) whether the means or full effects model parameterization is used.

Following Milliken et al. [1], a contrast $\Psi = \sum_i \sum_j c_{ij}\mu_{ij}$ is an *A main effects* contrast if $c_{ij} = c_i$, for each $j = 1, \ldots, J$, in which case $\sum c_i = 0$, as usual. In this context, Ψ may be expressed as $\Psi = \sum c_i \overline{\mu}_i.$, where $\overline{\mu}_i. = \sum_j \mu_{ij}/J$ is the *population marginal mean* (also referred to as the "least squares mean", LSMEAN, in the SAS [2] procedure GLM) for level i of factor A. Similarly, a *B main effects* contrast requires that $c_{ij} = c_j$, for each $i = 1, \ldots, I$. Finally, a contrast Ψ is an *interaction contrast* if (i) $\sum_i c_{ij} = 0$ for each $j = 1, \ldots, J$ and (ii) $\sum_j c_{ij} = 0$ for each $i = 1, \ldots, I$.

A contrast Ψ in the IJ means (3) is equivalently written as a contrast in the full effects parameters

$$\Psi = \sum_i c_{i\cdot}\alpha_i + \sum_j c_{\cdot j}\beta_j + \sum_i \sum_j c_{ij}\gamma_{ij}, \tag{4}$$

where $c_{i\cdot} = \sum_j c_{ij}$ and $c_{\cdot j} = \sum_i c_{ij}$. Consequently, if Ψ is an A main effects contrast, $c_{\cdot j} = 0$ and $c_{i\cdot} = Jc_i$, in which case Ψ in (4) may be written $\Psi = J\sum_i c_i\alpha_i + \sum_i c_i\gamma_{i\cdot}$, where $\gamma_{i\cdot} = \sum_j \gamma_{ij}$. Similarly, if Ψ is a B main effects contrast, $c_{i\cdot} = 0$ and $c_{\cdot j} = Ic_j$, whence $\Psi = I\sum_j c_j\beta_j + \sum_j c_j\gamma_{\cdot j}$. Finally, an interaction contrast in the means (3) has exactly the same form in the interaction parameters $\{\gamma_{ij}\}$, that is, $\Psi = \sum_i \sum_j c_{ij}\mu_{ij} = \sum_i \sum_j c_{ij}\gamma_{ij}$ provided Ψ is an interaction contrast.

Orthogonal Contrasts

Suppose that $\Psi_k = \mathbf{c}_k'\beta$, $k = 1, \ldots, q (2 \le q \le p - 1)$ are q *linearly independent* contrasts in the parameters, β. Then these q contrasts are *mutually orthogonal* if they are uncorrelated with each other (*see* **Orthogonality**). Thus, if $\mathbf{C}$ is the $(p \times q)$ matrix whose kth column is $\mathbf{c}_k$, then these q contrasts are mutually orthogonal if, by (2), $\mathbf{C}'(\mathbf{X}'\mathbf{X})^-\mathbf{C}$ is a diagonal matrix. Orthogonality of contrasts is useful when the errors, ε_i, are **normally distributed**, in which case the contrast estimators are statistically independent, as are the sums of squares for each contrast (see below), which may simplify practical interpretation of results. For example, in an experiment with a factor at four quantitative and equally spaced levels, and equal replication at each factor level, linear, quadratic and cubic orthogonal polynomial contrasts defined by $\mathbf{c}_1 = (-3, -1, 1, 3)'$, $\mathbf{c}_2 = (1, -1, -1, 1)'$, and $\mathbf{c}_3 = (-1, 3, -3, 1)'$ may be used to test for the degree of a polynomial describing the mean response. See Milliken et al. [1] for a data analysis using orthogonal polynomial contrasts.

For the clinical study example above, $q = 2$ contrasts are orthogonal if $\sum_i c_{i1}c_{i2}/n_i = 0$. If the experiment is *balanced*, i.e. if $n_i = n$, $i = 1, 2, 3$, then orthogonality is equivalent to $\mathbf{c}_1'\mathbf{c}_2 = \sum_i c_{i1}c_{i2} = 0$, which states that the contrast coefficient vectors $\mathbf{c}_1$ and $\mathbf{c}_2$ are at right angles. This is true for the contrasts Ψ_1 and Ψ_2 in this example. However, if $n_2 \neq n_3$, then Ψ_1 and Ψ_2 are not orthogonal in this example. If Ψ_2 is defined by $\mathbf{c}_2 = (n_2 + n_3, -n_2, -n_3)'$ instead, then Ψ_1 and Ψ_2 are orthogonal, although it is unlikely that

Ψ_2 is a meaningful comparison in this experiment. Typically, sets of orthogonal contrasts are of more theoretical than practical convenience.

For the two-way treatment structure (3), two contrasts Ψ_1 and Ψ_2 are orthogonal if

$$\sum_i \sum_j \frac{c_{ij1}c_{ij2}}{n_{ij}} = 0. \quad (5)$$

This simplifies to $\sum_i \sum_j c_{ij1}c_{ij2} = 0$ in the equally replicated case, that is, $n_{ij} = n$ for all $i = 1, \ldots, I$ and $j = 1, \ldots, J$. For example, in this latter case of equal replication, two A main effect contrasts are orthogonal if $\sum_i c_{i1}c_{i2} = 0$, where $c_{i1} = c_{ij1}$ and $c_{i2} = c_{ij2}$. A similar statement holds for orthogonality of two B main effects contrasts. Two interaction contrasts are orthogonal if their coefficients satisfy (5).

Sums of Squares from Contrasts

If $\Psi_k = \mathbf{c}_k'\beta$, $k = 1, \ldots, q (1 \le q \le p-1)$ are q linearly independent estimable contrasts, then the sum of squares for testing the **null hypothesis** $H_0 : \mathbf{C}'\beta = \mathbf{d}$, where the kth column of the $(p \times q)$ matrix $\mathbf{C}$ is $\mathbf{c}_k$ and $\mathbf{d}$ is a $(q \times 1)$ vector of constants (usually $\mathbf{d} = \mathbf{0}$) is [1]

$$\mathrm{SSH}_0 = (\mathbf{C}'\hat{\beta} - \mathbf{d})'[\mathbf{C}'(\mathbf{X}'\mathbf{X})^{-}\mathbf{C}]^{-1}(\mathbf{C}'\hat{\beta} - \mathbf{d}). \quad (6)$$

This sum of squares has q df. If the errors ε_i are iid $N(0, \sigma^2)$, then SSH_0 has a $\chi^2(q)$ distribution (central under H_0) (*see* **Chi-square Distribution**) and is independent of the error mean square [4].

For example, in the one-way ANOVA model for a single treatment factor with p levels, the contrasts $\Psi_i = \mu_i - \mu_p = \tau_i - \tau_p$ $(i = 1, \ldots, p-1)$ are linearly independent and estimable. Their sum of squares given by (6), with $\mathbf{d} = \mathbf{0}$, reproduces the treatment/model sum of squares reported in an ANOVA table. See the *contrast* option to the *repeated* statement in the SAS [2] procedure GLM for the polynomial, Helmert, mean, and profile sets of linearly independent, estimable contrasts that achieve the same result. Alternatively, a set of $p-1$ orthogonal contrasts may be chosen instead, with the added benefit that the sum of squares for each individual contrast will be uncorrelated with the others and the $p-1$ individual sums of squares will add to the treatment/model sum of squares.

Generating ANOVA table sums of squares for main effects and interactions in multiway treatment structures is more complicated and depends on the replication of each treatment combination. SAS [2] procedure GLM defines and computes the sum of squares for four *types* of contrasts, types I–IV, for each class of effects (main effects, two-factor interactions, etc.). Type IV contrasts/sums of squares are relevant only when one or more treatment combinations is not observed [1] and will not be discussed further here. Types I–II contrasts have coefficients that depend on the replication numbers n_{ij} and are, in general, not meaningful in unbalanced experiments. For example, the A main effect type I contrasts (for the usual order of A, B, and AB effects classes) are

$$\frac{1}{n_{i\cdot}}\sum_j n_{ij}\mu_{ij} - \frac{1}{n_{I\cdot}}\sum_j n_{Ij}\mu_{Ij} = 0,$$
$$i = 1, \ldots, I-1.$$

Note that these contrasts do not satisfy the more restrictive definition for main effects contrasts given above; also note that they have coefficients that are functions of the amount of data collected (for details, see Milliken et al. [1]).

Type III contrasts and their sums of squares are appropriate for most experiments, whether the experiment is balanced or not. The type III contrasts for each class of effects result from equal averaging over the levels of all factors that are not part of the class of effects of interest. For treatment structure (3), type III A main effects contrasts are $\overline{\mu}_{i\cdot} - \overline{\mu}_{I\cdot} = 0$, $(i = 1, \ldots, I-1)$, or *any* contrast formed from a linear combination of these $I-1$ contrasts. Similarly, type III B main effect contrasts are any linear combinations of $\overline{\mu}_{\cdot j} - \overline{\mu}_{\cdot J} = 0$ $(j = 1, \ldots, J-1)$. The AB interaction contrasts are $\mu_{ij} - \mu_{ij'} - \mu_{i'j} + \mu_{i'j'}$, $(i \ne i', j \ne j')$. These type III contrasts in the population marginal means extend to higher-factor interactions in an analogous manner.

If each treatment combination is equally replicated, so $n_{ij} = n$, then type I–IV contrasts and sums of squares are the same for each class of effects. Under normality, the sums of squares for each class of effects have a χ^2 distribution and they are mutually independent [4].

Extensions

Contrasts may represent meaningful comparisons of interest in experiments analyzed by models other than the linear model discussed here. For example, **generalized linear models** (GLMs), which include the normal-theory linear models used above with the identity link between mean response and the linear predictors, are appropriate for a wide variety of non-Gaussian error distributions. If a GLM model contains treatment factors, then contrasts among the levels of these factors may be estimated and tested. For example, with a dichotomous response, a **logistic regression** (logit analysis) may be used. If a factor has two levels (e.g. gender), then a contrast in the parameters between the two levels of this factor would represent the log-**odds ratio** between the two genders.

Contrasts among fixed factor parameters may be estimated in *mixed models* that have two or more **random effects** (e.g. **split plot designs**, repeated measures). In mixed models, unbiased estimators of contrasts are typically available. However, estimates of the variances of such contrasts usually require iterative computation, may be at best approximate (and biased, especially in unbalanced experiments), and may have nonstandard distributions even when all errors are Gaussian. Milliken et al. [1] provide examples for mixed ANOVA models.

Controlled Clinical Trials

The need for the Journal developed from the emergence of the controlled trial as the ultimate test of a treatment touted for use in human beings (*see* **Clinical Trials, Overview**). The work of **Sir Ronald A. Fisher** [9], in the 1930s and 1940s, and the teachings and writings of **Bradford Hill** [11] in the 1940s and 1950s, along with the **Medical Research Council (MRC)** of the UK, calling in 1931 for trials of new remedies [17], created the basis for modern-day trials. That basis was strengthened, following World War II, by unprecedented expansion of Federal funding for medical research in the US, starting in the 1950s and continuing into the 1980s. The US Congress, concerned with the safety and efficacy of drugs approved for use on human beings, acted to strengthen the **Food and Drug Administration** and to set approval standards based on evidence of efficacy as provided by "adequate and well-controlled trials" [36]. As a result, the clinical trial came to be seen as the "indispensable ordeal" for evaluating new and old treatments, even if protracting the "moment of truth to excruciating limits" [10].

The resources and resolve of the 1960s led to the emergence of **National Institutes of Health** sponsored long-term, **multicenter trials** designed to investigate treatments for chronic diseases (*see* **Clinical Trials, Early Cancer and Heart Disease**; **Cooperative Cancer Trials**; **Cooperative Heart Disease Trials**). In order to enroll and treat the numbers of patients necessary to evaluate therapies for treatment or prevention of these diseases, the trials sometimes involved thousands of patients and a decade or more to complete. One of the first trials in this class was the **University Group Diabetes Program (UGDP)**, started in 1960 and aimed at answering the question of whether drug control of blood glucose levels in persons with adult-onset diabetes is useful [34, 35]. It was followed in the mid-1960s by the Coronary Drug Project (CDP) [8]; and thereafter by a series of primary and secondary prevention heart disease trials [2, 3, 6, 7, 12, 13, 15, 16, 24, 25]. Although there was record growth in the numbers of these multicenter trials, there was little or no interchange among the different centers funded to coordinate the trials and to receive, process, and analyze the data generated by them.

Efforts to improve communication and to encourage the exchange of information on methods and procedures for designing and conducting large-scale multicenter trials commenced with a meeting of representatives from several coordinating centers held in Columbia, Maryland, in 1973. That meeting was followed by a second one in 1975 and thereafter by annual meetings through 1981 [4, 5]. The format of the meetings changed from "show and tell" descriptions of processes or procedures, to one reminiscent of meetings of professional societies.

The interchanges helped to underscore the fact that there is both an art and a science to coordination and data processing and to the realization that there was no obvious "home" for papers having to do with the methods and science of the design and conduct of trials. That realization gave rise to the urge to create the means for receiving and publishing such papers. The call for a journal issued from a workshop entitled "National Conference on Clinical Trials Methodology", held at the NIH on October 3–4, 1977 [14, 23].

Following the workshop, representatives from Elsevier [1, 18] approached Robert Gordon, then Director of the NIH Clinical Trials Committee, for advice as to persons they might approach to head such a journal. They were directed to one of us (C.L.M.). The conversations regarding assumption of the editorship took place in the summer of 1979. The first issue was published in May of 1980, followed by three other issues in that year and by four issues thereafter through 1989. The Journal has been published six times yearly since then [19–22, 26].

The meetings of coordinating centers that started in 1973 and the NIH workshop in 1977 gave rise, as well, to the Society for Clinical Trials. It emerged from a working group created following the 1977 NIH workshop [14, 23, 29] and was chartered on October 5, 1978, in the State of Maryland. The last two meetings of coordinating centers (Annual Symposium on Coordinating Clinical Trials) were, in fact, held in conjunction with the first two meetings of the Society for Clinical Trials. The first such joint meeting coincided with the Seventh Annual Symposium on Coordinating Clinical Trials and the first meeting of the Society for Clinical Trials in Philadelphia in 1980 [27, 28, 30–33]. The Society adopted the Journal as its official organ by virtue of a contract, dated July 19, 1979, between the Publisher, the Society, and, the Editor-in-Chief of the Journal.

The Journal, as reflected in its aims and scope, is intended to attract and publish papers having to do with issues related to the design, conduct, organization or analysis of trials. It is not a traditional results journal, as such. It has, over the years, published papers dealing with the basic design and operating features of trials and in some cases has provided detailed descriptive information as to the baseline characteristics of study population of trials. It has published several monographs with papers related to a particular trial and on topics such as data processing or recruitment. Some of the pages of the Journal are devoted to commentary, letters to the editor, book reviews, and software reviews. The **Society for Clinical Trials** provided editors for *CCT* from its inception in 1980: Curtis Meinert (1980–1993), Janet Wittes (1994–1998), and Jim Neaton (1999–2003). The SCT terminated its relationship with the journal in 2004, founding a new journal, ***Clinical Trials***. The current editor of *CCT* is Kathleen B. Drennan.

Controls

Controls are subjects against whom a comparison is made in experimental or **observational studies**. In randomized **clinical trials**, the control group may receive no treatment, a placebo treatment, or the best currently accepted active treatment. This group is used as a basis of comparison against the group that receives the new experimental treatment. Sometimes the study subjects are stratified into risk groups and are allocated into experimental or control groups in such as way as to assure roughly equal numbers of subjects in the experimental and control groups within each stratum (*see* **Randomized Treatment Assignment**). In observational **cohort studies**, a comparison may be drawn with unexposed or less exposed members of the cohort ("internal" controls). If all members of a cohort are exposed, however, as in some studies of occupational risk (*see* **Occupational Epidemiology**), then an external unexposed or only slightly exposed control population, such as the general population of the US, may be taken as a basis of comparison (*see* **Standardization Methods**).

Controls chosen for comparison with cases in **case–control studies** may be selected from the general population (*see* **Case–Control Study, Population-based**; **Case–Control Study, Prevalent**) or from a selected source, as in **hospital-based case–control studies**. Controls may also be matched to cases on characteristics that may **confound** the **association** between exposure and disease status (*see* **Matching**).

MITCHELL H. GAIL

Convergence in Distribution and in Probability

To motivate convergence in distribution and in probability, suppose that $Y_1, Y_2, \ldots, Y_n$ is a random sample of size n taken from a population with unknown mean μ and variance σ^2. The sample mean $\overline{Y}_n = (Y_1 + \cdots + Y_n)/n$ is typically used to estimate μ. As the sample size n grows to infinity, does $\overline{Y}_n$ converge to μ (if so, in what sense) and what can one say about the deviations of $\overline{Y}_n$ from μ? It turns out that $\overline{Y}_n$ converges to μ in probability (in fact, even "almost surely") and $\sqrt{n}(\overline{Y}_n - \mu)/\sigma$ converges in distribution to a Gaussian random variable with mean 0 and variance 1. We shall now define these two modes of convergence.

Let $X_n, n = 1, 2, \ldots$ be a sequence of **random variables** (for example, the sample means $\overline{Y}_n$ considered earlier). The cumulative distribution function $F_{X_n}(x) = \Pr[X_n \le x], -\infty < x < \infty, n = 1, 2, \ldots$ describes the probability law of X_n. Let Z be another random variable with cumulative distribution function $F_Z(x) = \Pr[Z \le x], -\infty < x < \infty$.

Definition. The random variables X_n converge to Z in distribution as n tends to infinity, if the functions $F_{X_n}(x)$ converge to $F_Z(x)$ for all $-\infty < x < \infty$ that are points of continuity of F_Z.

To understand why we do not require that $F_{X_n}(x)$ converge to $F_Z(x)$ for all x, suppose that X_n equals $1/n$ and hence is not random. As n tends to infinity, $1/n$ tends to 0 and hence we expect the distribution of X_n to converge to that of Z, where Z is also not random and equals 0. Note that $F_{X_n}(x) = 0$ if $x < 1/n$ and $F_{X_n}(x) = 1$ if $x \ge 1/n$. Similarly, $F_Z(x) = 0$ if $x < 0$ and $F_Z(x) = 1$ if $x \ge 0$. It is easy to see that $F_{X_n}(x) \to F_Z(x)$ for all $x \ne 0$ but not at $x = 0$, because $F_{X_n}(0) = 0$, whereas $F_Z(0) = 1$. It is therefore not natural to require that F_{X_n} converge to F_Z at points of discontinuity of F_Z.

Let us now turn to convergence in probability.

Definition. The random variables X_n converge to Z in probability as n tends to infinity if, for all $\varepsilon > 0$, $\lim_{n\to\infty} \Pr[|X_n - Z| > \varepsilon] = 0$.

In other words, X_n converges to Z in probability if the probability that X_n differs from Z by any given small quantity tends to zero as n tends to infinity.

Convergence in probability always implies convergence in distribution, and if Z is nonrandom, then the two modes of convergence are equivalent.

Technically, since convergence in probability involves a joint probability statement about X_n and Z, the random variables X_n and Z have to be defined in the same probability space. This is not necessary if X_n merely converges to Z in distribution.

In practice, to verify convergence in probability, one uses Chebychev's inequality:

$$\Pr[|X_n - Z| > \varepsilon] \le \frac{\operatorname{var}(X_n - Z)}{\varepsilon^2}.$$

Thus X_n converges to Z in probability if X_n and Z have the same mean and $\lim_{n\to\infty} \operatorname{var}(X_n - Z) = 0$.

Returning to the example given at the beginning of the article, to verify that the sample mean $\overline{Y}_n$ converges to the population mean μ in probability, it is sufficient to check that $\lim_{n\to\infty} \operatorname{var}(\overline{Y}_n - \mu) = 0$. This relation holds because

$$\operatorname{var}(\overline{Y}_n - \mu) = \operatorname{var}\overline{Y}_n = \frac{1}{n^2}\operatorname{var}\left(\sum_{i=1}^{n} Y_i\right)$$
$$= \frac{1}{n^2} n\sigma^2 \to 0 \quad \text{as } n \to \infty.$$

The convergence in distribution of $\sqrt{n}(\overline{Y}_n - \mu)/\sigma$ to a Gaussian random variable is a consequence of the **central limit theory**. While $\overline{Y}_n - \mu \to 0$ (in probability), multiplying $\sqrt{n}/\sigma$ by $(\overline{Y}_n - \mu)$ yields an $\infty \times 0$ situation. The result (not a priori obvious) is that the limit is a well-defined random variable the range of which is $(-\infty, \infty)$ and the density function has the Gaussian bell-shaped curve centered at zero; that is, has the normal distribution N(0, 1).

Large-sample properties of estimators typically involve convergence in distribution (*see* **Large-sample Theory**). Hence, referring again to the example given at the beginning of this article, for large n, the distribution of $\sqrt{n}(\overline{Y}_n - \mu)/\sigma$ is approximately N(0,1) and that of $\sqrt{n}(\overline{Y}_n - \mu)/s$, where $s^2 = \sum_{i=1}^{n}(Y_i - \overline{Y}_n)^2/(n-1)$ is the sample variance, is approximately a **Student's *t* distribution** with $n - 1$ degrees of freedom. Similarly, the distribution of $(n-1)s^2/\sigma^2$ is approximately χ^2 (**chi-square distribution**) with $n - 1$ degrees of freedom. These limiting distributions are used to compute approximate confidence intervals for μ and σ^2, respectively.

Convergence in probability, on the other hand, is often used to show that the sample **moment** converges to the population moment. Thus, as n tends to infinity, $\overline{Y}_n \to \mu$ and $s^2 \to \sigma^2$, both in probability; that is, the sample mean converges to the population mean and the sample variance converges to the population variance.

Here are some additional facts that are useful to establish convergence results:

1. If $X_n \to Z$ in distribution and $X_n - W_n \to 0$ in probability, then $W_n \to Z$ in distribution.
2. $X_n \to Z$ in distribution if its **characteristic function** $\phi_{X_n}(t) = \mathrm{E}[\exp(\mathrm{i}tX_n)]$, where $\mathrm{i} = \sqrt{-1}$, tends, for all $-\infty < t < \infty$, to the characteristic function $\phi_Z(t) = \mathrm{E}[\exp(\mathrm{i}tZ)]$ of Z.
3. If X_n and Z are random vectors, then $X_n \to Z$ in distribution if all linear combinations of the components of X_n tend in distribution to the corresponding linear combination of the components of Z.

M.S. TAQQU

Cooperative Cancer Trials

The last four decades have witnessed a remarkable symbiotic relationship between clinical **oncology** and biostatistics. Research oncologists have become increasingly sophisticated with regard to statistical concepts and tools, and many are now quite familiar with terms such as **Mantel–Haenszel logrank test**, Gehan–Wilcoxon statistic, O'Brien and Fleming boundaries, and Simon optimal Phase II design, all of which relate to statistical techniques developed by biostatisticians working in cancer research. The magnitude of the cancer challenge is enormous. One-third of Americans will develop cancer of at least one of the 65 specific types; 1.4 million new cases and 550 000 deaths occurred in 1996. However, after observing persistent rises in age-adjusted mortality ever since statistics began to be maintained in the 1930s, there has been a drop of 2%–4% over the last 5 years [20]. Biostatisticians have played a crucial role in defining, refining, and applying the methodology of cancer **clinical trials**. In this article we emphasize the development, status, and achievements of the US clinical trials cooperative group program over the last decade (approximately 1986–1996), and we will briefly review some of the important methodological advances that have been made in biostatistics, in the same time period, in response to the challenges posed by these trials [42]. (*See* **Clinical Trials, Early Cancer and Heart Disease** for developments from approximately 1955 to 1965.)

The clinical trials cooperative group program grew out of the Cancer Chemotherapy National Service Center, established in 1955 [18] (*see* **Multicenter Trials**). By 1960, there were 11 cooperative oncology groups, with 10–20 new agents taken to clinical trial per year, of the 25 000–30 000 agents screened per year in the laboratory, in tissue culture and in animals. This pattern has persisted, with approximately 20 000 agents per year screened currently in the National Cancer Institute (NCI) *in vitro* human tumor cell line assay, and with 20–25 per year taken to clinical trial. Also by 1960, the current clinical developmental pathway had been defined: **Phase I trials** (of approximately 20 patients) to determine the appropriate dose of an agent, followed by **Phase II trials** (of 30–50 patients) to provide an initial test of its ability to shrink tumors, followed by randomized Phase III trials to test its efficacy, usually defined in terms of ability, alone or in combination, to prolong survival, compared with a control therapy. As they do now, the cooperative groups in 1960 collaboratively accrued to standardized **clinical trials protocols**, with standardized criteria of diagnosis, treatment, and measurement of effect, with **randomization** (that eventually became centralized), and with a prospective statistical design and collaborative analysis and reporting. The early development of the statistical centers was led by NCI statistician **Marvin Schneiderman** [18].

In the mid 1960s the focus of cooperative group cancer trials was expanded from new agent testing to encompass the development of new disease-oriented combination chemotherapy regimens. In 1972, the trials program formally entered a period of further expansion with the establishment by Congress of the National Cancer Program. In particular, patients with early stage disease were included in larger numbers (up to 1974, at least 85% of trial patients had advanced disease). By 1979, the configuration of the cooperative groups approximated the current one. Of the 31 groups that had been established since 1955, 14 remained under NCI sponsorship. A proliferation of small regional and single-disease groups had given way to primarily national multidisease groups [6], with correspondingly larger statistical centers, made up of statisticians and data managers under the supervision of a "group statistician" (Table 1 lists the extant cooperative groups). Statisticians played an increasingly prominent part in the groups. In addition to their lead role in the monitoring, analysis and reporting of group studies, the statisticians played a crucial role in their design.

Table 1 US cooperative cancer groups

Group	Acronym
Cancer and Leukemia Group B	CALGB
Children's Cancer Group	CCG
Eastern Cooperative Oncology Group	ECOG
Gynecologic Oncology Group	GOG
Intergroup Rhabdomyosarcoma Study Group	IRSG
National Surgical Adjuvant Breast and Bowel Project	NSABP
National Wilms' Tumor Study Group	NWTSG
North Central Cancer Treatment Group	NCCTG
Pediatric Oncology Group	POG
Radiation Therapy Oncology Group	RTOG
Southwest Oncology Group	SWOG

By the mid 1970s, NCI Biometric Research Branch (BRB) statisticians, then and now under the leadership of Richard Simon, had taken over statistical oversight of NCI-sponsored cancer treatment trials. The design, monitoring, and analysis of the trials was conducted at the statistical centers, with the exception of some of the prostate, central nervous system, and lung cancer trials, with statisticians in the NCI Clinical Trials Section under the leadership of **David Byar**. Between 1979 and 1982 the cooperative groups' grants and contracts were replaced by "cooperative agreements", which involved an expanded role for the NCI staff, in particular, for the BRB. By the early 1980s, as now, BRB statisticians were prospectively reviewing the design and conduct of all treatment studies and were acting as liaisons to the group statistical centers. In addition, they were deeply involved in the conception of drug development and disease-oriented strategies and in the design of many particular phase III studies. NCI and cooperative group statistical center statisticians have been extensively involved in the development of new statistical methodology concerning the design, conduct, and analysis of clinical studies; these contributions are discussed below.

The number of cooperative groups increased to 18 by 1985 and then decreased, from 1985 to 1988, to the 11 groups currently in existence. In the same period, total accrual and total number of trials for the cooperative group program increased by 15%, as emphasis was placed on increasing accrual through enhanced involvement of community hospitals and increased enrollment of minority patients [16, 17].

At this time, there was also substantial emphasis on studies to correlate potentially prognostic laboratory measures with clinical results and on translation of the rapidly emerging basic science findings to clinical advances (at present approximately 50% of treatment trials have explicit correlative science objectives). At the heart of this were the cancer centers, primarily large academic medical centers where advanced multidisciplinary basic, clinical, and translational research could be conducted. The cancer centers program developed in the early 1960s, with 12 institutions and a combined budget of 6 million dollars. The program was formally established through the National Cancer Act of 1971, and in 1996 there were 55 centers with a combined budget of 150 million dollars. The cancer centers participate in cooperative clinical trials through membership in the cooperative groups (and also conduct studies independently).

As a result of the community outreach efforts of the mid 1980s and later, 80% of cooperative group patients are currently treated outside of university and cancer center hospitals, through the Cooperative Group Outreach Program (CGOP) and the Community Clinical Oncology Program (CCOP). Approximately 50% of patients are accrued through CGOP, which was started in 1976 and involves small hospitals and practices that enter patients through cooperative group member institutions [7]. Approximately 30% of patients are accrued through CCOP, which was started in 1983 and involves larger hospitals that may independently affiliate with more than one cooperative group [7]. Studies have shown little or no differences in numbers of ineligible patients or protocol violations between academic and community hospitals [16].

The magnitude, structure, and cost of the US clinical trials cooperative group program have been relatively stable over the last decade. Of the 38 groups that have been established since 1955, the present 11 groups (Table 1) are those that constituted the program in 1988. These include seven adult patient groups – three multidisease national groups (CALGB, ECOG, SWOG), one regional group (NCCTG), one radiotherapy group (RTOG), one surgical adjuvant group (NSABP), and one gynecological cancer group (GOG) – and four pediatric patient groups – two multidisease national groups (CCG, POG) and two single-disease intergroup mechanisms (IRSG, NWTSG). In 1995, they comprised 6600 investigators at 1500 institutions, entering 16 000 patients on 340 open treatment studies, with a collective budget of 100 million dollars. (Over the past decade, the cooperative groups have accrued an average of 20 000 patients per year.) Also in 1995, they placed approximately 10 000 of these patients on 90 open nontherapeutic studies (ancillary **quality of life** and laboratory studies, associated with the therapeutic studies). To handle this work load, the statistical center of a typical large multidisease group employs approximately 12 statisticians and 20 data managers [6]. Typically, group statistical centers are associated with major university biostatistics departments, such as at Duke (CALGB), Harvard (ECOG), and the University of Washington (SWOG). In addition, the

NCI provides partial support to the data center of the **European Organization for Research and Treatment of Cancer (EORTC)**, under the statistical leadership of Richard Sylvester since 1975, which represents 350 institutions in 31 countries and places approximately 6000 patients per year on studies [46]. Finally, the National Cancer Institute of Canada, under the statistical leadership of Benny Zee since 1987, representing 50 institutions and placing 1500 patients per year on studies, has been very active in collaborating with the NCI-sponsored cooperative groups, as well as in conducting studies independently.

Over the past decade, the efforts of the cooperative groups have been divided roughly as follows with respect to treatment studies [17]. Phase I efforts have varied among the groups, but overall Phase I trials (dose–finding studies) made up only 10% of the total and accounted for only 2%–3% of the patients. Phase I trials have been primarily the domain of the cancer centers, working independently. Phase II trials (initial nonrandomized assessments of clinical benefit) made up 50%–60% of the total, and they accounted for 20%–25% of the patients. Phase III trials (randomized comparisons, usually against a control treatment) made up 35%–40% of the total, but because of their much larger size accounted for 70%–80% of the patients. Definitive Phase III trials are the "jewel in the crown" of the US cooperative group program; in Table 2 we give 15 of the most significant completed in the past decade. Accrual of the major histologic subgroups was approximately as follows [17]: breast cancer patients accounted for 4000 of the total annual accrual, colorectal cancer patients accounted for 2000, and lung cancer, ovarian cancer, central nervous system cancer, and prostate cancer patients accounted for 1000 each.

Pediatric cancer patients have accounted for approximately 5000 of the total annual accrual to treatment studies over the past decade, and this subgroup is remarkable in two respects. First, 95% of pediatric cancer patients in the US are seen at institutions belonging either to CCG or POG [36], with 80% of potentially eligible patients actually placed on a cooperative group protocol [7]. Secondly, there have been striking clinical advances in pediatric cancer, in particular since the advent of the National Cancer Program; for example, 4-year survival in pediatric leukemia on CCG protocols rose from 20% in the late 1960s to 80% in the mid 1980s [2], and dramatic survival increases in this disease and in other pediatric cancers have been seen on POG protocols [38].

Although the magnitude and structure of the clinical trials cooperative group program has been stable over the last decade, there have been two dramatic developments in the way in which Phase III trials are conducted. The first development involves the remarkable increase in the number of "intergroup" (involving more than one cooperative group) Phase III studies, particularly among the adult disease groups, where currently 80%–90% of phase III studies are intergroup efforts (accounting for 80%–90% of Phase III patients). Precise guidelines for the management of these trials were formulated in the early 1990s under the leadership of Eleanor McFadden, at Harvard. The second development involves the formalization of interim monitoring schemes and the establishment of **data and safety monitoring boards**. Up to the late 1970s it was common practice to report annual or semiannual interim outcome analyses of randomized studies to the entire cooperative group. By the mid 1980s the statistical dangers in such a practice were widely recognized, and interim outcome reporting was limited to a trial steering committee. Precise predefined interim monitoring schemes were used, which were developed by O'Brien et al. [15] to allow early termination in the case of dramatic treatment differences (*see* **Data and Safety Monitoring**) and then extended by Wieand & Therneau [49] to also allow early termination in the case of convincing evidence of lack of treatment differences. In the 1990s, under the leadership of NCI staff, in particular BRB statisticians, data safety monitoring committees were established. From the beginning these provided interim monitoring independent of individual trial leadership, and they now include a majority of members from outside the cooperative group itself.

Another dramatic recent development has been the increase in cancer prevention and control trials (*see* **Prevention Trials**), which have been conducted through the clinical trials cooperative groups and the CCOP. Over the last decade 30–40 such NCI-sponsored trials have been active at a given time. These trials tend to be much larger than the treatment trials, and they have their own particular statistical problems arising from low event rates and potentially high noncompliance rates [4] (*see* **Noncompliance, Adjustment for**). The two most

Table 2 Noteworthy US randomized trials of the last decade

Protocol no. Accretion dates Participants	Protocol name	Protocol significance
NSABP-B06 1976–84	A randomized clinical trial comparing total mastectomy vs. lumpectomy with or without irradiation in the treatment of breast cancer [12]	This study provided important data supporting the use of lumpectomy in patients with stage I or II breast cancer, and demonstrated that irradiation reduces the probability of local recurrence of tumor in patients treated with lumpectomy.
CALGB-8251 1982–87	Treatment of advanced Hodgkin's disease: randomized Phase III trial comparing MOPP vs. ABVD vs. MOPP alternating with ABVD [5]	While MOPP had been the standard chemotherapy regimen for advanced stage Hodgkin's disease, this study demonstrated that both ABVD and MOPP/ABVD were superior to MOPP. Additional advantages of ABVD compared to MOPP include lower risk of secondary leukemia and decreased incidence of sterility.
INT-0035 1985–87 ECOG NCCTG SWOG	Intergroup Phase III surgical adjuvant trial for stage B2 and C colon cancer [35]	The early results (the 1990 report) served as the basis for the National Institutes of Health Consensus Panel recommendation of 5-FU/levamisole as standard treatment in the US.
NWTS-3 1979–87 CCG POG	National Wilms' tumor study 3 [9] and subsequent National Wilms' Tumor Study Group trials have utilized the less intensive (yet efficacious) therapies identified in this study.	This study demonstrated that less intensive therapy does not appear to worsen results for low-risk patients,
POG-8314 1983–87	Localized non-Hodgkin's lymphoma: chemotherapy +/− radiotherapy [31]	This study demonstrated that radiotherapy can be safely omitted from the therapy of most children with localized non-Hodgkin's lymphoma without substantially jeopardizing their excellent chance of cure.
NSABP-B13 1981–88	A clinical trial to assess sequential MTX, 5-FU in patients with axillary node- and estrogen receptor + primary breast cancer [14]	This was one of the trials that resulted in the National Cancer Institute issuing a clinical alert in 1989 about the positive role of chemotherapy for selected subsets of women with node-negative breast cancer.
CALGB-8525 1985–90	Phase III comparison of post-remission intensive ara-C in patients with acute myelogenous leukemia in first remission [32]	This study demonstrated the importance of post-remission dose intensity of cytarabine for patients younger than 60 years of age, establishing high-dose cytarabine as standard consolidation therapy for this patient population.

Table 2 (*continued*)

Protocol no. Accretion dates Participants	Protocol name	Protocol significance
GOG-97 1986–90	Phase III randomized study of cyclophosphamide and cisplatin in patients with suboptimal stage III, IV ovarian carcinoma comparing intensive and nonintensive schedules [33]	Although preclinical and clinical data based on historical comparisons suggested that increased dose-intensity might improve outcome for women with ovarian cancer, this study demonstrated that a doubling of the dose-intensity in the treatment of bulky ovarian epithelial cancers led to no discernible improvement in patient outcome and was associated with more severe toxicity.
CALGB-8541 1985–91	Adjuvant CAF for pathologic stage II, node+ breast cancer: randomization among intensive CAF for 4 mo. vs. low-dose CAF for 4 mo. vs. standard-dose CAF for 6 mo. [50]	This study demonstrated a dose–response effect for adjuvant chemotherapy within the standard dose range. An important translational science finding that resulted from the clinical trial was the demonstration that the dose–response effect was limited to patients whose tumors overexpressed c-erbB-2.
INT-0032 1984–91 CCG IRSG POG	Intergroup rhabdomyosarcoma study III [8] Additionally, a subset of patients with favorable prognosis was identified for whom relatively non-toxic two-drug therapy resulted in very good outcome.	Intensification of therapy for most patients in this study, using a risk-based study design, significantly improved treatment outcome overall.
INT-0067 1986–91 ECOG SWOG	Phase III comparison of CHOP vs. M-BACOD vs. ProMACE-CytaBOM vs. MACOP-B in patients with intermediate or high grade non-Hodgkin's lymphoma [13]	Although single-institution, uncontrolled studies had suggested an advantage for third-generation regimens, this study demonstrated that CHOP remains the best available treatment for patients with advanced-stage intermediate-grade or high-grade non-Hodgkin's lymphoma, with decreased toxicity and expense compared to the third-generation regimens.
INT-R8501 1986–91 NCCTG RTOG SWOG	Phase III prospective trial for localized cancer of the esophagus comparing radiation as a single modality with radiation therapy plus chemotherapy [26]	This trial demonstrated an unequivocal survival advantage for combined modality therapy, specifically the addition of chemotherapy to radiation-based (nonsurgical) approaches in this rarely curable cancer. Studies to optimize combined modality therapy have followed this lead.

Table 2 (*continued*)

Protocol no. Accretion dates Participants	Protocol name	Protocol significance
GOG-111 1990–92	A Phase III randomized study of cyclophosphamide and cisplatin vs. paclitaxel and cisplatin in patients with suboptimal stage III and IV epithelial ovarian cancer [34]	This study was the first phase III trial of paclitaxel in the primary treatment of patients with cancer. It demonstrated that incorporating paclitaxel into first-line therapy improves both the duration of progression-free survival and overall survival in women with incompletely resected stage III and IV ovarian cancer.
RTOG-8808 1989–92 ECOG SWOG	Phase III study of radiation therapy alone or in combination with chemotherapy for patients with non-small cell lung cancer [40]	Patients with regionally advanced, surgically unresectable non-small cell lung cancer have a poor prognosis, and the standard therapy had been external beam irradiation to the primary tumor and regional lymphatics. The results from this trial confirmed the survival benefits and acceptable toxicity seen in a smaller randomized trial, and the standard of care for this patient population now includes a combination of radiotherapy and chemotherapy.
CCG-2891 1989–95	Treatment of children <21 with newly diagnosed acute myeloid leukemia and myelodysplastic syndrome [51]	This study is important for demonstrating that although early intensive therapy is more toxic than standard timing therapy, eventual outcome is improved by use of the timing intensive strategy.

noteworthy studies are the Breast Cancer Prevention Trial, conducted by NSABP and accruing 13 000 women from 1992 to 1997, which tests the ability of tamoxifen to prevent breast cancer in a high-risk population, and the Prostate Cancer Prevention Trial, conducted by SWOG and accruing 18 000 elderly men from 1993 to 1996, which tests the ability of dihydrotestosterone to prevent or delay prostate cancer [21].

Finally, we summarize some of the important developments in clinical trials methodology supported by the NCI in the last decade. Simon [42] has provided an excellent review of advances in clinical trials methodology in the 1980s, in which many of the NCI and cooperative group statisticians appear prominently, and we try to minimize overlap with this review. We organize the contributions into nine areas:

1. New Phase I trial designs: traditionally, phase I trial designs have used cohorts of three to six patients, treated at escalating doses of a new chemotherapeutic agent, to identify a maximum tolerated dose (MTD). New designs, with their associated methods for estimating the MTD, have been proposed by Storer [45], O'Quigley et al. [37], and Goodman et al. [22], and have had their statistical properties reviewed by Korn et al. [28].
2. New Phase II trial designs: Simon [41] proposed and studied two-stage Phase II designs that are optimal in the sense of minimizing the expected number of patients exposed to ineffective therapy.
3. Flexible interim monitoring rules: Lan & DeMets [29] further developed the "spending function" approach, which allows flexibility in the timing of formal interim analyses.

4. Stopping early for "negative" results: Thall et al. [47] and Wieand et al. [48] developed simple rules to allow early stopping if, with high probability, the treatment difference would not be statistically significant were the trial to continue to its originally planned end.
5. **Bayesian methods** in randomized trials: Breslow [3], Dixon & Simon [10], Spiegelhalter et al. [43], and Gray [24] used Bayesian methods to address some of the difficulties standard frequentist methods have with combining information from diverse sources for use in **sample size** calculations, inference after early stopping of trials, and **multiple comparison** problems.
6. **Surrogate endpoints**: Prentice [39] elucidated the statistical conditions necessary for an intermediate outcome to be a valid surrogate, thereby saving trial time or avoiding **confounding** because of treatment cross-over prior to the final outcome.
7. Innovative methods for identifying **prognostic factors**: Durrleman & Simon [11], LeBlanc & Crowley [30], and Gray [25] developed new methods to identify variables that may predict survival, including **spline** smoothing of variables, **quantile regression** and **tree-structured statistical methods**.
8. **Quality-of-life** endpoints: Gelber et al. [19] and Korn [27] proposed and studied new methods for analyzing quality-of-life endpoints, which have assumed increasing importance in clinical trials.
9. **Cure models**: Gray & Tsiatis [23] and Sposto et al. [44] developed and applied models for the case where treatment is anticipated to cure disease in addition to increasing survival for those not cured.

Cooperative Heart Disease Trials

The National Heart, Lung, and Blood Institute (NHLBI) of the **National Institutes of Health**, initially the National Heart Institute (NHI) and then the National Heart and Lung Institute (NHLI), has undertaken cooperative (**multicenter) clinical trials** in heart disease since the early 1960s (*see* **Cardiology and Cardiovascular Disease**). This article describes the evolution of trial structure, and draws on several of the best known trials as examples of how these large, cooperative trials were organized and carried out. A summary of early methodological developments for clinical trials at the National Heart, Lung, and Blood Institute, with greater emphasis on methodology, was given by Halperin et al. [43] (*see* **Clinical Trials, Early Cancer and Heart Disease**).

Prior to 1960, the National Heart Institute supported one multicenter clinical trial, a cooperative study of the relative merits of adrenocorticotropic hormone (ACTH), cortisone, and aspirin in the treatment of rheumatic fever and the prevention of rheumatic heart disease. This trial enrolled 497 children, a small number by present standards, at centers in Great Britain, Canada, and the United States. After six weeks of treatment and another three weeks of observation, it was concluded there was no evidence that any of the three agents cured the disease. At five years, there was no difference in the amount and severity of rheumatic heart disease, but it was observed that the status of the heart at the time treatment was begun was the major factor in determining prognosis. The final report (Rheumatic Fever Working Party of the Medical Research Council of Great Britain and the Subcommittee of Principal Investigators of the American Council on Rheumatic Fever and Congenital Heart Disease, American Heart Association [67]) contained extensive data tabulations by various subgroups, but virtually no statistical analysis. This trial gave little indication of the number of methodological developments that were to come out of trials sponsored by the NHI and its successors.

The Greenberg Report

In the mid-1960s, the National Advisory Heart Council appointed a Heart Special Project Committee chaired by Dr. Bernard **Greenberg** of the University of North Carolina School of Public Health, to set down guidelines for the organization, review, and administration of cooperative studies. The resulting "Greenberg Report", completed in 1967, was published in 1988 [64] and laid down a structure for NHLBI-sponsored clinical studies. The foresight of this committee is remarkable, as the procedures they laid down have been followed ever since, with only minor modifications.

The report defined a cooperative study as "an identified activity in which two or more investigators in separate institutions contribute toward a common research goal. . ., follow a common protocol and work within a clearly defined structure for the project as a whole." The pooled resources would minimize the length of time it would take to accrue subjects in order to obtain a significant answer to a clinical or epidemiologic problem.

There were four criteria for good studies:

"1. The problem to be studied is an important one that must be resolved (a) from a purely scientific point of view, or (b) for the benefit of mankind through improved methods of prevention, diagnosis, and/or therapy;
2. An answer must be obtained in a relatively short time, and a multiinstitutional collaborative effort is the best way to reach a solution in the briefest period;
3. The study is feasible within the potential cooperating institutions, and likely to lead to an answer; and
4. There is assurance of adequate leadership and control of performance for the duration of the study."

Ideally, the question to be answered would be clearly defined and simple. Competent biometric advice would be sought early for assistance in protocol design (*see* **Clinical Trials Protocols**). This set the stage for the active participation of the Biometrics Branch (later the Biostatistics Research Branch and now the Office of Biostatistics Research of NHLBI) as collaborators involved in the planning, design, implementation, and analysis of cooperative studies. The protocol itself should be clear in order to maintain a high scientific level in the project. Continuing strong leadership with a well-defined administrative structure and control of performance at all levels

would assure that the project was carried out to completion (*see* **Clinical Trials Audit and Quality Control**).

The basic units that were essential to achieve the aims of a cooperative study are the local units, which see the participants and collect the data. The Coordinating Center would receive the data, assure their quality, and undertake appropriate, and timely analyses. The Director of the Coordinating Center would monitor performance of the local units and have the authority to carry out policing activities (*see* **Data Management and Coordination**). An Executive or Steering Committee, comprised of a limited number of strong investigators, should supervise the Coordinating Center. It should be led by a study chair, the most important position in a cooperative project. An independent Policy Board or Advisory Committee of experts in the field of the study, but not contributing to the study should review study plans and offer substantial advice. Last, the Institute staff would interact with both the Steering Committee and the Policy Board, as well as with other advisors to the Institute (such as the National Advisory Heart Council as it was then called).

The role of the Institute in cooperative studies was also described. The staff should play an active role during the early planning phases, drawing on past experience, and acting as a liaison between review committees, the National Advisory Heart Council, and investigators. Continuing communication with investigators was also advocated, as was exertion of a considerable degree of control over the study itself. The suggestion was made that one staff member serve as the Project Officer for each study and that an appropriate means of funding such studies would be a phased contract mechanism.

Major Clinical Trials Sponsored by NHLBI

The major multicenter heart disease clinical trials sponsored by the NHLBI and initiated before 1980 are listed in Table 1. Several of the trials are discussed in detail below and references to the others are given for the interested reader [4–6, 12–14].

The Coronary Drug Project (CDP)

Preceding the Greenberg Report in design, but not completion, the Coronary Drug Project (CDP) was the first large, multicenter clinical trial sponsored by

Table 1 Multicenter clinical trials in heart disease sponsored by NHLBI with at least 500 patients initiated prior to 1980

Trial	No. centers	Treatments (sample size)	Dates
Coronary Drug Project (CDP)	53	Clofibrate (1103) Niacin (1119) Dextrothyroxine (1110) Estrogen - low dose (1101) Estrogen - high dose (1119) Placebo (2789)	1966–1969
Hypertension Detection and Follow-up Program (HDFP)	14	Stepped care (5485) Referred care (5455)	1971–1975
Multiple Risk Factor Intervention Trial for the Prevention of Coronary Heart Disease (MRFIT)	22	Special intervention (6428) Usual care (6438)	1972–1983
Lipid Research Clinics Coronary Primary Prevention Trial (LRC)	12	Cholestyramine (1906) Placebo (1900)	1973–1983
Coronary Artery Surgery Study (CASS)	15	Surgery (390) Medical (390)	1973–1983
Program on Surgical Control of Hyperlipidemias (POSCH)	4	Surgery (421) Control (417)	1973–1990
Aspirin Myocardial Infarction Study (AMIS)	30	Aspirin (2267) Placebo (2257)	1974–1979
β-Blocker Heart Attack Trial (BHAT)	31	Propranolol (1916) Placebo (1921)	1977–1981
Multicenter Investigation of Limitation of Infarct Size (MILIS)	5	Propranolol (134) Hyaluronidase (420) Placebo (431)	1978–1988

NHI and was designed to assess the efficacy of several lipid modifying drugs in men between 30 and 64 years of age who had previously had a myocardial infarction (MI). The initiation of such a trial was recommended by the National Heart Advisory Council in 1960 and planning began in the Institute in early 1961 [78].

Several years of budgetary and political negotiations followed. Finally, with a Policy Board, a Coordinating Center, and five clinics in place, the first participant was enrolled in 1966, and with 48 additional clinics, enrollment of 8341 participants was completed in 2.5 years. All participants were followed for a minimum of 54 months, with 96% followed up for at least five years [17].

Randomization was performed by the Coordinating Center, stratified on clinic and risk (whether the participant had one prior MI with no complications or was of higher risk) (*see* **Randomized Treatment Assignment**). Double-blinded (neither participant nor treating physician knew which treatment a participant received) and placebo controlled (*see* **Blinding or Masking**), the study treatments included two doses of equine estrogens, clofibrate, dextrothyroxine, nicotinic acid, and a lactose placebo. Two and a half times as many subjects were assigned to placebo as to any other treatment, which is optimal allocation when five treatments are being compared with a single **control**. The sample size was set to detect a 30% mortality in the control group and 22.5% (a 25% reduction in mortality) in any treatment group when the mortality percentage in any treatment group was compared to that of the control group at the 1% significance level (one-sided test using an arc sine **transformation** with 95% **power** (*see* **Sample Size Determination for Clinical Trials**). Further sample size adjustments were made for the possibility of dropouts and treatment withdrawals as well as the time necessary to achieve maximum benefit of treatment [31, 45].

The CDP investigators had the foresight to consider many important aspects of trial design: optimal allocation when multiple treatments are compared to a single control; that there would be dropouts, which would cause loss of power and so the sample size should be increased to compensate; that treatment benefit was not likely to be attained instantaneously; and that there should be an adjustment of the significance level at which tests were conducted because there would be **multiple comparisons** [31]. Although methodology for sample size calculations has greatly advanced, new methods consider these same principles. The final results paper of the CDP, reported results based on an **intention to treat analysis**: all patients randomized were included, no matter how well or poorly they adhered to the treatment plan [35]. The final analysis reported on both the planned analysis (the proportion of events at the end of the trial, which was used for trial design), and the **Cox proportional hazards** model [33]. At the time of the design of the CDP, no methods for calculating sample size for time-to-event data were known (*see* **Sample Size Determination in Survival Analysis**).

The Steering Committee of the CDP consisted of the study chair, the director of the Coordinating Center, several study principal investigators (some permanent and others rotating), the NHI Medical Liaison Officer, directors of the ECG reading center and the central laboratory, and biostatistical representation from the Biometrics Research Branch. It met twice a year throughout the study. The CDP technical group represented all operational units participating in the CDP. Initially, unblinded data reports by study treatment were presented to the CDP technical group but, recognizing the potential for compromising the trial, in 1968, a data and safety monitoring committee (DSMC) (*see* **Data Monitoring Committees**) was appointed to review the accumulating data by treatment group. The Policy Board advised on policy matters and consisted of five voting members, all of whom were independent of the study investigators. In addition, nonvoting members from the Coordinating Center, Steering Committee, and Institute attended meetings. The Policy Board acted on the recommendation of the DSMC regarding continuation of the study or discontinuation of one or more treatment groups. Aside from these structural committees, there were trial committees, such as the Editorial Review Committee that reviewed and approved all plans for papers and composition of writing committees and all oral presentations [17].

As for the results of the CDP, adverse effects of the two estrogen treatments and of dextrothyroxine led to successive halting of these treatments [29, 30, 32] and continuation of the others. Several monitoring procedures were used as the data accumulated [16, 28, 46] (*see* **Data and Safety Monitoring**). A good summary is given by Canner [18]. Of participants who had received the treatments that were stopped

early, 1529 were randomized into a double-blind trial of aspirin versus placebo [34].

At the end of the CDP, no evidence of efficacy was found for clofibrate, and some was found for nicotinic acid with respect to definite, nonfatal MI, but not for total mortality [33]. Subsequent 15-year follow-up of the study participants showed a statistically significant reduction in total mortality from nicotinic acid [19].

Hypertension Detection and Follow-up Program (HDFP)

While the CDP developed or implemented many of the designs and biostatistical features that are currently used in multicenter clinical trials, modifications and new concepts were incorporated into subsequent trials. The Hypertension Detection and Follow-up Program (HDFP) began in the early 1970s [47–50]. This trial of the effects of antihypertensive treatment on mortality in 10 940 high blood pressure participants was novel in several respects. First, it had broad **eligibility criteria**: anyone aged between 30 and 69, with diastolic blood pressure 90 mm Hg or over was eligible. As a result, some of the participants had preexisting diseases (stroke, myocardial infarction, and renal disease), although most did not. Secondly, all but one of the collaborating centers enrolled participants in residential areas, thus making it a community-based study. Thirdly, almost half (about 45%) of the participants were women and about the same number were black. Fourthly, the HDFP used a stepped care approach to intervention, with medication being prescribed in a standard sequence in order to achieve the blood pressure goal. The control group received "referred care", that is, usual medical care, and the study was not blinded; in other words both participants and investigators were aware of the treatment arm to which each participant was assigned. To assure no bias was introduced as a result of treatment being known to participants (*see* **Bias, Overview**), the primary **outcome** was five-year all-cause mortality, and secondary outcomes were objective measures of heart disease and stroke, which were assessed at regular intervals. It might be noted that, like the CDP, the HDFP had two monitoring groups. One, called the *Toxicity and Endpoints Evaluation Committee*, reviewed data, endpoints, and toxicity reports at specified intervals. Membership on this committee included the chair of the Policy Advisory Board, the head of the Coordinating Center, several clinical investigators (some of whom were involved in the study, but did not see study patients), and Institute staff. The other monitoring group, the Policy Advisory Board, was entirely external to the study, and monitored the trial and advised the Institute on its progress.

The conclusion of HDFP was that stepped care was superior to referred care both with respect to control of diastolic blood pressure and with respect to overall mortality at five years. Five-year mortality from all causes was 17% lower in the stepped care group compared to the referred care group. The trial led to a recommendation for systematic, effective management of hypertension for its great potential to reduce mortality from hypertension, including those with "mild" hypertension (diastolic blood pressure 90–104 mm Hg) [48]. Because it was recognized that power was limited to detect differences in various subgroups of interest, substantial care was taken in reporting results in race, sex, and age subgroups (*see* **Treatment-covariate Interaction**); no ***P*-values** were reported [49, 50].

Multiple Risk Factor Intervention Trial (MRFIT)

A third major multicenter clinical trial was the Multiple Risk Factor Intervention Trial (MRFIT) [61], which was started in 1972. This primary **prevention trial** selected participants at high risk of developing heart disease, based on a **logistic regression** equation developed by **J. Cornfield**, and others of **prognostic factors** based on the **Framingham Heart Study** [71]. A combination of serum cholesterol and blood pressure levels as well as number of cigarettes smoked per day determined eligibility. The intervention consisted of efforts to reduce those risk factors (diet for cholesterol, drug for blood pressure, and behavioral intervention for smoking). The power to detect benefit from any one of the interventions was quite low, and therefore, the study was designed to compare the intervention to the control group. As with the HDFP, the control group received only usual medical care, the study was not blinded, and the outcomes were measured only annually, so the more frequent evaluations of the intervention group would not bias the endpoint assessment. This trial began with a dual external data monitoring/oversight organization, but evolved to a single oversight committee because of greatly overlapping responsibilities [41]. Despite the

use of the best available data for outcome incidence during the design phase, the event rates at the end of the trial were lower than expected and no difference was found in the primary endpoint, coronary heart disease deaths, at six years [62]. It is likely that a combination of self-selection factors for volunteer studies (*see* **Selection Bias**) and secular trends, due to enhanced appreciation in the community of the need to treat risk factors, were largely responsible. Efforts have been made in subsequent studies to account for such possibilities. Long-term assessment of mortality in MRFIT was continued, and a trend in favor of the special intervention group was seen after 10.5 years [63].

Lipid Research Clinics Cholesterol Primary Prevention Trial (LRC-CPPT)

While HDFP had broad eligibility criteria, the Lipid Research Clinics Cholesterol Primary Prevention Trial (LRC-CPPT) [54], started two years later, had much narrower eligibility criteria. It was entirely a primary prevention study in the sense that all participants were to be free of existing heart disease. Also, it used a combination primary outcome, definite coronary heart disease death and/or a definite nonfatal myocardial infarction. The bile acid sequestrant, cholestyramine, was compared with placebo after 7.4 years of double-blinded treatment of 3806 asymptomatic 35 to 59 year old men with hypercholesterolemia.

Of note, according to the original analysis plan, a one-sided significance level of 5% was used to declare statistical significance (*see* **Hypothesis Testing**). The one-sided **logrank** test (stratified on eight baseline risk factors and adjusted for multiple looks at the data: *see* **Multiplicity in Clinical Trials**) yielded a P-value just under 5% in favor of the active treatment [55, 56]. Because the results would not have been statistically significant, had a two-sided significance level of 5% been used, they generated some controversy [51]. Many in the cardiovascular clinical trials community prefer two-sided hypothesis testing to one-sided testing and believe that if a one-sided test is done, the significance level should be 2.5% rather than 5%. Had the LRC-CPPT been designed with a two-sided significance level of 5% (or a one-sided significance level of 2.5%), the sample size would have had to be larger. Despite the controversy, it was clear that cholestyramine decreased primary outcome events compared with placebo, and the results of this trial were instrumental in public campaigns to reduce serum cholesterol levels.

Other Secondary Prevention Trials of the 1970s and 1980s

Several secondary prevention trials that began in the mid- to late 1970s, and the 1980s made further design and biostatistical advances. New stopping guidelines for data monitoring were incorporated. In the Multicenter Investigation of Limitation of Infarct Size (MILIS), patients who had had a myocardial infarction in the previous 18 hours were randomized to propranolol or placebo, or in patients in whom propranolol was contraindicated, to hyaluronidase or placebo [60]. Conditional power was used to declare propranolol ineffective before the scheduled end of the trial [68]. Conditional power assesses the probability that a difference will be found at the end of a trial considering the results up to the time of the calculation, and making a variety of assumptions about the future, including continuation of the current trend (leading to "stochastic curtailment"; *see* **Data and Safety Monitoring**). The final results, that hyaluronidase was no better than placebo, were later reported [59].

The β-Blocker Heart Attack Trial (BHAT) randomized 3837 patients recovering from myocardial infarction to propranolol or placebo administered in a double-blind manner to assess overall mortality during a two- to four-year period [8–10]. The sample size was set by a new method to allow for **noncompliance** [8, 15, 37, 76]. Both conditional power and group sequential boundaries (*see* **Sequential Methods for Clinical Trials**) were used to stop the study nine months early because of significant benefit of propranolol [9, 10, 37, 44, 52, 53]. Also, assuming the current trends, the gain in precision in estimating survival distributions had BHAT continued to its planned termination was examined [37].

The Coronary Artery Surgery Study (CASS) compared coronary artery bypass surgery to medical therapy in participants with either angina or previous myocardial infarction [24]. No significant difference was found between the two treatments with respect to survival or to nonfatal myocardial infarction, although the bypass group had a lower event rate than did the medical group. The results were explained by the event rate in the medical group being lower than

others had reported. This was perhaps due to entry of participants with better prognostic factors or due to the method used to confirm nonfatal myocardial infarction [25, 26].

One of the concerns about clinical trials is that the **study population** is not representative of the general population of those with the condition (*see* **Clinical Trials, Overview**). To address this criticism, CASS used a registry of participants not enrolled in the randomized trial to assess generalizability of the trial results. It found that results from the trial were comparable with findings from the registry [27], and were certainly reassuring.

The Cardiac Arrhythmia Suppression Trial (CAST) was designed in 1986 to assess the effectiveness of antiarrhythmic therapy in postmyocardial infarction patients with ventricular arrhythmias. In preparation, a pilot study, the Cardiac Arrhythmia Pilot Study (CAPS) was conducted to assess feasibility, and answer certain other design questions essential to the optimal design of the full-scale trial [20, 21]. This pilot study was separate from the full-scale trial. Other studies have since employed an internal pilot [7]; that is, the study is designed so that the pilot data can be included in the final trial's analysis. The sample size for the whole study can be based on certain pilot information (such as variability and estimation of control group event rates) and if there are no changes in the eligibility or interventions, there is little impact on the trial's significance level. Some have argued that an internal pilot approach increases study efficiency [72].

One of the results of CAPS was that it was recognized that some patients with arrhythmias could have them suppressed by at least 80% by some, but not all, of the drugs under study. In CAST, during a run-in period, patients received one of the three active treatments. If that first drug suppressed their arrhythmia, they were randomized between it and placebo. If the first drug did not suppress their arrhythmia (either at the initial dose or at a higher dose), they received another active drug. After this run-in, if their arrhythmias were not suppressed, they were not randomized. Thus, CAST did not compare three active treatments and placebo, but tested the hypothesis that suppressing arrhythmias with *any* of the three drugs would reduce the risk of arrhythmic death or cardiac arrest when compared to placebo. This design was an attempt to mimic treatment in clinical practice.

In CAST, the formal test of significance was one-sided (for benefit) with a 2.5% significance level, but there were advisory stopping guidelines for harm. The CAST Data and Safety Monitoring Board decided initially to remain blinded to which group was intervention and which was control. In the first part of CAST, the advisory stopping boundary for harm was symmetrical to the guideline for benefit [65]. A strong trend for difference in mortality was noted early, but the Data and Safety Monitoring Board decided that regardless of the direction, the study should continue. Because of an increasing difference, the Board was unblinded, and learned that it was in a direction harmful for the treatment group, with the advisory boundary for harm being crossed [11, 42]. As a result, encainide and flecainide, two of the three drugs being used in the treatment arm, were discontinued [22].

In CAST II, randomization between the third antiarrhythmic drug, moricizine, and placebo continued. The advisory stopping boundary for harm was less extreme than the boundary for benefit, reflecting the view that less evidence would then be required to stop if the trend were going in an unfavorable direction. Another difference in the second part of CAST was that assessment of the proper dose of antiarrhythmic drug, which had been done in an open fashion in the first part of CAST, was done blinded, with a placebo control. CAST II was also stopped ahead of schedule. Conditional power calculations showed that the remaining antiarrhythmic drug was extremely unlikely to be proven beneficial. In addition, during the dose-ranging incorporated in the study, there was strong evidence of harm from the active agent [23].

As has been noted [42], CAST provided several data monitoring lessons. First, if a one-sided test of hypothesis is used, a plan to monitor the data should be in place, even for trends in the unanticipated direction. Second, adverse events can accumulate quickly, and the monitoring guidelines need to be in place from the beginning of the trial. Third, in placebo-controlled trials, monitoring adverse events is not a symmetric process, suggesting that it is not wise for a data monitoring committee to be blinded to treatment assignment. Fourth, a variety of factors, both statistical and nonstatistical, are considered in monitoring. Statistical monitoring guidelines can assist, but cannot replace, judgment about when to stop, continue, or modify a study protocol.

Designs of Other Multicenter Trials

Multicenter clinical trials since the late 1980s evolved in other directions, with more studies including **cluster randomization** designs, large simple designs, and **factorial designs**.

Cluster (group) randomization has been undertaken in several trials in which special health-promoting interventions in schools or communities are compared with usual procedures. The Child and Adolescent Trial of Cardiovascular Health (CATCH) randomized schools and intervened in the third through fifth grades with respect to lower fat content school lunches, enhanced physical education, and enhanced classroom health curricula [57, 77]. The Rapid Early Action for Coronary Treatment (REACT) trial randomized 10 matched pairs of cities to evaluate a community-based intervention aimed at reducing delay time from onset of heart attack symptoms to hospital arrival [58]. In such trials, the cluster is the unit of randomization and it is imperative to consider that in both the design and analysis (*see* **Unit of Analysis**).

The large, simple trial design has been adopted, when appropriate, as in the Digitalis Investigation Group (DIG) trial, a trial of digitalis in patients with heart failure [38, 39]. Although earlier studies had collected limited data and had many clinics, they had short-term interventions and follow-up. DIG was one of the first to use that approach in a trial requiring long-term drug administration and follow-up. Other trials, such as the Studies of Left Ventricular Dysfunction (SOLVD), a trial of an angiotensin-converting enzyme inhibitor in patients with poor left ventricular ejection fraction, combined a relatively simple protocol with numerous substudies aimed at assessing detailed physiologic, biochemical, or behavioral mechanisms [69, 70].

Factorial designs have become more commonly used. Sometimes this design has been used in the traditional manner, as in the Post-Coronary Artery Bypass Graft Trial (Post-CABG), a two-by-two factorial trial of intensive versus moderate lipid-lowering and low-dose anticoagulation versus placebo in patients who had had coronary bypass surgery [66]. Other trials have had a "partial factorial" design. These have consisted of separate trials of interventions believed to be independent (as in a factorial design), with some, but not all of the subjects enrolled in more than one of the trials. These partial factorial designs are often analyzed as independent trials as they would be in a factorial design.

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) consisted of two large, simple trials with a partial factorial design. One of the trials compared a diuretic to three newer antihypertensive agents (amlodipine, a calcium agonist, lisinopril, an ACE inhibitor and doxazosin, an α-adrenergic blocker) in high-risk hypertensive people to see if there were differences in the occurrence of fatal coronary heart disease or nonfatal myocardial infarction. This trial was designed to enroll 40 000 eligible participants with hypertension, and intervene and follow them for a mean duration of six years. The second ALLHAT trial offered those who were moderately hypercholesterolemic the opportunity to be randomly assigned to open-label pravastatin, a lipid-lowering drug, or usual care, with total mortality as the primary outcome. Not only was this trial a partial factorial design, intended to be conducted with limited data collection, it was designed to be carried out in clinical practice settings. Over 600 practices took part in the antihypertensive component and over 500 in the lipid-lowering component [36].

The α-adrenergic blocker arm of ALLHAT was stopped early because of an excess of combined cardiovascular events, in particular, heart failure. The other three hypertensive treatment arms continued, with the result that each of the newer agents was no better than the diuretic [1, 2]. The results of the lipid-lowering component were that pravastatin did not reduce either all-cause mortality or CHD significantly when compared with usual care, perhaps due to the modest differential in total cholesterol between pravastatin and usual care groups [3]. This study demonstrated that given important clinical questions and a sufficiently simple protocol, many physicians and nurses not traditionally associated with clinical research could effectively participate.

A large study that is far from simple is the Women's Health Initiative (WHI) (*see* **Women's Health Initiative: Statistical Aspects and Selected Early Results**). This study in postmenopausal women was started in 1992, and includes four clinical trials with a partial factorial design. Two trials, in women with and without a uterus, randomized participants to hormone replacement therapy (combined estrogen and progesterone in women with a uterus and estrogen alone in women without a uterus) or placebo

to test whether coronary heart disease and other cardiovascular diseases and hip and other fractures could be reduced. A third trial of a low-fat eating pattern versus usual dietary advice was designed to see if breast cancer, colorectal cancer, and coronary heart disease could be reduced. Subjects could enter both a hormone replacement trial and the diet trial. The fourth trial of the WHI randomized women to calcium and vitamin D supplementation or placebo to see if hip and other fractures and colorectal cancer could be reduced. To enter the calcium and vitamin D supplementation trial, a subject had to be enrolled in either one of the hormone replacement therapy trials or the diet trial. In addition, a large observational study component was conducted along with the clinical trial [74].

The WHI is notable for several reasons. First, it is a very large undertaking, with approximately 68 000 women in one or another of the trials. Second, a partial factorial design was employed and the trials are treated as independent trials. Third, the observational component has over 93 000 women, providing considerable information along with the trial. Fourth, a trial of such complexity and societal import requires careful monitoring of the many endpoints of interest. The statistical stopping rules for the hormone replacement trial not only monitored the primary and secondary endpoints, but also considered adverse events. An overall measure of risk and benefit was also assessed [40].

The first results from the WHI were published in 2002. The hormone replacement trial in women with an intact uterus was stopped early due to an early increase in breast cancer, the primary adverse event. Somewhat surprisingly, the combination of estrogen and progestin not only led to an expected increase in breast cancer and reduction in bone fractures, it caused an increase in cardiovascular disease [75]. This last finding was contrary to expectation based on many epidemiology studies, showing the hazards of relying only on **observational studies**. In 2004, the WHI trial of estrogen-alone, in women who had had a hysterectomy, was also stopped ahead of schedule. This was a more difficult decision. The study showed the expected reduction in bone fractures, and there was an unexpected non-significant trend in the direction of fewer cases of breast cancer. Importantly, however, estrogen increased the risk of stroke and did not reduce the risk of coronary heart disease [73].

Summary

This review of NHLBI-sponsored multicenter trials in heart disease illustrates some design and biostatistical advances that selected trials have developed or used effectively to answer important public health questions. Many of the design, organizational characteristics, and methods for monitoring modern clinical trials were implemented as a result of the Greenberg Report and were first used in the CDP. While more recent studies employed more efficient organizations, newer designs, and newer monitoring guidelines, the genesis of multicenter clinical trial practice in heart disease was outlined in the 1960s and that early structure has endured the test of time.

Cooperative Studies Program, US Department of Veterans Affairs

The Department of Veterans Affairs (VA) is in a unique position in the US, and perhaps the world, in conducting **multicenter clinical trials**. This is due to several factors: (1) its network of 172 medical centers geographically dispersed throughout the country, under one administrative system; (2) a dedicated group of talented physicians and other health professionals serving at these medical centers; (3) a loyal and compliant patient population of nearly four million veterans; (4) a system of experienced coordinating centers that provide biostatistical, data processing, pharmacy and administrative support; and (5) a research service that recognizes the uniqueness and importance of the program and strongly supports its mission. The VA has conducted multicenter clinical trials for more than half a century, beginning with its first trial, which was organized in 1945 to evaluate the safety and efficacy of chemotherapeutic agents for tuberculosis. This article describes the history of the program, its organization and operating procedures, some of its noteworthy trials, and current challenges and opportunities.

History of the Cooperative Studies Program (CSP)

The first cooperative clinical trial conducted by the VA was a joint study with the US Armed Forces to evaluate the safety and efficacy of chemotherapeutic agents for tuberculosis. Drs John B. Barnwell and Arthur M. Walker initiated a clinical trial to evaluate various drugs in the treatment of tuberculosis, including the antibiotic streptomycin [3, 48]. The challenge of caring for 10 000 veterans suffering from the disease following World War II was the impetus for the study. Not only did the results revolutionize the treatment of tuberculosis, they also led to the development of an innovative method for testing the effectiveness of new therapies – the cooperative clinical trial.

A VA Program for conducting cooperative studies in psychiatry was started in 1955 and supported by a newly developed Central Neuropsychiatric Research Laboratory at the Perry Point, Maryland VA Medical Center (VAMC). This Program emphasized the design and conduct of randomized trials for the treatment of chronic schizophrenia. Trials were completed evaluating the efficacy of prefrontal lobotomy [2], chlorpromazine and promazine [8], phenothiazine derivatives [10], other psychotropic drugs [9, 31], the reduction or discontinuation of medication [6], the combination of medication and group psychotherapy [20], brief hospitalization and aftercare [7], the need for long-term use of antiparkinsonian drugs [30], and intermittent pharmacotherapy [43].

Noteworthy VA cooperative clinical trials in other disease areas were started in the late 1950s and 1960s. A VA cooperative study group on hypertension was started in the 1950s (and still exists today). This group was the first to show that antihypertensive drug therapy reduces the long-term morbidity and mortality in patients with severe [54] and moderate [55] elevations of blood pressure. Other areas researched by the early VA cooperative studies included: use of long-term anticoagulants after myocardial infarction; lipid lowering drugs to prevent myocardial and cerebral infarction; treatment of gastric ulcer disease; efficacy of gamma globulin in posttransfusion hepatitis; analgesics to reduce postoperative pain; surgical treatment of coronary artery disease; the effect of portal caval shunt in esophageal varices; and the effects of radical prostatectomy, estrogens, and orchiectomy in the treatment of prostate cancer.

In 1962, the VA developed a concept, novel in Federal Government medical research programs at that time, of providing its investigators access to techniques and specialized help and information essential to their research. Four regional research support centers were established: the Eastern Research Support Center at the West Haven, CT VAMC; the Midwest Research Support Center at the Hines, IL VAMC; the Southern Research Support Center at the Little Rock, AR VAMC; and the Western Research Support Center at the Sepulveda, CA VAMC (*see* **Data Management and Coordination**). Individual investigators were assisted in such areas as research design, statistical methods, data management, computer programming, and biomedical engineering. The early VA cooperative studies were coordinated by VA Central Office staff in Washington, DC, by these regional research support

centers, and by contracts with university coordinating centers. The program was led by Mr Lawrence Shaw.

Beginning in 1972, a special emphasis was placed on the CSP in the VA's Medical Research Service and its budget was quadrupled over the next decade. Under the leadership of James Hagans, MD, PhD, the program's current organization and structure were developed and codified in the *Cooperative Studies Program Guidelines* [1]. This included the establishment of four statistical/data processing/management coordinating centers and a research pharmacy coordinating center solely dedicated to conducting cooperative studies; central human rights committees attached to each of the statistical coordinating centers; a standing central evaluation committee for the review of all new proposals for VA cooperative studies and all ongoing studies every three years; and clearly defined procedures for the planning, implementation, conduct, and closeout of all VA cooperative studies. The Central Neuropsychiatric Research Laboratory at the Perry Point, MD VAMC; the Eastern Research Support Center at the West Haven, CT VAMC; the Midwest Research Support Center at the Hines, IL VAMC; and a new center at the Palo Alto, CA VAMC were established as the four new VA Cooperative Studies Program Coordinating Center (CSPCCs). The Cooperative Studies Program Clinical Research Pharmacy Coordinating Center (CSPCRPCC) was established at the Washington, DC VAMC, but later relocated to the Albuquerque, NM VAMC in 1977.

Daniel Deykin, MD was the first person to head simultaneously the VA research programs both in Health Services Research and Development and the CSP, from 1985 to 1996. He took advantage of this opportunity to promote the development of a series of multicenter clinical trials in the organization and delivery of health services. These trials represented unique challenges in design and conduct. Some of these trials have recently been completed and are in the process of being published [25, 44, 57].

In 1996, John Feussner, MD, MPH was appointed as the VA's Chief Research & Development Officer, and simultaneously assumed leadership of the CSP. Up until the time Dr Feussner was appointed, the VA Research Service was composed of three major research programs – Medical Research (of which the CSP was a part), Rehabilitation Research & Development, and Health Services Research & Development. Dr Feussner moved the CSP out of the VA Medical Research Service and elevated the Program to an equal level with the three other major VA research programs. New emphases brought to the Program by Dr Feussner include: initiation of a strategic planning process; more integration and interdependence of the coordinating centers; institution of good clinical practices and standard operating procedures at the coordinating centers; pharmaceutical manufacturing; experimentation to improve the process of informed consent [32]; educational programs in clinical research for VA investigators; partnering with industry, National Institutes of Health (NIH), and international clinical trials groups; the development of three new Epidemiology Research and Information Centers at the VAMCs in Seattle, WA, Boston, MA, and Durham, NC [5]; and Intranet and Internet communications. The strategic planning process initiated in 1997 defined the vision, mission, and specific goals for the Program (Table 1).

Organization and Functioning of the CSP

This section describes how a VA cooperative study evolves and the support provided by the VACSP.

Table 1 Vision/mission/goals of the VACSP

Vision
- The CSP is a premier research program conducting multicenter studies with world-wide impact on health care

Mission
- To advance the health and care of veterans through education, training, and collaborative research studies that produce innovative and effective solutions to national healthcare problems

Goals
- To enhance the proficiency of CSP staff and CSP partners (chairpersons, participating investigators) in the conduct of multicenter trials
- To enhance the consistency of management support for the CSP
- To increase the flow of new research ideas for cooperative studies
- To increase the application of research products into clinical practice
- To enhance the interdependence of the CSP coordinating centers
- To improve the capabilities of dissemination of research findings

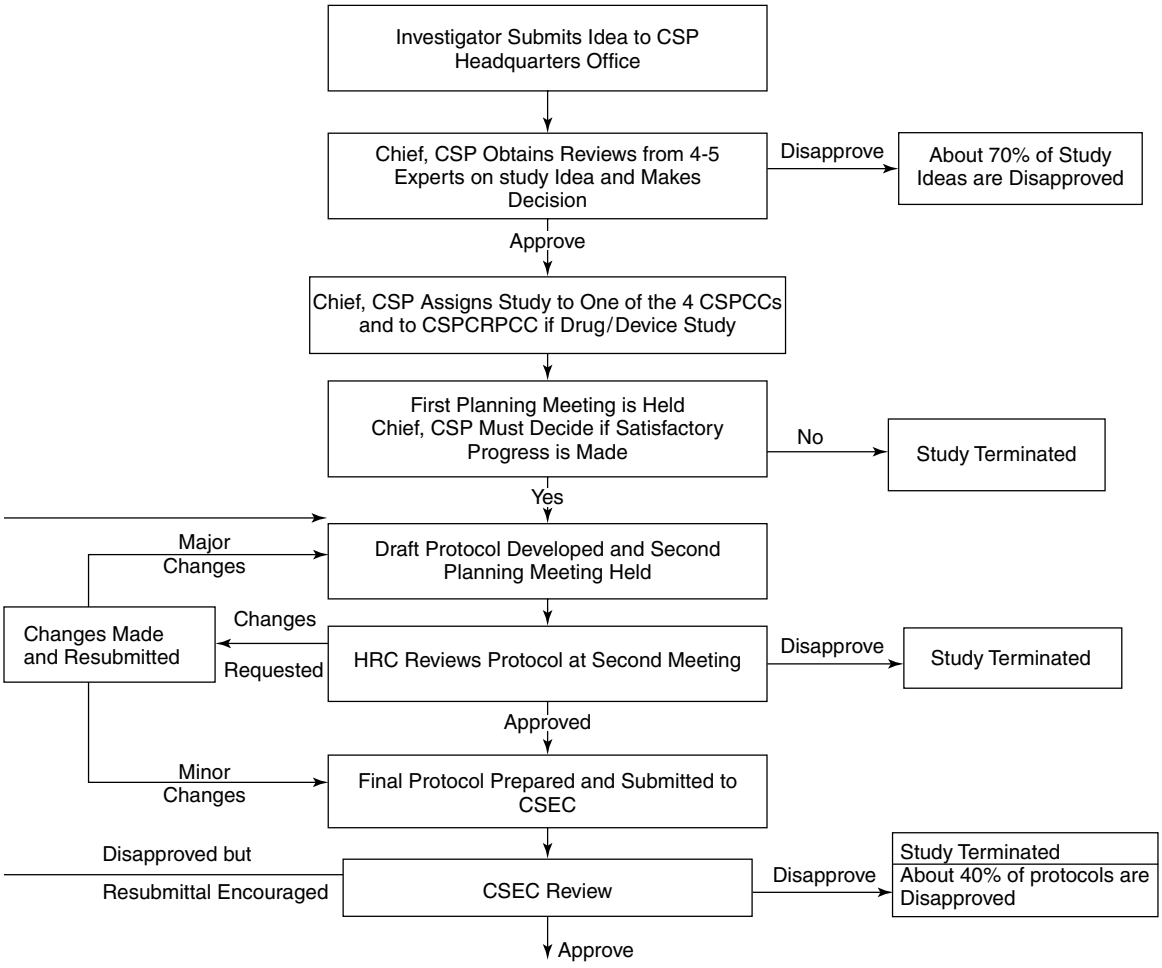

Figure 1 Development of a VA cooperative study

These aspects of the Program have been reported previously [24, 27, 28].

Planning Request

Initiation of a planning request through the evaluation phase is outlined in Figure 1. The VA Research Program, including the CSP, involves strictly intramural research. To receive VA research funding, the investigator must be at least five-eighths time VA. One of the strengths of the CSP is that most of its studies are investigator-initiated. The research questions come from investigators throughout the VA health care system who are on the front lines in providing health care for veterans.

To start the process, the investigator submits to VA Headquarters a 5–10 page planning request outlining the background of the problem, the hypothesis, a brief overview of the design, and anticipated size of the study. The planning request is given a CSP number to aid in tracking the study through its evolutionary phases. The planning request is sent to four or five independent experts in the field who initially judge the importance and feasibility of the study. If this review is sufficiently positive, the study is put into planning and assigned to one of the CSPCCs (and the CSPCRPCC if it involves drugs or devices) for development of the full proposal.

This process has evolved to satisfy two important needs. First, the CSP recognizes that the ability to

come up with a good idea needing rigorous test does not necessarily carry with it the ability to pull together all the expertise necessary to plan a clinical trial. This was especially true in the early days, when "trialists" were few and far between, and clinical researchers seldom had training in modern statistical trials design. So it is important to provide access to this expertise early in the planning process. However, such aid is expensive and scarce, so it is important not to waste it on ideas that do not show promise. Thus, the second need is for an initial concept review. This has proved to be a very efficient allocation method; about 70% of all initial proposals are not approved to go on to planning, and of the surviving 30%, about two-thirds complete the planning process. Of those that are successfully planned, about three-quarters are approved and funded. Thus, the method helps to avoid the problem of insufficiently developed **protocols**, while conserving the scarce resources of planning.

Planning Phase

Once the study is approved for planning, the resources of the CSPCCs are applied to the development of the full proposal. Within the coordinating centers, the study is assigned to a specific biostatistician and clinical research pharmacist. These individuals work with the principal proponent in nominating a planning committee which is reviewed and approved by the CSPCC and CSP Directors. The planning committee generally consists of the principal proponent, study biostatistician, study clinical research pharmacist, CSPCC Director, two or three potential participating site investigators, and outside consultants, as needed. The planning committee is funded for two planning meetings. At the first meeting, the basic design features of the study are agreed upon (hypothesis, patient population, treatment groups, primary and secondary endpoints, pharmacologic and drug handling issues, baseline and follow-up data collection and frequency, treatment effect size, sample size, number of sites, duration of study, publication plan, and budget). The full proposal is then written, and at the second planning meeting a draft of the protocol is fine-tuned. Development of a full proposal generally requires six to nine months.

Evaluation Phase

The completed proposal is first reviewed by the Human Rights Committee (HRC) attached to the CSPCC. This committee is comprised of scientists and laypeople from the community who review proposals for all new VA cooperative studies and all ongoing studies annually. The committee serves as a central Institutional Review Board (IRB) for studies assigned to the CSPCC and considers such aspects of the proposal as risks versus benefits to the patients, patient management, burdens placed on the patients from participation in the study, community equipoise with regard to the treatments being compared, and the informed consent procedures. This committee has absolute authority over approval or disapproval of the study. Only the HRC has the authority to change its own decisions. The composition of the committee follows VA regulations and is consistent with Food and Drug Administration (FDA) guidelines. Minimum membership of the HRC includes a VA chairperson, a practicing physician from the community, a nonphysician scientist, a veteran representative, a member of a recognized minority group, a clergyman or ethicist, and an attorney.

If the HRC approves the study, then the proposal is submitted to VA Headquarters for scientific review and a funding decision. The proposal is sent to four or five experts in the field and a biostatistician for written reviews. All cooperative study proposals are reviewed by a standing scientific review committee, called the Cooperative Studies Evaluation Committee (CSEC). This committee is composed of senior physician scientists and biostatisticians who have had extensive experience in cooperative studies and clinical trials. The CSEC meets in the spring and fall of each year. The principal proponent and study biostatistician present the study to the CSEC in person (reverse site visit), defend their proposal and answer questions from the CSEC members. The CSEC then goes into executive session, and decides to recommend approval or disapproval of the study and, for approvals, gives a scientific priority score, ranging from 10 to 50 with 10 being the best score. The final funding decision is made by the CSP Director. The advantages of this review process are that the study investigators have the opportunity to interact personally with the review body to answer their criticisms and concerns, and the final decision is known immediately following the review and executive session.

Implementation of the Trial

Implementation and conduct of a VA cooperative trial are outlined in Figure 2. Once the CSP Director

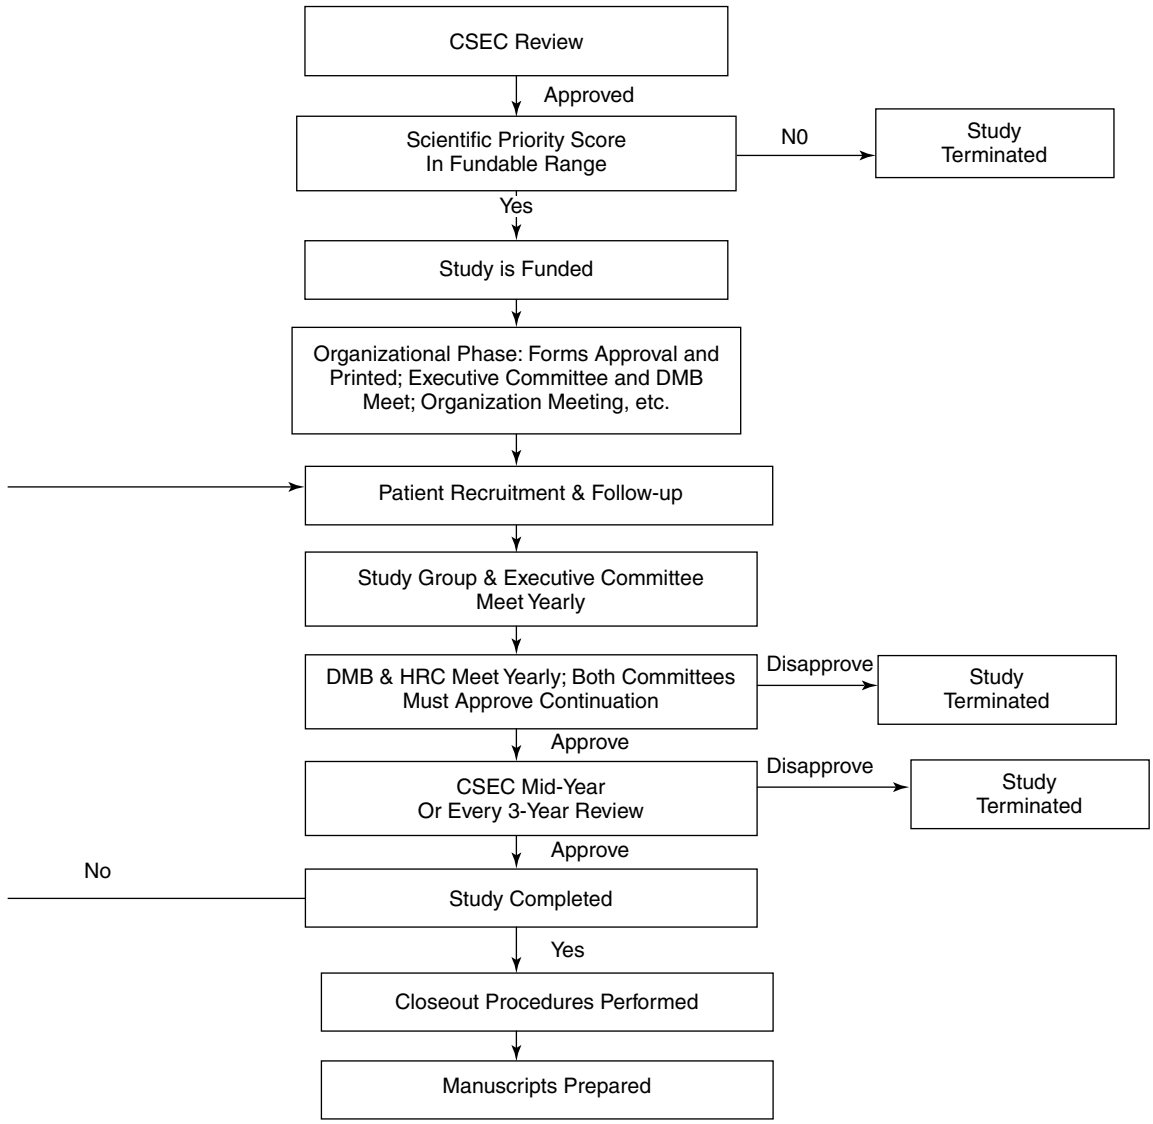

Figure 2 Conduct of a VA cooperative study

approves funding, the implementation phase of the cooperative study begins. All activities in this process are closely coordinated by the CSPCC, CSPCRPCC and the Study Chairperson's Office.

The necessity for carefully controlled medical treatment and data collection procedures for the successful conduct of multicenter clinical trials is well recognized. Because of its administrative structure, the VA provides an environment that is uniquely suited to this type of research. Each participating facility is funded by one control point for the entire period of the study, and the VAMC system provides a structure in which a relatively high degree of medical, scientific, and administrative control can be exercised. This same degree of control is often more difficult to obtain in studies that involve participating sites from different administrative systems [27].

The CSPCC recommends funding levels and monitors the performance of the individual medical centers. This information is reviewed regularly by the

study biostatistician, center director, the Executive Committee, and at least annually by the **Data and Safety Monitoring Board**. This integrated monitoring of scientific, biostatistical, and administrative aspects by the CSPCC provides a comprehensive approach to the management of multicenter clinical trials, in contrast to other clinical trials biostatistics groups that are responsible only for the analytical and data processing aspects and exercise no administrative control [27].

The Research and Development Committee and the IRB of each participating medical center must review and approve a cooperative study before it can be implemented at that facility. They are able to make modifications to the prototype consent form approved by the CSPCC HRC, but all local modifications must be reviewed and approved by the CSPCC.

Included in the implementation component of a cooperative study is the establishment of the Executive Committee and Data and Safety Monitoring Board (DSMB) who share responsibility for the conduct and monitoring of the cooperative study in the ongoing phase. The Executive Committee, which often includes several members of the original Planning Committee, consists of the study chairperson who heads the committee, the study biostatistician, the clinical research pharmacist, two or three participating investigators, and one or two consultants. This committee is responsible for the detailed operational aspects of the study during its ongoing phase and ensures adherence to the study protocol, including aspects relating to patient recruitment, treatment, laboratories, data collection and submission, biostatistical analysis, data processing, subprotocols and reporting. The Executive Committee sometimes recommends probation or termination of sites whose performance is poor.

The DSMB consists of five to eight individuals who have not been involved in the planning and development of the proposal, and includes one or two biostatisticians and two or more subject-matter experts in the field(s) of the cooperative study. This committee is charged with the responsibility of monitoring and determining the course of the ongoing study and considers such aspects as patient accrual; performance of the participating sites, CSPCC, and chairperson's office; and safety and efficacy data. Perhaps a unique feature of the CSP is that the CSPCC HRC also reviews each ongoing study annually and receives the same data reports as presented to the DSMB. The study chairperson, participating site investigators, and other members of the Executive Committee are masked to the outcome data during the course of the study. Only the DSMB, HRC, CSPCC and CSPCRPCC see the outcome data during the conduct of the study.

The fourth body involved in the conduct of the cooperative study is the Study Group, which consists of all participating investigators, the study chairperson (co-chairpersons), biostatistician, clinical research pharmacist, and consultants. This body meets once annually to consider the progress of the study and to resolve problems that may arise at the participating centers.

Within the CSPCC, the biostatistician heads a team of administrative, programming and data management personnel that provides regular monitoring of the study. This team develops an operations manual (*see* **Clinical Trials Protocols**), in conjunction with the chairperson's office, to train study personnel in the day-to-day conduct of the trial. They also develop a computer data management system to edit, clean, and manage the study data. Automated query reports are generated by the computer system and sent to the participating sites for data checking and cleaning. Statistical progress reports are published by the CSPCC and distributed to the Study Group, Executive Committee, and DSMB at scheduled meetings.

An initial kickoff meeting is held before the study starts to train site personnel in the conduct of the study. Annual meetings are held thereafter to refresh training and discuss issues in the conduct of the study. Frequent conference calls of the study committees are also used to facilitate communication and training.

Another unique aspect of the CSP is the CRPCC, which operationalizes the pharmaceutical aspects of the clinical trials (Table 2). In the planning stages of the study the clinical research pharmacist designs the drug or device treatment and handling protocol and works with the study chairperson and pharmaceutical and device industries to purchase or obtain donations of clinical supplies for the study. The CRPCC coordinates the development of appropriate drug dosage formulations and the manufacture of study drugs or devices. In the event that drug donations are not possible, the CRPCC has the expertise and capability to provide the in-house manufacture of active drugs and matching placebo. Drugs for all cooperative studies

Table 2 Unique functions and roles of the CSP pharmacy coordinating center

- Design of a drug or device handling protocol for each study involving drugs or devices
- Preparation and submission of INDAs or IDEs
- Obtaining donations or purchase of clinical supplies for study
- Coordination of appropriate drug dosage formulations and manufacture of study drugs or devices
- Quality control testing of drugs
- Development of blinding methods
- Storage, packaging and shipment of clinical supplies to pharmacies at the participating sites
- Computerized drug inventory and information system to track and replenish supplies at site pharmacies
- Monitoring adverse medical events and reporting to appropriate authorities
- Monitoring, auditing and education services to ensure sites are in compliance with GCP
- Preparation of final drug/device accountability reports

must pass the testing of the CRPCC's quality control testing laboratory. The CRPCC also assesses study product **blinding** methods.

At the CRPCC, study medications are stored in an electronically controlled and secured environment. The CRPCC customizes labels and packages all study medications, which are centrally distributed to the pharmacies at the participating sites. In doing so, the CRPCC provides a computerized drug inventory and information system for complete accountability of clinical supplies. This includes automated study supply tracking and replenishment systems for maintaining adequate study supplies at participating sites as well as automated telephone randomization and drug assignment systems. The clinical research pharmacist is then able to direct and monitor the study prescribing and dispensing activities as well as to monitor the **compliance** with the study protocol treatments at the participating sites. At the end of the study the CRPCC directs the retrieval and disposition of unused clinical supplies and prepares a final drug/device accountability report.

The clinical research pharmacist also works closely with the study chairperson and the manufacturers to prepare, submit, and maintain Investigational New Drug Application (INDAs) or Investigational Device Exemption (IDEs), which includes preparing and submitting annual and special reports to the FDA. Along with this responsibility, the clinical research pharmacist coordinates the monitoring and reporting of all adverse medical events to study management, FDA and associated manufacturers. Recently the CRPCC established a central Good Clinical Practices (GCP) Assurance Program. The Program provides monitoring, auditing, and educational services for all VA cooperative studies to ensure that the participating sites are in GCP compliance. If needed, the Program is capable of providing full GCP monitoring for studies under regulatory (FDA) scrutiny.

Final Analysis and Publication Phase

Upon completion of patient intake and follow-up, the study enters the final analysis and publication phase. If the Executive Committee, the CSPCC, and the study biostatistician have performed their tasks well, this phase should be quite straightforward. It requires an updating of all study files and the processing and analysis of the complete data set. The interim statistical analyses that were run during the ongoing phase of the study are now executed on the complete data. In addition, some analyses may point to additional questions that would be of interest; however, it is anticipated that the majority of final analyses and interpretation of results will occur within 6 to 12 months after study termination. All publications emanating from the cooperative study must be approved by the Executive Committee. Although the responsibility of the DSMB terminates at the end of data collection, the Board is at times requested to review manuscripts and give advice prior to submission for publication [27].

Usually each trial generates a number of manuscripts. The Executive Committee establishes priorities for statistical analyses and manuscript development and appoints writing committees composed of members of the Executive Committee and Study Group for each paper. Authorship of the main paper(s) usually consists of the chairperson, study biostatistician, study clinical research pharmacist, members of the Executive Committee, and, in some cases, the participating site investigators. Secondary papers are often written by other members of the Executive Committee and site investigators.

The CSPCC serves as the final data repository for the study. The study database, protocol, operations manuals, forms, study correspondence and interim and final statistical progress reports are archived at the CSPCC.

Role of the Biostatistician and Pharmacist in the CSP

One of the unique features of the CSP is that the biostatistician at the CSPCC plays a major organizational, fiscal, and administrative role, in addition to the usual technical role. In recent times, as the administration of studies has become more complex, the biostatistician may be assisted by a study coordinator but, as in the past, the greater part of the burden of management falls on the biostatistician. In contrast to the pharmaceutical industry and to many Contract Research Organization (CROs), the biostatistician is responsible for monitoring site adherence to protocol, recruitment, and many other aspects of the study conduct. In addition, the study pharmacist plays a key role in monitoring adverse effects, maintaining supplies of the study drug, regulatory reporting, and the like. In a sense, the study team is deployed to support the investigators, but has independent authority and responsibility as well.

One of the strengths of this approach to study management is that it is possible to guarantee some degree of uniformity in the conduct of the studies, independent of the varying managerial skills and style of the study chairs. The biostatistician and pharmacist, together with the coordinating centers of which they are a part, provide institutional memory and continuity. Their central position on the study teams reinforces the key idea that the studies mounted by the VACSP are the joint responsibility of the program and the investigators. Such an intramural program can only succeed on a limited budget if issues of cost and complexity are kept to the forefront during the planning process. A consequence that is easily observed is that the typical CSP trial is a lean, focused attack on a single important clinical question, rather than a broad-based research project with many interwoven strands of investigation.

In contrast to the much larger NIH clinical trials efforts, which are organized along disease lines, the CSP biostatisticians and CSPCCs are generalists, doing studies in all areas of medicine with relevance to the VA. Along the way, some centers have developed some special experience in certain areas, but there has never been a "heart" center or a "cancer" center. Because the CSP has such a broad medical purview, but a relatively low volume of studies, it has not made economic sense to specialize. The scarce resource of statistical and data management expertise has needed to be allocated efficiently to support the proposals that were emerging from the field. Since VA resources have followed the strength of the proposals rather than disease areas, the CSPCCs have not specialized to any large degree.

While there are undoubted advantages to specialization, as shown by the contributions made by the National Cancer Institute (NCI) (*see* **Cooperative Cancer Trials**) and the National Heart, Lung, and Blood Institute (NHLBI) (*see* **Cooperative Heart Disease Trials**) statisticians to the statistical science of their disease areas, there are some advantages to generalizing. In particular, it has been possible to transplant methods and lessons learned from well-studied areas such as cancer and heart disease, to other areas such as psychopharmacology, device research, health services research, and trials of surgical procedures. The absence of disease-area "stovepiping" has facilitated a high general level of sophistication in the conduct of trials, with techniques travelling readily across borders.

This cross-pollination has also been facilitated by the structure of the VACSP scientific peer review. The standing committee that reviews and recommends studies for funding mixes disciplines with common expertise in multisite studies. *Ad hoc* reviewers provide the crucial discipline-specific input to the committee, but the same committee may review a heart failure trial in the morning and a psychopharmacology trial in the afternoon. The result is a high degree of uniformity in the standards for the research across disease areas, and this has been an enduring strength of the program.

Ongoing and Completed Cooperative Studies (1972–2000)

One hundred and fifty-one VA cooperative studies were completed or are currently ongoing in the period 1972–2000. Table 3 presents the health care areas

Table 3 Health care areas of ongoing and completed VA cooperative studies (1972–2000)

Health care area	Number of studies	Percent of studies
Cardiology/cardiac surgery	24	15.9
Hypertension	15	10.0
Gastrointestinal	14	9.3
Substance abuse	11	7.3
Mental health	10	6.6
Infectious diseases	9	6.0
Cancer	8	5.3
Dental	6	4.0
General surgery/anesthesia	6	4.0
Cerebrovascular	5	3.3
Peripheral vascular	5	3.3
Military service effects	4	2.6
Ambulatory care	4	2.6
Epilepsy	4	2.6
Genitourinary	4	2.6
Diabetes	3	2.0
Renal	3	2.0
Sleep	3	2.0
Pulmonary	2	1.3
Hematology	2	1.3
Hearing	2	1.3
One each in seven areas[a]	7	4.7
Total	151	100.0

[a]Analgesics, arthritis, geriatrics, hospital-based home care, laboratory quality control, computerized neuropsychological testing, ophthalmology

of these studies. These areas are generally reflective of the major health problems of the US veteran population, consisting mainly of middle-aged and senior adult males. Studies in cardiology and cardiac surgery represent 15.9% of the 151 studies, followed by hypertension (10.0%), gastrointestinal diseases (9.3%), substance abuse (7.3%), mental health (6.6%), infectious diseases (6.0%), and cancer (5.3%).

There are a few notable disease areas that are prevalent in the VA population and yet might be considered underrepresented in the CSP. These include diabetes (2.0%), renal diseases (2.0%), pulmonary diseases (1.3%), hearing diseases (1.3%), arthritis (0.7%), and ophthalmologic diseases (0.7%). Because the CSP mainly relies on investigator-initiated studies, the conclusion might be drawn that these subspecialties have underutilized the Program. Although studies on effects of military service represent only 2.6% of the 151 studies, studies listed in other categories have investigated treatments for service-connected illnesses (e.g. posttraumatic stress disorder studies are categorized under mental health, and the substance abuse studies could be considered consequences of military service).

Table 4 briefly summarizes some of the noteworthy VA cooperative clinical trials that were completed in the 1980s and 1990s. Many of these trials resulted in advances in clinical medicine that could immediately be applied to improve the health care of US veterans and the US population in general.

Current Challenges and Opportunities

Although the VACSP has had numerous past successes, it faces many challenges and opportunities in the future. These include: (1) changes in the VA health care system and their effects on research; (2) nationwide concerns about violations of patients' rights in research; (3) increasing the efficiency and interdependence among the coordinating centers and standardizing procedures; (4) ensuring the adequacy of flow of research ideas and training of investigators; and (5) partnering with industry, other federal agencies, nonprofit organizations, and international clinical trial groups to enhance the capacity of the Program.

Changes in the VA Health Care System

The VA health care system has been undergoing substantial changes that could adversely affect research. In 1996, the VA reorganized into 22 geographically defined Veterans Integrated Service Networks (VISNs). Much of the central authority, decision-making, and budgeting once performed in VA Headquarters in Washington, DC, has been delegated to the 22 VISN offices. Within the VISNs, administrative and health care services and in some cases entire VAMCs are being consolidated. The largest component of the VA patient population, the World War II veterans, is rapidly declining. Health care personnel in some VISNs are experiencing reductions in force, with the result that the remaining personnel have limited time to devote to research. These factors may already be adversely affecting the Program's ability to meet recruitment goals in ongoing trials [23].

Concerns About Patients' Rights in Research

The nature of the veteran population treated at VA hospitals raises some special issues in human rights

Table 4 Noteworthy VA cooperative studies

- 80% of strokes in patients with atrial fibrillation can be prevented with low-dose warfarin [15]
- Carotid endarterectomy is effective in preventing strokes in symptomatic and transient ischemic attacks in asymptomatic patients [26, 39]
- Aggressive treatment of moderate hypertension works well in elderly patients [19, 37]
- Age and racial groupings can be used to optimize selection of first line drugs in hypertension [38]
- Coronary artery bypass surgery prevents mortality in patients with left main disease and in high-risk patients without left main disease [42, 49]
- Low dose aspirin reduces heart attacks and death in 50% of patients with unstable angina [34]
- Vasodilators and angiotensin converting enzyme inhibitors prevent deaths in patients with congestive heart failure [12, 13]
- Low dose aspirin started 6 hours after coronary artery bypass surgery and continued for one year prevents the occlusion of the bypass grafts [17, 18]
- Mechanical artificial aortic heart valves prolong survival more than bioprosthetic aortic heart valves [22]
- A conservative, ischemia-guided strategy is safe and effective for management of patients with non-Q-wave myocardial infarction [4]
- Digoxin does not reduce mortality but does reduce hospitalizations in patients with congestive heart failure [50]
- The rate of coronary events (myocardial infarction or death) in men with coronary heart disease can be reduced by 22% with Gemfibrozil therapy, which increases high density lipoprotein cholesterol and lowers triglyceride levels [45]
- Progression of human immunodeficiency virus (HIV) infection to full blown acquired immune deficiency syndrome (AIDS) can be delayed with the drug zidovudine [21]
- Steroid therapy does not improve survival of patients with septic shock [52]
- Patients with advanced laryngeal cancer can be treated with larynx-sparing chemotherapy and radiation compared with standard surgical removal of the larynx and have equivalent long-term survival [14]
- The drug Terazosin is more effective than Finasteride in relieving the symptoms of benign prostatic hyperplasia [33]. Transurethral resection of the prostate is an effective operation, but Watchful Waiting can be effective in many patients [56]
- An implantable insulin pump is more effective than multiple daily insulin injections in reducing hypoglycemic side-effects, and enhancing quality of life in adult-onset Type II diabetes mellitus [46]
- Multi-channel are superior to single-channel cochlear implants in restoring hearing to patients with profound hearing loss [11]
- Sclerotherapy is an effective treatment for esophageal varices in patients who have had prior bleeds but not in patients without prior bleeds [51]
- Antireflux surgery is more effective than medical therapy in patients with complicated gastroesophageal reflux disease [47]
- Severely malnourished patients benefit from pre-operative total parenteral nutrition but mildly malnourished patients do not [53]
- Clozapine is a cost-effective treatment for patients with refractory schizophrenia who have high hospital use [44]
- Erythropoietin administered subcutaneously compared with intravenously can significantly reduce the costs of hemodialysis [29]
- Use of intrapleural tetracycline reduces recurrence rate by 39% in patients with spontaneous pneumothorax [35]
- Rapid access to high quality primary care for patients with severe chronic illnesses greatly improves patient satisfaction with care but may lead to an increase in hospital readmissions [57]
- Levomethadyl acetate (LAAM) is a safe and efficacious drug to use for heroin addiction. Studies were used to gain FDA approval for LAAM as treatment for heroin addiction [16, 36]
- Systemic corticosteroids improve clinical outcomes up to three months in patients with chronic obstructive pulmonary disease [40]

protections (*see* **Medical Ethics and Statistics**). The VA treats about four million veterans, who tend to be less well off than the average veteran (or the average citizen). They are often more severely ill than non-VA patients with the same age and diagnosis, and often have multiple co-morbidities. They are on average more dependent on the VA for their health care than the typical non-VA patient is on his or her usual health care provider. Against this background we note the extraordinary willingness of the veteran patient to engage in research, trusting the clinical researcher to an astonishing degree. Such trust demands an extraordinary level of protection in response.

The CSP has instituted a unique framework of human subjects' protections, going beyond the usual procedures that other federal sponsors and drug companies require. This begins in the planning stage, when each proposal must undergo a rigorous review by the HRC attached to the coordinating center. It typically meets for several hours over a single protocol, reviewing it in fine detail. The protocol cannot go forward without their independent approval.

The CSP also requires the usual individual site IRB approval, and other reviews that are mandated at the local site, before a study can start at a site. The ongoing IRB reviews at the local sites (annually, or more often, as stipulated in the initial review) are monitored by the CSP staff. As has become standard in multisite trials, each CSP study has its own independent DSMB that meets at least annually to review the progress of the study.

The unique CSP innovation to this process is the joint review by the HRC and DSMB. Thus, after every DSMB meeting, the two groups meet to review and recommend, with the same basis of information on study progress. The CSP has found that the HRC is able to hear the recommendation of the DSMB, which is typically heavily weighted with subject-matter expertise, and interpret it in the light of the other perspectives they bring. The CSP believes that this has been a successful experiment in resolving the knotty issue of how to obtain full and informed ongoing review of studies where investigators are kept blind, and site-level information must be far less informative than the big picture presented to the DSMB. We believe that such joint reviews add considerably to the level of protection of human subjects.

In addition, members of the central HRCs conduct three site visits per year during which patients are interviewed about their participation in the trials. Thus, the Program as a whole conducts 12 such visits per year. The Albuquerque auditing group periodically site visits VAMCs participating in cooperative studies and performs audits to ensure that the sites are complying with GCP guidelines. The CSPCCs also receive copies of consent forms from all patients in all of the trials as further evidence of proper consent procedures.

The VA recently established its own office to oversee the protection of patients' rights in VA research, performing functions similar to those of the Office of Protection from Research Risks (OPRR) of the Department of Health and Human Services. IRBs at VAMCs currently are required to be accredited by an external, non-VA entity.

In addition to these standard procedures, followed in all studies, the CSP has recognized two other areas of human subjects' protection in which it can make a contribution. The Enhancing the Quality of Informed Consent (EQUIC) program [32] is designed to institutionalize the process of testing innovations in methods for obtaining informed consent. It piggybacks tests of new methods on ongoing CSP studies, and provides a centralized assessment of the quality of informed consent encounters (by remote telephone interview of patients). In the spirit of EQUIC, a substudy is being conducted in one ongoing VA cooperative study to evaluate the utility of an informed consent document developed by a focus group of subjects eligible for the trial [41].

The second topic that the CSP has engaged are the ethical, legal, and social implications of genetics research, specifically of deoxyribonucleic acid (DNA) banking with linked clinical (phenotype) data. The CSP has begun a project to provide uniform methods for obtaining and banking such samples.

Steps to ensure human subjects' protection in VA cooperative studies are listed in Table 5.

Efficiency and Interdependence of the CSPCCs

The VACSP recently contracted with an outside vendor to help develop standard operating procedure (SOPs) for the CSPCCs. Twenty-two SOPs were developed in the areas of administration, planning and implementing clinical trials, data management,

Table 5 Steps to ensure human subjects' protection in the VACSP

- Investigator's integrity
- Development of proposal through collaboration between investigators and CSPCCs
- HRC review of proposal initially
- Site Monitoring and Review Team (SMART) audit of consent form contents
- CSEC review of proposal
- Initial review of proposal by participating site R&D and IRB
- Annual central reviews of trial by DSMB and HRC
- Annual reviews of study by local R&D committee and IRB
- SMART audit of participating sites
- HRC site visits and interviews of study patients
- Receipt of copies of patient consent forms by CSPCC, local research offices, and local pharmacies
- Implementation of SOPs and good clinical practices
- Compliance with all FDA and VA regulations
- Innovative studies on improving informed consent

Table 6 Recently adopted SOPs for the VACSP

Administration

- Preparing, issuing and updating SOPs
- Training and training documentation

Planning and implementation of clinical trials

- Developing, approving and amending protocols
- Study/training meetings
- Preparing and approving operations manuals
- Study initiation
- Developing and approving case report forms
- Creating and validating data entry screens and programs
- Preparing, documenting and validating data checking programs
- Preparing, documenting and validating statistical programs
- Developing and conducting statistical analyses

Handling data from clinical trials

- Randomization, blinding and unblinding
- Central monitoring
- Case report form flow and tracking
- Data entry and verification
- Data cleaning
- Reporting adverse events

Study closeout

- Archiving study documentation
- Study closeout

Study oversight

- Assuring site R&D and IRB approvals
- DSMB
- HRC

study closeout, and study oversight (Table 6). By standardizing among and within the coordinating centers certain procedures that are performed in every study, we will achieve an even higher level of support to all studies more efficiently than previously done. The SOPs will also enable the CSPCCs to be in better compliance with GCP principles and International Conference on Harmonization (ICH) **guidelines**.

Since 1996, the Directors of the Program and centers have been meeting as a group semiannually to identify current and future challenges and opportunities, and to develop annual strategic plans to respond to these challenges and opportunities. This has enhanced the development of mutual projects which the centers can work on together to further the goals of the organization as a whole, such as the development of a Clinical Research Methods Course, a one-year sabbatical program for clinical investigators to enhance their training and skills, and SOPs for the central HRCs.

Ensuring the Adequacy of Flow of Ideas and Training of Investigators

In recent years, the CSP has developed several educational opportunities to help train VA investigators in clinical research and to encourage utilization of the Program to answer important clinical questions. These include a five-day course in clinical trials and sabbatical and career development programs focused on clinical research methodology.

The five-day course is taught once each year and involves 10 faculty members (two from each of the five coordinating centers) and 60 VA investigators selected from applications from throughout the country. The course consists of 15 lecture/discussion sessions on various aspects of designing a clinical trial, interspersed with breakout sessions during which the students are divided into five planning committees to design a clinical trial. On the last day of the course, the student groups take turns in presenting their clinical trials and receiving critiques from the audience. The course has been taught twice and has received excellent feedback from the students.

The CSP Career Development Program provides protected time to clinician–investigators for a period of concentrated clinical research activity. The objective is to build capacity in a wide geographic distribution for the Department of Veterans Affairs to conduct clinical research in acute-care hospitals, long-term care facilities, or outpatient settings. The Program is designed to foster the research careers of clinician–scientists who are not yet fully independent but who seek to become independent clinical researchers. The award provides three years of salary and some supplemental research support, and the awardees are expected to work at least part of the time at one of the five CSPCCs or three Epidemiology Research and Information Center (ERICs).

In 1999 CSP announced a sabbatical program for established clinician–scientists to train at one of the CSPCCs or ERICs for up to one year. The purpose of the program is to support clinician–investigators who wish to secure training time to learn about the conduct of cooperative studies and epidemiologic research.

Partnering with Outside Organizations

The VACSP has partnered with NIH and industry for many years in conducting multicenter clinical trials. In recent years, a special emphasis has been placed on partnering with outside agencies to enhance the effect of the limited VA research funding, and these efforts have been fruitful.

Recent examples of this partnering include: the Digitalis in Heart Failure Trial, sponsored by the VA, NHLBI, and Burroughs–Wellcome Company and conducted in 302 VA and non-VA sites in the US and Canada; a series of trials sponsored by the VA and the National Institute of Drug Abuse (NIDA) to evaluate new treatments for drug abuse; the Prostate Cancer Intervention Versus Observation Trial (PIVOT), sponsored by the VA, Agency for Healthcare Quality and Research (AHQR) and NCI; the Beta-Blocker Evaluation of Survival Trial (BEST), funded by the VA, NHLBI, and industry; the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial, supported by the VA and 10 pharmaceutical companies; the VA/National Institute of Deafness and Other Communication Disorders (NIDCD) Hearing Aid Clinical Trial; and the Shingles Prevention Study sponsored by the VA, NIH, and a pharmaceutical company.

The VACSP has been working with the American College of Surgeons to promote clinical trials evaluating new surgical operations and technologies. This collaboration has resulted in a VA trial comparing the outcomes of laparoscopic vs. open tension-free inguinal hernia repair, a trial comparing open tension-free hernia repair vs. watchful waiting funded by AHQR, and a trial comparing pallidotomy vs. deep brain stimulation in Parkinson's Disease.

The VACSP has also issued a program announcement for the development of multinational clinical trials between the VA and the Medical Research Councils of Canada and the UK. As the field of clinical trials matures, it is likely that achievable treatment effect sizes will decrease, necessitating larger and larger trials, or "mega" trials. These types of collaborations will be important in the future, as the larger trials will exceed the capacity of any single clinical trials program.

Concluding Remarks

In summary, we believe that there are considerable strengths to conducting multicenter clinical trials in

Table 7 Strengths of the VACSP

Related to VA health care system

- Large veteran population willing to participate in research, well-represented by minority groups
- Largest integrated healthcare system in US with 172 medical centers under single administrative system
- High-quality physician–investigators
- National administrative databases that allow for tracking of patients
- Supportive management in VA Headquarters
- System of local research offices and IRBs at participating sites that facilitate multicenter research

Related to the CSP

- Quality and experience of the coordinating centers
- Well-established mechanisms for conducting multi-site trials
- Planning process usually produces tightly focused, cost-effective protocols
- Rigorous review process by HRC and CSEC
- Guidelines and SOPs for conducting trials
- Multiple levels of protection of research subjects
- Ability to conduct trials with high power and generalizability, so the impact on changing health care practices is maximized compared with other research programs

Table 8 Limitations of the VACSP

Related to VA health care system

- Primarily male population, limiting generalizability of results
- Large studies in female and childhood diseases are not possible
- Changes in the health care system, including aging and declining of veteran population, decentralization and consolidation of facilities
- Reduction in dedicated research time for physician–investigators

Related to the CSP

- Long duration from submission of planning request to publication of main results raises the risk of study becoming outdated
- Limitation of funding
- Limited capacity to conduct mega trials within VA system

the VA health care system, as enumerated in Table 7. There are also some acknowledged limitations of the Program, some of which can be addressed in the future (Table 8).

This article has described the history, organization and productivity of a clinical trials program designed as an integral part of a large health care system. The biostatistical and pharmacy positions in the Program are ideal from the standpoint that these people are integrally involved in the research from beginning to end and play a major role in the conduct of the trials. The Program is an example of how clinician–investigators and methodologists can work together successfully to design and conduct large-scale clinical research.

Acknowledgments

We are extremely indebted to the foresight and support of the US Congress, Executive Branch, and VA management, and to the dedication of the health care providers and veteran patients in the VA system to enable us to carry out this important research.

Copula

The term *copula* was introduced by Sklar [18] to denote a bivariate distribution function with uniform marginals. If X and Y are random variables with joint distribution function $H(x, y)$ and marginals $F(x) = H(x, \infty)$, $G(y) = H(\infty, y)$, then there exists a copula $C(u, v)$, uniquely determined on (Range F) $\times$ (Range G), such that

$$H(x, y) = C[F(x), G(y)] : \tag{1}$$

see [18], [15], and [16]. If X and Y are independent, $C(u, v) = uv$. The copula of a continuous bivariate distribution is invariant under separate continuous monotone transformations of each marginal distribution, and is maximal in the sense that any **measure of association** that is invariant under all such **transformations**, such as Kendall's τ, or Spearman's ρ, depends on H only through C. If $C(u, v)$ is a copula, then so also is $\overline{C}(u, v) = C(1 - u, 1 - v) + u + v - 1$: it corresponds to the distribution of $(-X, -Y)$ and represents the joint survivor function $\overline{H}(x, y) = 1 - F(x) - G(y) + H(x, y)$ of (X, Y) in terms of the marginal survivor functions $\overline{F}(x) = 1 - F(x)$ of X and $\overline{G}(y) = 1 - G(y)$ of Y (*see* **Survival Distributions and Their Characteristics**).

In statistical work, parameterization of the joint distribution H via distinct parameters α, β, and γ for the marginals F and G and the copula C allows specification of the marginals of the distributions to be separated from specification of the dependence structure, which is often desirable for interpretation. However, inferences about the three parameters are not generally orthogonal unless X and Y are actually independent.

Frank [6] described an important subclass, called "archimedean copulas". These arise mathematically as the class of associative copulas; that is those that satisfy $C[u_1, C(u_2, u_3)] = C[C(u_1, u_2), u_3]$ and have the general form $C(u, v) = \phi^{-1}[\phi(u) + \phi(v)]$, where ϕ decreases monotonically with u, $\phi(0) = 1$, and has an increasing first derivative. Genest & MacKay [7] discussed applications of this class in statistics. See also [14] for applications in survival analysis, and [10] and [1] for applications in **extreme value** theory. Oakes [14] showed how many members of this class, or more precisely of the complementary class

$$\overline{C}(u, v) = \phi^{-1}[\phi(u) + \phi(v)], \tag{2}$$

can arise from frailty models. Specifically, suppose that X and Y are conditionally independent given the value of a third, unobserved, variable W, called a frailty, and that each follows a (continuous) **proportional hazards** model in W, so that $\Pr(X > x|W = w) = A(x)^w$, $\Pr(Y > y|W = w) = B(y)^w$, for some *baseline* survivor functions $A(x)$ and $B(y)$. Then the joint survivor function of (X, Y) is

$$\begin{aligned}\Pr(X > x, Y > y) &= \mathrm{E}\left[\Pr(X > x, Y > y|W)\right] \\ &= \mathrm{E}\left[A(x)^W B(y)^W\right] \\ &= p\{-\ln[A(x)] - \ln[B(y)]\},\end{aligned} \tag{3}$$

where $p(s) = \mathrm{E}[\exp(-sW)]$ denotes the Laplace transform of the distribution of W. This is an archimedean copula model for $\overline{C}$ with $\phi^{-1} = p$, $\overline{F}(x) = p\{-\ln[A(x)]\}$ and $\overline{G}(y) = p\{-\ln[B(y)]\}$. Important examples include the gamma frailty model of Clayton [4] and Oakes [13], with $p(u) = (1 + u)^{-\kappa}$, and the positive stable model of Hougaard [11], with $p(u) = \exp(-u^\alpha)$ $(0 < \alpha < 1)$.

Models of the form given in (3) are natural in survival analysis, because of the close analogy with Cox's [5] proportional hazards regression model. Clayton [4] fitted the gamma frailty model to ages of occurrence of heart attacks in fathers and sons. He pointed out an appealing interpretation in terms of bivariate hazard functions. For the gamma frailty model the ratio of the hazards at y of the conditional distribution of Y given $X = x$ and of Y given $X > x$ is the same for all points (x, y). Oakes [14] extended this result to the general archimedean copula model, showing that the ratio of hazards in (3) depends on (x, y) only through $\overline{H}(x, y)$, and that this ratio of hazards characterizes the joint distribution. Genest & Rivest [8] explored a different characterization of archimedean copula models using Kendall's τ.

Bickel et al. [3, Chapter 4] discussed the challenging problems of semiparametric inference in (2) or (3). Genest et al. [9] and Shih & Louis [17] discussed a **pseudo-likelihood** approach to estimation of association in special cases of the model given in (2) from **censored data**.

There has been little work to date on the inclusion of observed **explanatory variables** (**covariates**) in copula models. For frailty models such as that given

in (2), covariate effects can be modeled either conditionally on the unobserved frailty, or unconditionally; that is, on the marginal distributions.

Extensions to higher dimensions have been considered in [2]. For a book-length treatment of copulas, see [12].

DAVID OAKES

Cornfield, Jerome

Born: October 30, 1912, in New York City, New York.
Died: September 17, 1979, in Herndon, Virginia.

Reproduced by permission of the Royal Statistical Society

Jerome Cornfield was arguably the most influential statistician in the biomedical sciences in the US from the 1950s until his death. He was the consummate statistical scientist. His understanding of the nature of the subject-matter of statistics and of its essential role in the inductive process of integrating data into a body of empirical knowledge, particularly in the biomedical sciences, was outstanding. This thorough view of statistics and scientific research enabled him to identify essential statistical problems. He exercised considerable influence as an advisor and consultant, and for over two decades was a major advocate for statistical reasoning in clinical research.

After attending elementary and high schools in the Bronx, New York, he entered New York University, graduating in 1933 with a major in history. Cornfield did not receive any advanced degrees. He did, however, take some formal graduate courses in history at Columbia University. After moving to Washington, DC, in 1935, Cornfield took a number of courses in statistics at the US Department of Agriculture Graduate School during the period 1936–1938, including courses with M.A. Girshick in general statistics and **multivariate analysis**. He also had a course in sampling which, together with what he learned on the job from Duane Evans, enabled him to advance the cause of getting **probability sampling** accepted by several Federal Agencies. Although his formal training was minimal, most of what he had to learn about statistical theory, reasoning, and methodology was self-taught from a continually expanding literature. This enabled him to be discriminatingly selective both as to subject-matter and to the time at which he felt it necessary to learn about a subject. In later years, biomedical associates and statistical colleagues were surprised to discover that he had no doctorate.

A brief review of the major positions he held begins with the Bureau of Labor Statistics, where he was a statistician from 1935 to 1947. In 1947 he joined **Harold Dorn's** methods unit in the Public Health Service. This unit was shortly transferred to the National Cancer Institute on the campus of the **National Institutes of Health (NIH)**. Cornfield remained in the Cancer Institute until 1955 or 1956 when both he and Dorn moved over to a new Division of Research Services. Here, he consulted with investigators in various Institutes of the NIH. In 1958 he was invited to succeed **William Cochran** as Chairman of the Department of Biostatistics in the School of Hygiene and Public Health of the Johns Hopkins University. He was also appointed Professor of Biomathematics in the School of Medicine. He returned to the NIH in 1960 as Assistant Chief of the Biometrics Research Branch of the National Heart Institute, became Branch Chief in 1963, and served in that position until his retirement from the NIH in 1967. In 1968 he joined the Graduate School of Public Health of the University of Pittsburgh as a Research Professor of Biostatistics. At the same time he founded a biostatistics research group with offices in the Washington, DC, area. In 1972 he joined the Department of Statistics at the George Washington University as Professor of Statistics and brought his research group into the Department as the Biostatistics Center. He served as Chairman of the Department from 1973 to 1976 and continued as Professor of Statistics and Director of the Center until his terminal illness.

Over a span of three decades, from 1947 to 1979, Professor Cornfield was one of the leading statisticians working in the biomedical area. He made

many original contributions to biostatistics, epidemiology, **clinical trials**, and to quantitative methods in the design and analysis of experiments (*see* **Experimental Design**) conducted in clinical and laboratory research. In addition, he wrote a number of papers on Bayesian **inference** and on the application of **Bayesian methods** in the biomedical sciences. Before presenting the highlights of the work in this period, it is important to comment on his contributions to economic statistics and sampling while at the Bureau of Labor Statistics (BLS).

From the very beginning of his career, Cornfield was a creative and original thinker, motivated by important real-world problems. He made a number of important contributions to economics and economic statistics during his work at the BLS. He played a major role in the revision of the Consumer Price Index, 1938–1940, introducing several new procedures. He developed a keen interest in sampling, which led to the development of a survey using probability sampling for a study of Family Spending and Saving in wartime. This complex design, according to Duncan & Shelton [26, pp. 46–49] "represented a significant advance in a number of respects. Indeed, it was the precursor of several ideas which were worked out more fully and justified mathematically a year later by Hansen and Hurwitz". In 1941 Cornfield consulted with the Bureau of Home Economics on a nutrition-related problem which was known as the "diet" problem. The mathematical problem requires the minimization of linear functions subject to a set of given inequality constraints, the problem of **linear programming**. Zelen [31, p. 12] refers to a 1958 book on linear programming by Dorfman et al. as crediting Cornfield "as being the first person to formulate the linear programming problem and find an approximate solution". His work appeared in 1941 in an unpublished BLS memorandum. It was also at the BLS that Cornfield made his first contribution to statistical theory. He developed a method using indicator variables for easily obtaining the first few moments of the sample mean when sampling from finite populations. He thus obtained an unbiased estimate of the sample variance and of the variance of the sample mean [2].

From 1948 to his death 31 years later, Cornfield devoted the major portion of his career to the development and application of statistical theory and methods to the biomedical sciences. His contributions were diverse both in the nature of his statistical interests and in the areas of biostatistical applications. He was involved in and touched upon every major public health issue that arose in that period – the polio vaccines [23], smoking and lung cancer (*see* **Smoking and Health**) [22, 29], risk factors for cardiovascular disease [5, 30], and the difficult statistical issues of estimating the low-dose carcinogenic effects in humans (*see* **Extrapolation, Low Dose**) of a food additive that becomes suspect because it produces cancer in animals at much higher doses [14, 20].

In the broad area of biomedical research, Cornfield was involved in a wide variety of problems, in each of which he made significant and lasting contributions. These studies and problems include the following: an imaginative method for estimating the volume–surface ratio of individual cells as observed under the microscope [15], the statistics of bioassay (*see* **Biological Assay, Overview**) [3, 6, 19], photosynthesis [1], the analysis of the toxicity of mixtures of the essential amino acids [28], chemical kinetic experiments using radioactive compounds (*see* **Pharmacokinetics and Pharmacodynamics**) [25], the physiological and biological effects of irradiated animals (*see* **Radiation**) [17], and the computer diagnosis of electrocardiograms [12] (*see* **Clinical Signals**).

In the amino acid problem, the question was: Which mixtures of the 10 essential amino acids were toxic? The investigators called on Cornfield for help when they were confronted with the impractical task of conducting 1013 experiments with two or more mixtures. Cornfield considered the issue of measuring the joint effects of two or more drugs administered in combination. The method usually employed was to assume the joint effects were additive in their individual responses. Cornfield saw that this simple method could give strange results. Instead, he chose a measure of additivity introduced by Gaddum, namely additivity of doses conditioned on a given response, a concept which Cornfield called dose-wise additivity. After some persuasion, the biochemists proceeded to conduct experiments implied by dose-wise additivity. These turned out to be highly successful, leading to the previously unknown result that L-arginine was essential for the combination of the 10 amino acids to be nontoxic in the human [28].

The animal radiation study is noteworthy for the development of a methodology that would later become a fundamental tool in epidemiologic research,

i.e. multiple **logistic regression**. The issue in the animal data was the effect on survival of irradiated mice as a function of certain observed blood characteristics, such as lymphocytes and granulocytes. This is clearly a regression problem with a straightforward solution if the traits could be controlled at a set of fixed values. Since survival is a 0, 1 variable, the solution would be a multiple logistic function. (Of course, since that period much work has been done on regression with variables subject to error.) Since the observed blood properties were uncontrolled, Cornfield chose to adopt the method of analysis as that of discrimination between two multivariate populations for surviving and nonsurviving animals. With the additional assumption of **multivariate normality** and equal **covariance matrices**, he derived the multiple logistic risk function whose coefficients were the same as those found by **R.A. Fisher** in the linear discrimination problem (*see* **Discriminant Analysis, Linear**) [5, 21]. This solution is obtained directly, requiring only the inversion of a matrix but no iterations. Cornfield would later say that the simplicity of the solution appealed to him and he believed that if the assumptions were reasonable, then the solution would be close to that of the regression approach. Cornfield later applied the same reasoning to use the multiple risk function to identify cardiovascular risk factors on the basis of data obtained from the famous **Framingham Study** [5, 30].

Cornfield made another very important contribution to epidemiology. When epidemiologists began turning their attention to the study of chronic diseases, prospective **cohort** designs for finding causes of, or risk factors for, chronic diseases were in many instances impractical. They therefore turned to **case–control** or retrospective types of strategies. A problem with these designs, assuming they are well planned, is that they do not yield traditional estimates of **absolute risk** or **relative risk**. Cornfield, in 1955 at the Third Berkeley Symposium in Mathematical Statistics and Probability [4, 18], presented a derivation which demonstrated that under a rather strong assumption (but rather reasonable in the case of chronic diseases) the **odds ratio** or cross product ratio (in a 2×2 table) is a fairly good approximation of the relative risk. The assumption was that the incidence of the disease under study should be small. This result strengthened and increased the use of the case–control design, since it set this research strategy on a much more solid inferential foundation.

In an important paper [22], responding to critics of the purported causal relationship between smoking and lung cancer, Cornfield argued for the preference of measures of association based on relative risk as opposed to differences of absolute risk, at least for scientific purposes. However, the significant matter here is not the issue of risks but the example he used to justify his position. The illustration bears on the question of the effect of latent, unobservable variables. Sir Ronald Fisher, in arguing against the smoking–lung cancer relationship, had offered an hypothesis that postulated the existence of some constitutional factor (latent and unobservable), e.g. genetic, that caused cancer and that was also associated with the need to smoke. Without giving the details of his argument here, Cornfield demonstrated that if cigarette smokers are shown to have nine times the risk of nonsmokers of getting lung cancer, but that this elevated risk is due, not to cigarettes, but to some latent factor X, then the proportion of smokers having X must be larger than nine times the proportion of nonsmokers having X. Cornfield's conclusion was that if X was a causative agent of this magnitude, then the relationship between the latent factor X and the observed agent would probably have been detected much before that of the agent and the disease. No such factor has been found.

In addition to epidemiologic methods, Cornfield devoted a substantial portion of his career to the theory and practice of randomized, controlled clinical trials (RCTs). His influence was far-reaching. He wrote papers on aspects of design of RCTs both for therapeutic and **prevention trials** [10, 13, 17, 24], on statistical problems in the interpretation of results [13], and on a Bayesian test of hypotheses arising in RCTs [7]. But the totality of his publications constituted only a small part of his vast influence as an advisor and consultant. He was personally involved in the Coronary Drug Project, one of the earliest **multicenter trials** sponsored by the NHLBI. It was in this trial that Cornfield introduced the Bayesian concept of relative betting odds (a measure related to the Bayes Factor) as a measure to assess the efficacy of a therapy instead of the classical ***P* value**. He was personally involved in many major multicenter trials, serving in various capacities as a member of planning committees, steering

committees, policy advisory boards, and data monitoring and safety committees. These RCTs include the National-Diet Study, a trial of urokinase in the treatment of myocardial infarction, the Coronary Drug Project (CDP), the **University Group Diabetes Program (UGDP)**, the Urokinase Pulmonary Embolism Trial (UPET), the Diabetic Retinopathy Study (DRS), the Multiple Risk Factor Intervention Trial (MRFIT), the Program for the Surgical Control of the Hyperlipidemias (POSCH), and the Persantin Aspirin Reinfarction Study (PARIS).

Throughout his career in statistics Cornfield was interested in, and contributed to, the foundations of statistics, first as a frequentist and then as a Bayesian. The first manifestation of his interest in Bayesian inference was his joint work with Geisser on deriving the posterior distribution for the multivariate normal parameters [27]. He then followed with a number of papers on the theory of Bayesian inference and on its practice and application to clinical trials [8, 11], to estimation in higher order cross-classifications [9], and to the analysis of **life tables** [16].

Cornfield was also actively engaged as a consultant in areas other than clinical trials and epidemiology. He was a member of the Three Mile Island Advisory Committee, on the NHLBI Policy Advisory Board on Coronary Bypass Surgery, Chairman of the Committee on Biometry and Epidemiology for the Food and Drug Administration, on the Scientific Advisory Board for the Sloan–Kettering Institute for Cancer Research, etc. He also served in a number of editorial roles, the principal ones being Associate Editor for the ***Journal of the American Statistical Association*** and Consulting Editor for the *Journal of Chronic Diseases*. Cornfield was President of the **American Statistical Association**, the American Epidemiological Society, Vice-President of the American Heart Association, and President of the Eastern North American Region of the **International Biometric Society**.

For a more detailed review of Cornfield's contributions to the theory of statistics, laboratory research, clinical trials, and epidemiology, the reader is referred to the March 1982 supplement to ***Biometrics*** vol. 38. Furthermore, Cornfield's American Statistical Association Presidential Address is a wonderful account in his own words of his contributions to statistics and science, and his personal perspective on being a statistician.

Cornfield married Ruth Bittler and they have two daughters, Ann and Ellen.

SAMUEL W. GREENHOUSE &
JOEL B. GREENHOUSE

Cornfield's Inequality

In response to claims that the relationship between smoking and lung cancer could be explained by a genetic or other omitted variable (OV), **Cornfield** et al. [6] developed an inequality linking the observed risk ratio (*see* **Relative Risk**) to the **prevalence** of the omitted variable in smoking and nonsmoking groups. They wrote:

> If an agent, A, with no causal effect upon the risk of a disease, nevertheless, because of a positive correlation with some other causal agent, B, shows an apparent risk, r, for those exposed to A relative to those not so exposed, then the prevalence of B, among those exposed to A, relative to the prevalence among those not so exposed, must be greater than r.
>
> Thus, if cigarette smokers have 9 times the risk of nonsmokers for developing lung cancer, and this is not because cigarette smoke is a causal agent, but only because cigarette smokers produce hormone X, then the proportion of hormone X-producers among cigarette smokers must be at least 9 times greater than among nonsmokers. If the relative prevalence of hormone X-producers is considerably less than ninefold, then hormone X cannot account for the magnitude of the apparent effect.

See [13, p. 40] for a discussion of the origins of the inequality.

Formally, the analysis involves three binary variables: (i) $Z = 1$ for treatment (smoker) and $Z = 0$ for control (nonsmoker), (ii) $D = 1$ for positive response (lung cancer) and $D = 0$ for negative response, (iii) $U = 1$ for presence of the unobserved omitted variable and $U = 0$ for its absence. We observe the joint distribution of Z and D, specifically $\pi = \Pr(Z = 1)$, $p_1 = \Pr(D = 1|Z = 1)$ and $p_0 = \Pr(D = 1|Z = 0)$, from which we calculate the observed risk ratio $R_{\mathrm{O}} = p_1/p_0$. Could the observed risk ratio R_{O} deviate from one solely because of the unobserved variable, U? If this were the case, then D would be independent of Z given U. Hence,

$$\begin{aligned} p &\equiv \Pr(D = 1|Z = 1, U = 0) \\ &= \Pr(D = 1|Z = 0, U = 0) \\ &= \Pr(D = 1|U = 0) \end{aligned}$$

and

$$\begin{aligned} pR_{\mathrm{U}} &= \Pr(D = 1|Z = 1, U = 1) \\ &= \Pr(D = 1|Z = 0, U = 1) \\ &= \Pr(D = 1|U = 1), \end{aligned}$$

where

$$R_{\mathrm{U}} = \frac{\Pr(D = 1|U = 1)}{\Pr(D = 1|U = 0)}.$$

Here, R_{U} is the unobserved risk ratio linking the response, D, with the unobserved variable, U. We may assume that the two categories of the variable U, $U = 1$, and $U = 0$, have been labeled so that $R_{\mathrm{U}} \geq 1$. Writing $f_1 = \Pr(U = 1|Z = 1)$ and $f_0 = \Pr(U = 1|Z = 0)$ gives

$$\begin{aligned} R_{\mathrm{O}} = \frac{p_1}{p_0} &= \frac{p(1 - f_1) + pR_{\mathrm{U}}f_1}{p(1 - f_0) + pR_{\mathrm{U}}f_0} \\ &= \frac{f_1R_{\mathrm{U}} + 1 - f_1}{f_0R_{\mathrm{U}} + 1 - f_0}. \end{aligned} \tag{1}$$

For a fixed $R_{\mathrm{U}} \geq 1$, expression (1) is maximized when $f_1 = 1$ and $f_0 = 0$, leading to the inequality

$$R_{\mathrm{O}} \leq R_{\mathrm{U}}. \tag{2}$$

Similarly, for fixed values of f_0 and f_1, expression (1) is maximized by letting $R_{\mathrm{U}} \to \infty$, yielding the inequality

$$R_{\mathrm{O}} \leq \frac{f_1}{f_0} = \theta, \text{ say.} \tag{3}$$

Eqs. (2) and (3) say that the unobserved risk ratio, R_U, must exceed both the observed risk ratio, R_{O}, and the unobserved prevalence ratio, θ, if U is to explain away the association between treatment Z and response D. Expressions (2) and (3) are the inequalities of Cornfield et al. [6], and (3) is described in the quotation above.

Gastwirth [9] gave a sharper version of (3) by solving (1) for θ to obtain

$$\theta = R_{\mathrm{O}} + \frac{R_{\mathrm{O}} - 1}{R_{\mathrm{U}} - 1}\frac{1}{f_0}, \tag{4}$$

or, equivalently,

$$f_1 = R_{\mathrm{O}}f_0 + \frac{R_{\mathrm{O}} - 1}{R_{\mathrm{U}} - 1}. \tag{5}$$

We illustrate the result on data from the cohort study [29] of lung cancer in asbestos workers, as described in [9, p. 807]. Over the entire period of the study, the relative risk of exposed workers dying from lung cancer was 6.8 times their

expected number, assuming workers had the rate of lung cancer in the general male population. As smoking is another risk factor for lung cancer, we apply Cornfield's inequality to see whether smoking could explain the asbestos–lung cancer association. It is known that blue-collar workers have a greater prevalence of smoking than in the general male population. At the time of the study, 60% of all males smoked, in contrast to about 80% of males in asbestos-related occupations. The prevalence ratio, $\theta = 0.8/0.6 = 1.33$, is much less than $R_{\mathrm{O}} = 6.8$, so Cornfield's inequality implies that smoking cannot explain the entire association between asbestos and lung cancer.

When information about R_{U} is available, (4) can provide a substantially stronger statement. Suppose that a large study of workers exposed to chemical A found a relative risk of three for lung cancer. While smoking was controlled for in this imagined study, prior substantial exposure to asbestos, U, was not, although the literature indicates that R_{U} is, at most, 10. The original inequality (3) implies that the prevalence of asbestos exposure (U) in the exposed workers needs to be at least three times its prevalence among workers not exposed to chemical A. From the job histories of the workers one might estimate that the prevalence, f_0, of U among the unexposed group was 0.05, say. Then (5) implies that the prevalence of U among workers exposed to chemical A would need to reach 0.374 in order for the observed association between lung cancer and chemical A to be explained by prior substantial exposure to asbestos. This is much larger than $3 \times 0.05 = 0.15$ implied by the original inequality. Indeed, inequality (3) is obtained from (4) by letting R_{U} become arbitrarily large.

While Cornfield et al. [6] preferred the relative risk measure for assessing causality, the difference in proportions, or the absolute risk difference, is useful in public health. Write $\Delta_U = \Pr(D = 1|U = 1) - \Pr(D = 1|U = 0)$ for the difference in mortality rates associated with the unobserved variable, and write $\Delta_Z = \Pr(D = 1|Z = 1) - \Pr(D = 1|Z = 0)$ for the difference in mortality associated with the exposure. The corresponding inequality is given in the following lemma.

Lemma. If U is to explain entirely the observed difference Δ_Z, then one must have $(f_1 - f_0)\Delta_U \geq \Delta_Z$, and, in particular, one must have both $\Delta_U \geq \Delta_Z$ and $f_1 - f_0 \geq \Delta_Z$.

Inequalities closely related to Cornfield's inequality have been proposed by Bross [3, 4] and Schlesselmann [28]. Related equalities are discussed by Miettinen [19], Breslow & Day [2, p. 96], and Gail et al. [7], and the equalities might be used to calculate adjusted risk ratios. Gastwirth [10] suggests that the inequalities (2) and (3) be used in conjunction with Koopman's [15] one-sided **confidence interval** for the risk ratio $\Pr(D = 1|Z = 1)/\Pr(D = 1|Z = 0)$ to account for sampling error. Gastwirth [11] uses the reasoning underlying the inequality of Cornfield et al. [6] to examine the potential effect of **nonresponse** or **missing data**. Gail et al. [8] discuss the effect of failing to adjust for a covariate in a clinical trial.

Cornfield's inequality was the first formal method of **sensitivity analysis** in **observational studies** or **nonrandomized** experiments. The inequality may be viewed as asking how the conclusions of an observational study might be altered by departures of various magnitudes from the random assignment of treatments (*see* **Randomized Treatment Assignment**), where the departure is measured by the prevalence ratio, θ. Viewed in this way, sensitivity analysis based on Cornfield's inequality is identical in purpose, similar in spirit, though different in technical detail, to the method of permutational sensitivity analysis proposed later by Rosenbaum [21–25] and Rosenbaum & Krieger, [26]. The latter approach applies not only to **binary** responses, but also to continuous responses, discrete scores, censored survival times (*see* **Censored Data**) and multivariate outcomes. It permits sensitivity analysis for **quantiles**, Wilcoxon's [30] rank sum test (*see* **Wilcoxon–Mann–Whitney Test**) and **signed rank** test, the **logrank test** and Gehan test [12] for survival times, the Hodges–Lehmann [14] point estimates of an additive effect, **McNemar test** [18], the **Mantel–Haenszel method** [17], and Mantel's extension for discrete scores [16], among others. In one very special case, Cornfield's inequality and Rosenbaum's sensitivity analysis give identical results. Specifically, with a binary response in a **case–control study** that approximates the relative risk by the **odds ratio**, the lower endpoint of the $1 - \alpha$ confidence interval for the relative risk in Cornfield's inequality occurs at the value of the sensitivity parameter yielding an upper bound of α for the significance level for testing no treatment effect; see Rosenbaum [22] for specifics. Other methods

of sensitivity analysis are discussed in [1, 5, 20], and [27].

Correlated Binary Data

In many studies, the primary measure of interest can take on one of two possible values, and is known as a binary response measure (*see* **Binary Data**). An example might be disease status (i.e. diseased/not diseased), in which the two categories are the only ones possible. In other situations, we might form the two categories by dichotomizing a continuous response, for example, whether or not systolic blood pressure is greater than 140 (*see* **Categorizing Continuous Variables**). The term *correlated binary response data* refers to two or more such binary outcome measures, which we assume are correlated. This situation could arise in a **longitudinal** study, where disease state (diseased/not diseased) is measured over time on the same person. Spatial proximity can also induce **correlation**, with measurements taken closer together assumed more highly correlated than those further apart. The similarity of sampling units can induce the correlation, such as when litter-mates or siblings are sampled, or when a matching process is used to build sets of similar sampling units. A fourth setting of correlated responses arises when the outcome variable is measured on subunits of a single, primary sampling unit, such as measuring the disease status of a person's right and left eyes separately.

The term *cluster* is often used in the literature to describe a set of correlated measurements (*see* **Cluster Sampling**). A measurement on each of two eyes on the same person would constitute a cluster of size two. Measurements on the same person taken at 6, 12, 18, and 24 months would constitute a cluster of size four. In some settings, there are multiple levels of clustering, otherwise described as a hierarchy of clusters. For example, measurements over time (level 1) on each of the two eyes (level 2) of a person (level 3) would constitute a cluster of two eyes of one person and a subcluster of multiple measurements over time on each of those two eyes. The individual measurements within the cluster are called subunits (or sub-subunits) of the cluster. Positive correlation among subunits is manifested by more homogeneous subunits and more variable cluster totals than would be expected with no correlation (i.e. simple Bernoulli sampling or **binomial** data). This effect is called extrabinomial variation or **overdispersion**. Ignoring this positive correlation in the analysis will result in statistical tests that overstate the significance of the differences seen among subunit responses.

This discussion is restricted primarily to settings in which there is a single random sample of clusters, such as a sample of different people in the **ophthalmologic** and longitudinal data settings, with some discussion of hierarchical clustering as well.

In some settings, the investigator may have other **explanatory variables** (or **covariates**, which can be used to model the probability of a binary outcome. When the covariate value must stay the same for all subunits of a cluster, it is called a *between-cluster or subunit-independent covariate*. When it can change from one member of the cluster to another, it is called a *within-cluster or subunit-dependent covariate*. In the context of longitudinal studies, the terms *time-independent* (for between-cluster) and *time-dependent* (for within-cluster) covariates have often been used. In hierarchical clustering, covariates could change or be constant at any level of the hierarchy.

We start by laying the groundwork in the context of a very simple setting with no covariates. The rest of the discussion is focused on **regression**-type methods that can accommodate covariates, separated into the major categories of response feature models, conditionally specified models, **transitional models**, **marginal models**, and cluster-specific models, and how **hierarchical models** can be accommodated in the different categories. Emphasis is placed on similarities and differences among them in terms of the questions that can be addressed, methods for fitting the model, interpretations of parameters, making inferences, and, to a lessor degree, computational aspects. Examples of many of these methods can be found in books by Diggle et al. [15] Goldstein, [20], Verbeke, and Molenberghs [60, 61] and Davis [14]. Our intent is to give the reader an overview of the work in this area and to point to key references in which more detail can be found.

Simple Setting with No Covariates

In the simplest setting, the cluster is of size two and there are no explanatory variables (*see* **Matched Pairs With Categorical Data**). The data could be laid out in a **two-by-two contingency table**, such as that given in Figure 1 for binary measurements taken at two time points.

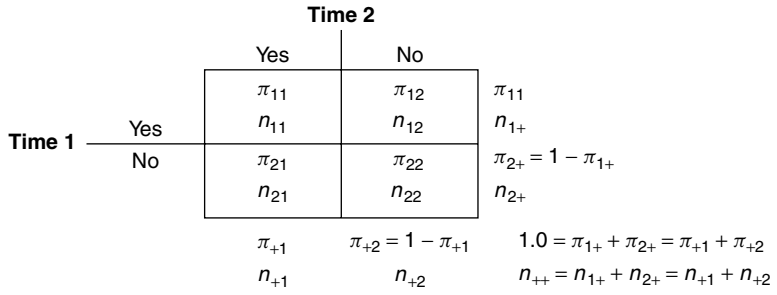

Figure 1 Notation for paired binary responses in contingency table format

Here, π_{11} represents the underlying joint probability of responding Yes at both time points, π_{12} and π_{21}, the probabilities of a Yes at one time point and a No at the other, and π_{22} the probability of responding No at both time points. The π_{1+} and π_{+1} are **marginal probabilities** – that is, π_{1+} is the probability of responding Yes at the first time point, regardless of whether a Yes or No was the response at the second time point.

The corresponding sample proportions, $p_{i,j} = n_{i,j}/n_{++}$ and $p_{1+} = (n_{11} + n_{12})/n_{++}$, can be used to address research questions. Different questions require different frameworks for modeling the data. If the goal is to assess the strength of the relationship between responses at the two time points, measures, such as an **odds ratio**, a **relative risk**, a tetrachoric correlation, or one of many other measures of **association** would be useful. If one were interested in determining if the proportion who answered Yes changed from time 1 to time 2, a **confidence interval** could be constructed on the difference in marginal proportions, $\pi_{1+} - \pi_{+1}$, or one could use the **McNemar test** of the **null hypothesis** $\pi_{1+} = \pi_{+1}$.

Cox [11] suggested a **logistic regression** approach to this problem of comparing marginal proportions, which only uses the clusters where a difference in responses was observed. Let $(y_{i,1}, y_{i,2})$ represent the pair of binary responses for the ith pair and let y take on the value 1 for Yes or success and 0 for No or failure. The model has the form

$$\log\left[\frac{P(y_{i,1}=1)}{P(y_{i,1}=0)}\right] = \alpha_i \qquad (1)$$

for the first member of the ith pair, and

$$\log\left[\frac{P(y_{i,2}=1)}{P(y_{i,2}=0)}\right] = \alpha_i + \beta \qquad (2)$$

for the second. The α_i parameters in both models simply measure variation from cluster to cluster. They are usually not of interest and are called **nuisance parameters**. The β parameter quantifies the difference between the two time points. The value exp (β) is called an odds ratio, meaning that the odds of a Yes (1) response (versus a No (0) response) are exp (β) times higher at time 2 than at time 1. The probability of a Yes response for the ith cluster at time 1 is $\exp(\alpha_i)/(1+\exp(\alpha_i))$ and $\exp(\alpha_i+\beta)/[1+\exp(\alpha_i+\beta)]$ at time 2. Because this model has as many α_i parameters as there are independent clusters of data, we could not estimate each of them. However, by conditioning on the number of Yes responses in the cluster, we find that the conditional joint distribution of responses only depends on those clusters with exactly one positive response and has the form of a **binomial distribution**, with mean parameter $\exp(\beta)/(1+\exp(\beta))$ and sample size parameter equaling the number of clusters, where $y_{i,1} + y_{i,2} = 1$ (*see* **Conditionality Principle**). Estimation and inference follow the usual theory for binomial data. We note that testing the mean parameter equal to 1/2 is equivalent to testing β equal to 0, a hypothesis of no difference between the responses at time 1 and time 2. This is an example of a **random-effects** model in which conditioning is used to enable **estimation**. Extensions of this type of model are further discussed in the section "Cluster-specific Models".

When $\pi_{1+} = \pi_{+1}$, it follows that $\pi_{2+} = \pi_{+2}$. This equality of all the marginal probabilities is known as marginal homogeneity (*see* **Marginal Models**). In a 2×2 table, marginal homogeneity also implies $\pi_{12} = \pi_{21}$. For the **square contingency table** in general, the condition $\pi_{ij} = \pi_{ji}$ for all $i \neq j$ is called symmetry of probabilities across the main

diagonal. The symmetry condition implies marginal homogeneity, but the reverse is not true for tables larger than 2×2.

In the case of binary responses at more than two time points, Cochran's Q test or, more generally, the Cochran–Mantel–Haenszel test, can be used to test for marginal homogeneity (*see* **Mantel–Haenszel Methods**).

Models with Covariates

In many settings, the researcher will be interested in learning not only if the response probabilities change over time (or among cluster subunits), but whether those changes are related to changes in covariates. For example, in **clinical trial** and **epidemiologic** settings, the goal may be to assess whether the probability of obtaining a disease differs across various randomized treatment regimens or is associated with observed **risk factors**. In other studies, however, the primary goal might be to investigate the structure of the within-cluster correlation or association. Models for these parameters could be set up to determine if the correlation/association within clusters is affected by between-cluster covariates. This type of analysis could, for example, have an application in determining the efficacy of a drug in preventing the spread of a contagious disease to other members of the cluster.

The types of models that can be fit in such situations depend upon the **measurement scale** of the covariates (nominal, ordinal, or continuous), the type and cluster level of covariates (between-cluster, within-cluster, or both), the types of assumptions the researcher is willing to make on the underlying joint distribution of the correlated responses, and the research questions to be answered. We focus primarily on regression-type methods that can accommodate both continuous and categorical covariates. Linear logistic regression models and probit models, which fall within a broad class of models known as **generalized linear models** (GLMs), play a central role in many analytic approaches to correlated binary data. Characterizing the underlying joint distribution of the responses within a cluster requires measures of the strength of the correlation or association within the cluster. Either first- and higher-order product-moment correlations or conditional odds ratios have typically been used to capture those intracluster relationships.

Modeling Strategies

Most modeling strategies for correlated binary data fall into at least one of five categories:

1. *Response feature models.* Collapse response information into one measure per cluster, and model using methods appropriate for independent univariate measures, such as logistic regression.

2. *Conditionally specified models.* The probability of a positive response for one member of the cluster is modeled conditionally on all other outcomes in the same cluster.

3. *Transitional models.* Model the probability of a positive response for one cluster member as a function of previous outcomes and covariates. This approach is applicable if the cluster members have a natural ordering, such as in longitudinal studies or studies concerning birth order.

4. *Marginal models.* Model the marginal probabilities in terms of covariates, often treating the correlation among cluster members as nuisance parameters, while focusing primarily on marginal mean parameters.

5. *Cluster-specific models.* Allow the model for each cluster to differ by including cluster-specific parameters, which can describe the correlation structure within the cluster. Since the number of such parameters grows along with the number of clusters, a popular approach is to consider these cluster-specific parameters as a **random sample** from some underlying distribution.

Once a modeling strategy has been chosen, there is also the issue of which method or methods can be used to fit the model. Because of the complexity of specifying a complete joint distribution for the set of correlated responses and the associated computational burdens, **maximum likelihood** estimation within a classical statistical approach is not always feasible. However, weighted **least squares**, conditional **likelihood**, **quasi-likelihood**, and different types of approximations to the desired likelihoods have been used. **Bayesian** approaches to specification and estimation in such models have gained a lot of attention recently, due to improved computational approaches to implementing the analyses and some attractive properties. However, they too provide

some challenges, such as the difficulty in specifying hyperparameters and the potential for badly behaved posterior distributions.

Naïve Approaches and Response Feature Models

Naïve approaches refer to the analysis of clustered binary data, which ignore the correlation between subunits. The advantage of such a method is that standard tools and familiar models can be used for the analysis. When all data are used but the association among subunits is ignored, the regression estimators will still be consistent for the parameters of a marginal model.

In some situations, the multivariate response from each cluster might be reduced to a univariate response without major loss, thus simplifying the situation considerably. Once the data have been reduced to a univariate response per cluster, the usual techniques applicable to independent univariate observations are appropriate. For example, an ophthalmologist may only be interested in analyzing binary outcomes from the "worst eye" or "best eye", which would allow the use of standard logistic regression techniques. In the case of longitudinal data, one might be interested in the peak response across a series of repeated measurements or the time until the first positive response (*see* **Summary Measures Analysis of Longitudinal Data**). It is important that this feature of the data be well-defined before the data were collected, rather than suggested by a particular sample.

There are a number of disadvantages of naïve approaches. Ignoring some of the data, such as choosing only one member of the cluster, is not fully **efficient** and **standard error** estimates will be incorrect. By summarizing the responses, we can lose valuable information and the chance to capitalize on the relationships among cluster members. Another difficulty is how to properly use within-cluster covariates. With response feature transformations that only take the data from one subunit, such as analyzing the "worst eye" of a patient with measurements on two eyes, using the covariate corresponding to the worst eye might have the undesirable effect of selecting the covariate on the basis of the response. However, with the idea of creating a "better" person-specific covariate value, sometimes functions of the subunit-dependent covariates are used, such as taking the sum or difference.

Conditional Specification of Models

Conditioning plays an important role in statistical methodology when independence assumptions are not applicable. We say that a model is *conditionally specified* if the joint distribution of the data is built up from a set of conditional distributions. In some settings, it is conceptually easier and more natural to specify such conditional distributions, viewing the joint distribution as merely a consequence of their synthesis. A key implication is that the model parameters are interpreted in terms of conditional probabilities, rather than in terms of joint or marginal probabilities.

Conditioning enters only on the cluster level, so it is reasonable to simplify the discussion and to consider models for one representative cluster of size n_i, that is, $\mathbf{y}_i = (y_{i,1}, \ldots, y_{i,n_i})$, where $y_{i,j}$ is the binary response of the jth member of the ith cluster.

General Loglinear Model

The joint distribution of $\mathbf{y}_i$ in a general **loglinear model** [17, 66], is

$$\log(\Pr(\mathbf{y}_i)) = \gamma_i' \mathbf{y}_i + \delta_i' \mathbf{w}_i - A(\gamma_i, \delta_i). \qquad (3)$$

Here, $\mathbf{w}_i$ is a vector of length $(2^{n_i} - n_i - 1)$ that contains all cross-products of y_i, that is, all pairwise products $(y_{i,j} y_{i,k},\ j \neq k)$, three-way cross-products $(y_{i,j} y_{i,k} y_{i,l},\ j \neq k \neq l)$, up to the n_i-way cross-product $(y_{i,1} y_{i,2\ldots}, y_{i,n_i})$. $\boldsymbol{\gamma}_i$ and $\boldsymbol{\delta}_i$ are vectors of parameters, and $A(\boldsymbol{\gamma}_i, \boldsymbol{\delta}_i)$ is a normalizing constant.

The components of $\boldsymbol{\gamma}_i = (\gamma_{i,1}, \ldots, \gamma_{i,n_i})$ have an interpretation in terms of the **conditional probability**:

$$\gamma_{i,j} = \text{logit}[\Pr(y_{i,j} = 1 | y_{i,k} = 0, k \neq j)]. \qquad (4)$$

Rather than using correlation parameters to characterize within-cluster relationships, this parameterization uses conditional odds ratios. The components of $\boldsymbol{\delta}_i = (\delta_{i,12}, \delta_{i,13}, \ldots, \delta_{i,12\ldots n_i})$ can be interpreted in terms of contrasts of log conditional odds ratios, which determine the second-order and higher-order associations between the subunits within a cluster.

The general regression strategy is to model $(\boldsymbol{\gamma}_i, \boldsymbol{\delta}_i)$ as a function of covariates $\mathbf{x}_{i,j}$ and unknown parameters $\boldsymbol{\theta}$. Depending on the setting and the questions to be addressed, modeling either the conditional probabilities or the marginal probabilities could be the more

natural approach. If the marginal model approach is preferred, the $\boldsymbol{\gamma}_i$ could be transformed to marginal probabilities, $\Pr(y_{i,j} = 1)$, and the log-conditional odds ratios to pairwise and higher-order correlations or other marginal measures of association. We note that such correlations will have a range of possible values constrained by the marginal probabilities and other correlation parameters. Because the number of association or correlation parameters in a fully specified joint distribution becomes large quickly as the cluster size increases, another issue in our modeling strategy is the question of which higher-order associations we can set to zero to simplify matters. For example, if we set all the associations to be equal to zero, that is $\boldsymbol{\delta}_i = 0$ for all i, then all the subunits within clusters are assumed independent. If we then model $\gamma_{i,m} = \mathbf{x}'_{i,m}\boldsymbol{\beta}$, we obtain the independent logistic regression model. For correlated data, a reasonable choice might be to select a set of higher-order association parameters to be zero. One computational problem that affects models based on (3) is that the normalizing constant $A(\boldsymbol{\gamma}_i, \boldsymbol{\delta}_i)$ often needs to be calculated explicitly.

These two modeling choices generate four different strategies for conditional modeling:

1. Model the conditional probabilities and not assume any of the associations are zero. Examples of this sort of model include saturated log-linear models.
2. Model the conditional probabilities directly, and fix the three- and higher-way moments to zero. Examples of these models are autologistic and response conditional models.
3. Model the marginal probabilities that are transformations of the conditional probabilities, and not assume that any of the associations are zero. Examples of this sort of model include mixed parameter models.
4. Model the marginal probabilities and assume the three- and higher-way moments are zero. Models that could accommodate this assumption include quadratic exponential models.

A particular research question may require specification of a model for the joint distribution, while a second research question might be better addressed by a model for the marginal distributions, or possibly marginal means and first-order associations. What method is used to fit a model depends not only on the assumptions the investigator is willing to make and the questions to be answered, but also (to some extent) on the availability of computational **algorithms**.

Marginal models for categorical data have been commonly fitted using weighted least squares methods, but this method has difficulty with sparse data. Traditionally, maximum likelihood methods for fitting categorical data marginal models have not been widely used, due to their perceived complexity. However, this is changing with more recent work. In the more general setting of modeling marginal means using any generalized linear model, the **generalized estimating equation** approach (discussed further in the Marginal Models section) has become common.

Autologistic Model

Consider a conditionally specified model where third- and higher-order associations are set to zero. In developing methods for **spatial** statistics, Besag [7] introduced the autologistic model having precisely this form:

$$\text{logit}[\Pr(y_{i,j} = 1 | y_{i,1}, y_{i,2}, \ldots, y_{i,j-1}, y_{i,j+1}, \ldots, y_{i,n_i})] = \alpha_j + \sum_{k \neq j} \beta_{j,k} y_{i,k}. \quad (5)$$

Although this proposal did not include covariates, it was perhaps the first extension of the linear logistic regression model to dependent binary data. Likelihood equations can be obtained from the joint distribution of the data and solved iteratively (*see* **Optimization and Nonlinear Equations**). However, as mentioned above, the requirement that the normalizing constant be evaluated during each iteration often causes difficulties. As an alternative estimation strategy, Besag [7] suggested the use of a **pseudo-likelihood** formed from the full conditional distributions. Logistic regression **software** can be used to compute the pseudo-likelihood estimates. Simply, the responses $y_{i,k}$, which are assumed to have a nonzero association with $y_{i,j}$, are used as covariate values for that case. Thus, while the model may properly account for dependence, the pseudo-likelihood estimation differs from likelihood estimation in that it ignores certain aspects of this dependence.

Given recent computational advances, exact likelihood evaluation is often possible, at least with relatively small clusters. In special cases, the normalizer

A collapses, or can be absorbed into a computable quantity [1]. Geyer & Thompson [19] present a **Markov chain Monte Carlo** method that enables likelihood inference.

Response Conditional Models

A flexible extension to the autologistic model in (5) allows covariates and a nonlinear contribution from associated responses.

Rosner [50] presents a model where dependence on the other responses in the ith cluster comes through their sum $s_{i,j} = \Sigma_{k \neq j} y_{i,k}$. The full conditional specification is

$$\begin{aligned} &\text{logit}[\Pr(y_{i,j} = 1 | y_{i,k}, k \neq j)] \\ &\quad = F(s_{i,j}, n_i, \theta_1, \theta_2) + \mathbf{x}'_{i,j}\boldsymbol{\beta}, \end{aligned} \tag{6}$$

where $\mathbf{x}_{i,j}$ is a covariate vector for the jth cluster member, $\boldsymbol{\beta}$ is a regression parameter, n_i is the size of the ith cluster, and

$$F(s, n, \theta_1, \theta_2) = \log \left\{ \frac{(\theta_1 + s\theta_2)}{[1 - \theta_1 + (n - 1 - s)\theta_2]} \right\}. \tag{7}$$

When the term $\mathbf{x}'_{i,j}\boldsymbol{\beta}$ equals 0 for all subunits of the cluster, Rosner's model reduces to the **beta-binomial distribution**, a model commonly used to account for overdispersion in binary data measured without covariates.

Several authors have proposed more general forms for F in this model, allowing negative intraclass correlation and extensions to multivariate **time series** [10, 37, 49], (*see* **Multiple Time Series**).

Transitional Models

The previous section details general strategies and models via the conditional distribution, where the underlying probabilities of interest are conditioned on all other responses in the cluster: $\Pr(y_{ij} | y_{ik}, k \neq j)$. An important special case occurs when the subunit responses within a cluster have an inherent ordering. The obvious classical example involves ordering over time, such as longitudinal data collected repeatedly and with familial data with an ordering over generations or birth order. In these cases, the analyst would not be interested in comparing or modeling the full conditional probabilities, since each would be conditional on events occurring both in the past and in the future. Instead, models that retain the inherent ordering and logical consistency of conditioning on only past responses are of interest. These models are generally termed *transitional* models.

The cornerstone of transitional models lies with **Markov chains** and **Markov processes**, which model the conditional probability given q prior outcomes. With binary responses, the collection of conditional probabilities can be combined into a transition matrix. To model the conditional probabilities as a function of covariates, regression models that explicitly use the past responses as additional covariates have been used. In particular, these build on the model by Cox [11], who is recognized as among the first to describe a transitional model for binary data. Specifically, given a first-order Markov structure, the log likelihood could be written as the sum of marginal and conditional likelihoods: $l(y_1) + l(y_2|y_1) + \cdots + l(y_n|y_{n-1})$. Ignoring the initial term, each log-likelihood component could be easily seen to be the same as sampling from a **multinomial distribution**, with the matrix of transition counts sufficient for the unknown transitional probabilities. Models for the probabilities could be formed by considering logistic equations of the form

$$\begin{aligned} &\text{logit}[\Pr(y_{i,t} = 1 | y_{i,(t-1)})] \\ &\qquad = \alpha + \beta_1 y_{i(t-1)}, + \text{ other terms.} \end{aligned} \tag{8}$$

Higher-order Markov models could be fitted, enhancing $\beta_1 y_{i,(t-1)}$ with other functions of $y_{i,(t-2)}$, $y_{i,(t-3)}, \ldots$. This model can be fitted using standard logistic regression software, and the interpretation of covariate regression coefficients is as a log odds ratio of outcome, given two people with identical past responses in addition to holding other covariates constant. **Interaction** terms of prior outcomes and covariates can be incorporated to see if the effect of a covariate is dependent on past responses.

Subsequent work by others has extended this idea in conjunction with random-effects models and generalized estimating equation approaches. When transitions between states do not occur at equally spaced (time) intervals, continuous time analogs of Markov chains can be used. Kalbfleisch & Lawless [33] provide a comprehensive discussion of extension of these models with covariates and efficient computation of parameter estimates. Heagerty [29]

takes a different approach by using a generalized linear model to relate the marginal means (i.e. $\Pr(y_{i,j} = 1|\mathbf{x}'_{i,j})$) to the covariates for that time point, assuming that the responses in the past do not influence covariate values of future observations. A separate pth order dependence model (e.g. Markov model) is used to capture the serial dependence, and together they fully specify the parametric model, which he describes as a *marginalized transition model of order p* (MTM(p)). Maximum likelihood estimation is possible, and the method allows for data both missing completely at random (MCAR) and missing at random (MAR) [39] (*see* **Missing Data**).

Marginal Models

In the previous section, the natural parameterization of the joint distribution was in terms of conditional probabilities. Often, the research question of interest is more appropriately described in terms of marginal parameters for modeling the relationship between the response and covariates. The parameters of such models have a "population-averaged" interpretation in the sense that the effect of the covariates is averaged across clusters or subsets with different values of cluster-level covariates which form the population, rather than conditional on parameter(s) identifying one particular cluster. Bahadur [6] specified the joint distribution of correlated binary data $(y_{i,1}, \ldots y_{i,n_i})$ in terms of marginal means, $\pi_{i,j} = \mathrm{E}(y_{i,j})$ standardized **residuals**, $e_{i,j} = (y_{i,j} - \pi_{i,j})/[\pi_{i,j}(1 - \pi_{i,j})]^{1/2}$, and correlation-type association parameters, $\rho_{i,12\ldots q} = \mathrm{E}(e_{i,1} \ldots e_{i,q})$, $q = 2, 3, \ldots, n_i$. A regression-type model could be used to model $\pi_{i,j}$ as a function of the covariates, and the usual maximum likelihood methods could be applied. Unfortunately, these association parameters are functions of the marginal probabilities $\pi_{i,j}$ and other association parameters, which constrains their values. The complexity of these interrelationships has deterred efforts to model all these parameters in terms of the covariates, particularly when only the marginal means, not the association parameters, are of scientific interest. To overcome this problem, models and methods have been formulated, which separate the marginal mean model from the specification of the dependency structure, often dealing specifically with only the (first-order) mean and second-order correlation components, operating under the assumption that the higher-order association parameters are not of critical importance.

Quadratic Exponential Models

The model introduced by Gourieroux et al. [22] is based on the loglinear model in (3), where the conditional probabilities $\boldsymbol{\gamma}_i$ are transformed to marginal probabilities, the second-order log conditional odds ratios in $\boldsymbol{\delta}_i$ are transformed to correlation parameters, and the three- and higher-way associations of $\boldsymbol{\delta}_i$ are set to zero. These authors show that maximum likelihood estimation yields consistent and asymptotically normal estimates.

Unfortunately, this estimation method requires calculation of third and fourth **moments**, which requires estimation of a normalizing constant. Zhao & Prentice [66] proposed solving a set of related estimating equations in lieu of the score equations. Further discussion of this and related models can be found in the section "Modifications and Extensions of the GEE method".

Generalized Estimating Equation (GEE) Approach

An estimation approach that places the emphasis on estimating marginal mean parameters, while treating the association parameters as nuisance parameters, is called the *generalized estimating equation (GEE) approach* [36], for which software is readily available [9, 51, 54, 58], The marginal means are modeled via any generalized linear model (GLM), which includes the familiar **linear regression** and logistic regression models. For binary data, the logit (i.e. logistic regression), probit, or complementary log–log links are commonly used to relate the marginal mean to the linear combination of the covariates (i.e. the linear predictor $\mathbf{x}'_{i,j}\ \boldsymbol{\beta}$).

If the analyst incorrectly assumed that all observations, both within and between clusters, were independent, maximum likelihood estimation of the β regression coefficients using standard software for generalized linear models would result in estimates that were **consistent**, but not efficient. To obtain better efficiency, the association within clusters must be built into the estimation method. The GEE method provides a way to do this.

The introduction of GLMs expanded the classical regression model by allowing the expected value of the response to be a nonlinear function of the

linear predictor and the variance of the responses to depend on the expected value. The relationship between the variance and the expected value, however, is restricted to those found in **exponential family** distributions. The data distribution in GLMs is completely specified, and thus, maximum likelihood estimation is possible. This estimating strategy is optimal in the sense that the solution to the score equations has minimum asymptotic variance among all estimates that are obtained from **unbiased** estimating equations.

If the constraint that the marginal distributions have exponential family form is relaxed so that the variance can be an arbitrary function of the mean, then we obtain quasi-likelihood models [62]. For these models, which still make between- and within-cluster independence assumptions, a quasi-score equation is derived via a quasi-likelihood function. The estimators obtained by solving the quasi-score function (estimating equation) are "optimal" in the sense that they have smallest variance among a class of linear unbiased estimators.

The GEE approach extends quasi-likelihood models by including a within-cluster "working" correlation matrix in the quasi-score (estimating) equations. The analyst can specify a form of this within-cluster correlation matrix or allow it to be completely unspecified. For example, one could specify a common correlation for every pair of cluster members (which would be assumed the same in every cluster), called an "exchangeable" correlation structure, or an autoregressive structure, where cluster members closer in time or space would be assumed to be more highly correlated than those further apart (*see* **ARMA and ARIMA Models**). This method allows unequal cluster sizes, but any missing data are assumed missing completely at random (MCAR) in the sense of Little & Rubin [39] (*see* **Nonignorable Dropout in Longitudinal Studies**).

The GEE method will produce consistent and asymptotically normal estimates of the $\boldsymbol{\beta}$ parameters (assuming some weak regularity conditions and the correct specification of the mean), even if the working correlation structure is specified incorrectly. The stronger the within-cluster correlation and the closer the working correlation is to the true underlying correlation, the higher the gain in efficiency. The resulting estimates of correlation parameters generally will not have good statistical properties. If they are considered nuisance parameters of no scientific interest, this lack of useful estimates is of little concern. Wald tests are used to assess the magnitude of the $\boldsymbol{\beta}$ parameters (*see* **Chi-square Tests**).

Modifications and Extensions of the GEE Method

The association parameters in the original GEE method were parameterized by pairwise moment correlations, which are constrained by the marginal probabilities, and other higher-order correlation parameters in the binary data setting. Because of this constraint and their treatment as nuisance parameters, other measures of association have been suggested and explored. Pairwise odds ratios, relative risks, and tetrachoric correlation have been considered. In practice, little difference has been found among the estimates of regression coefficients obtained using different measures of within-cluster dependencies.

As mentioned previously, an alternative approach to modeling marginal parameters of a multivariate binary distribution is to start with a characterization of the joint distribution in terms of conditional parameters and then transform to marginal parameters. An estimate of the normalizing constant is required to calculate third and fourth moments and the computation burden increases as the cluster size increases. As an alternative, an extension of the GEE method was proposed, which includes estimating equations for association parameters, treating them as scientific parameters of interest and allowing them to change as a function of the covariates. It uses a "working" structure that replaces the actual third and fourth moments with working estimates [48]. If the correlation (or other measure of association) between subunits changes for different covariate values, the parameters and their variance estimates should be closer to the truth using this approach and therefore more efficient. This extension of the GEE method, in which the estimation of the modeled mean and second-order association/covariance parameters are done simultaneously, is often referred to as the GEE2 method.

An advantage of the GEE2 over the GEE method is that the association parameters can now be treated as parameters of interest, with the same asymptotic normality and consistency properties of the GEE method. Like GEE, efficiency is improved if the working third- and fourth-order moments are approximately correct. Both GEE and GEE2 assume that the model for the mean is correctly specified. The GEE2

also assumes that the model for the dependency parameters is correct. If not, the consistency property of the mean regression parameters is lost – a trade off towards improved efficiency if both are correct.

Marginalized and Mixed Parameter Models

Several authors have taken a likelihood-based approach rather than a GEE estimation approach to the estimation of marginal means as a function of covariates (e.g. [17, 24, 26, 29, 43]). Likelihood-based methods have the advantages of a well-established framework for inference, **goodness-of-fit** measures, and the ability to accommodate data both MCAR and MAR [39]. This is in contrast with GEE estimation, which can only handle data MCAR. The basic approach is to characterize the relationship between the marginal mean and the covariates via a generalized linear regression model and complete the specification of the full multivariate distribution via canonical or marginal higher-order correlation parameters. In contrast to quasi-likelihood and GEE estimation approaches, the complete specification of the multivariate distribution allows the use of maximum likelihood estimation (when computationally feasible). For example, the mixed parameter model of Fitzmaurice & Laird [16] was built on the same family of distributions as described in (3), but uses a different parameterization. Instead of transforming from the canonical parameters ($\boldsymbol{\gamma}_i$, $\boldsymbol{\delta}_i$) to the marginal moments ($\boldsymbol{\mu}_i$, $\boldsymbol{\Delta}_i$), as was done by Zhao & Prentice [66], they use a one-to-one transformation to ($\boldsymbol{\mu}_i$, $\boldsymbol{\delta}_i$), forming a "mix" of marginal mean and canonical association parameters. The marginal mean is modeled as a function of the covariates via a link function. The canonical association parameters can also be modeled as a function of the linear predictor $\mathbf{z}'_i\boldsymbol{\alpha}$, where $\boldsymbol{\alpha}$ is a parameter vector and $\mathbf{z}_i$ is a set of covariates, as in the GEE2 method. The elements of $\mathbf{z}_i$ could, for example, be indicator variables setting some higher-order associations to zero or a subset of the between-cluster covariates for the mean. Similarly, Azzalini [5] reparameterized Markov models to allow regression modeling of the induced marginal means. In this sense, both Fitzmaurice & Laird [16] and Azzalini [5] "marginalized" the response conditional model of (3).

Heagerty [26], generalized by Heagerty & Zeger [27], builds on this approach, "marginalizing" the latent variable model (**generalized linear mixed model**) described in the "Cluster-specific Models" section. These marginally specified mixed models use a general linear model to characterize the relationship between the marginal means and covariates, for example, $\text{logit}(\Pr(y_{i,j} = 1|\mathbf{x}'_{i,j})) = \mathbf{x}'_{i,j}\boldsymbol{\beta}$, and a general linear mixed model for the dependency parameters, captured by modeling the conditional mean $\mu^b_{i,j} = \Pr(y_{i,j} = 1|x'_{i,j}, b_{i,j})$, conditioned on unobserved subcluster specific latent variables $b_{i,j}$:

$$\text{logit}(\Pr(y_{i,j} = 1|\mathbf{x}'_{i,j}, b_{i,j})) = \Delta(\mathbf{x}'_{i,j}) + b_{i,j}. \quad (9)$$

Here, the $b_{i,j}$ represent cluster subunit-specific random effects with joint distribution $f_\alpha(\mathbf{b}_i|\mathbf{X}_i)$ characterized by the parameter $\boldsymbol{\alpha}$, and $\Delta(\mathbf{x}'_{i,j})$ is a parameter implicitly defined by both the marginal linear predictor $\mathbf{x}'_{i,j}\beta$ and the random-effects distribution $f_\alpha(b_{i,j})$. The $b_{i,j}$ can be modeled further, such as $b_{i,j} = b_{i,0}$ (a cluster-level random intercept) inducing variability from cluster to cluster or $b_{i,j} = b_{i,0} + b^*_{i,1}x^*_i$ (different variability depending on value of cluster-level covariate x^*_i – for example, $b_{i,j} = b_{i,0}$ for control clusters ($x^*_i = 0$) and $b_{i,j} = b_{i,0} + b^*_{i,1}$ for treatment clusters ($x^*_i = 1$)). In longitudinal data settings, one might assume that the $b_{i,j}$ have an autoregressive covariance structure, to model decreasing correlation for measurements further apart. Such approaches assume that the observations $(y_{i,1}, y_{i,2}, \ldots, y_{i,n})$ are conditionally independent, given the $\boldsymbol{b}_i$. Using the fact that the marginal mean can be expressed as the expected value of the cluster-specific conditional mean

$$\begin{aligned}\Pr(y_{i,j} = 1|x'_{i,j}) &= \mathrm{E}_{f_\alpha}(\mu^b_{i,j}) \\ &= \mathrm{E}_{f_\alpha}[\Pr(y_{i,j} = 1|x'_{i,j}, b_{i,j})], \end{aligned} \quad (10)$$

$\Delta(\mathbf{x}'_{i,j})$ can be estimated via the convolution equation

$$\Pr(y_{i,j} = 1|x'_{i,j}) = \int (\mu^b_{i,j}) f_\alpha(b_{i,j}|x'_{i,j})\, \mathrm{d}b_{i,j}. \quad (11)$$

Letting $h(x) = \mathrm{g}^{-1}(x)$ as the inverse link function (inverse logit function here), this convolution equation can be written

$$h(x'_{i,j}\beta) = \int h(\Delta(x'_{i,j}) + b_{i,j}) f_\alpha(b_{i,j}|x'_{i,j})\, \mathrm{d}b_{i,j}, \quad (12)$$

thus more explicitly showing the relationship between the parameter $\Delta(\mathbf{x}'_{i,j})$, the linear predictor $x'_{i,j}\beta$, and the distribution of the random effects $f_\alpha(b_{i,j}|x'_{i,j})$.

A key feature of the marginal model approach of Fitzmaurice & Laird [16] is that the joint likelihood for $(\boldsymbol{\beta}, \boldsymbol{\alpha})$ separates into distinct likelihoods for $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$, due to the **orthogonality** of the parameters' spaces. This implies that the information about the within-cluster covariance structure will not asymptotically help estimate $\boldsymbol{\beta}$ or be detrimental if misspecified, as would be the case with GEE2. The inverse of the Fisher **information matrix** can be used to approximate $\text{cov}(\boldsymbol{\beta}, \boldsymbol{\alpha})$. If the marginal model for the mean is specified correctly, but the model for the dependency structure is not, the inverse of the Fisher information matrix can give inconsistent estimates of $\text{cov}(\boldsymbol{\beta})$.

Because of the conditional interpretation of the canonical parameters in $\boldsymbol{\delta}_i$ in the mixed model of Fitzmaurice & Laird, they are most applicable when the cluster sizes are the same. Varying cluster sizes require the estimation of a set of canonical parameters for each cluster size, and the canonical parameterization is not reproducible – meaning that the distribution of a subset of $\boldsymbol{y}_i$ cannot be written in the same form as that of the complete $\boldsymbol{y}_i$ by using a subset of the canonical parameters. The parameterization of $\text{cov}(\boldsymbol{Y}_i)$ and higher-order moments in the marginalized mixed model of Heagerty and Zeger [27], however, does not depend on the dimension of $\boldsymbol{Y}_i$ and thus presents no interpretation difficulties when the number of responses varies across clusters. Since the focus of these models is often the relationship between the marginal means and covariates, one might argue that the association/dependency parameters could simply be viewed as nuisance parameters, whose interpretation is of little interest. What might be of more concern, however, is the appropriateness of setting some higher-order association terms equal to zero to simplify the analysis, because the effect of such assumptions on the marginal mean parameters has not been fully explored. Several authors have investigated the effect of **misspecifying** the distribution of the random effects $f_\alpha(b_{i,j}|x'_{i,j})$ or failing to recognize its dependence on covariates in the marginally specified mixed model approach, and found it can cause substantial bias in the $\boldsymbol{\beta}$ parameters. However, the impact is less in the marginally specified mixed model than that observed in the conditional mixed model, which is discussed in the next section ([28, 42]).

Cluster-specific Models

Cluster-specific models are differentiated from population average or marginal models by the inclusion of parameters that are specific to cluster. The Cox model for a 2×2 contingency table described at the beginning of this article is a simple example. A somewhat more complex cluster-specific model includes a covariate that is linearly related to the log odds of the marginal probability of a positive response. We might also expect the intercept and slope of the relationship to vary from cluster to cluster. A model for this situation would take the following form:

$$\text{logit}[\Pr(y_{i,j} = 1|x_{i,j})] = \beta_{i,1} + \beta_{i,2}x_{i,j}, \qquad (13)$$

where $\beta_{i,1}$ and $\beta_{i,2}$ are the intercept and slope parameters for cluster i. Inference under this model is complicated by the fact that the number of parameters grows with the number of clusters.

Random-effects Models

A popular approach to reducing the number of parameters in a cluster-specific model is to assume that the clusters are a random sample from some underlying population of clusters and that the parameter values for the clusters follow a distribution. A typical choice is the **multivariate normal** (Gaussian) distribution:

$$\begin{bmatrix} \beta_{i,1} \\ \beta_{i,2} \end{bmatrix} \sim \text{N}\left(\begin{bmatrix} \alpha_1 \\ \alpha_2 \end{bmatrix}, \mathbf{D} \right), \qquad (14)$$

where α_1 and α_2 are the mean intercept and slope values for the population of clusters, and $\mathbf{D}$ is a 2×2 **covariance matrix**. This assumed distribution on the parameters makes this cluster-specific model a random-effects model. Models of this type are also commonly called **mixed-effects**, **hierarchical**, two-stage, and **empirical Bayes** models (*see* **Multilevel Models**).

If we define

$$b_{i,1} = \beta_{i,1} - \alpha_1 \text{ and } b_{i,2} = \beta_{i,2} - \alpha_2, \qquad (15)$$

then $b_{i,1}$ and $b_{i,2}$ are the deviations from the mean intercept and slope term for the ith cluster, sometimes described as *latent variables,* capturing an unmeasured, underlying variable. We can rewrite the model for the ith cluster's response in terms of the mean intercept and slope α_1 and α_2 (fixed effects) and the

(unobserved) individual deviations $b_{i,1}$ and $b_{i,2}$ (random effects) as:

$$\text{logit}[\Pr(y_{i,j} = 1|b_{i,1}, b_{i,2}, x_{i,j})] = (\alpha_1 + b_{i,1}) + (\alpha_2 + b_{i,2})x_{i,j}, \begin{bmatrix} b_{i,1} \\ b_{i,2} \end{bmatrix} \sim \text{N}(\mathbf{0}, \mathbf{D}). \quad (16)$$

In this formulation, the fixed effects are interpreted as the typical parameter values for the population, while the random effects modify the average parameters to be specific to that cluster. Unless the link is linear, predicted values from the fixed effects only will not produce a prediction of the mean response.

Conditional independence within the cluster is commonly assumed in random-effects models. That is, $y_{i,j}$ (given $b_{i,1}$, $b_{i,2}$, $x_{i,j}$) and $y_{i,j'}$ (given $b_{i,1}, b_{i,2}, x_{i,j'}$) are assumed independent for all $j \neq j'$, where j indexes the member within the cluster. Follmann & Wu [18] have proposed a random-effects model that accounts for informative missing data.

Inference in random-effects models is always based on a marginal or conditional distribution of the data, which does not include the random effects $b_{i,1}$ and $b_{i,2}$. This solves the problem of the number of parameters depending on the number of clusters.

Marginal Inference

If a parametric distribution G is assumed for the cluster-specific parameters, then the usual way to proceed is to obtain the marginal distribution of $\boldsymbol{y}_i$ by integrating out the random effects. This resulting distribution will depend on G but not on the random effects themselves. While G must be specified and estimated, inference about the regression coefficients tends not to be sensitive to misspecification of G if the marginal distribution of $\mathbf{y}_i$ is rich enough [44]. This should also hold for sensitivity to the assumption of conditional independence within the cluster. However, some recent work has shown greater sensitivity to unrecognized dependence of the distribution G on covariate values. [28]. In most cases, there is no closed-form expression for the marginal distribution, and direct maximum likelihood estimation requires either **numerical integration** or **Monte Carlo** integration. Alternatively, estimation can be accomplished using a maximum likelihood or **restricted maximum likelihood** approach based on closed-form approximations to the relevant distributions. These include implementations of the **EM algorithm** and generalized estimating equations [56, 65]. At this time, publicly available software for marginal estimation in cluster-specific models is becoming more readily available (MIXOR [30], PROC NLMIXED [52], GLMMIX Macro [53], EGRET [55].) When there are sufficient observations per cluster, a simple two-stage estimation procedure can be used as an approximation to maximum likelihood estimation [35]. First, individual logistic regressions are fit to each cluster. Secondly, weighted averages of these estimates are used to estimate the fixed effects.

Conditional Inference

Conditional estimation avoids the need to estimate the parameters in the random-effects distribution (*see* **Conditionality Principle**). This is accomplished by deriving the distribution of $\mathbf{y}_i$ conditional on **sufficient statistics** for the cluster-specific parameters. When the canonical link is used in a generalized linear model (such as the logit link with binomial errors), a sufficient statistic can be found. In general, however, such a sufficient statistic may not exist.

One simple model for which conditional estimation is tractable is a model with only one random effect corresponding to a cluster:

$$\text{logit}[\Pr(y_{i,j} = 1|\mathbf{x}_{i,j})] = \alpha_i + \beta_1 x_{i,j,1} + \beta_2 x_{i,j,2} + \cdots + \beta_q x_{i,j,1}. \quad (17)$$

Conditioning on the total number of responses in the ith cluster removes the α_i from the likelihood. The resulting conditional likelihood derives from a permutation argument [8]. Small-sample inferences for this model, which are similar to the well-known **Fisher's exact test** for 2×2 tables are also available and have been implemented in the LogXact and Proc-LogXact packages [12] (*see* **Exact Inference for Categorical Data**; **Logistic Regression, Conditional**; **StatXact**).

Interpretation of Regression Parameters

Since the models discussed above will often lead to different interpretations of the $\boldsymbol{\beta}$ parameters, an understanding of their differences is crucial. The choice of an appropriate model will be guided by how

well the interpretations address the research question of interest.

In the response conditional models, the interpretation of the $\boldsymbol{\beta}$ requires both the responses and the covariate values of the other cluster members to be held fixed. Also, the parameter interpretations change with cluster size, so it is more appropriate for data with common cluster sizes. For example, in a study of twins (cluster size of two) (*see* **Twin Analysis**), the regression coefficient for the kth covariate, β_k, represents the increase in log odds of the response related to a one-unit increase in the kth covariate for a particular twin, when holding all other covariates fixed *as well as* the response of the other twin. This dependence of the interpretation on the outcome of the sibling makes it different from the usual interpretation of a regression coefficient in logistic regression, underscoring the distinction between conditional and unconditional models. If the intent is to predict the outcome of one sibling (say, the one born second), conditioning on the information provided by the first-born may be highly desirable. However, if the intent is to study the association between outcome and a covariate, such conditioning would not be desirable.

The issue of how to interpret and compare the kth regression parameter, β_k, from a response conditional model relative to its counterpart in a marginal or cluster-specific model has been investigated by several authors [29, 45, 47]. Key factors are the magnitude and direction of the within-cluster dependencies both of the response measure and of the covariates.

Comparing the interpretations of β_k in the marginal model and as a fixed-effects parameter in a cluster-specific model has also received a great deal of attention. The difference between these two models may be difficult to internalize, partly because intuition carried over from classical linear regression models (correlated Gaussian data with the identity link) breaks down when considering non-Gaussian data (e.g. binary) and nonidentity links (e.g. logit link). We illustrate this with an example presented by Zeger et al. [65]. In a study of respiratory infections in children aged 7 to 11, the presence or absence of a respiratory infection in the previous year was recorded each year for 5 years. Thus, the child constitutes a cluster and the five observations over time per child are the subunits of the cluster. The mother's smoking status (Yes or No) was recorded at the beginning of the study, but not updated at follow-up visits. Thus the mother's smoking status would be a between-cluster covariate, assumed not to change over the five years.

Consider first a marginal model with an intercept, mother's smoking status, and age of the child at the time of measurement. If there were independence among responses across time, the interpretation of the regression coefficient would be precisely that of a simple logistic regression model. That is, every response would form its own cluster of size one. In the marginal model, the dependence is recognized in the estimation methodology, but not in the model for the marginal mean. The parameter β_k for smoking status represents the difference in the log odds ratio for respiratory infection between children with a smoking mother at baseline and those whose mother did not smoke at baseline. Mathematically, this is the difference in the log odds of the mean risk between these two groups, where the mean is taken over all children (clusters) and all observations (subunits), weighted by the working dependency structure used in the estimation method.

In a cluster-specific random-effects model with fixed effects for the same covariates as listed above, plus a random effect for child (i.e. a random cluster effect), the interpretation is conditional on that random effect for the child. Within this child, the coefficient represents the magnitude of change in the log odds one would expect with his mother smoking at baseline versus his mother not smoking at baseline. (Of course, this effect is unobservable because we cannot go back in time and change the mother's baseline smoking status.) Since the model specifies that this coefficient is the same for all children, it is estimated by combining information from different children, such as averaging over all children according to the distribution of that random effect for the child. Because the effect we are trying to measure is not observable, its estimation is heavily model-based.

If the mother's smoking status was recorded at each visit, thus considering smoking a within-cluster covariate, some mothers might change smoking status during the course of the study; hence, information on the effect of that change would be available. The cluster-specific model would capitalize on this observable change and allow estimation of the average effect (in terms of log odds ratios) of the change in smoking status on respiratory disease status, assuming there were clusters in which such changes took place. Mathematically, the collapse

of information across different children occurs after taking the difference in log odds at time points where the mother did and did not smoke, as opposed to first averaging across children and time points to obtain mean risks and then computing the log odds. The beta coefficient then represents the assumed common log odds ratio for respiratory disease of mother's smoking status across children, rather than the log odds ratio of the mean risk of respiratory disease.

The marginal model in this setting, on the other hand, would ignore the fact that the effect of change in smoking status was directly observable in some children, and persist in estimating only the odds ratio between smoking and nonsmoking mothers. Mothers who had changed smoking status would appear in both groups. Information obtained when individuals serve as their own controls when a change is observed is not used. In a marginally specified mixed model, the effect of a smoking mother versus a nonsmoking mother also involves averaging over the unobserved latent variables (random effects) in each group.

Extensions for Correlated Ordinal Responses

The focus of this article has been to review modeling strategies for correlated binary data by building upon the standard logistic regression model with a binomial sampling distribution. Models have also been introduced that extend regression models for ordinal responses with a multinomial sampling distribution. A brief review of two classes of extensions, marginal and random-effects, is discussed below. Agresti & Natarajan [3] provide a more complete review of these models.

The correlation structure of repeated ordinal data may be of interest but can be difficult to model. Dependence between ordinal responses has been described by Dale [13], and Heagerty & Zeger [25] discuss an approach extending the correlogram to categorical responses using log odds ratios.

Marginal Models

Stram et al. [57] introduced a marginal model for repeated ordinal measurements (*see* **Ordered Categorical Data**). Assuming that all patients are measured at common time points, they compute time-specific parameters for the **proportional odds model** proposed by McCullagh [40] and then combine these parameters using linear combinations weighted by the variance. However, as with the model of Wei & Stram [63], their model falls short in not allowing for **parsimonious** working correlation structures to be used. This has lead to the extensions of the generalized estimating equations methods for correlated ordinal measurements using cumulative logit models of McCullagh [40] ([24, 38, 41]). The current versions of SAS PROC GENMOD [51] and Stata [54] allow estimation of ordinal GEE models.

Because the GEE models are only valid with datasets that may have data missing completely at random (MCAR), there has been some concern about using these methods when data are missing at random (MAR). Kenward et al. [34] demonstrate potential problems as compared to likelihood-based approaches, such as those proposed by Molenberghs and Lesaffre [43].

Random-effects Models

Random-effects models for ordinal data were first proposed by Harville & Mee [23], whose purpose was best linear unbiased predictors (BLUP) of parameters of an underlying (latent) distribution. A more general approach was discussed by Hedeker & Gibbons [31], which uses a faster Fisher-scoring algorithm for estimating parameters of a model with multiple random effects. This model has been implemented in publicly available software [32]. An alternative method, which has not been specifically implemented, might be to use the Gibbs sampling methods of Zeger & Karim [64] to avoid direct numerical integration.

As mentioned above, another method for overcoming the increasing number of parameters in cluster-specific models is to treat the cluster-specific parameters as nuisance parameters, condition on their sufficient statistics, then maximize this conditional likelihood. Agresti & Lang [2] investigate this method for categorical, cluster-specific covariates.

Summary

Our focus has been on different estimation and modeling approaches for the general problem of clusters of correlated binary responses in the presence of both within- and between-cluster covariates. We have also generally restricted attention to methods

that can handle continuous covariates, rather than open the door to the large and dynamic literature on this topic presented within the general framework of categorical data models. We do not claim to have thoroughly covered or even mentioned all the relevant literature on this topic. For example, more could be said on goodness-of-fit testing and model **diagnostics**, Markov Chain models, estimation in the presence of missing data, design issues, Bayesian methods, small sample properties, adaptations to make these models more **robust**, and computational issues. Interested readers are referred to several books and survey articles that place emphasis on these and related models [4, 14, 15, 20, 21, 44, 46, 59].

Correlation

In a rather loose sense, two characteristics or variables are said to be correlated if changes in one variable tend to be accompanied by changes in the other, in either the same or the opposite direction. Thus, the incidence of ischemic heart disease is *positively* correlated with the softness of drinking water, since many epidemiologic studies have shown that the incidence tends to be higher in areas with softer water; and, conversely, the incidence is *negatively* correlated with water hardness.

In view of the more specific definitions to be discussed below, it would perhaps be preferable to use the term **association** for this informal usage. Correlation implies a *linear* relationship with superimposed random variation; association often loosely implies a monotone relationship, but the term may also be applied to nominal data where rank order is undefined.

For an account of the early history of the term *correlation*, see [10], especially pp. 297–299. The term was current during the middle of the nineteenth century, but its statistical usage is rightly attributed to Francis **Galton**, who initially used the spelling "co-relation". Galton was concerned with the correlation between characteristics of related individuals; for example, between an individual's height and the mean height of the two parents. The *correlation coefficient* emerged from Galton's work, after further elucidation by F.Y. **Edgeworth** and Karl **Pearson**, to become a central tool in the study of relationships between variables, especially (in Pearson's work) between physiological and behavioral measurements on human beings.

The Product–Moment Correlation Coefficient

The *product–moment correlation coefficient* (normally abbreviated to *correlation coefficient*) is a measure of the closeness of the association to a straight line. If the variables X and Y are **random variables** with a joint probability distribution, then the correlation coefficient is defined as

$$\rho = \frac{\sigma_{XY}}{\sigma_X \sigma_Y}, \tag{1}$$

where σ_{XY}, σ_X, and σ_Y are, respectively, the covariance of X and Y and the standard deviations of X and Y. The value of ρ is bounded between -1 and $+1$, taking these extreme values only when there is a linear functional relation between X and Y. Thus, if $Y = \alpha + \beta X$ exactly (as, for instance, with temperatures recorded in Fahrenheit for Y and centigrade for X), then $\rho = 1$ if $\beta > 0$ (as in this example), and $\rho = -1$ if $\beta < 0$.

Biologic variables are not normally connected by linear functional relations, and the correlation coefficient usually lies between the two extremes. There is a close connection between the concept of correlation and that of **linear regression**. Let $\beta_{Y.X}$ be the slope of the linear regression of Y on X, and $\beta_{X.Y}$ that of the regression of X on Y. Then

$$\beta_{Y.X} = \frac{\sigma_{XY}}{\sigma_X^2}, \qquad \beta_{X.Y} = \frac{\sigma_{XY}}{\sigma_Y^2}$$

and, from (1), $\beta_{Y.X}\beta_{X.Y} = \rho^2$. Since $\rho^2 \leq 1$, $|\beta_{Y.X}| \leq |1/\beta_{X.Y}|$ (the latter expression being the slope of the regression of X on Y in a diagram with Y as the ordinate), equality being achieved only for perfect correlation. Thus, the two regression lines are in general inclined at an angle. When the correlation coefficient $\rho = 0$, both $\beta_{Y.X}$ and $\beta_{X.Y}$ are zero, and the two regression lines are at right angles.

For a particular value of X, define Y_0 to be the value predicted by the linear regression of Y on X. Then the variance of the residuals about regression, $\mathrm{E}[(Y - Y_0)^2]$ is equal to $\sigma_Y^2(1 - \rho^2)$. One interpretation of the correlation coefficient is, therefore, the fact that its square is the proportion of the variance of one variable that is "explained" by linear regression on the other. The relationship is symmetric, being equally true for the other regression.

The Sample Correlation

The correlation coefficient may also be defined, in similar manner, for a finite set of n paired quantitative observations $(x_1, y_1), \ldots, (x_n, y_n)$. The correlation coefficient, denoted now by r, may be calculated as

$$r = \frac{\sum (x_i - \overline{x})(y_i - \overline{y})}{\left[\sum (x_i - \overline{x})^2 \sum (y_i - \overline{y})^2\right]^{1/2}}. \tag{2}$$

Here, $\overline{x}$ and $\overline{y}$ are the mean values of the x_i and y_i, respectively, and the summations run from 1 to n.

The basic properties of the sample correlation coefficient are essentially those outlined above for random variables. The relationship with regression now applies to the slopes of the **least squares** regression lines, $b_{y.x}$ and $b_{x.y}$. The squared correlation coefficient, r^2, is the proportion of the total sum of squares $\Sigma(y_i - \overline{y})^2$ "explained" by the regression of y on x.

Some scatter diagrams representing simple situations are shown schematically in Figure 1. In Figures 1(a) and (e) the points lie on a straight line, and $r = +1$ and -1, respectively. In Figure 1(c) the variation in one variable is approximately independent of the value of the other variable, and $r = 0$. In Figures 1(b) and (d) there is an intermediate degree of correlation, the variance of one variable being reduced when the value of the other variable is fixed, so $0 < r < 1$ for (b) and $-1 < r < 0$ for (d).

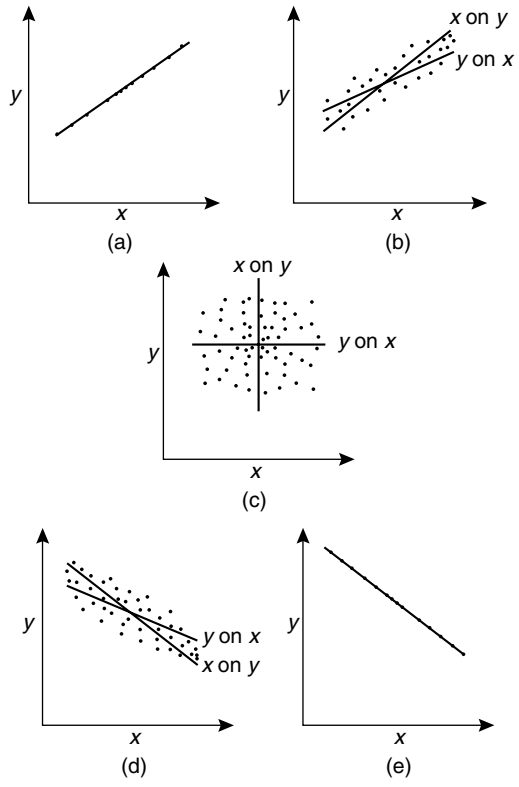

Figure 1 A schematic representation of scatter diagrams with regression lines, illustrating different values of the correlation coefficient. Reproduced from [1] by permission of Blackwell Science, Oxford

The sample correlation coefficient given in (2) is sometimes referred to as the *Pearson product–moment correlation coefficient*, the reference here being to Karl Pearson [7]. It provides the method of calculation for any finite set of paired values, and invites consideration of its sampling error.

Sampling Error

Suppose that the n pairs of observations are drawn at random from a **bivariate distribution** of random variables X and Y. The **sampling distribution** of r will depend on the characteristics of the parent distribution, in particular on the population correlation coefficient ρ. In general, r is a consistent but biased estimator of ρ (*see* **Unbiasedness**), but the bias is of order $1/n$ and likely to be small except for very small values of n (*see* **Estimation**). More specific results are available if stronger assumptions are made about the nature of the parent distribution, and the traditional assumption is that of a **bivariate normal distribution**. This model was widely used in the early work of Galton and Karl Pearson; appropriately enough, since it provides a reasonable description of many of the biometric variables studied by them.

Under the bivariate normal assumption, the distribution of r depends only on ρ and n. The density was first derived in 1915 by Fisher [4] and subsequently tabulated by David [3]. If $\rho = 0$, then the statistic

$$\frac{(n-2)^{1/2} r}{(1-r^2)^{1/2}} \tag{3}$$

follows a **Student's *t* distribution** with $n - 2$ degrees of freedom, and can be used to test the null hypothesis that $\rho = 0$ (*see* **Hypothesis Testing**). In fact, this test is valid more generally, for the standard model for linear regression (*see* **Linear Regression, Simple**), in which the values x of X are chosen arbitrarily but Y is distributed normally with constant variance around a linear function of x.

Returning to the bivariate normal model, Fisher derived a variance-stabilizing **transformation** of r,

$$z = \tanh^{-1} r = \frac{1}{2} \log \left(\frac{1+r}{1-r} \right),$$

the distribution of which approaches normality more rapidly than that of r, as the sample size, n, increases. Asymptotically, $\mathrm{E}(z) = \tanh^{-1}\rho$, and, approximately, $\mathrm{var}(z) = 1/(n-3)$. An alternative transformation [9] provides a generalization of (3): for $\rho \neq 0$, the statistic

$$\frac{(n-2)^{1/2}(r-\rho)}{[(1-r^2)(1-\rho^2)]^{1/2}}$$

follows approximately a t distribution with $n-2$ degrees of freedom. For further details about the distribution of r, see [6, Chapter 10].

Intraclass Correlation

Suppose that observations on a single variable y are arranged in n groups, each containing m observations, and that there is reason to expect possible differences in the mean level of y between groups. If such differences exist, observations in the same group will tend to be positively correlated. This phenomenon is called *intraclass correlation*.

Fisher [5] illustrates this for the case $m = 2$ by referring to measurements on pairs of brothers. He distinguishes between situations in which the brothers fall into labeled categories such as "elder" and "younger", and those in which no such categorization is required. In the first case, there are two variables – measurements for elder and younger brothers – and the standard product–moment correlation coefficient may be calculated. This is called the *interclass correlation*. In the second case, each pair would enter into the calculation twice, since they are not naturally ordered, and the denominator of the correlation coefficient may be based on a single sum of squares about the mean for all the $2n$ observations. This is the *intraclass correlation*. It is interesting to note that Fisher used the term "class" to denote the possible labeling categories ("elder" and "younger" here), whereas many modern writers use it to denote the groups into which the observations are clustered ("sibships" here).

The intraclass correlation coefficient, r_I, may be calculated as a modified variant of (2) for all the $nm(m-1)$ pairs of observations in the same group, each pair being counted twice. In the cross product in the numerator in (2), all deviations are taken from the mean, $\overline{y}$, of all mn observations. Since each observation appears $m-1$ times in the cross product, the denominator of (2) is $m-1$ times the sum of squares of deviations of all mn observations about $\overline{y}$.

An equivalent formula for r_I clarifies the relation between intraclass correlation and variation between the group means. Denote by $\overline{y}_i$ the mean for the ith group, and by v the variance of the mn observations with divisor mn rather than $mn-1$. Then

$$r_I = \frac{m\sum(\overline{y}_i - \overline{y})^2 - nv}{(m-1)nv},$$

the summation running from 1 to n. It follows that

$$-\frac{1}{(m-1)} \leq r_I \leq 1,$$

the lower limit of $-1/(m-1)$ being achieved when all the y_i, are equal, and the upper limit of 1 when there is no variation within the groups so that $\Sigma(\overline{y}_i - \overline{y})^2 = nv$.

Data of the type considered here would normally be analyzed by a one-way **analysis of variance**, and, as Fisher [5] showed, there is a close connection between the two approaches. If, in the analysis of variance, the mean squares between and within groups are denoted by s_b^2 and s_w^2, respectively, then

$$r_I = \frac{s_\mathrm{b}^2 - \left[\frac{n}{(n-1)}\right]s_\mathrm{w}^2}{s_\mathrm{b}^2 + (m-1)\left[\frac{n}{(n-1)}\right]s_\mathrm{w}^2},$$

so, for large n,

$$r_I \sim \frac{s_\mathrm{b}^2 - s_\mathrm{w}^2}{s_\mathrm{b}^2 + (m-1)s_\mathrm{w}^2}.$$

Equivalently, $r_I \sim (F-1)/(F+m-1)$, where F is the usual variance ratio statistic, $s_\mathrm{b}^2/s_\mathrm{w}^2$.

Two approaches may be followed in discussion of the sampling error of the intraclass correlation coefficient, using either **finite population** theory as is usual for **multistage sampling**, or the **random effects** model more usual in biologic applications.

The first approach assumes that the n groups are randomly selected from a larger set of N, and that each set of m observations within a group is randomly selected from M. If the intraclass correlation coefficient for the finite population of MN observations is denoted by ρ_I, the sample value r_I may be regarded as an estimator of ρ_I.

The random effects model effectively assumes infinite values for M and N. The group means are assumed to be distributed with a **variance component** σ_b^2, and the within-group deviations with a component σ_w^2. Then

$$\rho_I = \frac{\sigma_b^2}{\sigma_b^2 + \sigma_w^2}.$$

Inferences about ρ_I may be made using standard results for the ***F* distributions** in the one-way analysis of variance.

Some examples of the use of intraclass correlation as a descriptive tool are as follows:

1. In sample survey theory (*see* **Cluster Sampling**; **Multistage Sampling**; **Cluster Sampling, Optimal Allocation**), to indicate the correlation between observations in the same cluster due to systematic between-cluster variation.
2. In statistical genetics, to indicate the correlations in genetic traits between members of the same family: see the articles on **familial correlations** (which deals in detail with the situation in which the family groups vary in size) and **genetic correlations and covariances**. The numerical values of intraclass correlation coefficients are more meaningful in genetics than in most other applications, because of the predictions of Mendelian theory (*see* **Mendel's Laws**), although the predicted values for familial correlations, for example between siblings, may be distorted by the additional effects of environmental correlation.
3. In studies of the reliability of repeated measurements, or the agreement between observers in measuring characteristics of the same subject (*see* **Kappa**; **Observer Reliability and Agreement**). Note that when the same observers are used for each subject, there may be systematic differences in the level of recording for different observers, and the one-way analysis of variance analogue is no longer valid [2].

Some Generalizations

The concepts underlying the product–moment correlation coefficient may be generalized or modified in various ways. The (x, y) pairs may not be closely *linearly* related, but may nevertheless be perfectly associated through a nonlinear relation. If this relation is monotone, the observations will be ranked in the same order by both x and y. Two commonly used coefficients of **rank correlation** are **Spearman's** ρ (essentially the product–moment correlation of the ranks), and Kendall's τ (based on the number of discrepancies in the ranking of paired observations by the two variables). Both coefficients are bounded by the values -1 and $+1$ for perfect negative and positive agreement between the rankings.

When there are more than two quantitative variables, the correlations between pairs play an important part in various methods of multivariate analysis (*see* **Multivariate Analysis, Overview**). In **multiple linear regression**, two generalizations of r are commonly used. The *multiple correlation coefficient, R*, generalizes a property of r, in that the proportion of the variance of the dependent variable y that is "explained" by the multiple regression on $x_1, \ldots, x_k$ is R^2. (Since the squared form carries the essential information, R is never given a negative sign.) The *partial correlation coefficient* measures the product–moment correlation between y and one of the predictor variables, x_i say, when all the other predictors are kept constant. It is therefore useful in assessing the separate effects of different predictors, especially if they are themselves closely correlated.

In the early work of the Galton–Pearson school, much effort was put into the estimation of correlation coefficients when the observed values were nominal – perhaps even binary – but were supposed to represent divisions of some underlying, unobserved, continuous variables. The correlation between the presumed continuous variables had to be estimated from the discrete observations. It was usually assumed that the underlying distribution was bivariate normal. For two binary classifications, the measure is called *tetrachoric correlation*. When one variable is binary and the other is quantitative, the measure is called *biserial correlation*. These methods are less frequently used now, as alternate models for categorical data seem more appropriate (*see* **Association, Measures of**; **Categorical Data Analysis**).

Interpretation

The high profile assumed by the concept of correlation during the early part of the twentieth century has now largely vanished. This is partly due

to the emergence of more penetrating methods of statistical analysis. In particular, the emphasis has gradually moved away from an index measuring a degree of association, to an attempt to describe more explicitly the nature of that association. In a word, the emphasis has moved from correlation toward regression.

Apart from this general shift in viewpoint, there are some specific problems in the interpretation of correlation coefficients, which need to be taken into account in any data analysis in which they are used:

1. Correlation does not imply **causation**. Two variables may be highly correlated because they are both causally related to a third variable or a group of such variables, and yet have no causative relation to each other. Relations of this type are often called *nonsense* or *spurious correlations*. Often, the intervening variable is time. That is, two variables x and y may both be steadily increasing with time, over a certain time period, or one may be increasing while the other decreases. The two variables are then likely to be highly correlated. For instance, during the first two-thirds of the twentieth century, imports of tobacco into the UK increased steadily, as did the number of divorces granted. The two variables, measured in successive decades, are highly correlated. It would certainly not be correct to assume that either variable *caused* the other. Nonsense correlations are among the most prevalent causes of injudicious inferences from statistical data by the general public and the media.
2. Correlation measures closeness to a *linear* relationship. Two variables may be very closely associated by a nonlinear relation, and yet have a low correlation coefficient. As an extreme example, in Figure 2 (reproduced from [8]) is shown a scatter diagram between randomly drawn **standard normal deviates** and their squares. The population correlation coefficient is exactly zero, but it would have been entirely wrong to assume a lack of dependence. Independent random variables have zero correlation; but zero correlation does not imply independence.
3. The correlation between two biologic variables may be affected by selection of particular values of one variable. For instance, if X and Y have a distribution approximating to a bivariate normal distribution, with correlation coefficient ρ, restriction of the range of X by removal of extreme values in both directions will tend to decrease the correlation coefficient below the original value ρ. Thus, the correlation between height and age of children is higher for the age range 5–12 years than for the range 7–8 years. Conversely, omission of central values of X with retention of extreme values will tend to increase the correlation coefficient. This phenomenon may make it difficult to compare correlation coefficients in different populations differing in the degree and type of selection.
4. The effect of sampling variation is often underestimated, so that undue importance is given to moderately high correlations based on few observations. The upper 5 percentile of the distribution of $|r|$ when the population value $\rho = 0$, from (3), is 0.878 for $n = 5$, and 0.632 for $n = 10$. In this sense, moderately large correlations from small numbers of observations are inherently unreliable.

Correlational Study

A correlational study is an **ecologic study** in which rates of disease in populations are correlated with average exposures or other features of such populations. The populations may be defined by geographic regions of residence, for example. Such correlations are useful for generating etiologic hypotheses, but because individual-level information is not available on exposure, disease outcome, and potential **confounders**, such **correlations** are subject to the **ecologic fallacy** and may be misleading.

MITCHELL H. GAIL

Correspondence Analysis of Longitudinal Data

Correspondence analysis is an exploratory tool for the analysis of **association(s)** between **categorical** variables. Usually, the results are displayed in a **graphical** way.

There are many interpretations of correspondence analysis. Here we make use of two of them. A first interpretation is that the observed categorical data are collected in a **matrix**, and correspondence analysis approximates this matrix by a matrix of lower rank [12]. This lower rank approximation of, say, rank $M+1$ is then displayed graphically in a M-dimensional representation in which each row and each column of the matrix is displayed as a point. The difference in rank between the rank $M+1$ matrix and the rank M representation is matrix of rank 1, and this matrix is the product of the marginal counts of the matrix, that is most often considered uninteresting. This brings us to the second interpretation, that is, that when the two-way matrix is a **contingency table**, correspondence analysis decomposes the departure from a matrix where the row and column variables are independent [8, 9]. Thus, correspondence analysis is a tool for **residual** analysis. This interpretation holds because for a contingency table estimates under the independence model are obtained from a product of the margins of the table (divided by the total sample size).

Longitudinal data are data where observations (e.g. individuals) are measured at least twice using the same variables. We consider here only categorical (i.e. nominal or ordinal) variables, as only this kind of variables is analyzed in standard applications of correspondence analysis [7].

Two Time Points

When there is one categorical variable measured at two time points, a so-called transition matrix can be constructed [1]. In this transition matrix, the row variable is the categorical variable measured at time 1, and the column variable is the categorical variable at time 2. The aim of a correspondence analysis of a transition matrix is to get an insight into the transitions from time 1 to time 2. Different questions about these transitions exist, and these lead to different form of correspondence analysis.

We index the levels of the row variable (time 1) with i, $(i = 1, \ldots, I)$ and the levels of the column variable (time 2) with j, $(j = 1, \ldots, J)$. We denote relative frequencies by p_{ij}, probabilities by π_{ij}, and estimates of probabilities by $\hat{\pi}_{ij}$. Marginal elements are found by replacing the index by "+", for example, row marginal elements of the matrix with relative frequencies are p_{i+} and column marginal elements are p_{+j}.

A first analysis would be a standard correspondence analysis of the contingency table with elements p_{ij}. The interpretation discussed above shows that the resulting graphic display can be interpreted as showing a decomposition of the residuals from the independence model, that is, $\hat{\pi}_{ij} = p_{i+}p_{+j}$ [7–9].

A problem with this standard analysis is that often interest goes out to the off-diagonal elements (i.e. the cells for which $i \neq j$) in the contingency table, as these represent the individuals that change. In a standard correspondence analysis, the view on these cells might be blurred by the diagonal cells, especially, when $p_{ij} \gg p_{i+}p_{+j}$ (which is the case when many individuals remain in the same level of the categorical variable from time point 1 to 2). A solution to this problem is not to study the residuals from the independence model, but from the so-called quasi-independence model, defined here as $\pi_{ii} = p_{ii}$ for $i = j$ and $\pi_{ii} = \alpha_i \beta_j$ for $i \neq j$ [1]. It is possible to adjust correspondence analysis so that residuals from quasi-independence are decomposed. This can be done in two ways: by adjusting the computer program or by changing the input data. The last option seems most simple, and the way to do it is as follows: the diagonal elements p_{ii} have to be replaced by elements for which independence holds. This can be accomplished by filling in elements $p_{i+}p_{+i}$ for the diagonal. By doing this, the margins of the new table have changed so that the elements on the diagonal are not independent, and therefore, using the new margins, again elements $p_{i+}p_{+i}$ have to be filled in. After a few iterations, these elements have stabilized, and a correspondence analysis of the resulting table can be interpreted as a decomposition of quasi-independence [7, 8, 11].

This approach can be extended further by adjusting correspondence analysis so that it can decompose residuals from the symmetry model or from the quasi-symmetry model [7, 8]. Another development

is to use statistical models instead of the exploratory approach described here. There are also close connections between correspondence analysis and **latent class analysis** [12].

We give a small example to illustrate an analysis of the departure from independence. Space limitations withhold us from a detailed interpretation, and for interpretation principles, we refer to **correspondence analysis**. The data are 5 import car types out of 16 car types published in [8]: subcompacts (subi), small specialties (smai), compacts (comi), midsize (midi), and luxury (luxi). In the rows of Table 1, we find the cars disposed of, and in the columns the new cars. Notice the dominant observed frequencies on the diagonal. These values dominate the first dimensions of a correspondence analysis (see Figure 1), especially, the diagonal luxi-cell compared with the rest. In a second analysis, we decompose the residuals from quasi-independence. Such an analysis can be accomplished by filling in "independent" values for the diagonal. These values are 12 790, 1381, 1033, 503 and 71. The interpretation of this correspondence analysis uses the same principles as for standard correspondence analysis of the table with the adjusted margins. For the margins, the residuals are zero, and therefore, the graph only shows car type changes. The car order for cars disposed off is luxi, midi, comi, subi, and smai, but for new cars it is luxi, midi, smai, comi, and subi (see Figure 2). Notice, for example, the different position of smai. It is due to asymmetries in the data that become visible now that the dominance of the diagonal elements has been suppressed. For example, when people dispose of a smai, they buy a luxi very often (relative to the margins of the adjusted table, i.e. observed 459 but predicted by margins 239) but the reverse does not hold (observed 341 but predicted by margins 413).

Table 1 1979 car changing data

	subi	smai	comi	midi	luxi	Total
subi	25 986	5400	2257	1307	288	35 238
smai	3622	5249	738	1070	459	11 138
comi	6981	1023	1536	1005	127	10 672
midi	2844	772	565	3059	595	7835
luxi	997	341	176	589	3124	5227
Total	40 430	12 785	5272	7030	4593	70 110

Rows denote cars disposed, columns denote new cars. Abbreviations are in the text.

More than Two Time Points

When there is one categorical variable measured at more than two time points, it is usual to code the response profiles into a so-called superindicator matrix (*see* **Correspondence Analysis**). Correspondence analysis of a superindicator matrix is also known as multiple correspondence analysis. A superindicator matrix has N individuals in the rows and the categories for each of the time points in the columns. This correspondence analysis has the aim to

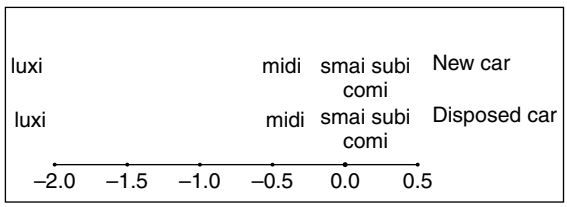

Figure 1 Ordinary CA of car changing data

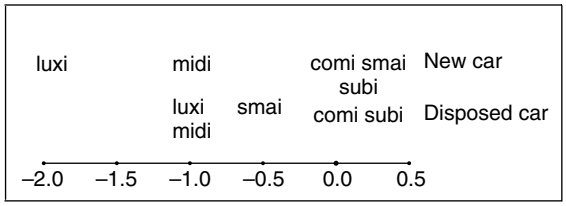

Figure 2 Generalized CA decomposing residuals from quasi-symmetry

get insight into the transitions between all time points simultaneously. The analysis also yields quantifications for the individuals, and the quantifications for an individual can be considered as summaries of the response profile of this individual that can be used, but it can also be used to obtain a classification of the response profiles of the individuals [2–7, 10].

As an example, we give a superindicator matrix of one dichotomous variable measured at three time points for $N = 101$ individuals (see Table 2). (In many computer programmes, the column vector with frequencies cannot be specified, but instead a matrix with 101 rows will serve as the data input file.) The matrix can be made larger in a straightforward way when the number of categories is larger than two, when there are more time points, or when there are more individuals. A correspondence analysis of this matrix will yield a three-dimensional display with 101 points, one for each individual, and a graphical display with 8 points, one for each category at each time point. Without going into technical details (see [5, 10]), individuals with similar profiles will be close together, categories that are often used by the same individuals will be close together, and, when we overlay the two graphs, individuals will be close to the categories that they use. It is also important to notice that, since correspondence analysis displays the departure from the row and from the column margin of a table, it follows that correspondence analysis will *not* show the trend in "a" and "b" over the three time points. This trend can be studied from the counts in the 3×2 table of time points by categories [7, 10].

Another way to interpret this analysis is when we realize that a correspondence analysis of the superindicator matrix, say $\boldsymbol{G}$, is mathematically related to a correspondence analysis of the so-called Burt matrix $\boldsymbol{G'G}$ (*see* **Correspondence Analysis**). The Burt matrix for this example is shown in Table 3. This matrix is a concatenation of a two-way contingency table for each pair of time points, and diagonal matrices with marginal frequencies. This shows that the solution of correspondence analysis only uses two-way **interactions**, and ignores higher-way interactions. Thus, a Burt matrix contains sufficient information for a nonstationary **Markov chain** (the table of time points 1 and 3 is the matrix product of the tables of time points 1 and 2, and 2 and 3) [7, 10].

Examples of such analyses can be found in [2–4, 7, 10]. If the number of individuals is not very large, the estimates for the category points will be unstable. More stability is obtained by constraining category points of adjacent time points to be the same. Such a solution can be obtained by adding up the indicator matrices of the adjacent time points [6]. This is also the way to go when the data to be analyzed are **event history** data, where the observations are in continuous time, or career data. Examples of unconstrained and constrained analyses are in [3–7, 10].

Table 2 A small example of a categorical data matrix (panel A) and its superindicator matrix (panel B)

Panel A		Panel B		
t		t_1	t_2	t_3
1 2 3	Freq	a b	a b	a b
a a a	40	1 0	1 0	1 0
a a b	16	1 0	1 0	0 1
a b a	4	1 0	0 1	1 0

Correspondence Analysis

Correspondence analysis facilitates the exploration and display of interrelations among two or more sets of variables. Historically, it has been identified by a variety of labels including canonical analysis and dual or optimal scaling [9]. A core operation in correspondence analysis and other metric scaling procedures is the decomposition of a matrix of data to find the underlying characteristic vectors and roots [3, 6, 8, 9, 14] (*see* **Eigenvector**; **Eigenvalue**). This mathematical procedure is equivalent to the method of reciprocal averages, **analysis of variance, principal components analysis**, and generalized canonical analysis [11]. **Transformations** of the data before and of the component vectors after decomposition, however, allows for the scaling of both row and column variables in the same spatial configuration. This latter feature, the joint scaling of both row and column variables in the same space, differentiates correspondence analysis from multivariate analyses which focus on either a row or a column variable representation. Thus, correspondence analysis provides information on the interrelationships among variables *within* a set (among the column or among the row variables, as does principal components analysis) and on the interrelationship *between* the row and column variables. Furthermore, correspondence analysis can be used on either qualitative (**categorical**) or quantitative (continuous) multivariate data. A data matrix, $\mathbf{X}$, may contain test scores for individuals (where the entry x_{ij} indicates subject i's score on test j, as is appropriate for a principal components analysis); it may be a cross-classification of cities by types of crimes (where entry x_{ij} indicates city i's frequency count for crime j, as is appropriate for a **contingency table** analysis with a **chi-square test**); or the matrix may contain proximity data (where the entry x_{ij} indicates the distance or similarity between items i and j, as is appropriate for **multidimensional scaling** (*see* **Similarity, Dissimilarity, and Distance Measure**)). Correspondence analysis can be used descriptively with a wide variety of data types, but the use of **inference** requires **random sampling** and frequency count data.

Because correspondence analysis is appropriate for contingency table data, it may be used to visualize and help interpret complex interactions as detected in a **loglinear** analysis [12]. By removing the effects of unequal marginal totals from the data, correspondence analysis is able to provide a detailed description of the **interaction** or **association** among variables or categories. Spatial plots of variables on the interactive factors aid in the interpretation of complex data. They can be used to answer questions about the nature of the association: whether the association is constant across categories and if categories are ordered and equally spaced [7] (*see* **Ordered Categorical Data**). Correspondence analysis also can be used to determine which categories should be combined [4, 5].

Predecomposition Transformation of Data

Correspondence analysis consists of three steps: an initial transformation of the raw data, a singular value decomposition of the transformed data, and a rescaling of the resultant eigenvectors. While metric scaling methods share a core decomposition procedure, they vary in terms of predecomposition transformations of the data and postdecomposition transformation of the eigenvectors. For example, a principal components analysis on a **correlation** matrix of column variables parallels a singular-value decomposition of a column-standardized matrix [14]. In correspondence analysis, the data are first transformed by dividing each x_{ij} entry by the square root of the product of the corresponding row and column marginal totals ($x_{i.}$ and $x_{.j}$, respectively):

$$h_{ij} = \frac{x_{ij}}{\left(\sum_j x_{ij} \sum_i x_{ij}\right)^{1/2}} = \frac{x_{ij}}{(x_{i.}x_{.j})^{1/2}}, \qquad (1)$$

where the matrix $\mathbf{H}$ contains the transformed data. In matrix notation, $\mathbf{H} = \mathbf{S}^{-1/2}\mathbf{X}\mathbf{C}^{-1/2}$, where $\mathbf{S}^{-1/2}$ and $\mathbf{C}^{-1/2}$ are diagonal matrices containing the reciprocal of the square root of the row and column marginal totals. This transformation removes the "magnitude" effects due to differences in marginal totals, so that the pattern of "interaction" may be examined in detail. In the analysis of cross-classified data this is equivalent to removing the Pearson chi-square expected values for the independence model. In fact, an alternative transformation parallels the calculation of each cell's contribution to the total chi-square $[(o_{ij} - e_{ij})^2/e_{ij}]$, and is each cell's contribution to

the overall association:

$$t_{ij} = \left[\frac{(o_{ij} - e_{ij})}{(e_{ij})^{1/2}}\right]\left[\frac{1}{n^{1/2}}\right], \qquad (2)$$

where $\mathbf{T}$ contains the transformed data, o_{ij} indicates the observed frequencies (x_{ij}), and e_{ij} indicates the chi-square expected values ($x_{i.}x_{.j}/x_{..}$). Either (1) or (2) may be used to transform the data without affecting the results, except as noted below.

Decomposition to Basic Structure

In the second step, a singular-value decomposition is used to find the underlying or characteristic vectors in the data. A matrix $\mathbf{X}$ with n rows and m columns, where $n \geq m$, may be represented as the product of three matrices:

$$\mathbf{X}_{(n\times m)} = \mathbf{U}_{(n\times m)}\mathbf{d}_{(m\times m)}\mathbf{V}^{\mathrm{T}}_{(m\times m)}. \qquad (3)$$

Each of the three new matrices contains information regarding the data in $\mathbf{X}$. The $\mathbf{U}$ matrix summarizes the rows, e.g. the row variables, of $\mathbf{X}$: the rows in $\mathbf{U}$ correspond to the rows in $\mathbf{X}$ and the columns in $\mathbf{U}$ are the underlying or characteristic vectors of the row variables. The $\mathbf{V}$ matrix similarly summarizes the information in the columns of $\mathbf{X}$: each row in $\mathbf{V}$ corresponds to a column in $\mathbf{X}$, and the columns of $\mathbf{V}$ are the characteristic vectors of those variables. The columns of $\mathbf{U}$ and $\mathbf{V}$ are all of unit length, so that $(\sum_i u_{ik}^2)^{1/2} = (\sum_j v_{jk}^2)^{1/2} = 1.0$. Also, when the $\mathbf{X}$ matrix is square and symmetric, the $\mathbf{U}$ and $\mathbf{V}$ matrices are equal. In this special case, $\mathbf{X} = \mathbf{U}\mathbf{d}\mathbf{V}^{\mathrm{T}} = \mathbf{U}\mathbf{d}\mathbf{U}^{\mathrm{T}} = \mathbf{V}\mathbf{d}\mathbf{V}^{\mathrm{T}}$. The $\mathbf{d}$ matrix is a square diagonal matrix with entries along the main diagonal and zeros elsewhere. The main diagonal cell entries are the singular values or roots corresponding to the columns of $\mathbf{U}$ and $\mathbf{V}$, so that the entry d_{jj} corresponds to the jth column of $\mathbf{U}$ and the jth column of $\mathbf{V}$. The singular values are ordered from largest to smallest, and so the dimensions in $\mathbf{U}$ and $\mathbf{V}$ are ordered in terms of their relative importance in accounting for the variance or shape of the configuration of data points.

Spatially, the initial configuration of data points is stretched and/or shrunk and rotated onto new, Euclidean, coordinate axes *without any loss of information*. The new axes (the columns of $\mathbf{U}$ and $\mathbf{V}$) are orthonormal (*see* **Orthogonality**); that is, they are orthogonal or perpendicular to one another and are normalized to unit length. The $\mathbf{U}$ and $\mathbf{V}$ matrices represent the data in normalized space, with each dimension weighted equally. The normalization changes a (Rugby) football-shaped cluster of points into a round spherical shape. The $\mathbf{d}$ matrix entries indicate the relative importance of each dimension and may be used to stretch or shrink dimensions of the configuration to return it to its original shape.

If the data do not contain redundant information, the number of columns in $\mathbf{U}$ and $\mathbf{V}$ will equal the minimum dimension m of $\mathbf{X}$. If the data contain mathematically redundant information, the dimensionality of the solution will be less than m. The dimensionality of the subspace spanned by the configuration of points is equal to the number of nonzero elements in $\mathbf{d}$ (the rank of the matrix). Models of reduced dimensionality may be used to represent the data by using fewer dimensions of the $\mathbf{U}$, $\mathbf{d}$, and $\mathbf{V}$ matrices. For example, a k-dimensional estimate of the data can be obtained by multiplying together the first k dimensions of the $\mathbf{U}$ and $\mathbf{V}$ matrices and the first k weights in $\mathbf{d}$. Note that in correspondence analysis the matrix $\mathbf{H}$ of (1) is factored and not the observed data, $\mathbf{X}$. Because of this, the maximum dimension of the solution is $m - 1$ and multiplication of the $\mathbf{U}$, $\mathbf{d}$, and $\mathbf{V}$ matrices results in the matrix $\mathbf{H}$. Correspondence analysis contains procedures for retrieving models of the original, observed data ($\mathbf{X}$).

One effect of the transformation in (1) is that the first column in the $\mathbf{U}$ and $\mathbf{V}$ matrices, corresponding to the independence model, contains a constant equal to 1.0. This factor is ignored and is sometimes referred to as the "trivial" factor. The first singular value, d_{11}, is also equal to 1.0 and is ignored for most purposes. Subsequent singular values in $\mathbf{d}$ are called **canonical correlations**. When (2) is used to transform the data, the trivial factor and the first singular value are not evident in the solution.

The $\mathbf{U}$, $\mathbf{V}$, and $\mathbf{d}$ matrices may be found directly with a singular-value decomposition of $\mathbf{X}$ or indirectly by performing eigenanalyses on the cross-product matrices of $\mathbf{X}$. Pre- or postmultiplication of a matrix by its transpose results in a square, symmetric matrix, so that the characteristic vectors of a rectangular (nonsquare, nonsymmetric) matrix may be found by performing eigenanalyses on $\mathbf{X}\mathbf{X}^{\mathrm{T}}$ and $\mathbf{X}^{\mathrm{T}}\mathbf{X}$, where $\mathbf{X}\mathbf{X}^{\mathrm{T}} = \mathbf{U}\mathbf{D}\mathbf{U}^{\mathrm{T}} = \mathbf{U}\mathbf{d}^2\mathbf{U}^{\mathrm{T}}$ and $\mathbf{X}^{\mathrm{T}}\mathbf{X} = \mathbf{V}\mathbf{D}\mathbf{V}^{\mathrm{T}} = \mathbf{V}\mathbf{d}^2\mathbf{V}^{\mathrm{T}}$. The singular values are equal to the square root of the eigenvalues, so that

$\mathbf{X} = \mathbf{U}\mathbf{D}^{1/2}\mathbf{V}^{\mathrm{T}} = \mathbf{U}\mathbf{d}\mathbf{V}^{\mathrm{T}}$. Decomposition of $\mathbf{X}, \mathbf{X}\mathbf{X}^{\mathrm{T}}$, or $\mathbf{X}^{\mathrm{T}}\mathbf{X}$ results in solutions of the same rank. While the characteristic vectors and singular values can be derived from either an eigenanalysis or a singular-value decomposition, the singular-value decomposition algorithm offers greater numerical stability, especially with ill-conditioned matrices. The solution is a **least squares** solution with results typically providing a close approximation to the **maximum likelihood** solution [5, 13].

Transformation of Component Vectors to Obtain Optimal Scores

In the last step, the columns of the **U** and **V** matrices are rescaled. The rescaled characteristic vectors are referred to as optimal scores, canonical scores, or canonical variates. Rescaling is performed as follows:

$$u_{ik}{}^{*} = u_{ik}\left(\frac{x_{..}}{x_{i.}}\right)^{1/2} \tag{4}$$

and

$$v_{jk}{}^{*} = v_{jk}\left(\frac{x_{..}}{x_{.j}}\right)^{1/2}, \tag{5}$$

where k indexes the component vectors (ignoring the first trivial vector if (1) was used) and matrices $\mathbf{U}^{*}$ and $\mathbf{V}^{*}$ contain the optimal scores for **U** and **V**, respectively. The optimal scores are normalized, Euclidean spatial coordinates. Multiplication of the scores by the canonical correlations stretches or shrinks the configuration so that the relative importance of the factors is evident. For comparing scores between rows and columns and between dimensions, the scores must be weighted relative to the singular values. A common practice is to multiply the scores by the square root of the corresponding singular value, although other methods are available [2].

Modeling Observed Data

The number of interactive factors ($\leq m - 1$) needed to represent the data can be determined by sequentially creating models of increased dimensionality and testing the **goodness of fit** of each model to the observed data. With cross-classified data, this should be preceded by a chi-square test for independence. A significant chi-square indicates that the observed data are significantly different from the model of independence and that an analysis of the interaction may then be pursued. Models of successively higher dimensionality are constructed with the interactive factors until a model is obtained that is not significantly different from the observed data. Chi-square tests are used to test the goodness of fit between the models and observed data. The expected values (e_{ij}) for a k-dimensional model are calculated as

$$e_{ij} = \sum_{k}\left[\left(\frac{x_{i.}x_{.j}}{x_{..}}\right)d_{kk}u_{ik}{}^{*}v_{jk}{}^{*}\right], \tag{6}$$

where k is the number of dimensions (beyond the trivial factor) to be used in reconstructing the data, $\mathbf{U}^{*}$ and $\mathbf{V}^{*}$ are the optimal scores, and **d** contains the singular values or canonical correlations. Thus, data are reconstructed from the sum of successive models: the chi-square independence model (the trivial factor and the first singular value) and then the first nontrivial interactive factor and its canonical correlation, and so on. There may be as many factors as the minimum dimension of the matrix **X** minus one ($\leq m - 1$ pairs of factors).

With cross-classified data, goodness of fit is tested directly with the Pearson chi-square. With other types of data, goodness of fit can be expressed descriptively as a function of the singular values. Ratios of squared canonical correlations may be used in a correspondence analysis to describe the "proportion of explained variance" in the same way that eigenvalues are used in a principal components analysis. The ratio of the sum of the first k squared canonical correlations to the sum of all squared canonical correlations provides a descriptive index of explained variance. In correspondence analysis this is the proportion of the total association captured by a k-factor representation and in some applications is called "inertia" [1, 8]. In fact, the sum of the squared canonical correlations is equal to the total degree of association in the data (the Pearson chi-square score divided by the sample size). Since applications of correspondence analysis to nonfrequency data cannot use a Pearson chi-square to test how much data deviate from marginal totals, the ratio of the first (trivial) singular value to the sum of all squared singular values (including the trivial one) may be used to estimate the proportion of total variance in the original data that is explained by magnitude differences in marginal totals [14].

Alternative Data Formats: Indicator Variables

Qualitative data also may be analyzed as indicator variables (*see* **Dummy Variables**). If data are expressed as dichotomous variables (1 = characteristic present and 0 = absent), with a dichotomous indicator variable for *each* category of each variable, and if the cases with identical profiles are summed together, then results are parallel to those obtained from the cross-classification table of the same data [10, 14]. Analysis of indicator variables has the interesting advantage of scaling not only the categories of each variable but also the types of cases. The unique case profiles become an additional set of variables in the analysis, and thus the relationship between the type of case and the categories of each variable may be seen.

Ordination, Seriation, and Guttman Scaling

Correspondence analysis can also be used to find the optimal ordering of variables for a given set of characteristics. This problem has different names in different fields of study: ordination, seriation, and **Guttman scaling**. Because items that occur closer in time (or space) have more similar profiles than items further apart, rearrangement of the data by similarity in profiles helps to establish their optimal ordering. Guttman scaling is a specific type of ordering, wherein the order is cumulative and transitive: if someone has an object on the list, then they tend to have the objects that precede it; and if they lack an item on the list, then they tend not to have subsequent items. Correspondence analysis provides a weighted least squares solution to this problem. Analysis of a matrix of cross-classified data (location by type of archeological specimen) or of indicator variables (households by the presence or absence of specific consumer goods) provides optimal scores for row and column variables that establish the optimal order of variables. The scores may be used to reorder the original data matrix to see the pattern or they may be plotted spatially. The plot of the scores will often yield a curvilinear rather than a strictly linear result.

Multiple Correspondence Analysis

Multiple correspondence analysis involves three or more variables or sets of variables. The analysis is performed on indicator matrices or stacked contingency tables. Continuous variables can be recoded into categories for the analysis with a variable for each category. Indicator matrices, where the matrix rows represent cases (or unique case profiles) and the columns represent *all* categories of all variables, can be used. Guttman scaling is an example of a multiple correspondence analysis on indicator variables. Similarly, a cross-product or Burt [8] matrix ($\mathbf{X}^{\mathrm{T}}\mathbf{X}$) of the indicator variables can be analyzed to obtain the solution. In a stacked table analysis, a k-way contingency table is arrayed as a series of two-way contingency tables. The tables are analyzed as a single two-way table with the tables stacked side by side vertically or horizontally. In an analysis of age, gender, and methods of suicide the different ways of arraying the two-way tables emphasizes different aspects of the data: gender and age patterns for suicide methods; or gender differences in choice of a suicide method for different age groups [12].

SUSAN C. WELLER

Cosine of Angle Between Two Vectors

Two vectors in 2-space are shown in Figure 1, with (x_1, x_2) being a point on one vector and (y_1, y_2) on the other. Let A_x and A_y be the angles the vectors make with the horizontal axis, and define B as the angle between the vectors. Thus

$$\begin{aligned} B &= A_x - A_y, \\ \cos B &= \cos(A_x - A_y) \\ &= \cos A_x \cos A_y + \sin A_x \sin A_y. \end{aligned}$$

On dropping perpendiculars from the points to the horizontal axis, it is then easily seen from right-angle triangle geometry that

$$\begin{aligned} \cos B &= \frac{x_1}{(x_1^2 + x_2^2)^{1/2}} \frac{y_1}{(y_1^2 + y_2^2)^{1/2}} \\ &\quad + \frac{x_2}{(x_1^2 + x_2^2)^{1/2}} \frac{y_2}{(y_1^2 + y_2^2)^{1/2}} \qquad (1) \\ &= \frac{x_1 y_1 + x_2 y_2}{d_x d_y} \qquad (2) \end{aligned}$$

for

$$d_x^2 = x_1^2 + x_2^2 \quad \text{and} \quad d_y^2 = y_1^2 + y_2^2. \qquad (3)$$

Thus (2) is the formula for the cosine of the angle between two vectors in 2-space.

Another derivation of (2) with d_x and d_y being the distances from the origin to the points (x_1, x_2) and (y_1, y_2), respectively, is to apply the cosine rule to the angle B in the triangle formed by the origin and the points (x_1, x_2) and (y_1, y_2). This gives

$$\begin{aligned} &\cos B \\ &= \frac{d_x^2 + d_y^2 - [\text{the distance from } (x_1, x_2) \text{ to } (y_1, y_2)]^2}{2 d_x d_y} \\ &= \frac{d_x^2 + d_y^2 - [(x_1 - x_2)^2 + (y_1 - y_2)]^2}{2 d_x d_y}, \end{aligned}$$

which with (3) reduces to (2).

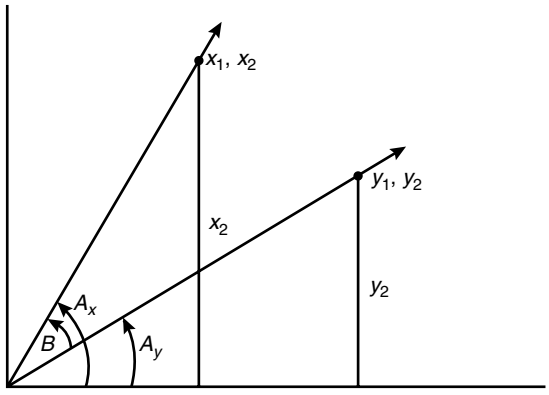

Figure 1 Two vectors in 2-space

Three-Space

For two vectors in 3-space a diagram analogous to Figure 1 can be drawn (see Searle [3]). Applying to that 3-space diagram some triangle geometry more complicated than that used for deriving (1) yields the result

$$\cos B = \frac{x_1 y_1 + x_2 y_2 + x_3 y_3}{d_x d_y}, \qquad (4)$$

with

$$d_x^2 = x_1^2 + x_2^2 + x_3^2 \quad \text{and} \quad d_y^2 = y_1^2 + y_2^2 + y_3^2, \quad (5)$$

where (x_1, x_2, x_3) is a point on one vector and (y_1, y_2, y_3) is on the other. Details are in Searle [3].

n-Space

Let $\mathbf{x}' = [x_1 \ x_2 \ldots x_i \ldots x_n]$ and $\mathbf{y}' = [y_1 \ y_2 \ldots y_i \ldots y_n]$ be two points in n-space, one on one vector and one on another. Then results (2), (3) and (4), extend very directly for n-space to

$$\cos B = \sum_{i=1}^{n} \frac{x_i y_i}{d_x d_y} \qquad (6)$$

for

$$d_x^2 = \sum_{i=1}^{n} x_i^2 \quad \text{and} \quad d_y^2 = \sum_{i=1}^{n} y_i^2 \qquad (7)$$

so that, in terms of the vectors $\mathbf{x}'$ and $\mathbf{y}'$,

$$\cos B = \frac{\mathbf{x}'\mathbf{y}}{(\mathbf{x}'\mathbf{x})^{1/2} (\mathbf{y}'\mathbf{y})^{1/2}}. \qquad (8)$$

Viewed from the geometry of two and three dimensions, (6) may not seem very satisfying. Moreover,

its derivation demands arguments in the geometry of n-space. These arguments are more theoretical than those for deriving (2) and (4) of 2-space and 3-space, respectively. Thus it is easier to simply take (6) as an algebraic definition of B as the angle between two vectors in n-space. Indeed, some books on **multivariate analysis** do just that, e.g. [2, p. 16] and [1, p. 99].

Invariance

The prime property of a vector is its direction, not its length. Yet each of (2), (4) and (6) seems to depend upon the actual values of the xs and the ys, i.e. their lengths. Fortunately this is not so. For example, with (2), if on the vector through (x_1, x_2) some other point (x_1^*, x_2^*) is taken, it will be found from the geometry of congruent triangles that if $x_1^* = \lambda_x x_1$, then $x_2^* = \lambda_x x_2$. Therefore $\cos B$ of (2), with the x^*s and y^*s replacing the xs and ys, becomes

$$\begin{aligned}\cos B &= \frac{x_1^* y_1^* + x_2^* y_2^*}{(x_1^{*2} + x_2^{*2})^{1/2}(y_1^{*2} + y_2^{*2})^{1/2}} \\ &= \frac{\lambda_x \lambda_y (x_1 y_1 + x_2 y_2)}{\lambda_x (x_1^2 + x_2^2)^{1/2} \lambda_y (y_1^2 + y_2^2)^{1/2}} \\ &= \frac{x_1 y_1 + x_2 y_2}{d_x d_y}\end{aligned}$$

as before; i.e. $\cos B$ of (2) is unchanged. Similar geometry also leaves (4) unchanged. And arguing in n-space that changing x_1 to $x_1^* = \lambda_x x_1$ leads to $x_i^* = \lambda_x x_i$ for all i, then (6) will be unchanged also.

A second form of invariance is when rotation of axes is considered. Although coordinates of a point will change under rotation, the angle between two vectors will not; and the cosine of that angle is unchanged and is the same function of the new coordinates as the old. Suppose for 2-space that the axes are rotated counterclockwise through an angle θ. It can then be shown (as in Searle [3]) that the coordinates x_1 and x_2 of Figure 1 become

$$\begin{aligned}x_1' &= x_1 \cos\theta + x_2 \sin\theta \quad \text{and} \\ x_2' &= x_2 \cos\theta - x_1 \sin\theta. \end{aligned} \tag{9}$$

From these it is easily seen that $d_x' = x_1'^2 + x_2'^2 = x_1^2 + x_2^2 = d_x$ (as one would expect). Furthermore, with y_1' and y_2' being the same function of y_1 and y_2 as the x's are of the xs in (9), it is straightforward to show that $x_1' y_1' + x_2' y_2' = x_1 y_1 + x_2 y_2$. Hence, comparable with (2),

$$\cos B = \frac{x_1 y_1 + x_2 y_2}{d_x d_y} = \frac{x_1' y_1' + x_2' y_2'}{d_{x'} d_{y'}}.$$

Thus, rotating the axes gives the cosine of the angle between two vectors being the same expression of the new coordinates as it does of the old ones.

Correlation

When the entries in $\mathbf{x}$ and $\mathbf{y}$ are data (e.g. height and weight of each member of a rowing club), define $\overline{x}$ and $\overline{y}$ as the observed averages:

$$\overline{x} = \sum_{i=1}^{n} \frac{x_i}{n} \quad \text{and} \quad \overline{y} = \sum_{i=1}^{n} \frac{y_i}{n}.$$

In $\mathbf{x}$ and $\mathbf{y}$ replace each element x_i by $x_{i0} = x_i - \overline{x}$ and y_i by $y_{i0} = y_i - \overline{y}$. Define $\mathbf{x}_0$ and $\mathbf{y}_0$ as the vectors of elements x_{i0} and y_{i0}. Then $\cos B$ for $\mathbf{x}_0$ and $\mathbf{y}_0$ is

$$\begin{aligned}\cos B &= \frac{\mathbf{x}_0' \mathbf{y}_0}{(\mathbf{x}_0' \mathbf{x}_0)^{1/2} (\mathbf{y}_0' \mathbf{y}_0)^{1/2}} \\ &= \frac{\sum_{i=1}^{n} (x_i - \overline{x})(y_i - \overline{y})}{\left[\sum_{i=1}^{n} (x_i - \overline{x})^2 \sum_{i=1}^{n} (y_i - \overline{y})^2\right]^{1/2}}\end{aligned}$$

is the product–moment **correlation** between the two variables.

Cost–Benefit Analysis, Willingness to Pay

An important distinguishing feature between different methods of health care economic evaluation (*see* **Health Economics**) is the way in which health-related outcomes are defined, measured, and valued [10]. Cost–benefit analysis (CBA) is a technique where health benefits are valued in monetary units for comparison against program costs [16]. CBA holds appeal for at least three reasons: (i) it has a theoretical foundation in welfare economics [22]; (ii) by enabling direct comparison of program costs and benefits it permits the calculation of a program's net benefit and thereby avoids much of the ambiguity associated with cost-effectiveness "league tables" [4, 5, 21]; and (iii) the same principle of net benefit can be applied to other sectors such as transport and environment so that intersectoral comparisons of resource use can be considered.

CBA might become the method of choice for more researchers in health care if there was one unambiguous and generally agreed-upon method for estimating money values for health outcomes. Debate over CBA in health care and other areas of project appraisal requiring monetary valuation of health outcomes has a controversial history. In the 1960s and 1970s the prevalent notion of CBA was restricted simply to comparing health care costs with and without the program being evaluated. Studies such as those by Koplan [18] on pertussis vaccination, although labeled as CBA, are essentially cost comparisons because they make no attempt to place dollar values on health benefits. Following Becker [2], it became popular to quantify health benefits in monetary units, characterized as a return on human capital investment, using discounted future earnings streams (for an example in rubella vaccination, see Schoenbaum [28]).

In a seminal contribution, Mishan [23] argued that the human capital approach in CBA studies was flawed for two general reasons: (i) it builds upon the questionable assumption that society's main goal is the maximization of national income, and this has some worrisome implications for valuing programs that improve the health of persons with low or zero future earnings; and (ii) the method is inconsistent with the foundation of CBA from welfare economic theory. Mishan argued that the monetary valuation of programs that reduced **risks** to "life and limb", as with other goods, should be based upon the concept of consumer surplus; that is, the relevant economic notion of value for a program is the most that consumers are willing to give up to receive it – i.e. their maximum willingness to pay. Such measurement is based on the decision rule for CBA, where the goal is to determine whether the value of the program to those who gain is sufficiently large that they could, in principle, compensate in full all those who lose and still remain better off themselves (the so-called Potential Pareto improvement criterion).

Subsequent empirical work has taken two main directions. First, there are *revealed-preference studies* which document observed trade-offs between health risks and money. The principle here is that the analyst can only assess a person's preferences for trade-offs between money and health by actually observing market behavior. For example, this might be in the form of a person's willingness to pay for extra safety features on a new car. A major focus of revealed preference studies has been labor market studies, relating wage premiums to health risks for particular occupations [20, 31]. Secondly, there are *stated preference surveys* of hypothetical dollar – health risk choices such as road transport safety and consumer decisions [17]. This second approach is not based on observing actual market behavior and money – health trade-offs, but operates by offering hypothetical choices to respondents in a survey. This survey-based approach has been termed *contingent valuation*, because the respondent is being asked to consider the contingency of a market existing for the thing being valued, even though an actual market may not exist.

Much of the conceptual and empirical development of contingent valuation methods has been done in the areas of transport economics with a predominant focus on the value of life [17], and lately in environmental economics with application to the valuation of environmental and health goods such as improved air quality [24] (*see* **Environmental Epidemiology**). Contingent valuation studies are becoming more widespread in health care and have been undertaken in areas such as arthritis management [30], ultrasonography [3], care of the elderly [9], management of hypertension [15], blood transfusion [11], the use of ionic vs. nonionic contrast media

[1], and *in vitro* fertilization [25] (*see* **Clinical Epidemiology**; **Health Services Research, Overview**).

We review some of the statistical issues that have arisen for researchers who seek to measure willingness to pay (WTP). We will argue that choosing among the various measurement techniques presents the analyst with a variety of practical trade offs between **bias** and precision.

Measurement Objectives

There are numerous approaches to assessing WTP in health care, and in this limited discussion of selected statistical issues we cannot review all possible approaches. A conceptual framework and tutorial on WTP in health care has recently been published [26]; it gives a deeper understanding of linkages between the theory and practice of WTP.

To explore statistical issues we will focus on a hypothetical example of a **program evaluation** where WTP in the context of CBA is to be determined. An insurance-based WTP problem is described in Figure 1. Using this example, there are advantages and disadvantages to a number of measurement techniques that are available.

WTP Estimation Techniques

Open-Ended Questions

The measurement task is to find out the *maximum* that an individual (or group) would be willing to pay for the new program. The open-ended question format is the most direct format for determining this value from an individual. But simply asking the maximum a person would pay poses a difficult cognitive task for a respondent who may be unfamiliar with the program being valued and not accustomed to buying similar things in a market without price tags. Consequently, the open-ended format tends to produce large numbers of nonresponses or protest zero responses to WTP questions: this is true for both environmental valuation (e.g. [8]) and health (e.g. [15] and [30]). Such experience led researchers to try to simplify the choices presented to the respondents by making the market scenario more realistic.

Bidding Games

Mitchell & Carson [24] report that the oldest and most widely used elicitation method in contingent valuation surveys until recently has been the *bidding game*. Similar to an auction, an initial starting money value is bid up or down by the respondent. Some market realism is instilled because each bid level requires only a Yes/No response. It has been argued that the advantage of the bidding game is that the process of iteration and search enables the respondent to consider more fully the value of the program [14]. A major disadvantage is the potential for **bias** because the starting bid (chosen by the researcher) tends to imply a value for the good. In a health care contingent valuation study, O'Brien & Viramontes [27] tested the hypotheses of starting point bias using random assignment to different starting bias (*see* **Randomization**) in a bidding game. Although not statistically significant, these data suggest that higher starting bids were associated with higher final WTP. More recently, Stalhammer [29] has found evidence to support the hypothesis of starting point bias.

Suppose we wish to conduct a CBA of a new treatment program that is proposed to be added to the benefits covered in a Health Maintenance Organization (HMO) in the United States. Based on utilization projections and the costs of the new treatment we can estimate the total additional cost of the new program for the next year. To assess the dollar value of the new program, we want to estimate the total willingness to pay (WTP) among enrollees of the HMO. The proposal is to contact a random sample of enrollees, inform them of the benefits of covering the new program as an additional insured benefit, and then elicit the maximum they would be willing to pay – in additional monthly insurance premiums – to have the new treatment covered. These sample responses would then be projected to the total HMO population so that total benefits (i.e. WTP) could be compared with total cost.

Figure 1 Hypothetical willingness-to-pay problem

Payment Cards

The payment card method was developed by Mitchell & Carson [24] as an alternative to the bidding game. The payment card is a visual aid which contains a large array of potential WTP amounts ranging from \$0 to some large amount. According to Mitchell & Carson, this method "... circumvents the need to provide a single starting point, yet offers the respondent more of a context for her bid than the direct question method provides" [24]. A related technique is the checklist method, where respondents indicate which of a list of payment *ranges* includes their WTP amount. Neumann & Johannesson [25] used a form of payment card in their study of *in vitro* fertilization; they found evidence that the range of values listed influenced the final WTP.

Dichotomous Choice (Take it or Leave it)

Open-ended questions, bidding games, and payment cards are all approaches that have been used as methods for finding maximum WTP *for each sampled individual*. In contrast to this within-person search strategy, many researchers in environmental economics have moved to a strategy of a between-person search to find maximum WTP *for a sample of respondents*.

Using this approach, Bishop & Heberlein [6] developed another elicitation method known as the "take-it-or-leave-it" approach. This method uses a large number of predetermined prices and each respondent is asked if she is willing to pay a single one of these prices (Yes or No) for the program, with no further iteration. The prices are randomly assigned to respondents so that one can use statistical techniques such as probit analysis (*see* **Quantal Response Models**) to model bid acceptance as a function of respondent characteristics and determine **median** WTP [7]. The main problem is that, relative to other elicitation methods, the take-it-or-leave-it method is inefficient, requiring a much larger sample size for the same level of statistical precision as other methods. However, the method has been used with some success in health care [15].

To illustrate the basic approach of the dichotomous choice method, consider the bid curve in Figure 2. The goal of sampling is to be able to plot the bid curve which models the probability of accepting a bid (price) at different levels of bid. From the derived bid curve one can determine either the median WTP (i.e. bid at which 50% of the sample would pay) or the mean WTP, this being the area under the bid curve. Given the variation among respondents in demographic characteristics, the analyst would typically use **logistic (or probit) regression** to model the accept/reject probability as a function of bid level and demographics. Using this function it is possible to project the total WTP for a population if one knows its demographic characteristics.

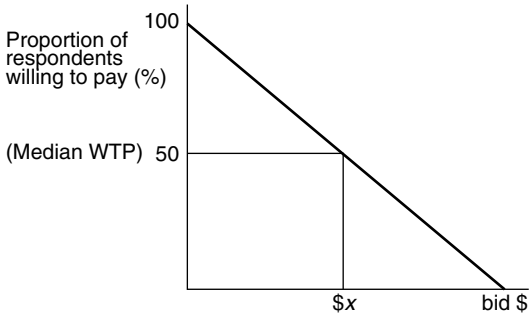

Figure 2 The population of respondents willing to pay as a function of the bid in a WTP study. Note that median WTP is \$$x$ and mean WTP is the area below the curve. The method is analogous to survival analysis and the calculation of life expectancy in biostatistics. For simplicity we have drawn the bid curve as a straight line, but in practice this observed "survival curve" will not be a linear, nor necessarily smooth, relationship

The main disadvantage of the simple dichotomous choice approach is that each individual is asked one question, i.e. "would you pay an additional insurance premium of \$2 to have this program covered?" Hence, to derive the bid curve one may need quite large sample sizes. Also note that if the upper end of the bid range is not sufficiently high, then the bid curve will not reach zero, making it problematic to estimate the area under the curve for the expected value.

Double-Bounded Dichotomous Choice

An extension to the previous method, to improve its statistical efficiency, is that of *take it or leave it with follow-up*. Here a follow-up bid question is asked of the respondent, higher or lower, conditional upon the response to the first bid; the higher or lower bid is randomly selected from a range. The increased statistical efficiency of this method using probit analysis

The probability of a positive response to the close-ended WTP question is the probability that the respondent's WTP exceeds the bid amount. The double-bounded, dichotomous choice model as derived by Hanemann et al.. [13] is described below. When confronted with a bid or dollar amount t, the respondent will accept the bid with a probability

$$\Pr(\text{Yes}|t; \mathbf{X}, \boldsymbol{\beta}) = 1 - F(t; \mathbf{X}, -\boldsymbol{\beta}),$$

where $F[\cdot]$ is the cumulative distribution function, t is the bid (or dollar) amount, $\mathbf{X}$ is a vector of socioeconomic characteristics or other demand shift variables, and $\boldsymbol{\beta}$ is a vector of parameters to be estimated.
Substituting the cumulative normal distribution function, $\Phi[\cdot]$, for $F[\cdot]$, we get

$$F(t; \mathbf{X}, -\boldsymbol{\beta}) = \begin{cases} \Phi(t_U; \mathbf{X}, -\boldsymbol{\beta}), & \text{if Yes–Yes response,} \\ \Phi(t_L; \mathbf{X}, -\boldsymbol{\beta}) - \Phi(t_U; \mathbf{X}, -\boldsymbol{\beta}), & \text{if Yes–No or No–Yes response,} \\ 1 - \Phi(t_L; \mathbf{X}, -\boldsymbol{\beta}), & \text{if No–No response,} \end{cases}$$

where t_U is the higher bid amount, t_L is the lower bid amount, and $\boldsymbol{\beta}$ is a vector of coefficients to be estimated.
The probability distribution of WTP is simply the derivative of Pr(Yes) or the change in Pr(Yes) at various bid levels. The mean WTP is the area under the Pr(Yes) function, whereas the median WTP is the bid value for which the estimated probability of answering "Yes", [Pr(Yes)] equals 0.5. In this article, we report median WTP values.

Figure 3 Double-bounded dichotomous choice WTP model

has been shown by Hanemann [13]. As indicated by the algebraic exposition in Figure 3, the goal of this method is to select ranges so as to "bound" as many respondents as possible between the extremes of their "Yes–Yes" and "No–No" responses. To minimize framing biases one can randomly select both the starting bid and the second conditional bid.

Future Trends: Conjoint Analysis

The most recent approach under evaluation for WTP in environment and health is conjoint analysis. Used widely in consumer economics to establish consumer preferences over attributes of commodities (e.g. a car's safety, fuel consumption, performance, and price), conjoint analysis is very similar in origin to multiattribute utility theory [12]. The method works by first defining a number of attributes of the product or program and then asking the respondent to choose between hypothetical pairs (e.g. program A vs. program B) that vary in their attribute composition and where one of the attributes is how much the individual would have to pay. As reviewed by Green & Krieger [12], there are various adaptive search algorithms that determine the modification of attributes conditional upon individuals' responses. Conjoint analysis has been used successfully in the evaluation of consumer products where health outcomes are attributes [19].

Concluding Remarks

In summary, there are a number of elicitation methods for WTP, and each approach has strengths and weaknesses. There are no obvious conceptual reasons, from economic theory, to predict that these measurement approaches will yield different valuations; each is an approach to revealing an underlying monetary valuation. In practice, for some of the reasons outlined above, estimates do vary when different methods are used in the same respondents (see [15]) on open-ended vs. take-it-or-leave-it methods in hypertension). Each estimation technique varies in terms of measurement properties of precision and bias. A further practical consideration is that formats such as bidding games necessitate in-person interviewing, perhaps even with computer-based bidding algorithms with random starting points. Other formats such as open-ended questions can be done by mail survey but suffer from low completion rates and greater **variance** due to the cognitive burden for respondents.

Currently there is considerable conceptual and statistical variation in the assessment of WTP, both in environmental health and health care program evaluations. Guidelines for WTP studies in environment were issued in 1993 in the US by the National Oceanic and Atmospheric Administration, who propose that WTP studies should use a dichotomous choice format and that values should be elicited by in-person interviews. Whether such guidance can be generalized to health care WTP studies is unclear. The nature of the health care commodity for WTP studies is very different from many environmental program benefits, and methods appropriate for the former may not be suited to the latter. Ongoing experiments using computer-based interviewing with the approach of conjoint analysis hold great promise for the future of WTP in health care.

BERNIE O'BRIEN

Cost-effectiveness in Clinical Trials

Cost-effectiveness analysis (CEA) is a method used to evaluate the outcomes and costs of a project or intervention. It is a tool aimed at assisting decision-makers in judging the efficiency consequences of various courses of action. In the health care arena CEA is used to assess the costs of alternative approaches to achieving certain health outcomes [11]. Usually the results of a CEA are summarized in a series of cost-effectiveness ratios that show the difference in costs divided by the difference in outcomes of one treatment relative to another. This ratio of differences is called the incremental cost-effectiveness ratio (ICER). When cost-effectiveness studies use the same **outcome measures** (such as quality-adjusted life years), researchers can compare ICERs across different types of interventions and populations. In an idealized world, if a health plan wanted to maximize the health of its enrolled population generated by a given budget, then it would order interventions so that those with the lowest ICERs would be adopted first. It would distribute funds across diseases and service categories so that the ICERs in each category would be equal. This would ensure that each dollar of expenditures worked equally hard in producing health effects.

In the context of evidence-based medicine, CEA can be viewed as a tool for quantifying and interpreting data on costs and outcomes. The modern era of managed care in the US and constrained budgets in publicly funded systems has led to clinical decisions being more influenced by budgetary considerations than was commonly the case in the 1960s and 1970s. If the design of clinical programs, clinical pathways and other decision-making support systems are to be founded on evidence, then it is important to use all types of evidence in designing them. It is therefore logical to recommend including evidence on cost-effectiveness in the evidence base used in supporting therapeutic choices. Such information can be (and is) used by national health systems and health plans in deciding which interventions to introduce and pay for as well as how to structure the treatment process.

There are a number of different approaches to obtaining the necessary data for conducting CEAs [7, 11]. Since good outcome measures are a fundamental component of all CEAs, and because clinical trials are considered the gold standard for evaluating outcomes stemming from clinical interventions, there is interest in incorporating cost-effectiveness studies into clinical trials [7, 9, 19, 21] This interest includes both adding a cost-effectiveness component to a clinical trial that is being planned to test the efficacy of a specific intervention, as well as conducting clinical trials for the purpose of determining whether a given intervention is cost-effective. (The former is sometimes described as adding an economic component to a clinical trial while the latter are sometimes called pragmatic trials.)

In this article we focus on how the design and measurement strategies of clinical trials need to be adapted to successfully add a cost-effectiveness component. Key considerations include the appropriateness of adding a cost-effectiveness component to the type of clinical trial that is being planned, sample size considerations, and the nature of the additional data that would need to be collected [4, 6]. Although these are identified as separate issues, they are obviously interrelated. Detailed discussions of various approaches to conducting cost-effectiveness analyses *per se* can be found elsewhere [7, 11, 13].

Definition of Terms

Before examining these issues, it is useful to set out some definitions. The term *treatment* is construed to include a range of clinical interventions (such as drugs and surgical procedures), settings (inpatient, outpatient), providers (such as physicians and nurse practitioners) and management strategies. The term *efficacy* generally describes the benefits generated by a treatment administered under ideal conditions, such as those found in clinical trials where patients are carefully selected according to specified criteria and then randomized to treatment and control groups to eliminate the confounding impacts of patient self-selection into treatment and clinical outcomes. *Effectiveness* describes the benefits of efficacious treatments that are realized under clinical conditions that reflect the usual circumstances under which medical care is delivered. Using a different terminology, efficacy studies are generally designed to have a high degree of internal validity, while effectiveness studies must have a high degree of external validity. Although there is some overlap, the endpoints of clinical trials and effectiveness studies tend

to differ. Traditionally clinical trials have focused on end-points such as mortality and clinical symptoms (blood pressure and cholesterol levels). Effectiveness studies often include these end-points. However, in recent years there has been a movement towards including outcome measures that are more meaningful to patients, such as quality of life. Wells [37] provides a good overview of the major differences between efficacy and effectiveness research.

A *cost-effectiveness* study examines both the use of resources (the costs) and the resulting changes in patients' health status (the outcomes) associated with the two or more treatments that are being compared. It is worth pointing out that the terms cost-effectiveness and cost-saving are distinct. A new treatment that produces outcomes identical to usual care but at lower cost would be both cost-saving and cost-effective (more health gain per dollar spent relative to usual care). However, a new intervention that both increased costs and improved health outcomes would be cost-effective if the ICER is similar to that of treatments that are part of usual care. Although cost-effectiveness studies can be narrowly focused (e.g. the determination of the incremental cost of lowering systolic blood pressure by one unit), the greatest interest lies in estimating cost-effectiveness ratios in terms of the cost per quality-adjusted life year (QALY) gained from an intervention [10]. As a measure of health outcome, a QALY assigns a weight to each health state in each time period. These weights range from 0 to 1, where a weight of 1 corresponds to optimal health and a weight of 0 corresponds to death. The weights reflect patient preferences for a particular health state. Because the states of health are weighted by the preferences or utility associated with a health state, a QALY is also called a utility-based quality of life indicator.

Cost-effectiveness studies can be conducted from a number of perspectives. The perspective taken determines which outcomes and costs are taken into consideration and how they are measured. The three most common perspectives are those of the individual, the health plan or society at large. When a CEA is conducted from a social perspective, the analyst considers all the effects of the interventions, and counts all health outcomes and costs associated with the intervention regardless of who benefits and who bears the costs. In what follows we focus on CEAs from a social perspective.

Considerations for Adding a Cost-effectiveness Component to a Clinical Trial

General

Clinical trials are undertaken to study a wide range of issues from testing new drugs to evaluating new treatment methods for breast cancer. Some trials are very large and involve thousands of patients and multiple sites (*see* **Multicenter Trials**), while others are more limited in terms of their size and patient population. An investigator would add a cost-effectiveness component to a clinical trial in pursuit of answers to two questions:

1. What is the ICER of the intervention?
2. Does the estimated ICER indicate that the treatment is cost effective; that is, is the ICER equal to or less than some benchmark? (For example, a Canadian research team [18] assigned grades to different ICERs. It assigned a "B" to technologies that were more effective than existing ones and cost about $20 000 per QALY gained. It recommended that Grade B technologies be adopted.)

In deciding whether it makes sense to add a cost-effectiveness component to a clinical trial four questions should be posed [5, 11, 20]:

1. Does the trial address an issue that is likely to be of economic importance? Will the information generated by adding a cost-effectiveness component be of sufficient value to decision-makers to justify the cost of adding the component?
2. Is the trial testing something that is relevant to community practice? For example, a trial that compares an innovative treatment to usual care is more informative than one that compares a new drug to a placebo (unless of course there are no existing treatments for the condition under study).
3. Are the results likely to be of interest to decision-makers? Decision-makers include patients, physicians, large-scale provider organizations (hospitals, integrated delivery systems), health plans and government agencies.
4. Will the results of the trial have external validity? The more highly selected the patient population to be studied and the more closely monitored

the treatment protocol, the less likely it is that the outcomes would be representative of those observed in the community under conditions of community care.

Sample Size Considerations

It is likely that adding a cost-effectiveness component will raise issues with respect to sample size. There are two main problems that have to be addressed: (i) the fact that cost data typically display different properties than common clinical indices and (ii) the challenge of calculating confidence intervals for a ratio such as an ICER.

The ICER is a ratio that is composed of parameters that measure costs and outcomes. As such, the variance around an ICER encompasses the variance in costs and the variance in outcomes. Typically, a clinical trial is designed so that the sample size is based on the minimum number of subjects required to detect a given (predetermined) clinically important difference in outcomes with a given power (e.g. 0.90) at a conventional level of significance (e.g. $P < 0.05$) (*see* **Sample Size Determination**). The designers of clinical trials often impose strict exclusion and inclusion criteria (*see* **Eligibility and Exclusion Criteria**) to reduce the variation in outcomes in order to reduce the necessary sample size. In addition, many clinical measures have been designed to display particular statistical properties such as a Normal distribution.

Data on health care costs have different properties than do clinical data such as symptom counts and blood pressure measurements. Cost data typically do not follow a standard Normal distribution. They tend to exhibit density masses at minimum levels of expenditure and are highly skewed to the right. (For instance, hospitalizations related to side-effects associated with treatment may be very rare. However, the costs associated with the few hospitalized episodes are very high.) The implication of this is that the variance in costs will tend to be considerably greater than the variance in clinical outcome measures. Thus, it is likely that the sample size requirements for testing the significance of an estimated ICER will be larger than those for testing the significance of a clinical outcome.

There are other issues related to determining the variance of the ICER, and thus the confidence intervals. For instance, cost and outcome estimates in an ICER and their variances may not be independent. On the one hand, if the correlation between costs and outcomes is negative (higher costs associated with worse outcomes), then the variance of the ICER will increase. On the other hand, if the correlation between costs and outcomes is positive, then the variance will be reduced. Furthermore, the ICER is a ratio. Since the difference in outcome measure enters in the denominator of the ICER, small differences in outcomes between interventions can create very large differences in the ICER.

Several empirical strategies have been advanced for estimating confidence regions for ICERs [24, 34]. These methods involve different levels of computational burden and assumptions about the underlying relations between treatments and effects. Briggs & Gray [2], for example, use this literature to explore techniques for deriving a sample size formula for a CEA based on simple combinations of the confidence limits on costs and outcomes.

Effectiveness Data

In most cases the outcome measures collected under the trial will have to be expanded to include information on the quality of life experienced by subjects in all treatment arms. These measures should include generic measures of quality of life so that ICERs can be compared across disease types and interventions.

Ideally, utility-based quality of life information should be obtained [10]. There is a variety of methods for collecting this utility-based quality of life information. One method is to administer a general preference rated instrument for assessing quality of life. These instruments, which measure a number of concepts (health perceptions, social functioning, psychological functioning, physical functioning and impairment), are administered to the subjects periodically during the trial. Preference scores that have been obtained through earlier research projects are then used to weight the responses. Examples of such instruments are the EuroQol instrument [3, 8, 17], Quality of Well Being [15, 16] and the health utilities index [31, 33]. A second method is to map clinical indicators (such as the Hamilton rating scale, an instrument used to measure depressive symptoms [12]), into QALYs by using published information on the quality of life associated with that condition [20]. A third method is to obtain the utility estimates from the people who are actually enrolled in the trial. There are three standard ways of obtaining these. These are

asking subjects to: (i) respond to standard gamble questions (where subjects are asked to compare life in a given health state that is a sure thing to a gamble with a probability P that perfect health is the outcome and $1 - P$ that death is the outcome) [33]; (ii) respond to time–trade off questions (where subjects are asked to trade off life years in a state of less-than-perfect health for a shorter life span in a state of perfect health) [32]; or (iii) complete a visual analog (a direct rating scale where they are asked to place a mark at some point between two anchor points that indicates their rating of a give health state) [22].

The second approach to obtaining information on quality of life is to administer a nonpreference weighted quality of life instrument. There are several such instruments available. These instruments generally assess the same domains as the utility-based quality of life instruments, but the scores are not utility weighted. Examples of such instruments are the Medical Outcomes Scale (MOS) or SF-36 [29, 35], the Nottingham Health Profile [14] and the Sickness Impact Profile [1].

The third approach is to use a disease-specific instrument such as the Hamilton Rating Scale for Depression [12] and the McGill Pain Questionnaire [23]. As indicated above, it is not possible to compare the ICERs found in these studies with those of other studies that examine other disease conditions.

It should be noted that the field of health assessment is still developing and there is no general agreement on which is the best instrument. A general overview of rating scales and questionnaires can be found in Hunt et al. [14], McDowell & Newell [22] and Patrick & Erickson [26].

A quite different approach to measuring the "value" of outcomes on a common scale is to use what economists refer to as the "willingness-to-pay" approach. This involves estimating individuals' willingness-to-pay for new medical interventions that may improve health [28, 30]. Under this approach, the researcher still has to assess the outcomes of the trial; that is, the effect of the intervention relative to the status quo in terms of change in physical functioning, mental functioning and pain would still have to be assessed. However, the weights to be applied to these effects would come from studies that estimate the willingness-to-pay for these effects. The theoretical advantage of the willingness-to-pay measure is that it allows for a comprehensive consideration of what individuals value about medical treatments, including intangible benefits such as pain and discomfort which are not easily captured by most outcome measures. Some economists have suggested that the additional premiums that people are willing to pay in order to have a new intervention added to a health plan's set of reimbursable procedures summarizes the value of benefits from new interventions [27]. However, many are offended by valuing the gain in health in monetary terms. Furthermore, willingness-to-pay measures typically favor the health of the wealthy over the poor.

Adding additional outcome measures to the set of outcomes measures to be gathered during a clinical trial will both increase the cost of the trial and increase patient burden. Therefore, the designers of the cost-effective component will have to assess the impact of adding these outcome variables and to select the outcome variables carefully.

Cost Data

It is necessary to collect information on the costs incurred by subjects in all treatment arms. However, there is some discretion in determining the exact cost data to be collected. The range of the data to be collected will depend on the nature of the intervention and the health condition being treated. For instance, if the treatment is narrowly focused, and if it is unlikely that there is any relationship between the health condition that is being targeted and other health conditions, then it may be sufficient to focus only on the costs associated with the targeted condition. For example, in examining a trial that compared hospital with outpatient treatment for pelvic inflammatory disease, the researchers focused on health care costs associated with conditions related to fertility and gynecological problems [25]. However, treating some conditions may have broad health consequences. In this case it is necessary to measure the costs associated with treating not only the targeted condition but also other conditions that may be affected. For example, in looking at alternative treatments for depression, the researchers captured both mental and physical health costs [20] because there were strong arguments in the literature that the costs of good treatment for mental disorders would be offset by a decrease in the costs of treating physical health problems. Finally, it is possible that treating specific conditions may have effects on sectors of the economy other than the health care sector. For

example, in a study that compared intensive outpatient therapy with usual inpatient care for people with severe mental illness, Weisbrod [36] collected information on the costs associated with treating mental health conditions, the criminal justice system, family burden and care-taking costs.

In most cases costs are estimated by obtaining information on the quantity of services used and then by applying cost weights to those data. There are a number of ways to gather the utilization data. These include: obtaining information from the records maintained by the clinical trial, using administrative records maintained by the health care centers in which the subjects receive their medical care services, using the administrative records maintained by health plans or government agencies that pay for care, and from direct patient interview. The nature of the administrative records will vary by provider setting, agencies and across countries. Some records (such as medical records and hospital discharge records) will include only utilization information. Other administrative records systems (such as the hospital billing records in the US and the information maintained by insurance plans) will include information on the use of specific services, the charges (prices) associated with those services and the payments made.

The use of services must be assigned a monetary value. Ideally the researcher should estimate the social cost of resources used, or equivalently the marginal cost of those resources. Economic theory indicates that in efficient markets, prices are equal to marginal cost. However, health care markets are not competitive in the theoretical sense and thus the prices do not typically reflect costs. (This is true both in national health systems as well as in more market-based systems such as the US.) Thus, other methods must be used to assign cost weights to the service used and other resources. In some cases the analysts may conduct specific cost-finding studies. However, in most cases they use information from other sources – the hospital cost accounting systems and external fee schedules – to assign cost weights. For example, in the US researchers often use the fees from the Medicare fee schedule to assign cost weights to the different types of physician services. They use prices published in standard references such as the *Red Book* to assign prices to pharmaceuticals. They may use the information from the hospital bill to estimate the cost of a hospital stay; however, they will usually adjust the charges by the hospital cost to charge ratio in order to obtain a measure that is a continuing proxy for costs. In other countries costs are estimated by valuing the inputs into the treatment process by using salaries and input purchase prices (drugs).

In general, researchers need to collect information not only on the medical care costs but also on the time and transportation costs incurred in accessing and receiving care. If volunteers are used in any portion of their treatment interventions, then their time must be measured and costs impacted. The costs associated with actually conducting the trial itself (the design costs, data-collection costs, administrative/managerial costs and analyses costs) should not be included since they are not part of delivering care.

Gathering the cost data necessary to conduct a cost-effectiveness study will increase the cost of conducting the study and may increase patient burden. Therefore, it is necessary to select cost measures carefully.

Extending the Analysis to the Posttrial Period

If there are significant differences in the outcomes between the people who are enrolled in the clinical trial, it may be necessary to model the differences that would expected to be observed after the completion of the trial. The short timeframe of many clinical trials makes this an important consideration. For example, suppose that a trial is conducted to test the efficacy of a new antidepressant medication. Suppose that it is a six-month trial and that at the end of the sixth month a higher proportion of subjects who have been randomized to the experimental arm have recovered. The cost-effectiveness of that drug will differ depending on whether that different recovery rate can be expected to be maintained or whether a comparable number of subjects in each treatment arm will have recovered at the end of eight months or a year. Thus, an ICER ratio based only on the trial data will not be a good indicator of the true ICER of one treatment versus another. In this case, simulation and modeling methods must be used to extend the data beyond the trial period [7].

Sensitivity Analyses

It is clear that a number of judgments have to be made in conducting a CEA. Researchers must make

more judgments in estimating the ICERs than they do in analyzing the clinical findings of the trial. These judgments are related to the selection of the approach used to measure quality of life, the cost weights, the range of costs to include in the analyses and so forth. Judgments also have to be made about the reliability of the outcome treatment effect. Since the researchers often monitor the treatment being applied to the experiment group very closely, it is likely that the outcomes observed during the trial may be better than those that will be observed in practice. Thus, the researchers have to make some assumptions either about the costs that a practice would have to incur if care were to be monitored or about the decreases in effects that will be observed in practice without the monitoring that took place during the trial. As a result, researchers who conduct CEAs often estimate a number of ICERs in which they make different assumptions about several of the values. They then determine how sensitive their conclusions are to these assumptions.

Interpretation of CEAs

CEAs conducted in the context of clinical trials offer important information about the *potential* efficiency of a new clinical intervention or technology. CEAs in clinical trials are conducted under a particular set of allocation rules. That is, particular patient populations are selected to participate in the trials; and participants are randomly assigned to treatment independent of clinician or patient preferences. In the community setting, clinical technologies are put into practice under very different allocation rules and therefore realized effectiveness may differ markedly from those found in a clinical trial even if the technologies are appropriately delivered. An example may illustrate the point. Proton Pump Inhibitors have been shown to be cost-effective interventions for severe esophagitis relative to older H-2 Blockers. However, in practice a substantial portion of Proton Pump Inhibitors are used for the treatment of milder forms of esophagitis and in those cases offer few clinical benefits over the H-2 Blockers at a considerably higher cost. Thus, in practice the ICER of Proton Pump Inhibitors is likely to be considerably higher than that found in the clinical trials. For this reason, a CEA based on clinical trials offers important yet incomplete information on the efficiency of adopting a new clinical intervention into practice.

Conclusions

CEAs can offer important insights into the "value" of a new medical intervention or even into old interventions. Increasingly payers, health plans and regulators are interested in understanding the budgetary demands associated with new clinical technologies that promise enhanced health outcomes. CEAs linked to clinical trials can sometimes offer a rigorous method of informing such questions.

It is clear that adding cost-effectiveness components to clinical trials will increase the costs of conducting the trial. Not only is it likely that the sample size will have to be increased, but also additional data will have to be collected. There will be additional patient burden. Thus, adding CEAs to all clinical studies would not itself be a cost-effective use of society's resources. Clinical trials that are good candidates for CEA augmentation include those that are testing new treatments that may be significant from an economic standpoint in that they offer significant improvements in outcomes at a significant increase in cost or that they offer significant cost savings for similar levels of outcomes when compared with existing interventions.

Counter-matching

Counter-matching is nested case–control study design (*see* **Case–Control Study, Nested**) in which a **covariate** is known on all cohort members, and controls are sampled to yield covariate-stratified case–control sets. The design is advantageous when a major analysis variable, or a correlate, is available on all cohort members and additional information is to be collected on a sample. Unbiased estimation requires the numbers of risk set members in each counter-matched sampling stratum.

The Design

Counter-matching was originally proposed as an exposure-stratified, individually matched nested case–control study method in the context of continuous failure-time (cohort) data [13, 15]. Counter-matched sets are characterized by the number of subjects m_l from each of the L *sampling strata* defined by the counter-matching variable. It is required that the counter-matching variable is known for all risk set members and, in addition to the case, controls are randomly sampled without replacement (*see* **Sampling With and Without Replacement**) from each of the sampling strata in the risk set to yield the required m_l subjects. As illustrated in Table 1, when the case is from sampling stratum 2, m_l controls are sampled from the n_l in risk set sampling stratum l except for stratum 2, from which $m_2 - 1$ controls are sampled. In the special case of two sampling strata, with one subject from each stratum (the 1 : 1 design), the control is sampled from the opposite sampling stratum of the case; the opposite of matching and thus motivating the name.

For grouped failure-time or simple **binary data** (multiple cases in the case–control set) counter-matching, the m_l would generally depend on total number of cases $|\mathbf{D}|$ in the study base [17]. (i.e. the design is characterized by $m_1(|\mathbf{D}|), \ldots, m_L(|\mathbf{D}|.)$ The actual number of cases that fall into counter-matched stratum l, $|\mathbf{D}_l|$, is random and determines the number of controls to be sampled from stratum l, $m_l - |\mathbf{D}_l|$. This is illustrated in Table 2.

Statistical Analysis

Estimation of Rate (Odds) Ratio Parameters. The analysis of the counter-matched data must take into account the **stratification** of sampled sets. For individual **matching** (continuous time risk sets), the **partial likelihood** is based on the probability that a subject is the case given the counter-matched set and requires the control sampling probabilities. In particular, with l_j indexing the sampling stratum for subject j, the probability of drawing the counter-matched sample if j were the case is given by $\pi_j = n_{l_j}/m_{l_j}\left[\prod_{l=1}^{L}\binom{n_l}{m_l}\right]^{-1}$. This leads to the **likelihood**

$$\prod_{\text{sets}} \frac{r_{case}(\beta)\dfrac{n_{l_{case}}}{m_{l_{case}}}}{\sum_{j\in\text{set}} r_j(\beta)\dfrac{n_{l_j}}{m_{l_j}}}, \tag{1}$$

where $r_j(\beta) = r(Z_j;\beta)$ is the rate ratio associated with Z_j and β is the rate ratio parameter from a **proportional hazards model**. This likelihood can be fitted using standard **conditional logistic regression** software that allows for fixing a regression parameter. For instance, for the standard **loglinear model** $(n_{l_j}/m_{l_j})r_j(\beta) = \exp(Z_j\beta + \log w_j)$ where $w_j = n_{l_j}/m_{l_j}$. So, the log weight can be included in the model with fixed parameter equal to one (an *offset* in the model). Aside from this offset, analysis proceeds as in any standard conditional logistic regression analysis for individually matched case–control studies. The likelihood (1) has the usual likelihood properties so that the standard likelihood inference techniques apply, with no additional modeling assumptions other than appropriate specification of the sampling weights [9, 15]. The full asymptotic theory has been derived [4, 13] and the performance,

Table 1 Individually matched counter-matched study (one case per counter-matched set). In this example, the case is in sampling stratum 2 so m_l controls are sampled from each stratum except stratum 2 for which $m_2 - 1$ controls are sampled.

	Sampling stratum				
	1	2	$\cdots$	L	Total
Cases	0	1	$\cdots$	0	1
Controls	m_1	$m_2 - 1$	$\cdots$	m_L	$\sum m_l - 1$
Total in sample	m_1	m_2	$\cdots$	m_L	$\sum m_l$
Total in risk set	n_1	n_2	$\cdots$	n_L	$\sum n_l$

Table 2 Unmatched counter-matched study (multiple cases per counter-matched set). The m_l are counter-matching design parameters representing the total number from stratum l. With $|\mathbf{D}_l|$ number of cases in stratum l, $m_l - |\mathbf{D}_l|$ controls are randomly sampled from stratum l to make a total of m_l subjects.

	Sampling stratum				
	1	2	$\cdots$	L	Total
Cases	$\lvert\mathbf{D}_1\rvert$	$\lvert\mathbf{D}_2\rvert$	$\cdots$	$\lvert\mathbf{D}_L\rvert$	$\lvert\mathbf{D}\rvert = \sum \lvert\mathbf{D}_l\rvert$
Controls	$m_1 - \lvert\mathbf{D}_1\rvert$	$m_2 - \lvert\mathbf{D}_2\rvert$	$\cdots$	$m_L - \lvert\mathbf{D}_L\rvert$	$\sum m_s - \lvert\mathbf{D}\rvert$
Total in sample	m_1	m_2	$\cdots$	m_L	$\sum m_l$
Total in risk set	n_1	n_2	$\cdots$	n_L	$\sum n_l$

compared with other designs, has been evaluated in a number of situations [1, 7, 10, 11, 16].

For counter-matching with multiple cases per set, the likelihood requires the (control selection) probability of picking a particular counter-matched set if a set of subjects $\mathbf{s}$ (of the same size as the actual set of cases $\mathbf{D}$) were the set of cases. With $\mathbf{s}_l$ the set of subjects from $\mathbf{s}$ in sampling stratum l, and $|\mathbf{s}_l|$ the number of subjects in $\mathbf{s}_l$, the counter-matching control selection probability is given by

$$\pi_{\mathbf{s}} = \left[\prod_{l=1}^{L} \frac{n_l(n_l-1)\cdots}{\frac{(n_l-|\mathbf{s}_l|+1)}{m_l(m_l-1)\cdots}\atop(m_l-|\mathbf{s}_l|+1)}\right]\left[\prod_{l=1}^{L}\binom{n_l}{m_l}\right]^{-1}. \quad (2)$$

This leads to the **likelihood** [17]:

$$\prod_{\text{sets}} \frac{r_{\mathbf{D}}(\beta)\left[\prod_{l=1}^{L} \frac{n_l(n_l-1)\cdots}{\frac{(n_l-|\mathbf{D}_l|+1)}{m_l(m_l-1)\cdots}\atop(m_l-|\mathbf{D}_l|+1)}\right]}{\sum_{\mathbf{s}\subset\tilde{\mathcal{R}}:|\mathbf{s}|=|\mathbf{D}|} r_{\mathbf{s}}(\beta)\left[\prod_{l=1}^{L} \frac{n_l(n_l-1)\cdots}{\frac{(n_l-|\mathbf{s}_l|+1)}{m_l(m_l-1)\cdots}\atop(m_l-|\mathbf{s}_l|+1)}\right]},$$

where $r_{\mathbf{s}}(\beta) = \prod_{j\in\mathbf{s}} r(Z_j;\beta)$ is the product of **odds ratios** associated with the Z_j in a **proportional odds (logistic) model** (*see* **Logistic Regression**). Although, in general, standard software does not accommodate this likelihood, conditional logistic software can be "tricked" to estimate the odds ratio parameters when the odds model is log-linear [17]. Because of the inherently correlated structure, derivation of the asymptotic properties of likelihood (2) poses some theoretical challenges that have not yet been addressed [2]. However, limited derivation and **simulation** studies indicate that the efficiency performance of (2) for the grouped data counter-matched is similar to that of (1) for individually matched data [17].

Estimation of Other Parameters. Methods for estimation of the cumulative baseline hazard and **absolute risk** from counter-matched data have been described [14] as well as methods for the estimation of regression parameters in the **Aalen linear model** [5]. A weighted unconditional logistic regression can be used to estimate baseline odds parameters from grouped data [17].

Examples

Crystalline Silica Exposure and Silicosis in Gold Miners. In a comparison of nested case–control study design options in an occupational cohort study of 3000 gold miners, counter-matching was compared with **random sampling** of controls [20]. A major cost component in this study was in obtaining silica exposure data from dust samples taken from the mines; a nested case–control study could have avoided much of this expense. Investigators compared random sampling and years-of-employment counter-matching of controls. The correlation between years of employment and cumulative silica dust exposure is about 0.7, and it was found that three counter-matched controls yielded the same statistical efficiency as 15 randomly sampled controls at the same cost. The situation considered in this example is typical of many **cohort studies** in which a "broad" measure (e.g. years of employment) is associated with disease and the nested case–control study is undertaken to identify better the possible causative agents (e.g. cumulative silica dust exposure). Counter-matching incorporates the cohort "broad measure" into the

sampling in order to obtain a sample that is more informative about the specific exposure, compared to random sampling.

Radiation, Hormones, and Breast Cancer in a Cohort of Japanese Atomic Bomb Survivors. A strong association of premenopausal breast cancer risk and radiation dose has been observed in the Radiation Effects Research Foundation's Life Span Study (LSS) of atomic bomb survivors [21] (*see* **Radiation Epidemiology**). For the Adult Health Study (AHS) cohort, a subgroup of LSS volunteers who participated in biennial clinical examinations, stored blood serum was available for 5724 women, from which estradiol levels could be measured, at some expense. The radiation-dose counter-matched study was undertaken to investigate associations with estradiol (and other hormonal and antioxidant factor) levels and radiation dose jointly on breast cancer risk. For each of the 80 premenopausal breast cancer cases, two controls were sampled with the counter-matching strata defined by radiation dose with a zero dose category and two exposure groups defined by the median of the distribution of the combined cases; that is, a control was randomly sampled from each of the (noncase) sampling strata [11, 19]. Given the actual radiation doses and a likely distribution of estradiol levels, the counter-matching design was compared with random sampling and radiation dose matching of controls. It was found that counter-matching was much more efficient than random sampling and of about equal efficiency to matching for a range of positive multiplicative radiation-estradiol **interactions**. But, unlike matching, counter-matching still allows for estimation of the radiation main effects so that a wider range of questions about the variation of breast cancer risk with radiation dose and estradiol levels can be addressed; in particular, about potential **confounding** [11]. In this study, the counter-matching variable was based on the actual exposure and the goal of the study is to investigate **effect modification** of the exposure-disease risk relationship.

Gene Susceptibility to Radiation Exposure for Second Breast Cancer Risk: The WECARE Study. The main goal of this study is to determine whether the risk of breast cancer after exposure to radiation is higher in women possessing **polymorphisms** of genes involved in double-strand break repair. The cohort consists of 31 243 women diagnosed with breast cancer identified by five **cancer registries**. There were 801 women with asynchronous bilateral breast cancer who were the cases in this study. A cohort of women with breast cancer is advantageous for addressing the study questions for two main reasons. First, women who have had a breast cancer are likely to have a higher **prevalence** of **genotypes** that cause the disease. Second, a large percentage of the women (about 40%) underwent radiation therapy for their first breast cancer. The "scatter" from the therapeutic radiation can result in significant exposure to the contralateral breast that is often well documented in treatment records. A nested case–control study with two controls per case was dictated by cost considerations. Now, although it may be imperfect, all the cancer registries record whether radiation therapy was part of the treatment regimen (RRT+) or not (RRT−). This was used in an RRT counter-matched design in which two controls were sampled so that the case–control set would possess two RRT+ subjects and one RRT− subject. From each enrolled subject, a blood sample was obtained for the genotyping; medical treatment records were obtained (for all participants) to determine if they had had radiation treatment and, if so, the dose to the contralateral breast was determined; and the women filled out a mailed questionnaire that asked about other treatments and breast cancer risk factors. In this study, the counter-matching variable is correlated to the exposure of interest. Intuitively, there is "more variability" in radiation dose among RRT+ than RRT− subjects suggesting that 2 RRT+, 1 RRT− allocation would be more efficient for assessing radiation dose response and radiation-gene interaction than random sampling two controls. This intuition was confirmed in a simulation study comparison [3]. In this study, the counter-matching variable was based on the a dichotomous correlate of exposure and the goals of the study include characterization of the dose response for exposure and to investigate effect modification of the exposure-disease risk relationship.

Early Asthma Risk Factors Study (EARS) of In Utero and Early Life Exposures and Asthma. In a cohort study of determinants of respiratory health, over 5000 children from 12 communities and three grade levels were surveyed for "baseline" data [18]. Information collected at enrollment to the study included whether the student had ever been diagnosed with asthma, exposed to tobacco smoke *in utero* and during

childhood, and other factors that are potentially related to respiratory health. Using these baseline data, it was found that an asthma diagnosis at age five or younger was associated with maternal smoking during pregnancy (*in utero* smoke exposure) but not with environmental tobacco smoke exposure in early childhood [12]. The EARS follows up on this finding, first, to augment the smoking during pregnancy information (this was just a yes/no question in the baseline questionnaire) to assess dose–response and within-pregnancy timing of exposure and, second, to ascertain the child's GST-T1 and GST-M1 genotypes and to assess gene susceptibility. For the purpose of this study, the cohort (or study base) consists of subjects enrolled into the longitudinal study, followed from birth to age five. Since *in utero* exposure (yes/no) information is available for the cohort members, children diagnosed with asthma at age less than five years, the cases, were counter-matched on *in utero* smoke exposure, with the number sampled from exposed and unexposed approximately equal to the number of cases within matching strata defined by community, grade, and gender. The additional maternal smoking exposure and other information was obtained in a short interview and genotype status was assessed using standard PCR methods from buccal cells collected from subjects by swabbing the inside of the mouth. In this study, "yes/no" *in utero* smoke exposure information was available on all cohort members, and it is of interest both to obtain more precise maternal smoking information to assess timing and dose-response, as well as joint effects with genetic factors. Because the counter-matching factor is fairly correlated with the number of packs smoked and other smoking information, the study has much more statistical information for inference about such factors than would a comparably sized study with randomly sampled controls [17]. In contrast with the studies described above that are individually matched, this study implements the grouped data version of counter-matching.

Design Considerations

General Considerations. Relative to random sampling, counter-matching enhances statistical efficiency for analyses involving the counter-matching variable or correlates. However, statistical efficiency is reduced for analyses of factors that are not correlated to the counter-matched variable. Thus, counter-matching is appropriate when the study is focused on questions related to the counter-matching (generally exposure-related) factor. Situations for which there is a large efficiency gain for the counter-matching variable appear to be the situations for which there is a large efficiency loss for factors uncorrelated to the counter-matching variable. In particular, the degree of this gain/loss depends on the rarity of exposure, so that counter-matching on a rare exposure can be very advantageous for exposure-related analyses, to the great detriment of analyses of (main effects) of other factors. Whether this trade off is worthwhile depends on the specific goals of the study.

Counter-matching on an Exposure Correlate. Increased variability of exposure from the exposure-correlate stratified sampling provides some intuition for why counter-matching on an exposure correlate can increase efficiency relative to random sampling, as well as suggest a favorable allocation of subjects across the sampling strata. However, this increase in variability is tempered by the need for a weighted analysis that, in the absence of adequate correlation, works against increased efficiency [9]. Some insight into the relative efficiency of counter-matching to simple random sampling is provided in the dichotomous exposure/correlate situation with $1:1$ counter-matching on the correlate. Under the "null" situation of no association between exposure and disease, and denoting the **sensitivity** and **specificity** of the correlate for exposure by η and γ, respectively, the asymptotic efficiency of $1:1$ counter-matching relative to $1:1$ random sampling is $2[\eta\gamma + (1-\eta)(1-\gamma)]$. Counter-matching on the correlate is more efficient when the correlate is both more (or both less) than 50% sensitive and specific. Further, if the "correlate" and exposure are independent, then the counter-matching efficiency is always less than or equal to 1; always worse than random sampling [15, 16]. This illustrates a general principle that the counter-matching factor must be "somewhat correlated" to the exposure in order to realize an efficiency gain.

Allocation of Subjects in Sampling Strata. Although analyses based on (1) or (2) with the appropriate weights are valid for any allocation of subjects in sampling strata, efficiency depends on how the sampling strata are formed and the m_l. As a general guideline, when there are more counter-matched

subjects than strata, an allocation that will yield the greatest exposure variability appears to be most desirable [3]. When the exposure or correlate has more categories than subjects to be sampled, then it is advantageous to create sampling strata that approximately results in equal numbers of cases in each stratum [11, 13, 16, 20]. Determination of the "best" counter-matched design for a given study can be addressed using asymptotic variance calculations and computer simulation.

Counter-matching and Studies of Effect Modification. Although the relative performance of case–control designs for assessing effect modification depends on the distributions of the factors involved and the relationships between these factors and disease risk in a complex way, the increased variability in one or both of the factors in a counter-matched design generally results in enhanced efficiency. An efficiency comparison of random sampling and matching or counter-matching on one of the exposure variables indicated that counter-matching was similar or superior to matched or random sampling over a wide range of situations [10]. A study of feasibility of nested case–control studies for investigation of gene-susceptibility studies compared designs using three controls per case including counter-matched designs with sampling strata defined by exposure only, family history only, and both exposure and family history, and found the latter to be the most efficient in a wide range of circumstances [1]. Other efficiency comparisons have been done in the context of the WECARE and the Radiation, Hormone, and Breast Cancer studies described in the section "Examples" [3, 19].

Other Issues

Marginal Information of the Counter-matching Variable. If the only analysis variable is a function of the counter-matching stratum variable, then counter-matching likelihood is proportional to that of the full cohort. To see this, let $Z(l)$ be a function of the counter-matching stratum l. Then, because there are m_l subjects from stratum l, contributions to (1) become

$$\frac{r_{\text{case}}(\beta)\dfrac{n_{l_{\text{case}}}}{m_{l_{\text{case}}}}}{\sum_{l=1}^{L} m_l r(Z(l);\beta)\dfrac{n_l}{m_l}} \propto \frac{r_{\text{case}}(\beta)}{\sum_{l=1}^{L} n_l r(Z(l);\beta)},$$

which is the full cohort contribution. This can be similarly shown for grouped time likelihood (2).

Counter-matching and Matching. Counter-matching is essentially the opposite of matching. Matching is a technique to create case–control sets that are *similar* in the matching factor. Counter-matching is a technique to create case–control sets that are *diverse* in the counter-matching factor. The analytic consequences of the two methods are also opposite. In particular, exact matching results in no statistical information for inference about the main effect of the matching factor, while counter-matching brings the full cohort "marginal" information for the counter-matching factor main effect into the sample. In the context of a nested case–control study, the application of the two techniques have a natural orthogonality. Matching is a natural method to incorporate information related to confounding, while counter-matching is a natural method to incorporate information related to exposure. Both methods can be used in a study by counter-matching within matching strata.

Related Designs. Two-phase exposure-stratified sampling (*see* **Case–Control Study, Two-phase**) differs from counter-matching in that case–control/exposure strata are sampled independently [8]. The design is appropriate for "large strata", that is, for grouped data with sufficient numbers of cases. A comparison of the two-phase approach and counter-matching is given in [17]. An exposure-stratified **case–cohort study** has been described [6].

Counting Process Methods in Survival Analysis

Event history analysis or generalized survival analysis finds applications in **actuarial** science, **demography**, epidemiology, medical research, and many other fields. This theory studies a collection of individuals, each moving between a finite (usually small) number of states. The exact transition times in continuous time form the modeling basis of the phenomena, although often these times are only incompletely observed. This article describes how counting processes provide a useful mathematical framework when studying event history data.

In survival analysis, often a model is needed when studying the occurrence of a recurrent phenomenon or events of different types. Such models can be studied within the framework of counting processes. A counting process $N(t)$ can be thought of as counting observed events up to time t.

The simplest and most important model for event history data is the following model of survival data. More complicated event history data include, among others, data on **competing risks**, the so-called multistate survival data, and the data that may be modeled by illness–death process or disability–death processes (*see* **Stochastic Processes**).

Suppose that a group of n patients is followed at some hospital from the time of diagnosis of a certain disease to the time of death or to the date last known in follow-up. We note that these are often patients who are alive at the time of data analysis. For the ith patient, we observe a disease duration $\overline{T}_i$, which is either his true survival time T_i, that is, the length of time from diagnosis to death, or a censoring time, that is, the length of time from diagnosis to the date last known in follow-up (*see* **Censored Data**). Let $D_i = 1$ if $\overline{T}_i$ is a true survival time and $D_i = 0$ otherwise. We assume that the pairs (T_i, D_i) are independent for $i = 1, \ldots, n$.

Let

$$N_i(t) = I(\overline{T}_i \le t, D_i = 1), \tag{1}$$

where $I(\cdot)$ is the indicator function. Thus, N_i is 0 before $\overline{T}_i$ and jumps to 1 at $\overline{T}_i$ if and only if $\overline{T}_i$ is a true survival time. At any time t, we know that the ith patient either has been observed to die, or has been censored because of incomplete follow-up, or is still alive and at risk. For the first two cases, the conditional probability of observing N_i to jump in a small interval near t is 0. For the latter, this conditional probability is near $\alpha_i(t)\mathrm{d}t$, where $\alpha_i(\cdot)$ is the hazard function of T_i (*see* **Survival Distributions and Their Characteristics**). Let

$$Y_i(t) = I(\overline{T}_i \ge t), \tag{2}$$

which indicates whether the individual is still alive just before time t. The previous remarks indicate that

$$Pr[\mathrm{d}N_i(t) = 1 \mid \mathcal{F}_{t-}] = \alpha_i(t)Y_i(t)\,\mathrm{d}t. \tag{3}$$

Here $\mathrm{d}N_i(t)$ is the increment of N_i in a small interval near t, and $\mathcal{F}_{t-}(\mathcal{F}_t)$ represents all the information available on the course of the disease just before (up to) time t. $\mathcal{F}_t$ is called a *filtration*.

We note that both the deterministic function α_i and the random process Y_i are predictable processes in the sense that their values at any time t are known just before t. If we define **stochastic processes** M_i by having increments

$$\mathrm{d}M_i(t) = \mathrm{d}N_i(t) - \alpha_i(t)Y_i(t)\,\mathrm{d}t, \tag{4}$$

then (3) says

$$\mathrm{E}[\mathrm{d}M_i(t) \mid \mathcal{F}_{t-}] = 0, \tag{5}$$

which means

$$M_i(t) = N_i(t) - \int_0^t \alpha_i(s)Y_i(s)\,\mathrm{d}s \tag{6}$$

is a *martingale* (see, for example, [1, 4, 26]). In particular, $\mathrm{E}M_i(t) = 0$ for all t. Here $\lambda_i(t) \equiv \alpha_i(t)Y_i(t)$ is called the *intensity process* of N_i. More generally, under some regularity conditions, a counting process N has a predictable process λ such that

$$M(t) \equiv N(t) - \int_0^t \lambda(s)\,\mathrm{d}s \tag{7}$$

is a martingale. λ is called the *intensity process* for N, and

$$\Lambda(t) = \int_0^t \lambda(s)\,\mathrm{d}s \tag{8}$$

the *cumulative intensity process* because of $\lambda(t+) = \lim_{\triangle t \to 0}(1/\triangle t)P\{N(t + \triangle t) - N(t) = 1 \mid \mathcal{F}_t\}$.

An important example arises when the n subjects in (1) are independent and identically distributed

(i.i.d.). In this case, let $N_\cdot = \sum_{i=1}^{n} N_i$, which is a univariate counting process that counts the number of observed deaths. Its intensity process is $\lambda_\cdot(t) = \alpha(t)Y_\cdot(t)$, with $\alpha(t)$ being the hazard function of T_i, and $Y_\cdot(t) = \sum_{i=1}^{n} Y_i(t)$ being the number of individuals observed to be at risk just before time t. We note that $Y_\cdot(t)$ increases as the number of subjects increases.

The relation (7) is the key to the counting process approach to event history analysis. We will see below that many important estimators and test statistics in survival analysis can be expressed as, or approximated by, stochastic integrals with respect to the martingales (7). This, together with martingale theory, forms the basis to the analysis of these statistics. Properties of these statistics such as unbiasedness and estimators of variability are obtained by applying results on stochastic integration with respect to the basic martingales like (7). Asymptotic statistical theory follows from martingale central limit theorems. Another important ingredient of the counting process methods in survival analysis is the fact that likelihoods are product-integrals of conditional terms for infinitesimal time intervals (see, for example, [6]).

We now formalize the above discussion by presenting some relevant martingale theory. A *multivariate counting process* $N = \{[N_1(t), \ldots, N_k(t)], \ t \in [0, 1]\}$ is a k-dimensional stochastic process with components N_h whose sample functions are nondecreasing, right-continuous step functions, $N_h(0) = 0$, and with jumps of unit size. Moreover, it is assumed that, with probability 1, no two components jump simultaneously, and that each $N_h(1)$ is almost surely finite.

A stochastic process M adapted to a filtration $\mathcal{F}_t$, satisfying $M(0) = 0$, $\mathrm{E}|M|(t) < \infty$ for $t \in [0,1]$, and having sample functions, which are right continuous with left-hand limits, is called a *martingale* if $\mathrm{E}[M(t) \mid \mathcal{F}_s] = M(s)$ a.s. for $s \leq t$ [cf. (4)]. A martingale is square-integrable if $\sup_{t\in[0,1]} \mathrm{E}M^2(t) < \infty$. A stochastic process $M(t)$ is called a local martingale if $M(t \wedge T_n)$ is a martingale for some sequence of stopping times T_n tending to infinity.

Note that if a process is adapted and has left-continuous sample paths, then it is predictable and locally bounded. Moreover, any Borel measurable deterministic function is predictable.

A process X has a *compensator* Λ if $X - \Lambda$ is a local martingale, and Λ is predictable and has paths of locally bounded variation. According to the Doob–Meyer decomposition, each component N_h of a multivariate counting process has a unique compensator Λ_h. Hence

$$M_h(t) = N_h(t) - \Lambda_h(t) \tag{9}$$

is a local martingale.

Let H_h be a predictable and locally bounded process and M_h a local martingale. We define a new process $\widetilde{M}_h$ by the stochastic integral

$$\widetilde{M}_h(t) = \int_0^t H_h(s)\,\mathrm{d}M_h(s). \tag{10}$$

Then $\widetilde{M}_h$ is a local martingale itself, because the increment $\mathrm{d}\widetilde{M}_h(t) = H_h(t)\mathrm{d}M_h(t)$ has zero conditional expectation:

$$\mathrm{E}[H_h(t)\,\mathrm{d}M_h(t) \mid \mathcal{F}_{t-}] = H_h(t)\mathrm{E}[\mathrm{d}M_h(t) \mid \mathcal{F}_{t-}] = 0 \tag{11}$$

Here the first equality is due to the predictability of H_h. The variance of $\widetilde{M}_h(t)$ equals $\mathrm{E}\int_0^t H_h^2(s)\,\mathrm{d}\Lambda_h(s)$.

Counting Process Models

Statistical models based on counting processes are specified according to their intensity processes. Here are some important models for which the previous mathematical framework is the most useful. From the point of view of statistical modeling, there are in the realm of multistate models. Important recent reviews of multistate models include [8, 31] (*see* **Event History Analysis**).

Multiplicative Intensity Models

If the intensity $\lambda_h(t)$ in (8) can be written as

$$\lambda_h(t) = \alpha_h(t, \theta)Y_h(t) \tag{12}$$

with an unknown nonnegative deterministic function $\alpha_h(\cdot, \theta)$, where θ is a parameter, and a nonnegative observable predictable process Y_h, then we say the multivariate counting process N is a multiplicative intensity model [2]. We note that θ may be infinitely dimensional.

Equation (3) shows that censored survival data is a multiplicative intensity model.

Markov Process Models

Another important example of a multiplicative intensity model is provided by the **Markov processes** with finite state space. Let $\{X(t) \mid t \in (0, 1]\}$ be a Markov process with finite state space and right-continuous sample paths. Let $N_{hj}(t)$ be the number of direct transitions for X from state h to state j, $h \neq j$, in $[0, t]$. Then the counting process $N = [N_{hj}(\cdot) \mid h \neq j]$ and $X(0)$ are equivalent to X in the sense that observation of $X(u)$ for $0 \leq u \leq t$ gives the same data as observing $X(0)$ and N on $[0, t]$. Assuming that locally integrable transition intensities $\alpha_{hj}(t, \theta)$ from state h to state j, $h \neq j$, exist, then the intensity process for N with respect to the filtration $\mathcal{F}_t \equiv \sigma[X(0), N(s) \mid s \leq t]$ is

$$\alpha_{hj}(t, \theta) Y_h(t),$$

where $Y_h(t) = 1_{(X(t-)=h)}$ is the indicator for X being in the state h just before time t (cf. [6, pp. 92–94, 126]).

A special case of the Markov process example is the **competing risks** model, obtained by considering one transient state 0 (alive) and absorbing states $h = 1, \ldots, k$. State h corresponds to "dead by cause h". Equivalently, let $X_i = (X_{i1}, \ldots, X_{ik})$ consist of k independent random variables with respective hazard functions $\alpha_{01}(t, \theta), \ldots, \alpha_{0k}(t, \theta)$, the multivariate counting process $N(t) = (N_1(t), \ldots, N_k(t))$ with $N_h(t) = \sum_{i=1}^{n} I(\min_l X_{il} = X_{ih} \leq t)$ is of main interest in the competing risks model. Here $X_1, \ldots, X_n$ are assumed independent and thus, $N_h(t)$ has intensity process $\alpha_{0h}(t, \theta) \sum_{i=1}^{n} I_{[\min_l X_{il} \geq t]}$ (cf. [6, p. 127]).

Illness–death Model

A more detailed event history analysis may be performed when individuals switch between the states "healthy" and "diseased" before the absorbing state "death". The model is known as the illness–death model; the illness may be recurrent or not.

For the case where there is no recovery, let states 0, 1, and 2 denote healthy, diseased, and dead, respectively, and define the counting processes of transitions between these states by $N(t) = [N_{01}(t), N_{02}(t), N_{12}(t)]$. $N_{0h}(t)$, $h = 1, 2$, has intensity process $\alpha_{0h}(t) Y_0(t)$ with $Y_0(t) = 1 - N_{01}(t-) - N_{02}(t-)$, which indicates that the individual is in state 0 at time $t-$, whereas $N_{12}(t)$ has intensity process $\alpha_{12}(t, d) Y_1(t)$ with $Y_1(t) = N_{01}(t-) - N_{12}(t-)$, indicating that the individual is in state 1 at time $t-$.

If the intensity of dying while diseased, denoted by $\alpha_{12}(t, d)$, only depends on time t, the process corresponds to a Markov illness–death process; when $\alpha_{12}(t, d)$ only depends on d, the duration in the disease states, one has a special case of a **semi-Markov process** (*see* **Event History Analysis**).

Regression Models

Let (X_i, Z_i), $i = 1, \ldots, n$, be random variables with nonnegative X_i denoting the survival time of the ith subject and $Z_i \equiv (Z_{i1}, \ldots, Z_{ip})'$ be p-dimensional random vectors denoting the covariates. We assume that $X_1, \ldots, X_n$ are conditionally independent given $Z = (Z_1, \ldots, Z_n)$.

In the **Cox regression model** for survival data [22], the conditional hazard of X_i given the covariates $Z = z = (z_1, \ldots, z_n)$ has the form

$$\alpha_i(t, \theta) = \alpha_0(t, \gamma) \exp(\beta' z_i), \tag{13}$$

where $\theta = (\gamma, \beta)$, and $\alpha_0(\cdot, \gamma)$ is a nonnegative deterministic function depending on a parameter γ, which can be infinite dimensional or finite dimensional. $\beta \in \mathcal{R}^p$ is called the relative risk coefficient and β' is its transpose.

Let $\widetilde{X}_1, \ldots, \widetilde{X}_n$ be the observed right censored survival times corresponding to $X_1, \ldots, X_n$. Let $D_i = I(X_i = \widetilde{X}_i)$, $N_i(t) = I(\widetilde{X}_i \leq t, D_i = 1)$, $Y_i(t) = I(\widetilde{X}_i \geq t)$ be defined as in the introductory example of censored survival times. Let $\mathcal{F}_t$ be the filtration generated by Z and $[(N_1, \ldots, N_n)(s), s \leq t]$. Then the counting process $N = (N_1, \ldots, N_n)$ has the intensity $\lambda = (\lambda_1, \ldots, \lambda_n)$ with $\lambda_i(t) = \alpha_i(t, \theta) Y_i(t)$ relative to $\mathcal{F}_t$.

Extensions of the Cox regression model using counting process formulation, initially studied by Andersen and Gill [7], are discussed in (44).

In **Aalen's additive regression model** [3] the conditional hazard of X_i given $Z = z = (z_1, \ldots, z_n)$ has the form

$$\beta_0(t) + \beta(t)' z_i. \tag{14}$$

Here $\beta_0(\cdot)$ is an $\mathcal{R}$-valued function and $\beta(\cdot) = (\beta_1(\cdot), \ldots, \beta_p(\cdot))'$ is an $\mathcal{R}^p$-valued function and $\beta(t)'$ is its transpose. This model is a special case of the matrix version of the multiplicative intensity model studied in (56).

Right censoring, Left truncation, and Filtering

Right censoring, left **truncation**, and filtering are important patterns of incomplete observation that can be handled quite satisfactorily with the counting process methods. This discussion indicates situations in which the multiplicative intensity model is retained under these patterns of incomplete observation. A similar discussion can be made with the regression models mentioned above. A quite thorough discussion of these concepts in specifying statistical models can be found in [6, Chapter III]. Important works in this regard include [35–37].

Assume we have a multiplicative intensity model (12). Let $0 \leq V_h \leq U_h$ be random variables independent of N_h. Then

$$\int_0^t 1_{(V_h, U_h]}(s)\, \mathrm{d}N_h(s) \tag{15}$$

has the compensator

$$\int_0^t 1(V_h, U_h](s)\lambda_h(s)\, \mathrm{d}s = \int_0^t \alpha_h(s, \theta)Y_h(s)1_{(V_h, U_h]}(s)\, \mathrm{d}s. \tag{16}$$

Thus, if (12) holds and both (15) and $Y_h(\cdot)1_{(V_h, U_h]}(\cdot)$ are observable, then we again have a multiplicative intensity model. When $U_h = \infty$, we say (15) is the left-truncated process of N_h. When $V_h = 0$, we say (15) is the right-censored process of N_h. The independent filtering process $1_{(V_h, U_h]}(\cdot)$ is called an Aalen filter.

Nonparametric Estimation

Let $N = (N_1, \ldots, N_k)$ be a multivariate counting process with the intensity process $\lambda = (\lambda_1, \ldots, \lambda_k)$ satisfying the multiplicative intensity model $\lambda_h(t) = \alpha_h(t)Y_h(t)$, where $\alpha_h(\cdot)$ is a nonnegative deterministic function, and $Y_h(t)$ is a predictable and observable process. Often α_h is a force of transition, whereas Y_h counts the number at risk.

Nelson–Aalen Estimator

An important statistical problem is to estimate the cumulative intensity

$$A_h(t) = \int_0^t \alpha_h(s)\, \mathrm{d}s \tag{17}$$

based on the data $[N_h(t), Y_h(t) \mid 0 \leq t \leq 1, h = 1, \ldots, k]$. To derive estimators for (17), we use (6) to write symbolically "$\mathrm{d}N_h(t) = \alpha_h(t)Y_h(t) + \text{noise}$". With this in mind, we let $J_h(t) = I[Y_h(t) > 0]$, and define the estimator

$$\widehat{A}_h(t) = \int_0^t \left[\frac{J_h(s)}{Y_h(s)}\right] \mathrm{d}N_h(s), \tag{18}$$

where $J_h(t)/Y_h(t)$ is interpreted as 0 whenever $Y_h(t) = 0$. Equation (18) is called the **Nelson–Aalen estimator** [1, 2, 45]; (*see* **Event History Analysis**).

Let $T_{h1} < T_{h2} < \cdots$ be the successive jump times for N_h. Then

$$\widehat{A}_h(t) = \sum_{(j:\, T_{hj} \leq t)} [Y_h(T_{hj})]^{-1}. \tag{19}$$

Thus, $\widehat{A}_h$ is an increasing, right-continuous step function with increment $1/Y_h(T_{hj})$ at the observed jump time T_{hj} of N_h.

Suitably normalized, $\widehat{A}_h(t)$ is asymptotically normally distributed with mean $A_h(t)$ and a variance which may be estimated by $\int_0^t J_h(s)[Y_h(s)]^{-2}\, \mathrm{d}N_h(s)$. Properties of the **Kaplan–Meier estimator** $\widehat{S}_h(t)$ can be obtained from that of $\widehat{A}_h(t)$. Note that $\widehat{S}_h(t) = \prod_{0<s<t}[1 - \mathrm{d}\widehat{A}_h(s)]$, which is the **product integral** of the Nelson–Aalen estimator $\widehat{A}_h$.

Kernel Function Smoothing

Another important problem is to estimate the intensity $\alpha_h(t)$. Ramlau–Hansen [53] proposed the following kernel smoothing estimator:

$$\widehat{\alpha}_h(t) = \frac{1}{b}\int_0^1 K\left(\frac{t-s}{b}\right) \mathrm{d}\widehat{A}_h(s), \tag{20}$$

as estimators for $\alpha_h(t)$, for $h = 1, \ldots, k$. Here $\widehat{A}_h(\cdot)$ is defined in (18). The kernel function K is a bounded nonnegative function that is 0 outside $[-1, 1]$ and has integral 1. The window (bandwidth) b is a positive number. The kernel function and the window have to be chosen in concrete applications and may depend on h. We note that (20) is equal to

$$\widehat{\alpha}_h(t) = \frac{1}{b}\sum_{T_{hj}} K\left(\frac{t - T_{hj}}{b}\right)\frac{1}{Y_h(T_{hj})}. \tag{21}$$

Note that only values of T_{hj} satisfying $t - b \leq T_{hj} \leq t + b$ contribute to this sum.

If Y_h increase uniformly in a neighborhood of t, and at the same time the window b tends to 0, then, subject to some regularity conditions, $\widehat{\alpha}_h(t)$ is asymptotically normally distributed with mean $\alpha_h(t)$ and a variance that may be estimated by

$$\frac{1}{b^2}\int_0^1 K^2\left(\frac{t-s}{b}\right)\frac{J_h(s)}{Y_h^2(s)}\,\mathrm{d}N_h(s).$$

To apply the kernel smoothing estimator (20), one has to decide upon a choice of the kernel function K and the window b. Some guidelines to the choice of K are given in [54], and the choice of the window b was discussed in [6, Chapter IV 2.2] (*see* **Smoothing Hazard Rates**).

Nonparametric Hypothesis Testing

One-sample Tests

Consider a univariate counting process $N(t)$, with intensity process $\alpha(t)Y(t)$, where $\alpha(\cdot)$ is a nonnegative deterministic function and $Y(\cdot)$ a nonnegative predictable and observable process. The null hypothesis $\alpha = \alpha_0$ is to be tested, where α_0 is a known intensity function. For example, in a mortality study for a certain population, one may like to know if it equals the general population mortality.

The idea behind the test statistic to be proposed comes from the properties of the Nelson–Aalen estimator. The key is to compare the increments of the Nelson–Aalen estimator $\mathrm{d}\widehat{A}(t)$ with $\alpha_0(t)\mathrm{d}t$ using the weight process $K(t)$ (cf. [5]). Formally, let

$$\widehat{A}(t) = \int_0^t \left[\frac{J(s)}{Y(s)}\right]\mathrm{d}N(s), \tag{22}$$

$$A_0^*(t) = \int_0^t \alpha_0(s)J(s)\,\mathrm{d}s, \tag{23}$$

where $J(s) = I(Y(s) > 0)$.

Then, under the **null hypothesis**, $\widehat{A} - A_0^*$ is a local square-integrable martingale. Its expected variation is $\mathrm{E}(\widehat{A}(t) - A_0^*(t))^2 = \mathrm{E}\int_0^t J(s)\alpha_0(s)/Y(s)\,\mathrm{d}s$. Our general test statistic is based on the following stochastic process:

$$Z(t) = \int_0^t K(s)\,\mathrm{d}[\widehat{A}(s) - A_0^*(s)], \tag{24}$$

where K is a locally bounded predictable nonnegative stochastic process. It is assumed throughout that $K(s) = 0$ whenever $Y(s) = 0$. It follows immediately from the definition that, under the null hypothesis, Z is a local square-integrable martingale with $\mathrm{E}(Z(t))^2 = \mathrm{E}\int_0^t K^2(s)\alpha_0(s)/Y(s)\,\mathrm{d}s = \mathrm{E}\int_0^t K^2(s)Y^{-2}(s)\,\mathrm{d}N(s)$. The hypothesis $\alpha = \alpha_0$ may now be tested using the standardized test statistic based on $Z(t)$, which can be shown to have an approximate standard normal distribution. Usually, t is chosen as some "large" time. By choosing a different weight process K, one can obtain a number of test statistics of one-sample tests. For example, the choice $K = Y$ corresponds to the one-sample **logrank test** [16] (*see* **Linear Rank Tests in Survival Analysis**).

k-Sample Tests

One of the most commonly encountered problems in clinical trails is the comparison of treatments on survivals. This is a special case of the following k-sample problem.

Consider a k-variate counting process N satisfying the multiplicative intensity model (12). We want to derive a test for the hypothesis

$$H_0\colon \alpha_1 = \alpha_2 = \cdots = \alpha_k. \tag{25}$$

The common value of the α_hs will be denoted by α.

The idea is to construct a test statistic by comparing the Nelson–Aalen estimators $\widehat{A}_h(t)$ [cf. (18)] with an estimator of the hypothesized common value

$$A(t) = \int_0^t \alpha(s)\,\mathrm{d}s. \tag{26}$$

This latter quantity can be estimated by

$$\widehat{A}(t) = \int_0^t \frac{J(s)}{Y.(s)}\,\mathrm{d}N.(s), \tag{27}$$

where

$$N. = \sum_{h=1}^k N_h, \quad Y. = \sum_{h=1}^k Y_h, \tag{28}$$

and

$$J(t) = I[Y.(t) > 0]. \tag{29}$$

Under the hypothesis, we know that $N.(t)$ is a (univariate) counting process with the intensity process $\alpha(t)Y.(t)$. Let

$$\overline{A}_h(t) = \int_0^t J_h(s)\,\mathrm{d}\widehat{A}(s) = \int_0^t \frac{J_h(s)}{Y.(s)}\,\mathrm{d}N.(s),$$

and note that, when (25) holds true, we have

$$\widehat{A}_h(t) - \overline{A}_h(t) = \int_0^t \frac{J_h(s)}{Y_h(s)}\,\mathrm{d}M_h(s) - \int_0^t \frac{J_h(s)}{Y_\cdot(s)}\,\mathrm{d}M_\cdot(s), \quad (30)$$

where

$$M_\cdot = \sum_{h=1}^{k} M_h.$$

Thus, except for random variations, $\widehat{A}_h$ and $\overline{A}_h$ are equal under the hypothesis. Let K_h be a nonnegative locally bounded predictable weight process, and

$$Z_h(t) = \int_0^t K_h(s)\,\mathrm{d}(\widehat{A}_h - \overline{A}_h)(s). \quad (31)$$

When (25) holds true, (30) shows that the Z_hs are linear combinations of stochastic integrals and hence $\mathrm{E}Z_h(t) = 0$ for all h and $t \in [0, 1]$.

It turns out that the special choice of weight processes,

$$K_h(t) = Y_h(t)L(t), \quad (32)$$

where L is a locally bounded predictable process that only depends on $(N_\cdot, Y_\cdot)$, covers most relevant examples. Under (32), we have

$$Z_h(t) = \int_0^t L(s)\,\mathrm{d}N_h(s) - \int_0^t L(s)\frac{Y_h(s)}{Y_\cdot(s)}\,\mathrm{d}N_\cdot(s). \quad (33)$$

We note that

$$\sum_{h=1}^{k} Z_h = 0. \quad (34)$$

It follows from the martingale central limit theorem that, under the hypothesis H_0, the Z_hs, properly normalized, converge weakly to a k-variate Gaussian martingale, as the Y_hs increase. In particular, $\mathbf{Z}(1) = \{Z_1(1), \ldots, Z_k(1)\}'$ is asymptotically multinormally distributed (*see* **Multivariate Normal Distribution**) with mean 0 and a (singular) **covariance matrix** that can be estimated by $\mathbf{V}(1) = \{V_{hj}(1)\}$, where

$$V_{hj}(1) = \int_0^1 L^2(s)\frac{Y_h(s)}{Y_\cdot(s)}\left(\delta_{hj} - \frac{Y_j(s)}{Y_\cdot(s)}\right)\mathrm{d}N_\cdot(s), \quad (35)$$

and δ_{hj} is the Kronecker delta [5, Theorem 3.1].

Thus, under the hypothesis (25), the statistic

$$\chi^2 = \mathbf{Z}(1)'\mathbf{V}(1)^-\mathbf{Z}(1), \quad (36)$$

is asymptotically **chi-square distributed** with $k - 1$ **degrees of freedom**, where $\mathbf{V}(1)^-$ is a generalized inverse [5, Section 9.1] (*see* **Matrix Algebra**). Note that we may denote by $\mathbf{Z}_0(1)$ and $\mathbf{V}_0(1)$, respectively, the vector and matrix obtained from $\mathbf{Z}(1)$ and $\mathbf{V}(1)$ by deleting the last component of $\mathbf{Z}(1)$ and the last row and column of $\mathbf{V}(1)$, and then using the relation $\mathbf{Z}(1)'\mathbf{V}(1)^-\mathbf{Z}(1) = \mathbf{Z}_0(1)'\mathbf{V}_0(1)^{-1}\mathbf{Z}_0(1)$ for (36).

Equation (36) covers not only many classical nonparametric tests but their generalizations to censored data as well. For example, the choice $L(t) = I[Y_\cdot(t) > 0]$ corresponds to the logrank (or Savage) test [48], while $L(t) = Y_\cdot(t)$ gives a generalization of the Kruskal–Wallis test [15]. Also the tests suggested by Tarone and Ware [61], Prentice [49], and Harrington and Fleming [30] are special cases of (36). More specifically, Harrington and Fleming [30] introduced a class of test statistics for censored survival data by letting $L(t) = [\widehat{S}(t-)]^\rho I[Y(t) > 0]$, where

$$\widehat{S}(t) = \prod_{s \le t}\left(1 - \frac{\Delta N_\cdot(s)}{Y_\cdot(s)}\right) \quad (37)$$

is the Kaplan–Meier estimator based on the combined sample and $0 \le \rho \le 1$. It is seen that $\rho = 0$ gives the logrank test, whereas $\rho = 1$ gives a test similar to Peto and Peto's and Prentice's generalization of the **Wilcoxon–Mann–Whitney** and Kruskal–Wallis tests.

Parametric Models

Let $N = (N_1, \ldots, N_k)$ be a multivariate counting process satisfying the multiplicative intensity model (12) with parametric α_hs, that is, the intensity process is given by

$$\lambda_h(t) = \alpha_h(t; \theta_0)Y_h(t), \quad (38)$$

where $\theta_0 = (\theta_{10}, \ldots, \theta_{q0})'$ is a q-dimensional parameter belonging to some open subset Θ of $\mathcal{R}^q$, and α_h are known functions. Under some regularity conditions, the log-**likelihood** function now takes

the form

$$l(\theta) = \sum_{h=1}^{k} \int_0^1 \log\{\alpha_h(s;\theta)\}\, \mathrm{d}N_h(s) - \sum_{h=1}^{k} \int_0^1 \alpha_h(s;\theta) Y_h(s)\, \mathrm{d}s, \qquad (39)$$

and the **maximum likelihood** estimator $\widehat{\theta}$ is defined as a solution to the set of equations

$$\sum_{h=1}^{k} \int_0^1 \frac{(\partial/\partial\theta_j)\alpha_h(s;\theta)}{\alpha_h(s;\theta)}\, \mathrm{d}N_h(s) - \sum_{h=1}^{k} \int_0^1 \frac{\partial}{\partial\theta_j}\alpha_h(s;\theta) Y_h(s)\, \mathrm{d}s = 0, \qquad (40)$$

where $j = 1, \ldots, q$. Under certain regularity conditions of the $\alpha_h s$, the likelihood equations (40) have, with probability tending to 1, exactly one consistent solution $\widehat{\theta}$ as the $Y_h s$ increase. Moreover, $\widehat{\theta}$ is asymptotically multinormally distributed with mean θ_0 and a covariance matrix that may be estimated by $-I(\widehat{\theta})^{-1}$, where $I(\theta) = \partial^2 l(\theta)/\partial\theta^2$ [14, Theorems 1 and 2]. Thus, the usual results for maximum likelihood estimation in the classical i.i.d. case continue to hold under the more general model (38).

With (6) and (38), we know that the left-hand side of (40), evaluated at the true parameter value θ_0, equals the stochastic integral:

$$\sum_{h=1}^{k} \int_0^1 \frac{(\partial/\partial\theta_j)\alpha_h(s;\theta_0)}{\alpha_h(s;\theta_0)}\, \mathrm{d}M_h(s). \qquad (41)$$

This makes it possible to use properties of martingales to derive the above-mentioned asymptotic results.

As in the i.i.d. case in which minus twice the logarithm of the **likelihood ratio test** statistic is asymptotically chi-square distributed, this is true also for the more general model (38). Other closely related test statistics, like Wald's test and the score test (*see* **Likelihood**), also have the desired properties as their counterparts in the i.i.d. case [14] (*see* **Parametric Models in Survival Analysis**).

Regression Models

Regression models are useful when it is desired to assess the effect of risk factors (**prognostic factors**) on survival. We discuss here some commonly used regression models in survival analysis where counting process and martingale techniques have played a central role. Readers are referred to [42] for general nonparametric models, to [67] for **marginal models**, and to [38, 55], and [63] for other **semiparametric regression** models.

The Cox Regression Model

Consider the multivariate counting process $[N_{hi}(t), h = 1, \ldots, k; i = 1, \ldots, n], t \in [0, 1]$, where $N_{hi}(t)$ counts the number of type h events in $[0, t]$ for individual i.

We assume that $N_{hi}(t)$ has an intensity process of the form

$$\lambda_{hi}(t) = \alpha_{0h}(t) \exp[\beta_0' Z_{hi}(t)] Y_{hi}(t). \qquad (42)$$

Here α_{oh} is an unspecified type-specific baseline whose integral

$$A_{0h}(t) = \int_0^t \alpha_{0h}(s)\, \mathrm{d}s \qquad (43)$$

satisfies $A_{0h}(1) < \infty$. Furthermore, $\beta_0 = (\beta_{01}, \ldots, \beta_{0p})'$ is a vector of unknown regression coefficients, $Y_{hi}(t)$ is a predictable indicator process and $Z_{hi}(t) = [Z_{hi1}(t), \ldots, Z_{hip}(t)]'$ a vector of predictable and locally bounded (type-specific) observable time-dependent covariate processes.

The relative risk function $\exp[\beta_0' Z_{hi}(t)]$ can be replaced by a general form of function (cf. [51]). Also, the baseline function $\alpha_{0h}(t)$ can be replaced by various forms of random processes [19, 52].

The basic assumption in the extended Cox model (42) is that each covariate $Z_{hij}(t)$ has a multiplicative effect on the intensity [7, 23]; in particular, for time-independent covariates, we have a model with proportional intensities.

The estimator $\widehat{\beta}$ of β_0 is defined to be the solution to the equations $U(\beta, 1) = 0$, which is called the Cox's partial score and defined below (cf. [7]). The key to the derivation of the statistical properties of $\widehat{\beta}$ is to notice that the Cox's partial score $U(\beta_0, \cdot)$, evaluated at the true value β_0, is a local square integrable martingale.

Let

$$S_h^{(0)}(\beta, t) = \frac{1}{n} \sum_{i=1}^{n} Y_{hi}(t) \exp[\beta' Z_{hi}(t)],$$

$$S_{hj}^{(1)}(\beta, t) = \frac{1}{n} \sum_{i=1}^{n} Y_{hi}(t) Z_{hij}(t) \exp[\beta' Z_{hi}(t)], \qquad (44)$$

$$S^{(2)}_{hjl}(\beta, t) = \frac{1}{n}\sum_{i=1}^{n} Y_{hi}(t) Z_{hij}(t) Z_{hil}(t) \exp[\beta' Z_{hi}(t)],$$

and

$$\mathrm{E}_{hj}(\beta, t) = \frac{S^{(1)}_{hj}(\beta, t)}{S^{(0)}_{h}(\beta, t)},$$

where $h = 1, \ldots, k$ and $j, l = 1, \ldots, p$. Then the jth component of $U(\beta, t)$ is given as

$$U_j(\beta, t) = \sum_{h=1}^{k}\left[\int_0^t \sum_{i=1}^{n} Z_{hij}(s)\, \mathrm{d}N_{hi}(s) - \int_0^t \mathrm{E}_{hj}(\beta, s)\, \mathrm{d}N_h(s)\right], \qquad (45)$$

and using (6) and (42) we see that

$$U_j(\beta_0, t) = \sum_{h=1}^{k}\sum_{i=1}^{n}\int_0^t [Z_{hij}(s) - \mathrm{E}_{hj}(\beta_0, s)]\, \mathrm{d}M_{hi}(s) \qquad (46)$$

are linear combinations of stochastic integrals. Here $N_h = \sum_{i=1}^{n} N_{hi}$. Thus, with some regularity conditions, the martingale central limit theorem can be applied to prove that the process $n^{-l/2}U(\beta_0, \cdot)$, as n tends to ∞, is asymptotically distributed as a mean zero Gaussian martingale.

By a Taylor expansion technique, this result can be transformed into a theorem concerning the asymptotic distribution of $\widehat{\beta}$, much in the same way as for standard maximum likelihood estimation. Under certain regularity conditions, it can be shown that $n^{l/2}(\widehat{\beta} - \beta_0)$ is asymptotically multinormally distributed $N_p(0, \Sigma^{-1})$, where $\Sigma = \{\sigma_{jl}\}$ is positive definite, and σ_{jl} can be estimated consistently by $-I_{jl}(\widehat{\beta})/n$. Here $I_{jl}(\beta)$ is the partial derivative of $U(\beta, 1)$ with respect to β_j, that is,

$$I_{jl}(\beta) = -\sum_{h=1}^{k}\int_0^1 \left[\frac{S^{(2)}_{hjl}(\beta, s)}{S^{(0)}_{h}(\beta, s)} - \mathrm{E}_{hl}(\beta, s)\mathrm{E}_{hj}(\beta, s)\right] \times \mathrm{d}N_h(s). \qquad (47)$$

On the basis of the above results, one can draw inference on the regression parameter β even with the presence of the nuisance functions $\alpha_{0h}(t)$ in the semiparametric model (42).

In some cases, the underlying intensities are also of interest. Under the same set of regularity conditions, the estimates for the cumulative intensities $A_{0h}(t)$:

$$\widehat{A}_{0h}(t) = \int_0^t J_h(u)[nS^{(0)}_h(\widehat{\beta}, s)]^{-1}\, \mathrm{d}N_h(s) \qquad (48)$$

with $J_h(u) = I[Y_h(u) > 0]$, is distributed asymptotically as a Gaussian process.

Notice that for a homogeneous group of individuals, that is, when all $Z_{hi} \equiv 0$, the estimator $\widehat{A}_{0h}$ reduces to the Nelson–Aalen estimator.

Parametric Regression

As in (42), we now assume that N_{hi} has the intensity process of the form

$$\lambda_{hi}(t) = \alpha_{0h}(t; \theta_0) \exp[\beta_0' Z_{hi}(t)] Y_{hi}(t), \qquad (49)$$

with unknown parameter θ_0 belonging to an open subset of $\mathcal{R}^q$, and α_{0h} being some known functions [14].

In the case of survival data, (49) covers the exponential regression where $\alpha_{0h}(t, \theta) = \theta_h$, the Weibull regression where $\alpha_{0h}(t, \theta) = \theta_h t^{\rho h}$, and the piecewise exponential where $\alpha_{0h}(t, \theta)$ is piecewise constant. References in which parametric models of the form (49) have been studied for survival data can be found in Kalbfleisch and Prentice [33], for example, (*see* **Parametric Models in Survival Analysis**).

Inferences from parametric regression models will be based on the log-likelihood function

$$l(\theta, \beta) \equiv \log L(\theta, \beta) = \sum_{h=1}^{k}\sum_{i=1}^{n}\left\{\int_0^1 [\log\alpha_{0h}(s; \theta) + \beta' Z_{hi}(s)]\, \mathrm{d}N_{hi}(s) - \int_0^1 \alpha_{0h}(s, \theta)\exp[\beta' Z_{hi}(s)] Y_{hi}(s)\, \mathrm{d}s\right\}, \qquad (50)$$

and the maximum likelihood estimators $\widehat{\theta}$ and $\widehat{\beta}$ are defined as solutions to the set of equations

$$\frac{\partial}{\partial\theta_j} l(\theta, \beta) = \sum_{h=1}^{k}\sum_{i=1}^{n}\left\{\int_0^1 \frac{(\partial/\partial\theta_j)\alpha_{0h}(s, \theta)}{\alpha_{0h}(s, \theta)}\, \mathrm{d}N_{hi}(s) - \int_0^1 \frac{\partial}{\partial\theta_j}\alpha_{0h}(s, \theta)\exp[\beta' Z_{hi}(s)] Y_{hi}(s)\, \mathrm{d}s\right\} = 0,$$

and

$$\frac{\partial}{\partial \beta_l} l(\theta, \beta) = \sum_{h=1}^{k} \sum_{i=1}^{n} \left\{ \int_0^1 Z_{hil}(s)\, \mathrm{d}N_{hi}(s) - \int_0^1 \alpha_{0h}(s, \theta) Z_{hil}(s) \exp[\beta' Z_{hi}(s)] Y_{hi}(s)\, \mathrm{d}s \right\} = 0, \tag{51}$$

for $j = 1, \ldots, q$ and $l = 1, \ldots, p$. Since the left-hand sides of the likelihood equations (51), evaluated at the true parameter values θ_0 and β_0, are linear combinations of stochastic integrals, the asymptotic properties of $\widehat{\theta}$ and $\widehat{\beta}$ can be obtained by the martingale central limit theorem.

Nonparametric Additive Hazard Models

Let $\mathbf{N}(t) = [N_i(t); i = 1, \ldots, n]$ be a multivariate counting process. Assume that the individual process N_i has an $\mathcal{F}_t$-intensity process

$$\lambda_i(t) = \alpha_i[t; Z_i(t)] Y_i(t), \tag{52}$$

with

$$\alpha_i[t; Z_i(t)] = \beta_0(t) + \beta_1(t) Z_{i1}(t) + \cdots + \beta_p(t) Z_{ip}(t). \tag{53}$$

Here $\alpha_i(\cdot, \cdot)$ is nonnegative, whereas the regression functions $\beta_j(t)$ are completely unspecified. A major problem for the **additive hazard model** of Aalen [3] is to estimate the integrated regression functions

$$B_j(t) = \int_0^t \beta_j(u)\, \mathrm{d}u, \tag{54}$$

for $j = 0, 1, \ldots, p$. Let $\beta(t) = [\beta_0(t), \beta_1(t), \ldots, \beta_p(t)]'$, $\mathbf{Y}$(t) be the $n \times (p + 1)$ matrix with the ith row, $i = 1, \ldots, n$, given by $Y_i(t)[1, Z_{il}(t), \ldots, Z_{ip}(t)]$ and $\mathbf{B}(t) = [B_0(t), B_1(t), \ldots, B_p(t)]'$. The model given by (52) and (55) can be written in matrix form as

$$\mathbf{N}(t) = \int_0^t \mathbf{Y}(u) \beta(u)\, \mathrm{d}u + \mathbf{M}(t) \tag{55}$$

and is sometimes called the matrix multiplicative intensity model, where $\mathbf{M} = (M_1, \ldots, M_n)$ is an n-vector of local square-integrable martingales. Then

$$\widehat{\mathbf{B}}(t) = \int_0^t J(u) \mathbf{Y}^-(u)\, \mathrm{d}\mathbf{N}(u) \tag{56}$$

can be viewed as a generalized Nelson–Aalen estimator for $\mathbf{B}(t)$. Here $\mathbf{Y}^-(t)$ is the predictable generalized inverse of $\mathbf{Y}(t)$, that is, a $(p + 1) \times n$ matrix satisfying $\mathbf{Y}^-(t)\mathbf{Y}(t) = I$, the $(p + 1) \times (p + 1)$ identity matrix, and $J(t) = I[\mathrm{rank}\, \mathbf{Y}(t) = p + 1]$ is the predictable indicator of $\mathbf{Y}(t)$ having full rank (assuming $p + 1 \leq n$).

To achieve some kind of optimality, we need to choose the generalized inverse $\mathbf{Y}^-(t)$ properly [32, 41].

Frailty Models

Let $N_{ik}(t)$ denote the number of certain events experienced up to time t by the kth member of the ith family in an experiment. Suppose that the hazard rate $\lambda_{ik}(t)$ of $N_{ik}(t)$ has the proportional form

$$\lambda_{ik}(t) = \Lambda_i(t) Y_{ik}(t) \exp[\beta Z_{ik}(t)] \tag{57}$$

for $k = 1, 2, \ldots, K$. Here $Y_{ik}(\cdot)$ is an observable nonnegative predictable process, $Z_{ik}(\cdot)$ is a predictable process representing an observable covariate, β is the relative risk coefficient to be estimated, and $\Lambda_i(\cdot)$ is the unknown baseline hazard rate for the ith family, termed random **frailty** and shared by the K members in the ith family.

We note that, when $\Lambda_i(t)$ is a deterministic function not varying from family to family, (57) is a special case of (42).

Nielsen et al. [46] assumed that

$$\Lambda_i(t) = \alpha_i \lambda_0(t), \tag{58}$$

where $\lambda_0(\cdot)$ is an unknown nonnegative deterministic function (parametric or nonparametric) and the $\alpha_i s$ are independent unobservable nonnegative random variables with a gamma distribution. In certain medical examples, the frailty variable α_i is thought of as a way to describe susceptibility to accident of members of the ith family, who share a common genetic background.

Assume now that $K > 1$ and $\Lambda_1(\cdot), \Lambda_2(\cdot), \ldots$ is a sequence of i.i.d. random elements valued in the

space of nonnegative measurable functions on $[0, \infty)$, not necessarily of the form (58). In some medical contexts, this means, for example, that genetic background specifies completely the baseline hazard rate function of members of a family at any age point, not just a multiplicative factor of it.

The true parameter β_0 in (57) can be estimated by $\hat{\beta}_n$, which is the root of

$$G_n(\beta, t) = \sum_{i=1}^{n} \sum_{k=1}^{K} \times \int_0^t \left\{ Z_{ik}(s) - \frac{\sum_{l=1}^{K} Y_{il}(s) \exp[\beta Z_{il}(s)] Z_{il}(s)}{\sum_{l=1}^{K} Y_{il}(s) \exp[\beta Z_{il}(s)]} \right\} \times \mathrm{d}N_{ik}(s). \quad (59)$$

Following the approach for (42), asymptotic normality for G_n and $\hat{\beta}_n$ can be obtained [20].

S-I-R Epidemic Model

A major parameter in the study of an infectious disease is the so-called basic **reproduction number**. Various models have been proposed to calculate this number. Here we give a very brief account of the counting process approach (*see* **SIR Epidemic Models**).

An individual experiences a sequence of events in case of an infectious disease. First there is the infection time t_A that one gets infected, then the time t_B that one enters the infectious period, the time t_C that one shows symptoms, the time t_E that marks the end of the infectious period. It is known that $t_A \le t_B \le t_E$, and $t_A \le t_C \le t_E$. Usually, only t_C and t_E are observable.

At time t, an individual is called a susceptible if $t < t_A$, an infective if $t_B < t < t_E$, and removed if $t > t_A$. A susceptible becomes an infective through contact with an infective.

Suppose we have a closed community in the sense that there is no immigrant nor emigrant. Suppose at time 0, there are s susceptibles and i infectives in this community.

Let $S(t)$, $I(t)$, and $R(t)$ denote respectively the number of susceptibles, infectives, and removed ones at time t. Let $N(t)$ denote the number of individuals infected during $(0, t]$. It is clear that these are counting processes with different jump times. In view of the law of mass action, one assumes $N(t)$ has intensity

$$\beta \overline{S}(t-) I(t-),$$

where $\overline{S}(t) = S(t)/S(0)$. Another convenient assumption is that $R(t)$ has intensity

$$\gamma I(t-).$$

β is called the infection rate and γ the removal rate. The basic reproduction number $\theta = \beta/\gamma$ gives the expected number of susceptibles infected by one infective. Depending on the data available, several estimation procedures have been proposed. Here we present one of them (cf. [10], Chapter 7). Suppose $n = S(t) + I(t) + R(t)$. We consider inference based on the data $\{S(0), I(0), R(0), R(\tau)\}$, where τ is the time that the epidemic ends with $I(\tau) = 0$. This is the situation that only the final state of the epidemic is observed.

Then estimation can be based on the following zero-mean martingale

$$\begin{aligned} M(t) &= \int_0^t \frac{1}{\overline{S}(u-)} [\mathrm{d}N_1(u) - \beta \overline{S}(u-) I(u-) \, \mathrm{d}u] \\ &\quad - \frac{\beta}{\gamma} \left[R(t) - R(0) - \int_0^t \gamma I(u-) \, \mathrm{d}u \right] \\ &= \frac{n}{S(0)} + \frac{n}{S(0)-1} + \cdots + \frac{n}{S(t)+1} \\ &\quad - \frac{\beta}{\gamma} [R(t) - R(0)]. \end{aligned} \quad (60)$$

Thus

$$\hat{\theta} = \frac{\left\{ \frac{n}{S(0)} + \frac{n}{S(0)-1} + \cdots + \frac{n}{S(\tau)+1} \right\}}{\{R(\tau) - R(0)\}}, \quad (61)$$

and the standard derivation is estimated by

$$se(\hat{\theta}) = \left[\frac{1}{S(0)^2} + \frac{1}{(S(0)-1)^2} + \cdots + \frac{1}{(S(\tau)+1)^2} + \frac{\hat{\theta}^2}{n} \{R(\tau)/n - R(0)/n\} \right]^{\frac{1}{2}} \Big/ \{R(\tau)/n - R(0)/n\}. \quad (62)$$

Becker and Hasofer [12] showed that if the removal process $R(t)$ is observed continuously, then both β and γ can also be estimated.

The previous discussion assumes a population of homogeneous individuals who mix uniformly. Extensions to more general models with different observables, including populations with heterogeneity between individuals, are important in health-case studies, and are discussed in [11, 17], and so on.

Some other Counting Process Models

Some Alternative Approaches

The statistical models discussed so far are models for which counting process methods are the most successful in formulating the problem, proposing statistical procedures, analyzing their distributional properties, and studying their efficiency. We now mention some examples in which counting processes provide useful modeling tools but extra work or even entirely different method is needed for the analysis of the models. More examples can be found in Kalbfleisch and Prentice [33]. In fact, some **goodness-of-fit** tests for certain counting process models were analyzed with techniques other than martingale central limit theorems (see, for example, [42] and [40]). In general, asymptotic theories, including **efficiency**, are often established using empirical process theory. (cf. [64, 65])

Correlated Gamma-Frailty Models and Cox-gene Models

To solve the problem of estimating the relative risk coefficient β_0 when $K = 1$ in (57) and (58), Nielsen et al. [46] suggested an estimator using the **EM algorithm** based on parametric and nonparametric maximum likelihood in the case where the $\alpha_i s$ are **gamma** random variables. Murphy [43, 44] established the **consistency** and asymptotic normality of the estimator in a one-sample frailty model. Parner [47] extended theory to correlated gamma-frailty model with covariates. Compared with (57) and (58), this means

$$\lambda_{ik}(t) = (\alpha_{i0} + \alpha_{ik})\lambda_0(t)Y_{ik}(t)\exp[\beta Z_{ik}(t)], \quad (63)$$

with $\alpha_{i0}, \alpha_{i1}, \ldots,$ and α_{ik} being independent, unobservable, gamma-distributed random variables with parameters of the form (γ, η), $(\gamma^*, \eta), \ldots,$ and (γ^*, η). Both Murphy [43, 44] and Parner [47] employed the empirical process approach.

Following the notation in (63), the so-called Cox-gene model means

$$\lambda_{ik}(t) = \lambda_0(t)Y_{ik}(t)\exp[\beta Z_{ik}(t) + \mu S_{ik}]. \quad (64)$$

Here for kth member in the ith human family, $N_{ik}(t) = I(\overline{T}_{ik} \le t, D_{ik} = 1)$ with $\overline{T}_{ik}$ being the observed disease duration, and $D_{ik} = 1$ if $\overline{T}_{ik}$ is the true survival time and $D_{ik} = 0$ otherwise; S_{ik} denotes the unobservable genotype at certain locus. In a sense, (64) is a discrete version of (58). Monte Carlo methods were studied by Li, Thompson and Wijsman [39] and Siegmund and McKnight [58]; and asymptotic theory was established by Chang, Hsiung, Wang, and Wen [21], using empirical process theory.

Multivariate Survival Functions

Nonparametric estimation of a multivariate distribution function under censoring has important applications in many areas. The aim is to estimate the multivariate survival function on the basis of multivariate censored data without assuming any special structure among the different time coordinates. A major difference with the one-dimension case is that in higher dimensions there are actually many nonequivalent representations of the survival function in terms of hazard, leading to many different estimators (see, for example, [24, 25, 27, 28, 50, 62]); (*see* **Multivariate Survival Analysis**.)

Semi-Markov Models

For **Semi-Markov** models, or Markov **renewal processes**, the intensity for a transition between two states depends on the time elapsed since the entry into the current state (cf. [34]). Thus, "time" starts anew at zero after each transition into a new state. Voelkel and Crowley [66] showed how, via a random time change, one may apply the counting process methods for some semi-Markov processes.

We note that for semi-Markov models the "counting process approach" cannot be used directly to study the large-sample properties of nonparametric estimators of the transition intensities. The reason for this is that there exists no filtration relative to "duration time".

For parameter models, Arjas' **"real time" approach** [9] can work. For semiparametric generalized proportional hazards models for counting processes, Chang and Hsiung [19] identify a useful filtration so that martingale theory is still useful in the derivation of large-sample properties of the efficient estimators.

Sequential Analysis of Censored Survival Data with Staggered Entry

In most clinical trials, the patients enter trial sequentially in calendar time (*see* **Sequential Analysis**), whereas the most relevant time dimension is the duration time on trial.

In most of the above discussion, we have assumed that in the statistical analysis, these duration variables have been all realigned to start at time (duration) zero, and that the counting process martingales were then defined in the duration time scale after alignment. This device is not completely satisfactory when calendar time monitoring is desired.

For sequential analysis with **staggered entry**, one wants to stop the trial according to calendar time filtration, instead of stopping the trial according to duration time filtration. If the duration time is modeled parametrically, this problem can be studied by martingale method completely [18]. If it is not parametric, one has to consider two time scales, which makes the theoretical problems complicated. For Cox method with staggered entry, Bilias, Gu, and Ying [13] provided a general asymptotic theory for both test and estimation, generalizing the theory of Sellke and Siegmund [56], Slud [59], and Gu and Lai [29]. The approach of Bilias, Gu, and Ying [13] employs empirical process theory and considers the Cox score process in two time scales.

One may specify in advance a finite number of time points $t_1, \ldots, t_n$ at which tests are to be performed, so that periodic reviews of the trial may be performed while controlling the total significance level (*see* **Interim Analysis of Censored Data**). For specific procedures, see [59, 60] and [57, Section V.6].

Conclusion

Detailed life history data may be given a thorough analysis using the methods based on counting processes. However, there are situations in which martingale theory is not sufficient and alternative techniques are necessary. Some such techniques can also be based on counting process ideas, but not in the simple form.

Covariance Matrix

Suppose that p variables have been measured on each of n sample individuals and the results have been displayed in an $n \times p$ data matrix. Write $\mathbf{x}_i' = (x_{i1}, x_{i2}, \ldots, x_{ip})$ for the vector of p values observed on the ith individual, so that $\mathbf{x}_i'$ constitutes the ith row of the data matrix ($i = 1, \ldots, n$). In order to provide a framework for parametric **inference**, the $\mathbf{x}_i$ are generally viewed as independent realizations of a random vector $\mathbf{X}' = (X_1, X_2, \ldots, X_p)$, the distribution of which specifies the population from which the sample has been taken. Geometrically, the population can be represented as a swarm of points in p-dimensional space by associating each variable X_j with an orthogonal axis in this space and assigning the observed value $\mathbf{x}_i$ to the point with coordinates $(x_{i1}, x_{i2}, \ldots, x_{ip})$ on these axes (*see* **Axes in Multivariate Analysis**). The main characteristics of this swarm are its location in space and its dispersion. The former is specified by the mean vector

$$\boldsymbol{\mu} = \mathrm{E}(\mathbf{X}) = [\mathrm{E}(X_1), \mathrm{E}(X_2), \ldots, \mathrm{E}(X_p)]',$$

and the latter by the matrix

$$\boldsymbol{\Sigma} = \mathrm{E}(\mathbf{X} - \boldsymbol{\mu})(\mathbf{X} - \boldsymbol{\mu})',$$

which contains variances of the variables down its principal diagonal and covariances between every pair of variables in its off-diagonal positions.

Whether any more parameters are required fully to specify the population depends on the specific assumptions made about the distributional form of $\mathbf{X}$. In the vast majority of practical applications, however, multivariate **central limit** arguments suggest that **multivariate normality** is a suitable assumption. In this case, the probability density function *only* depends on $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$, so interest has focused very heavily on these two parameters within multivariate inference. In this article we concern ourselves with questions about $\boldsymbol{\Sigma}$.

First, we consider its estimation. **Maximum likelihood** is the most commonly adopted method of obtaining estimates of parameters in a frequentist approach to inference. Assuming normality, the **likelihood** of the sample is

$$L = \frac{1}{(2\pi)^{np/2}|\boldsymbol{\Sigma}|^{n/2}} \times \exp\left[-\tfrac{1}{2}\sum_{i=1}^{n}(\mathbf{x}_i - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{x}_i - \boldsymbol{\mu})\right]$$

and a little algebra (see, for example, [1, pp. 60–65]) establishes that the maximum likelihood estimators of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are

$$\hat{\boldsymbol{\mu}} = \bar{\mathbf{x}} = (\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_p)',$$

i.e. the sample mean vector (where $\bar{x}_j = 1/n \sum_{i=1}^{n} x_{ij}$), and

$$\hat{\boldsymbol{\Sigma}} = \frac{1}{n}\sum_{i=1}^{n}(\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})'.$$

If we write

$$\mathbf{A} = \sum_{i=1}^{n}(\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})',$$

then the diagonal elements of $\mathbf{A}$ are the corrected sums of squares $\sum_{i=1}^{n}(x_{ij} - \bar{x}_j)^2$ of each variable, the off-diagonal elements are the corrected sums of products $\sum_{i=1}^{n}(x_{ij} - \bar{x}_j)(x_{ik} - \bar{x}_k)$ between every pair of variables, and

$$\hat{\boldsymbol{\Sigma}} = \frac{1}{n}\mathbf{A}.$$

The sampling distribution of $\mathbf{A}$ was derived first by Wishart [17] (*see* **Wishart Distribution**), whose results show that $\mathrm{E}(\mathbf{A}) = (n-1)\boldsymbol{\Sigma}$. Hence the maximum likelihood estimator of $\boldsymbol{\Sigma}$ is biased. When corrected for bias we obtain the estimator

$$\mathbf{S} = \frac{1}{n-1}\mathbf{A},$$

which has the usual sample variances of each variable down the main diagonal and sample covariances between every pair of variables in the off-diagonal positions. This is the *sample covariance matrix*; it is the estimator of $\boldsymbol{\Sigma}$ preferred by many practitioners.

Adopting approaches to inference other than the frequentist produces different estimators of $\boldsymbol{\Sigma}$. The two main approaches are **decision theoretic** and **Bayesian**, and we now briefly summarize the competitor estimates under each of these philosophies.

In decision theory we are required to supply a **loss function** $l(\boldsymbol{\Sigma}, \mathbf{T})$ that quantifies the "loss" incurred when $\boldsymbol{\Sigma}$ is estimated by $\mathbf{T}$. The expectation of this loss over the distribution of the data

defines the **risk** function $R(\boldsymbol{\Sigma}, \mathbf{T})$ associated with that loss, and this risk function is used to compare different estimators $\mathbf{T}_i$. An estimator $\mathbf{T}_1$ *beats* another estimator $\mathbf{T}_2$ if $R(\boldsymbol{\Sigma}, \mathbf{T}_1) \leq R(\boldsymbol{\Sigma}, \mathbf{T}_2)$ for all $\boldsymbol{\Sigma}$ and $R(\boldsymbol{\Sigma}, \mathbf{T}_1) < R(\boldsymbol{\Sigma}, \mathbf{T}_2)$ for at least one $\boldsymbol{\Sigma}$, and an estimator is *admissible*, i.e. "best", if no other estimator beats it. The **unbiased** estimator $\mathbf{S}$ turns out to be the best estimator of the form $\alpha\mathbf{A}$ under the loss function

$$l(\boldsymbol{\Sigma}, \mathbf{T}) = \text{tr}(\boldsymbol{\Sigma}^{-1}\mathbf{T}) - \log\ \det(\boldsymbol{\Sigma}^{-1}\mathbf{T}) - p,$$

but other (more complicated) estimators are best if we either look outside the class of estimators of the form $\alpha\mathbf{A}$ or consider other loss functions. Muirhead [11, pp. 128–136] summarizes the main results.

Turning to the Bayesian approach, it is first necessary to specify a joint **prior distribution** for all the unknown parameters. This is combined with the likelihood of the data to yield a joint posterior distribution of the parameters. Any parameters not of direct interest are then integrated out to give a marginal distribution of the parameters to be estimated, and a suitable summary measure of this marginal distribution (typically the mode) provides the estimator of the parameters. Assuming again that sampling is from a normal distribution, Press [14, p. 168] suggests using the "natural conjugate" prior

$$\pi(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \propto |\boldsymbol{\Sigma}|^{-(m+1)/2} \exp\{-\tfrac{1}{2}[\text{tr}\ \boldsymbol{\Sigma}^{-1}\mathbf{G} + (\boldsymbol{\mu} - \boldsymbol{\phi})'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu} - \boldsymbol{\phi})]\},$$

where $\boldsymbol{\phi}, \mathbf{G}$, and $m > 2p - 1$ are parameters the values of which quantify the prior knowledge about $\boldsymbol{\Sigma}$. Following through the above steps, Press then shows that the Bayes estimator of $\boldsymbol{\Sigma}$ is

$$\frac{\left[\dfrac{n\mathbf{A} + \mathbf{G} + n(\bar{\mathbf{x}} - \boldsymbol{\phi})(\bar{\mathbf{x}} - \boldsymbol{\phi})'}{1 + n}\right]}{(n + m - 2p - 2)}.$$

If there is no prior knowledge about $\boldsymbol{\Sigma}$, then a suitable choice of prior distribution is

$$\pi(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \propto |\boldsymbol{\Sigma}|^{-(p+1)/2},$$

which yields the Bayes estimator $[1/(n - p - 2)]\mathbf{A}$ on working through the same steps as before. Further results concerning Bayes estimation of $\boldsymbol{\Sigma}$ are given by Dickey et al. [3] and Leonard & Hsu [9].

All of the above results are appropriate when sampling from a multivariate normal distribution. In recent years there has been some interest in theory associated with *elliptic* distributions. These distributions share many of the features of the normal distribution (which is itself a member of this class of distributions), but they encompass distributions such as the **multivariate *t***, the multivariate Cauchy, and the multivariate **logistic**, all of which have heavier tails than the multivariate normal. Elliptic distributions thus provide good models for data involving either outliers or other contaminants. An elliptic distribution with mean $\boldsymbol{\mu}$ and dispersion matrix $\boldsymbol{\Sigma}$ has a density function of the form

$$f(\mathbf{x}) = |\boldsymbol{\Sigma}|^{-1/2}\psi[(\mathbf{x} - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{x} - \boldsymbol{\mu})]$$

for some function $\psi(\cdot)$. Fang & Zhang [4] show that if $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n$ form a random sample from this distribution, then the maximum likelihood estimator of $\boldsymbol{\Sigma}$ is $\lambda_0\mathbf{A}$, where λ_0 is the maximum of the function $\phi(\lambda) = \lambda^{-np/2}\psi(p/\lambda)$. It is easy to check that in the case of a normal distribution, $\psi(z) = (2\pi)^{-p/2}\exp(-z/2)$, so that $\lambda_0 = 1/n$ and we recover the maximum likelihood estimator $\hat{\boldsymbol{\Sigma}}$.

Despite all of the above results, in the overwhelming number of practical applications $\boldsymbol{\Sigma}$ is routinely estimated in frequentist fashion either by the maximum likelihood estimator $\hat{\boldsymbol{\Sigma}} = (1/n)\mathbf{A}$ or by the unbiased matrix $\mathbf{S} = [1/(n - 1)]\mathbf{A}$, so we restrict our attention to these estimators for the rest of the present section.

The asymptotic distribution of $\mathbf{S}$ provides a mechanism for obtaining large-sample inferences about $\boldsymbol{\Sigma}$ without making any assumptions of normality for the data. We simply require $\mathbf{x}_1, \ldots, \mathbf{x}_n$ to be independent realizations of the random vector $\mathbf{X} = (X_1, X_2, \ldots, X_p)'$, the distribution of which has mean vector $\boldsymbol{\mu}$ and dispersion matrix $\boldsymbol{\Sigma} = (\sigma_{ij})$. There are $\frac{1}{2}p(p + 1)$ distinct elements of $\mathbf{S}$ and these elements can be written as a vector $\mathbf{s}$. [One common way of doing this is by stacking successive columns of the lower-triangular portion of $\mathbf{S}$ on top of each other in a column vector; such a vector is denoted vech($\mathbf{S}$)]. The corresponding vector representation of $\boldsymbol{\Sigma}$ can be denoted $\boldsymbol{\sigma} = \text{vech}(\boldsymbol{\Sigma})$. Layard [8] has studied the joint distribution of elements of $\mathbf{s}$. He uses the multivariate central limit theorem to show that, asymptotically for $n \to \infty$, $\mathbf{s}$ has a multivariate normal distribution in which the mean vector is $\boldsymbol{\sigma}$, the

variance of any element s_{jk} is

$$\frac{1}{n}[\mathrm{E}(Z_j^2 Z_k^2) - \mathrm{E}(Z_j^2)\mathrm{E}(Z_k^2)],$$

and the covariance between any two elements s_{jk} and s_{ms} is

$$\frac{1}{n}[\mathrm{E}(Z_j Z_k Z_m Z_s) - \mathrm{E}(Z_j Z_k)\mathrm{E}(Z_m Z_s)],$$

where $Z_i = X_i - \mu_i$ for $i = 1, \ldots, p$. **Convergence** to normality can be speeded up by transforming the elements of **s**, taking logarithms of the variances s_{jj} and using $\tanh^{-1}[s_{jk}/(s_{jj}s_{kk})^{1/2}]$ in place of the covariances s_{jk}. However, this improvement in speed of convergence comes at the expense of complicating the terms in the asymptotic dispersion matrix. Details are given by Seber [16, pp. 99–101]. Asymptotically, of course, $\hat{\boldsymbol{\Sigma}}$ has the same distribution as **S**.

This asymptotic distribution enables large-sample (approximate) confidence regions and hypothesis tests to be constructed for elements of $\boldsymbol{\Sigma}$, irrespective of the distribution from which the sample has been drawn (*see* **Large-sample Theory**). However, for small sample exact tests or for tests of specified structure of $\boldsymbol{\Sigma}$ we need to assume normality of data. Moreover, even then it is virtually impossible to employ optimal theory of **hypothesis testing** as uniformly **most powerful tests** are derivable only in rather artificial circumstances. In most practical circumstances, therefore, recourse must be made to some general principle that can be relied on to produce a "good" test. The principle of *invariance* will often focus attention on a particular class of test statistics within which to search, but may not necessarily pinpoint one specific test. To do this, the most common approaches are to use either the **likelihood ratio** or the **union–intersection principles** of test construction.

Suppose that the null hypothesis H_0 imposes a set of d constraints on the parameters, say $\boldsymbol{\theta} = \boldsymbol{\theta}_0$, where $\boldsymbol{\theta}$ has d elements, and the alternative hypothesis H_a is the general "not H_0". Usually, also, there will be other (nuisance) parameters $\boldsymbol{\psi}$. Write $l(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\psi}})$ for the log likelihood of the sample when $\hat{\boldsymbol{\theta}}$ and $\hat{\boldsymbol{\psi}}$ are unconstrained maximum likelihood estimates of all the parameters, and $l(\boldsymbol{\theta}_0, \hat{\boldsymbol{\psi}}_0)$ for the log likelihood when $\boldsymbol{\theta} = \boldsymbol{\theta}_0$ and $\hat{\boldsymbol{\psi}}_0$ is the maximum likelihood estimate of $\boldsymbol{\psi}$ conditional on $\boldsymbol{\theta} = \boldsymbol{\theta}_0$. Then, under regularity conditions, the **likelihood ratio test** statistic is

$$\omega = 2l(\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\psi}}) - 2l(\boldsymbol{\theta}_0, \hat{\boldsymbol{\psi}}_0)$$

(or some monotonic function of ω).

On the other hand, any null hypothesis involving $d > 1$ constraints can be regarded as the union of an infinite set of simpler hypotheses. For example, $\boldsymbol{\theta} = \boldsymbol{\theta}_0$ implies $\mathbf{a}'\boldsymbol{\theta} = \mathbf{a}'\boldsymbol{\theta}_0$ for any vector $\mathbf{a}$. This is a univariate hypothesis, and univariate theory will generally supply some test statistic, V say, for this hypothesis. Finding the value of $\mathbf{a}$ (up to a multiplying factor) that maximizes V, choosing this hypothesis and then testing it (making due allowance for the maximization) is the basis of the union-intersection principle of test construction.

A full account of these principles of test construction can be found in most multivariate textbooks; see, for example, Mardia et al. [10]. Here we simply summarize the test statistics and their null distributions for the most common tests about $\boldsymbol{\Sigma}$. In all of these tests we assume normality of data, unknown population mean vector $\boldsymbol{\mu}$, and the general alternative H_a: not H_0. Thus, for deriving the likelihood ratio test statistic, $\boldsymbol{\theta}$ and $\boldsymbol{\psi}$ above are $\boldsymbol{\Sigma}$ and $\boldsymbol{\mu}$ respectively, while unconstrained maximum likelihood estimators are given by $\hat{\boldsymbol{\Sigma}} = (1/n)\mathbf{A}$ and $\hat{\boldsymbol{\mu}} = \bar{\mathbf{x}}$ as above.

1. $\mathrm{H}_0 : \boldsymbol{\Sigma} = \boldsymbol{\Sigma}_0$, a specified matrix. The likelihood ratio test statistic is $\omega = n\,\mathrm{tr}(\boldsymbol{\Sigma}_0^{-1}\hat{\boldsymbol{\Sigma}}) - n\log|\boldsymbol{\Sigma}_0^{-1}\hat{\boldsymbol{\Sigma}}| - np = np(a - \log g - 1)$, where a and g are the arithmetic and geometric means of the **eigenvalues** of $\boldsymbol{\Sigma}_0^{-1}\hat{\boldsymbol{\Sigma}}$. For the exact null distribution of this statistic, see Anderson [1] and Korin [6]. However, this distribution is not easy to use, so recourse has to be made to the general result that asymptotically, ω has a $\chi^2_{(1/2)p(p+1)}$ distribution (**chi-square distribution** with $\frac{1}{2}p(p+1)$ **degrees of freedom**) under H_0. The union–intersection statistic, on the other hand, is a function of just the extreme eigenvalues of $\boldsymbol{\Sigma}_0^{-1}\hat{\boldsymbol{\Sigma}}$. This test rejects H_0 if either $\lambda_p < c_1$ or $\lambda_1 > c_2$, where λ_i is the ith largest eigenvalue of $\boldsymbol{\Sigma}_0^{-1}\hat{\boldsymbol{\Sigma}}$ and c_1 and c_2 are chosen to make the size of test α (*see* **Level of a Test**). Tables for carrying out this test are given in Pearson & Hartley [13].

2. $H_0 : \boldsymbol{\Sigma} = k\boldsymbol{\Sigma}_0$, for unknown k. The maximum likelihood estimate of k is given by $\hat{k} = \text{tr}(\boldsymbol{\Sigma}_0^{-1}\hat{\boldsymbol{\Sigma}})/p$ and the likelihood ratio statistic is $\omega = np\log(a_0/g_0)$, where a_0 and g_0 are the arithmetic and geometric means of the eigenvalues of $\boldsymbol{\Sigma}_0^{-1}\hat{\boldsymbol{\Sigma}}$. Asymptotically this statistic has a $\chi^2_{(1/2)(p-1)(p+2)}$ distribution under H_0. The special case of $\boldsymbol{\Sigma}_0 = \mathbf{I}$ leads to the **sphericity test**, for which we have $a_0 = (1/p)\,\text{tr}\hat{\boldsymbol{\Sigma}}$ and $g_0 = |\hat{\boldsymbol{\Sigma}}|^{1/p}$. No straightforward union–intersection tests exist in these situations, but Olkin & Tomsky [12] give some modified versions. The test of sphericity plays an important role in **analysis of variance**. In general, the data vector should have a covariance matrix consonant with the sphericity hypothesis for the F tests on means in this analysis to be valid. Also, more particular model structures can be reduced to this hypothesis and tested. The most important of these is the usual covariance structure assumed for repeated measures data (*see* **Longitudinal Data Analysis, Overview**), in which all variances (diagonal elements of $k\boldsymbol{\Sigma}_0$) are assumed to be equal to σ^2 and all covariances (off-diagonal elements of $k\boldsymbol{\Sigma}_0$) are assumed to be equal to $\rho\sigma^2$. It can be shown that any p-element random vector $\mathbf{X} = (X_1, \ldots, X_p)'$ satisfies this covariance structure if and only if the $(p-1)$-element vector $\mathbf{Y} = \mathbf{CX}$ satisfies the sphericity hypothesis, where $\mathbf{C}$ is any $(p-1) \times p$ matrix the rows of which are orthogonal to each other and to the vector $\mathbf{1} = (1, 1, \ldots, 1)'$.
3. $H_0 : \boldsymbol{\Sigma}$ is diagonal. This is the hypothesis that all the variables are uncorrelated with each other. Under H_0, the mean and variance of each variable are estimated separately, whence $\hat{\boldsymbol{\Sigma}}_0^{-1}\hat{\boldsymbol{\Sigma}} = \mathbf{R}$, the sample **correlation** matrix. This has trace p, so $\omega = -n\log|\mathbf{R}|$. Under H_0, ω has an asymptotic $\chi^2_{(1/2)p(p-1)}$ distribution; Box [2] showed that the χ^2 approximation is improved if n is replaced by $n' = n - \frac{1}{2}(2p + 11)$. There is no straightforward union-intersection test in this case either.

Of course, the maximum likelihood estimate $\hat{\boldsymbol{\Sigma}}$ is equal to $[(n-1)/n]\mathbf{S}$, so each of the above test statistics can be expressed in terms of $\mathbf{S}$ if so desired.

Properties such as the unbiasedness and invariance of these statistics are discussed by Giri [5, Chapter 8] and Muirhead [11, Chapter 8 and 11]. Muirhead also details modifications to the statistics in order to insure unbiased tests, and establishes asymptotic null and nonnull distributional results for samples from elliptic as well as from normal distributions. A general review of all the tests, along with some significance levels, is provided by Krishnaiah & Lee [7].

One other problem of common interest is the testing of equality of dispersion matrices in several multivariate populations, since the assumption of equal dispersion matrices is made in multivariate techniques such as canonical variate analysis (*see* **Canonical Correlation**) and **multivariate analysis of variance**. The likelihood ratio test is a generalization of **Bartlett's test** of homogeneity of variance in univariate populations. We assume that random samples of sizes $n_1, n_2, \ldots, n_g$ are available from each of g populations, and we write $N = \sum_{i=1}^{g} n_i$. Suppose that $\mathbf{A}_i$ is the sums of squares and products matrix for the sample from population i, so that $\hat{\boldsymbol{\Sigma}}_i = (1/n_i)\mathbf{A}_i$ is the maximum likelihood estimator of the dispersion matrix for this population and $\mathbf{S}_i = [1/(n_i - 1)]\mathbf{A}_i$ is the unbiased version. Under the null hypothesis that all dispersion matrices are equal to $\boldsymbol{\Sigma}$, we have $\hat{\boldsymbol{\Sigma}} = (1/N)\sum_{i=1}^{g}\mathbf{A}_i$ and the corresponding unbiased version $\mathbf{S} = [1/(N-g)]\sum_{i=1}^{g}\mathbf{A}_i$. (The latter matrix is known as the pooled within-sample covariance matrix.) Then the likelihood ratio test statistic for testing the null hypothesis against the general alternative that at least one dispersion matrix differs from the rest is $N\log|\hat{\boldsymbol{\Sigma}}| - \sum_{i=1}^{g} n_i \log|\hat{\boldsymbol{\Sigma}}_i|$, and under the null hypothesis this statistic is asymptotically distributed as $\chi^2_{(1/2)p(p+1)(g-1)}$. Box [2] proposed the alternate statistic $(N-g)\log|\mathbf{S}| - \sum_{i=1}^{g}(n_i - 1)\log|\mathbf{S}_i|$, which has the same asymptotic chi-square distribution under the null hypothesis. He also gave an F approximation to the null distribution, and tables based on this latter approximation are given by Seber [16].

The union-intersection approach is viable in the special case $g = 2$, and produces a test based on the largest and smallest eigenvalues of $\mathbf{S}_1\mathbf{S}_2^{-1}$, with tables given by Schurrmann et al. [15]. However, this test does not generalize easily to the case $g > 2$.

This section has been concerned with inferential aspects of the sample covariance matrix. This matrix is at the heart of many multivariate techniques; see especially **principal components analysis** and **factor analysis**.

Covariate Imbalance, Adjustment for

Patients in a **clinical trial** tend to vary considerably with respect to clinical and demographic characteristics, some of which may affect their prognosis. It is clearly desirable that the characteristics of the patients in each group are as similar as possible, especially with respect to those characteristics which are prognostic. The enormous strength of randomized controlled trials for drawing **inferences** about treatments is very largely a direct consequence of the use of **randomization** to decide which patients receive each treatment (*see* **Randomized Treatment Assignment**). While randomization eliminates **bias**, it does not guarantee comparable baseline characteristics of the patients in the different treatment groups in a particular trial. Simple randomization is quite likely to yield some differences, especially in small trials. The use of stratified randomization or minimization (*see* **Adaptive and Dynamic Methods of Treatment Assignment**) will reduce such imbalances for selected variables.

Baseline balance is not a requirement. Because of the use of randomization, standard methods of analysis (**estimation** and **hypothesis testing**) will yield valid results regardless of the distribution of baseline variables. Nonetheless, it is often wise to try to avoid imbalance, using the simple design modifications indicated above, and to allow for imbalance if it arises.

Comparison of Baseline Characteristics

An important part of reporting the results of a clinical trial is to describe the patient characteristics for the different treatment groups. As well as characterizing the whole study sample, these data indicate how similar were the groups produced by randomization. In some sense the information is used to determine if the randomization has "worked". Here many investigators behave illogically, by using statistical tests to compare the groups. The aim is probably to attempt to establish that the groups really are comparable, thus strengthening the credibility of the trial. However, the **null hypothesis** for such tests is in essence that the data come from groups which are **random samples** from the same population. Because the treatment groups were indeed random samples, any differences observed between them are necessarily due to chance, and so the use of hypothesis tests is absurd [1]. Yet it is quite common to see groups described as having the "same" characteristics simply because no significant differences were observed, even when, say, there was a notable difference in mean age or the **prevalence** of smoking. A nonsignificant imbalance between groups can be quite important if that **covariate** is highly **prognostic**. Note that such imbalance can work in either direction, masking or overstating the true treatment difference. Significance testing for baseline differences does have one potential use, which is to see if the patients were indeed randomized. However, there is minimal **power** to test this hypothesis. As Senn [17] has noted, a significant imbalance ought really to lead to the conclusion that the trial was not properly randomized – not a conclusion that researchers are likely to draw about their own study. This test can be useful, however, in a **multicenter trial**. Trial coordinators may be able to detect a center which has not adhered to the protocol [8] (*see* **Clinical Trials Protocols**).

Over recent years many authors have examined the practice of testing baseline differences, with unanimous criticism of the practice [1, 3–5, 17]. These papers were mostly published in statistical journals, however, and hypothesis testing of baseline characteristics remains common in reports of trials in medical journals. Baseline testing was found in about 60% of trial reports in recent reviews of general and specialist journals [14]. Such tests are probably quite a recent development – testing was not mentioned in an early paper on baseline imbalance [12]. They are not a requirement of the regulatory bodies [17] (*see* **Drug Approval and Regulation**).

It might be thought that such testing is largely harmless, as it rarely has much impact on how the trial is analyzed and interpreted. However, carrying out one form of analysis conditional on the results of another can distort the results obtained, as described below. (A similar issue arises in other areas of statistics, such as in the analysis of **crossover designs**.) Baseline testing can have other adverse consequences. For example, it has been found that authors selectively report these tests: only 2% of about 1000 tests reported in 206 trial reports in obstetric journals gave results significant at the 5% level [14]. Some of this effect might be due to undisclosed stratification, but it appears that there is a tendency

to suppress the results of these tests if the imbalance is significant.

Effect of Imbalance

Imbalance in a patient characteristic will matter only if that characteristic is related to patient outcome, i.e. it is prognostic. In most situations gender will not be prognostic, but age often will be, especially in chronic diseases. Prognostic covariates are most often clinical or biochemical variables, some of which can have major importance. The effect of imbalance for a variable will depend both upon the size of the imbalance (e.g. difference in **means** or proportions) and the strength of the relation between that variable and the outcome.

When randomization leads to baseline imbalance in a prognostic variable, one group will have a poorer prognosis than the other before treatment starts. Thus chance imbalance will lead to a biased estimate of the treatment effect, in either direction according to the direction of the imbalance, when using a simple, unadjusted analysis. Also, a test of significance may yield a significant result when there is no true treatment difference or a nonsignificant result when there is. To take a specific example, Christensen et al. [7] carried out a randomized trial of azathioprine vs. placebo in patients with primary biliary cirrhosis. The unadjusted analysis gave $P = 0.2$ for the treatment comparison. There was some imbalance in serum bilirubin, which is a very strong prognostic variable in such patients. The azathioprine group had higher levels on average and hence a worse prognosis. An adjusted analysis gave $P = 0.02$ for the treatment effect. In practice some imbalance is likely in several prognostic variables, but the overall effect will be much the same as just outlined, especially when, as in this example, one variable is of primary prognostic importance.

Some authors [1, 10, 11] have suggested that imbalance is not so much of a problem for large trials, while others state the opposite [5, 15]. The apparent disagreement arises from the fact that there are several aspects that might be considered – the size of the test of treatment effect, the power of the test, the bias in estimating the treatment effect, and the precision of the estimated treatment effect. Some of these features diminish with increasing sample size, while others apply even to large trials. We certainly cannot rely on large sample size to overcome all of the problems associated with imbalance.

Rationale for Adjusting for Baseline Covariates

There are several reasons why investigators might wish to adjust for baseline characteristics when analyzing the data from a randomized trial, some of which have been mentioned already.

First, as already discussed, the aim of a randomized trial is to compare groups of patients who differ only in that they received different therapies. Imbalance in baseline variables may reduce the credibility of the results, both in the correctness of the randomization procedure and, more importantly, in the validity of the results. Even though such worries may not be well founded, this possibility should be regarded as reasonable grounds for concern. However, the necessary leap in complexity of the methodology (as described below) when adjusting for covariates may be disconcerting to medical readers [9] even though to statisticians it will not cause concern. To some extent transparency is replaced by opaqueness.

Given that chance imbalance in a prognostic variable will lead to some bias in the estimated treatment effect, one of the best reasons for adjusting is to remove this bias. We surely wish to obtain the most reliable estimate of treatment effect. Adjustment will also increase the power to detect a real treatment effect.

Another reason often given for adjusting is to increase the precision with which the treatment effect is estimated. However, while this is the case for normal **regression** models, it will not improve precision in **logistic** [13] or **Cox regression models** [6]. However, in these models, failure to adjust for prognostic variables will lead to underestimation of the treatment effect and hence a reduction in power [6, 13]. The bias associated with not adjusting in non-normal models applies even when there is perfect balance in a prognostic variable.

Methods of Adjusting for Baseline Covariates

The idea behind adjustment for baseline differences is to estimate what the treatment effect would have been if the groups had identical baseline variables, i.e. with

identical means for continuous variables and identical frequencies in each group for categorical variables. The generally recommended approach to adjustment is to use regression modeling, with treatment (as a **binary** variable) and prognostic variables included as the explanatory variables. I will follow convention in this context and refer to this approach as **analysis of covariance**, even though these analyses are not all encompassed within the usual idea of that analysis. Analysis of covariance can be used for all types of outcome measure – continuous, binary, and survival times. Its particular strength is that it gives a result that is **unbiased** regardless of the baseline distribution of prognostic variables – i.e. it is conditionally unbiased [16]. In addition, by comparison with an unadjusted analysis, analysis of covariance provides increased precision for the treatment effect (for normal models), an increase in the power of the trial, and a constant conditional size of the test comparing the treatment groups [15].

An alternative is to use a stratified analysis. This approach is more common in epidemiology, where outcomes are usually binary. Pocock [11] gives an example of the use of the **Mantel–Haenszel** test to perform a stratified analysis of a clinical trial. This method is appropriate for categorical covariates, but may not adjust fully for imbalance in continuous covariates [1]. This method may be seen as a special form of analysis of covariance.

There is rather greater difficulty associated with deciding for which covariates to adjust. I consider several possibilities.

Selection Based on Observed Imbalance

The first approach is to focus on the imbalance: two-sample tests, as discussed above, can be used in turn for each prognostic variable to compare the groups at baseline, with no regard to patient outcome. Those which are statistically significant can be used to adjust the treatment effect in a **multiple regression** analysis. While this strategy is very common, its use is unwise. Those variables with significant imbalance may or may not be prognostic, and by including variables conditionally on simple tests, the adjusted analysis is likely to lead to a biased estimate of the treatment effect. Also, as noted above, nonsignificant imbalance may be quite important, even in a normal model.

Selection Based on Relation to Patient Outcome

A second approach is to focus on patient outcome. A multiple regression model can be derived using stepwise selection to see which variables are significant predictors of the outcome, taking no account of baseline balance. While this analysis could be done ignoring treatment or separately within each treatment group, it is most sensible to include all patients and to include in the model an indicator for treatment. This analysis thus yields both the choice of important prognostic variables and the adjusted treatment effect. While far preferable to adjustment based on observed imbalance, this method is not fully satisfactory. Apart from the known overoptimism of regression models based on stepwise selection, adjustment is made for a data-dependent selection of prognostic variables using an arbitrary inclusion rule. We might instead choose those variables which have the largest effect on the estimated treatment effect, either as assessed by the change in the test statistic, as proposed by Canner [5], or the change in the magnitude of the estimated treatment effect (e.g. by 15%). While more reasonable than using ***P* values**, it is unclear here what the criterion should be for deciding which variables have a large enough effect to need adjustment.

An approach proposed by Tukey [19] can be outlined only briefly here. The idea is to minimize the number of regression coefficients without reducing the number of covariates. The outcome variable is regressed on each covariate in turn, with the patients in each group pooled. From each analysis a score is derived from the P value – he suggested scores of 1 to 4 corresponding to $P < 0.05$, $P < 0.01$, $P < 0.001$, and $P < 0.0002$, the scores being signed according to the direction of the effect. The method is easiest to explain with binary covariates each coded as "high" or "low". For a set of covariates, a "composite" is constructed for each patient as a weighted sum of the scores, where the weight is 0 if the variable is low and 1 if high. This composite is then treated as a single covariate to adjust the treatment effect. The weaknesses of this method include the use of the P value as a measure of the strength of the effect, the treatment of all covariates as providing independent information, and the lack of transparency.

Prespecified List of Variables

There are problems associated with all data-derived decisions about which variables to include in an

analysis. In particular, the use of significance tests to determine which variables to adjust for is not recommended. It seems far preferable to choose which variables to adjust for without regard to the actual data set to hand.

What criteria should be used to select such variables? Primarily one would wish to consider known important prognostic variables that have not been controlled by the design. It is advisable also to include any variables used for stratification. In addition, in multicenter trials it may be desirable to include centers. The prespecified strategy has the advantage of focusing attention on prognostic factors at the design stage, rather than leaving this issue to be dealt with in an ad hoc manner in the analysis. It means that for some trials the analysis will make adjustment for covariates which are in fact balanced. This will not matter greatly in the case of a **normally distributed** outcome, and is desirable, as noted above, for non-normal outcomes.

Baseline Measurements of the Outcome Variable

In many clinical trials where the object of treatment is to change the value of a continuous measurement (such as blood pressure), it is possible to measure the variable of interest at the start of the trial. The undesirability of baseline imbalance in the variable of primary interest is especially clear. One approach to the analysis of such trials is to analyze change from baseline. This would seem to solve the baseline imbalance problem, but it does not. The change from baseline within each group will usually be highly **correlated** with the baseline values (*see* **Regression to the Mean**), so the difference between the groups in change from baseline will be negatively correlated with the imbalance at the baseline [18]. In other words, while analyzing change from baseline seems to remove the problem associated with baseline imbalance, in fact the chance imbalance will still affect the difference in outcome, but in the opposite direction. In the case where we are seeking to increase lung function, say, and if by chance patients receiving treatment A have higher baseline values than those receiving treatment B, then the analysis of change from baseline will be biased in favor of group B, and vice versa if the imbalance goes the other way. Thus it can be seen that analysis of change from baseline does not deal adequately with baseline imbalance. It is often argued that in such trials change from the baseline is a clinically more relevant outcome measure. Senn [16] has argued strongly against this view. In any case, one can use analysis of covariance to adjust change from baseline for baseline values, with exactly equivalent answers, so the debate is irrelevant if analysis of covariance is used [16, 18] (*see* **Baseline Adjustment in Longitudinal Studies**).

Such trials may cause a further error. It is quite common to see authors report separate tests to assess whether each group has changed from the baseline. The resulting P values are compared and a difference claimed when one P value is significant and the other is not. This is not a valid form of statistical inference, and is likely to mislead [2, 15].

Comments

The main issues here are the proper analysis of randomized trials, and the distinction between substantive and **exploratory analyses**. A clear recommendation may be made for the analysis of trials. Ideally, a prespecified strategy should be developed as part of the protocol in which either no adjustment will be made for baseline variables or adjustment will be made for nominated variables using analysis of covariance.

Good statistical practice requires investigators to prespecify in the study protocol their intentions with regard to sample size (*see* **Sample Size Determination**), primary (and subsidiary) endpoints (*see* **Outcome Measures in Clinical Trials**), subgroup analyses (*see* **Treatment-covariate Interaction**), and so on. It is no different to suggest that the analysis strategy should also be prespecified, in particular intentions regarding adjusted analyses. It is usually known in advance which are the variables that are most prognostic of patient outcome. Whether or not these are used as stratifying variables, the trial protocol should specify which ones will be adjusted for in the analysis, and that this adjustment will not be conditional on the distribution of those variables across the treatment groups [4, 5, 15]. It would not be acceptable to specify in the protocol that adjustment would be made for any variables showing statistically significant imbalance; this would not circumvent the problems described above.

The protocol should also specify which will be the primary analysis. My view is that this should usually

be the adjusted analysis, otherwise there is little point in performing it. Sometimes, however, the adjusted analysis may be performed in order to strengthen belief in the results of the unadjusted analysis. Here it becomes unclear how similar the results need to be for the unadjusted analysis to be confirmed. It is not desirable for the choice of primary analysis to be conditional on the results.

It may not be as simple as just suggested to identify the "most prognostic variables". Clinicians may argue that all information being collected is potentially prognostic, which is why it is being collected. It may prove difficult to persuade them to identify in advance which variables will and which will not be adjusted for in the analysis, and harder still to get them to comply with this strategy when imbalance is seen within the latter group. Despite the wide recommendation of this general strategy, it is not common to see published studies reporting this as the basis for their chosen analysis. Partly, though, this may be because balance has been achieved through the design.

In practice, imbalance may arise when the possible need for adjustment has not been anticipated. What should the researchers do? They might choose to ignore the imbalance; as noted, this would be entirely proper. The difficulty then is one of credibility. Readers of their paper (including reviewers and editors) may question whether the observed finding has been influenced by the unequal distribution of one or more baseline covariates. It is still possible, and arguably advisable, to carry out an adjusted analysis, but now with the explicit acknowledgment that this is an exploratory rather than definitive analysis, and that the unadjusted analysis should be taken as the primary one. Obviously, if the simple and adjusted analyses yield substantially the same result, then there is no difficulty of interpretation. This will usually be the case. However, if the results of the two analyses differ, then there is a real problem. The existence of such a discrepancy must cast some doubt on the veracity of the overall (unadjusted) result. The situation is similar to the difficulties of interpretation that arise with unplanned subgroup comparisons. One suggestion in such circumstances is to try to mimic what would have been done if the problem *had* been anticipated, namely to adjust not for variables that are observed to be unbalanced, but for all variables that would have been identified in advance as prognostic. An independent source could be used to identify such variables. Alternatively, the trial data could be used to determine which variables are prognostic. This strategy too could be prespecified in the study protocol. Because this analysis would be performed conditionally on the observed imbalance, it does not remove bias and thus cannot be considered fully satisfactory.

Finally, I have assumed implicitly that the treatment effect is the same on average regardless of the values of the covariates. It may be desirable to examine whether there are any **treatment–covariate interactions**; here, too, prespecification of intentions is strongly advisable.

Covariate

Quantification of the relationship between a response variable and a group of **explanatory variables** is the goal of fitting **regression** models. Some explanatory variables may be the main focus of a study, such as treatment variables in experimental studies or **risk** factors in epidemiologic studies. Other variables may be measurements that must be controlled for in the analysis but are not of specific interest, such as **confounders**. These latter variables are often termed covariates. Other terms for these variables are covariables or concomitant variables.

For illustration, consider that often in epidemiologic studies it is known that age is associated with the outcome of interest and that age is also associated with the exposure under investigation. The primary hypothesis focuses on the relationship between the outcome and the exposure with age included in the model because of the possible confounding effect of age. Thus, age is a covariate since the relationship between the outcome and age is not a focus of the study but, nonetheless, age is included in the statistical model.

In the context of experimental design, the **analysis of covariance** is used so that one or more covariates are taken into consideration along with the treatment variables of primary interest. The inclusion of the covariate information is viewed as necessary to assess appropriately the relationship between the outcome measure and the treatments. An example is an investigation of the effect of dietary components on weight in experimental animals. The initial weight of the animals is a covariate, or covariable, and the quantification of the effect of the dietary components is more accurately assessed after controlling for initial weight.

As with other explanatory variables, a covariate can be quantitative or qualitative. Likewise, in the case of **survival analysis**, covariates, and other explanatory variables, can be time-independent (e.g. sex) or **time-dependent** (e.g. marital status).

It should be noted that, while the term *covariate* does have a specific meaning, it is often used interchangeably with the terms *explanatory variable, predictor variable*, or *independent variable*.

G.A. DARLINGTON

Cox Regression Model

The Cox or **proportional hazards** regression model [21] is used to analyze **survival** or failure time data. It is now perhaps the most widely used statistical model in medical research. Whenever the outcome of a **clinical trial** is the time to an event, the Cox model is the first method considered by most researchers. The model has also inspired an enormous statistical literature, ranging from the mathematical study of estimating the model parameters, to applied techniques for validating the model assumptions.

This article is divided into sections touching on some of the vast literature that has developed around the model:

1. model definition
2. history
3. using the Cox model–the basics
4. estimators and **algorithms**
5. asymptotic properties (*see* **Large-sample Theory**)
6. **time-dependent** explanatory variables
7. **model checking**
8. alternatives and extensions.

Several books have now been published on survival analysis that devote major sections to the Cox model. The first of these appeared in the early 1980s [23, 50]. Of the more recent books some are mathematically rigorous [6, 29], while others are more applied [20, 53, 60]. The book by Andersen et al. [6] is the most comprehensive.

Model Definition

Cox's essential novelty was to model the hazard function (*see* **Hazard Rate**) rather than the mean or some other measure of location. Let X denote a random failure time and $\mathbf{Z}$ a vector of **explanatory variables**. The conditional hazard of X given $\mathbf{Z} = \mathbf{z}$ at time t is defined as

$$\lambda(t|\mathbf{z}) = \lim_{\Delta t \downarrow 0} \frac{\Pr(X \leq t + \Delta t | X > t, \mathbf{z})}{\Delta t}. \quad (1)$$

The hazard function is sometimes called the intensity function or the force of mortality. Roughly, the hazard function is the probability that someone who is alive now will die in the next small unit of time. Cox proposed that the conditional hazard be modeled as the product of an arbitrary baseline hazard $\lambda_0(t)$ and an exponential form that is linear in $\mathbf{z}$:

$$\lambda(t|\mathbf{z}) = \lambda_0(t) \exp(\boldsymbol{\beta}'\mathbf{z}). \quad (2)$$

Here $\boldsymbol{\beta}$ is a vector of regression parameters and the infinite-dimensional parameter $\lambda_0(\cdot)$ is the hazard function for an individual with $\mathbf{Z} = \mathbf{0}$. The model in (2) forces the hazard ratio between two individuals to be constant over time:

$$\frac{\lambda(t|\mathbf{z}_2)}{\lambda(t|\mathbf{z}_1)} = \exp[\boldsymbol{\beta}'(\mathbf{z}_2 - \mathbf{z}_1)].$$

The exponential form of the relative risk function has become standard and is the most stable computationally, but it is not the only possibility. The more general model,

$$\lambda(t|\mathbf{z}) = \lambda_0(t) r(\boldsymbol{\beta}'\mathbf{z}),$$

for some known function r has also been considered [67, 82].

History

A distinguishing feature of survival data is that it is subject to **censoring**. Very often one does not observe the survival time for all individuals in a study. One may only know that a certain individual was still alive at some time T^*. If T_i^* is the last time at which individual i is known to be alive, it is called a censoring time – the individual's follow-up was censored at T_i^*. In 1958, Kaplan & Meier [51] studied the product-limit estimator of a survival function based on censored data (*see* **Kaplan–Meier Estimator**). The key concept of viewing the data as a process that reveals itself over time can be seen in their paper. Test statistics for censored data were considered a few years later [31, 59], and some may view the Cox model as the natural generalization to a regression setting of ideas present in Mantel's writing [59]. At about the same time, Feigl & Zelen [28] considered various **exponential** regression models. One of their models is equivalent to the Cox model with the baseline hazard constrained to be constant for all time, so that $\lambda(t|\mathbf{z})$ is a function of $\mathbf{z}$ but not t. However, unlike Cox [21], they formulate the model in terms of a parameterization of the mean

survival time, even though they use the exponential assumption to predict the entire survival distribution.

Cox's 1972 paper [21] was instantly acclaimed as a breakthrough in the analysis of right censored data, as can been seen from the enthusiastic discussion published together with the article. The model was rapidly adopted by applied statisticians, particularly in clinical trials. Its use became widespread once user-friendly software became readily available. Today, one can hardly open a leading medical or statistical journal without finding at least one reference to Cox (1972)! It is one of the most widely cited papers in scientific literature.

The original paper introduced a model that was to revolutionize the field, and provided the estimator that is today programmed into many statistical software packages. There were, however, several issues that were to challenge the statistical community. Some of these, such as how to deal with ties (two or more individuals with the same failure time) [63] (*see* **Tied Survival Times**), and the basis for the proposed estimator, were addressed at the Royal Statistical Society meeting. Cox provided justification for the estimator himself by introducing the concept of a **partial likelihood** [22]. But it was not until later that the estimators were shown to be **efficient** [11, 27]. Formal proofs of **consistency** and asymptotic normality took nearly a decade [5, 83]. Another topic of considerable interest to statisticians is the effect of **misspecification** on the estimates [80], and model interpretation. Various types of misspecification have been considered: explanatory variables measured with error [65] (*see* **Errors in Variables**); omission of important explanatory variables [16, 54, 78]; and rare but gross data contamination [9, 72] (*see* **Outliers**).

Parallel with the theoretical progress was work on model building and model checking. The results were less satisfactory than the elegant theory that developed around **counting processes** and martingales, but a variety of tools are now available. These included **goodness of fit** tests, as well as **residuals** and other **diagnostics**. Andersen [4] and others have discussed the quality of presentation of Cox regression analyses in the medical literature. Despite their constructive suggestions, the "Methods" sections of many papers are still no more informative than "we used the Cox model".

The basic model, (2), has been generalized in various directions. Even the original paper [21] considered time-dependent covariates, but these still cause a variety of difficulties [3]. A simple generalization is to permit different baseline hazard functions in each of a number of strata (*see* **Stratification**). The stratified Cox model assumes that, within each stratum, the proportional hazards assumption is justified and that the effect of the variable $\mathbf{Z}$ is the same in all strata:

$$\lambda_j(t|\mathbf{z}) := \lambda(t|\mathbf{z},\ \text{stratum}\ j) = \lambda_{0j}(t)\exp(\boldsymbol{\beta}'\mathbf{z}). \quad (3)$$

By incorporating constructed variables, that are constant in some strata, the stratified model, (3), can be used to model interactions between explanatory variables and strata. Suppose, for example, that one is stratifying by sex and including age as an explanatory variable. Let $z_1 = (\text{age} - 50)$ for men, $= 0$ for women; and let $z_2 = (\text{age} - 50)$ for women, $= 0$ for men. Then a model stratified on sex that includes z_1, z_2, and a treatment indicator z_3 permits interactions between age and sex, but assumes that the treatment acts proportionately on the hazards for any age–sex combination.

Many models used for analysis of **multivariate survival data** are generalizations of the Cox model, but they are not discussed here.

Using the Cox Model – the Basics

Before using the Cox model, or even attempting to interpret a published analysis, one must have some understanding of the assumptions that underlie the analysis. This section discusses those assumptions and explains a typical output from fitting the model in a statistical package.

There are three components to the data on each individual: the possibly censored failure time T; an indicator δ (*see* **Dummy Variables**) equal to 1 if T is a true failure time, 0 if it is censored; and $\mathbf{Z}$, the vector of explanatory variables. The model is flexible enough to incorporate explanatory variables that change value over the course of the study, but in this section we assume that $\mathbf{Z}$ is fixed and measured at time $t = 0$. The key censoring assumption is that the observation $(T = t, \delta = 0)$ tells us nothing more than that the true failure time X is greater than t.

In a clinical trial, the time origin for each individual will usually be his or her time of entry into the trial. If the trial ends at a particular calendar time, censoring all individuals who are not yet dead, then the censoring times are the times from entry until

the end of the trial and will vary from one individual to another. This is called administrative (or progressive type I) censoring. In such situations, it is necessary for survival to be independent of entry time for the above condition to be satisfied. To some extent this can be examined by including entry time as a covariate or by stratifying on the date of entry. Other forms of censoring are more problematic. If, for instance, a patient emigrates, one needs to consider whether this implies that the patient had in fact recovered. Conversely, a patient who fails to attend a follow-up clinic might be too sick to get out of bed. In such cases, the fact that the patient was censored at t tells us rather more than that she was alive at t.

The Cox model itself makes three assumptions: first, that the ratio of the hazards of two individuals is the same at all times; secondly, that the explanatory variables act multiplicatively on the hazard; and thirdly, that, conditionally on $\mathbf{Z}_i$ and $\mathbf{Z}_j$, the failure times of individuals i and j are independent. As with all regression models, one also assumes that the explanatory variables have been transformed so that they may be entered without further transformation and that all interactions have been included explicitly. We will see in the section on asymptotics that the independence assumption can be relaxed.

Table 1 presents the results of fitting a Cox model to data from 216 patients with primary biliary cirrhosis in a clinical trial of azathioprine vs. placebo [18]. The six variables were selected from an initial set of 25 partly using forward stepwise selection. An additional 32 patients were excluded because they had missing values of one or more of the six variables. Recruitment was over 6 years and follow-up a further 6 years. Of the 216 patients, 113 had censored survival times. The regression coefficients may be combined with their standard errors to obtain **confidence intervals** that rely on the asymptotic normality of the estimates.

The positive coefficient associated with treatment implies that patients on the placebo ($Z = 1$) had poorer prognosis than those on azathioprine ($Z = 0$): the hazard of those on placebo is about 1.7 times greater than that of those on active treatment. Similarly, older patients had poorer prognosis. The hazard ratio associated with two patients aged 50 and 30 is $\exp[0.0069(\exp 3 - \exp 1)] = 1.13$. Notice, however, that the effect on survival is not fully described by the information in Table 1 because, without estimating the baseline hazard, one cannot translate the regression coefficients into effects on 5-years survival nor on **median survival**.

Most statistical software for Cox regression will also estimate the cumulative baseline hazard function

$$\Lambda_0(t) = \int_0^t \lambda_0(u)\,\mathrm{d}u \tag{4}$$

(*See* **Survival Distributions and Their Characteristics**), and from this one can calculate the estimated survival function for a given $\mathbf{z}$:

$$\Pr(X > t|\mathbf{z}) = \prod_{\{i:T_i \le t\}} [1 - \mathrm{d}\hat{\Lambda}_0(T_i)\exp(\boldsymbol{\beta}'\mathbf{z})].$$

Plots of the estimated survival function can be made for various $\mathbf{z}$s, and these can be viewed like **Kaplan–Meier** graphs. Alternatively, the estimated survival function can be used to estimate 5-year survival, say, as a function of the prognostic index $\boldsymbol{\beta}'\mathbf{z}$ (*see* **Prognosis**).

Estimators and Algorithms

The regression coefficients $\boldsymbol{\beta}$ are estimated by maximizing the so-called partial likelihood $L(\boldsymbol{\beta})$ [22]. An

Table 1 Cox model fitted to data from a clinical trial comparing the effects of azathioprine and placebo on the survival of 216 patients with primary biliary cirrhosis [18]. The six variables shown were selected, partly by a forward stepwise procedure, from 25 candidate variables

Variable	Coding	Coeff. $\hat{\beta}$	se($\hat{\beta}$)	exp($\hat{\beta}$)
Serum bilirubin	$\log_{10}$ (value in μmol/l)	2.51	0.316	12.3
Age	exp[(age in years − 20)/10]	0.0069	0.0016	1.0
Cirrhosis	0 = No; 1 = Yes	0.88	0.216	2.4
Serum albumin	value in g/l	−0.0504	0.018	0.95
Central cholestasis	0 = No; 1 = Yes	0.68	0.275	2.0
Therapy	0 = azathioprine; 1 = placebo	0.52	0.201	1.7

individual is said to be at risk at t if he has not yet failed nor been censored. This concept can be generalized to allow for individuals who do not enter the study at time 0. Such **delayed entry**, or left **truncation**, as it is called, often arises when t is the age of a patient or the time from infection, so that patients enter the study at some time $T_i^0 > 0$. Consider $L_i(\boldsymbol{\beta})$, the conditional probability that individual i fails at time T_i given that exactly one individual fails at T_i and knowing the values of $\mathbf{Z}$ for all individuals at risk at T_i:

$$L_i(\boldsymbol{\beta}) = \frac{\lambda(T_i|\mathbf{Z}_i)}{\sum_{j\in R_i}\lambda(T_i|\mathbf{Z}_j)} = \frac{\exp(\boldsymbol{\beta}' Z_i)}{\sum_{j\in R_i}\exp(\boldsymbol{\beta}'\mathbf{Z}_j)}, \qquad (5)$$

where $R_i = \{j : T_j^0 < T_i \le T_j\}$ is the **risk set** just prior to T_i. The partial likelihood is the product of these **conditional probabilities** over all failure times: $L(\boldsymbol{\beta}) = \prod_i L_i(\boldsymbol{\beta})$. Notice that the partial likelihood is a function of $\boldsymbol{\beta}$ only – it does not depend on the baseline hazard $\lambda_0(\cdot)$. With certain types of censoring (or no censoring) the partial likelihood is just the marginal **likelihood** of the ranks of the failure times. If there are ties in the data (two or more individuals failing at the same time), then both the partial likelihood and the marginal likelihood become difficult computationally [50, pp. 74–78]. Instead, most packages use an approximation [13, 63]:

$$L_i(\boldsymbol{\beta}) = \frac{\exp(\boldsymbol{\beta}'\mathbf{S}_i)}{\left[\sum_{j\in R_i}\exp(\boldsymbol{\beta}'\mathbf{Z}_j)\right]^{d_i}}, \qquad (6)$$

where d_i is the number of individuals failing at T_i and $\mathbf{S}_i$ is the sum of the $\mathbf{Z}_j$ for these d_i individuals. The approximation is reasonable provided the number of ties at any failure time is small compared to the number in the risk set. Note that i indexes the N distinct failure times, whereas j indexes the n individuals ($n \ge N$).

It is standard practice to maximize the partial likelihood using Newton–Raphson to find a $\boldsymbol{\beta}$ at which the derivative of its logarithm is zero (*see* **Optimization and Nonlinear Equations**). Indeed, Jacobsen [47] has shown that, when the relative risk function $r(\boldsymbol{\beta}'\mathbf{z}) = \exp(\boldsymbol{\beta}'\mathbf{z})$, $l(\boldsymbol{\beta}) = \log L(\boldsymbol{\beta})$ is concave. (It is strictly concave provided there is no exact **collinearity** among the explanatory variables and that no linear combination of the variables is a perfect predictor of failure. The latter would imply an infinite observed hazard ratio.)

We use the following notation: let

$$\mathbf{S}^{(k)}(\boldsymbol{\beta}, T_i) = \sum_{j\in R_i}\mathbf{Z}^{\otimes k}\exp(\boldsymbol{\beta}'\mathbf{Z}_j),$$

where $\mathbf{Z}^{\otimes 0} = 1$, $\mathbf{Z}^{\otimes 1} = \mathbf{Z}$, and $\mathbf{Z}^{\otimes 2} = \mathbf{Z}\mathbf{Z}'$. Let $\mathbf{U}(\boldsymbol{\beta})$ denote the score

$$\mathbf{U}(\boldsymbol{\beta}) = \sum_i \frac{\mathrm{d}\log L_i(\boldsymbol{\beta})}{\mathrm{d}\boldsymbol{\beta}} = \sum_i \left[\mathbf{S}_i - d_i\frac{\mathbf{S}^{(1)}(\boldsymbol{\beta}, T_i)}{\mathbf{S}^{(0)}(\boldsymbol{\beta}, T_i)}\right], \qquad (7)$$

and $\mathbf{I}(\boldsymbol{\beta})$ minus the Hessian:

$$\mathbf{I}(\boldsymbol{\beta}) = -\frac{\mathrm{d}\boldsymbol{U}(\boldsymbol{\beta})}{\mathrm{d}\boldsymbol{\beta}} = \sum_i d_i \times \left\{\frac{\mathbf{S}^{(2)}(\boldsymbol{\beta}, T_i)}{\mathbf{S}^{(0)}(\boldsymbol{\beta}, T_i)} - \left[\frac{\mathbf{S}^{(1)}(\boldsymbol{\beta}, T_i)}{\mathbf{S}^{(0)}(\boldsymbol{\beta}, T_i)}\right]^{\otimes 2}\right\}. \qquad (8)$$

Given an estimate $\boldsymbol{\beta}^{(m)}$, one step of the algorithm gives

$$\boldsymbol{\beta}^{(m+1)} = \boldsymbol{\beta}^{(m)} + \mathbf{I}(\boldsymbol{\beta}^{(m)})^{-1}\boldsymbol{U}(\boldsymbol{\beta}^{(m)}).$$

The algorithm is generally started from $\boldsymbol{\beta}^{(0)} = \mathbf{0}$ and convergence is determined by the magnitude of $|\boldsymbol{\beta}^{(m+1)} - \boldsymbol{\beta}^{(m)}|$.

When there are S strata, one considers those at risk in each stratum separately. Let R_{si} denote the set of indices of individuals in stratum s at risk at time T_i, and let $L_{si}(\boldsymbol{\beta})$ be the partial likelihood contribution from stratum s and time T_i. Note that $\mathbf{S}_{si}$ is the sum of the $\mathbf{Z}_j$ of the d_{si} individuals in stratum s who fail at time T_i. The partial likelihood is then simply the product of the stratum specific partial likelihoods:

$$L(\boldsymbol{\beta}) = \prod_{s=1}^{S}\prod_i L_{si}(\boldsymbol{\beta}).$$

Although the partial likelihood is not in general a likelihood, it is usually treated as such. It is standard practice to report the value of the logarithm of the partial likelihood and to compare the partial likelihood ratio statistic to a **chi-square distribution** for testing between nested regression models (*see* **Likelihood Ratio Tests**). Similarly, the covariance of $\hat{\boldsymbol{\beta}}$

is estimated by $\mathbf{I}(\hat{\boldsymbol{\beta}})^{-1}$ and score tests (*see* **Likelihood**) are based on $\mathbf{U}(\mathbf{0})'\mathbf{I}(\mathbf{0})^{-1}\mathbf{U}(\mathbf{0})$. Indeed, in the absence of ties ($d_{si} = 1$ for all s and i), the score test from the Cox model with $K - 1$ dummy variables corresponding to a factor with K levels is identical to the K-sample log rank test. Further, the stratified log rank test is identical to the score test from the stratified Cox model.

Having computed $\hat{\boldsymbol{\beta}}$, the estimated regression coefficients, one can calculate the Breslow estimate of the cumulative baseline hazard [13] explicitly. The estimator for stratum s is

$$\hat{\Lambda}_{s0}(t) = \sum_{i:T_i \le t} \frac{d_{si}}{\sum_{j \in R_{si}} \exp(\hat{\boldsymbol{\beta}}'\mathbf{Z}_j)}. \tag{9}$$

Estimation of the hazard function itself can be done by taking a smooth derivative of the cumulative hazard. This is usually achieved by the kernel method [68] (*see* **Density Estimation**). The jumps in the Breslow estimate should not be used without **smoothing**. The jump at T_i crudely approximates $\lambda_0(T_i)(T_i - T_{i-1})$ not $\lambda_0(T_i)$. Breslow [13] also showed that the maximum partial likelihood estimate of $\boldsymbol{\beta}$ and the estimated cumulative baseline hazard, (5), can also be obtained by maximizing the full likelihood for $\boldsymbol{\beta}$ and Λ_0 simultaneously, assuming that Λ_0 is piecewise linear **spline**, i.e. the hazard $\lambda_0(t)$ is constant between each pair of ordered failure times. This heuristic argument was made precise by Johansen [48]. He showed that, in certain circumstances, the partial likelihood is formally the profile likelihood for $\boldsymbol{\beta}$. He permitted Λ_0 to be a step function and assumed that at the jumps $\mathrm{d}\Lambda(t|\mathbf{z}) = \exp(\boldsymbol{\beta}'\mathbf{z})\,\mathrm{d}\Lambda_0(t)$.

During the 1970s anyone wishing to fit a Cox model had to use a stand-alone computer program such as the FORTRAN code provided in the book by Kalbfleisch & Prentice [50]. Today, however, the situation is very different and there are many commercially available general statistical packages that will fit a Cox model to large data sets (*see* **Software, Biostatistical**).

Asymptotic Properties

The large sample properties of the maximum partial likelihood estimator of $\boldsymbol{\beta}$ and of the Breslow estimator of Λ_0 are unsurprising, but proofs of these results took some time. When the Cox model holds with parameters $\boldsymbol{\beta}_0$ (and Λ_0), the distribution of $\hat{\boldsymbol{\beta}}$ can be approximated by **multivariate normal** with mean $\boldsymbol{\beta}_0$ and a **covariance matrix** that can be estimated by $\mathbf{I}^{-1}(\hat{\boldsymbol{\beta}})$.

Two quite different approaches were successful. The first due to Tsiatis [83] was to consider independent and identically distributed triples $(X_i, \mathbf{Z}_i, C_i)$, where X_i is the failure time and C_i is the censoring time. It is assumed that the X_i are generated from a Cox model with covariates $\mathbf{Z}_i$ and that X_i are conditionally independent of C_i given $\mathbf{Z}_i$. The observed data are $(T_i, \mathbf{Z}_i, D_i)$, $i = 1, \ldots, n$, where $T_i = \min(X_i, C_i)$ and $D_i = 1$ if $T_i = X_i$ (the event is observed), and $D_i = 0$ otherwise (the event is censored). The estimators are functionals of the observed data, and classical large sample theory is applied. Under this model it can be shown that

$$\frac{\mathbf{S}^{(1)}(\hat{\boldsymbol{\beta}}, t)}{\mathbf{S}^{(0)}(\hat{\boldsymbol{\beta}}, t)} \to \mathbf{E}(\mathbf{Z}|T = t, D = 1)$$

and that $\mathbf{I}(\hat{\boldsymbol{\beta}})/n \to \mathbf{E}[D\mathrm{var}(\mathbf{Z}|T, D)]$ [70]. By viewing the estimators as functionals of the empirical distribution of the unobserved triples and using results from the theory of empirical processes, it is possible to study the large sample properties of the Cox estimators even when the data come from some other model [72].

The other approach to large sample theory using a martingale **central limit theory** requires reformulating the model. This approach adds much insight to the model and will be outlined here. The counting process view of survival analysis is due to Aalen [1]. Andersen & Gill [5] redefined the Cox model and provided elegant proofs of its large-sample properties under mild regularity conditions.

Counting Process Formulation

A multivariate counting process

$$N = \{N_i(t) : 0 \le t < \infty; i = 1, \ldots, n\}$$

is a nondecreasing integer-valued stochastic process with n components. It is assumed that $N_i(0) = 0$ for all i and that the jumps are all of size +1. The process may count the number of events that have occurred in each of n individuals by time t. If the event is the death of a person, then $N_i(t) \in \{0, 1\}$ since people only die once! For technical reasons, N_i is taken to be

right continuous (so that $N_i(t)$ represents the number of events in $[0, t]$) and no two components of N jump at the same time.

Associated with such a counting process is a cumulative intensity process A with components defined by

$$A_i(t + \mathrm{d}t) - A_i(t) = \Pr\{N_i(t + \mathrm{d}t) - N_i(t) = 1 | \mathcal{F}_{t-}\},$$

where $\mathcal{F}_{t-}$ represents everything that has happened until just before t. The history $\mathcal{F}_{t-}$ will certainly include the paths of $N_j(\cdot)$ on $[0, t)$, $j = 1, \ldots, n$, and may include other information such as censoring or explanatory variables from $[0, t)$. $M = N - A$ is a multivariate martingale with respect to the history (filtration) $\{\mathcal{F}_t : t \geq 0\}$. The Andersen & Gill [7] generalization of the Cox model is that

$$A_i(t + \mathrm{d}t) - A_i(t) = \alpha_i(t)\,\mathrm{d}t = Y_i(t)\lambda_0(t) \times \exp[\boldsymbol{\beta}_0' \mathbf{Z}_i(t)]\,\mathrm{d}t,$$

where $Y_i(t)$ is equal to 1 if individual i is under observation just before time t, and is equal to 0 otherwise. $Y_i(\cdot)$ is called the ith "at-risk" indicator process. Here we are assuming that the process A is absolutely continuous with derivative α. Note that we have written the explanatory variables as processes depending on t, and that the definition of the intensity process requires $\{\mathbf{Z}_i(u) : 0 \leq u \leq t, i = 1, \ldots, n\}$ to be in the history $\mathcal{F}_{t-}$. This means that the value of $\mathbf{Z}(t)$ should be known just before t.

The classical Cox model corresponds to a very simple counting process, each component of which jumps at most once. We have

$$N_i(t) = I\{T_i \leq t, T_i \leq C_i\}$$

and

$$Y_i(t) = I\{X_i \geq t, C_i \geq t\} = I\{T_i \geq t\}.$$

N_i starts at 0 and jumps to one when individual i is observed to die. If individual i is censored, N_i remains 0 for ever. Recall that $\alpha_i(t)\,\mathrm{d}t$ is the probability of N_i jumping in the interval $[t, t + \mathrm{d}t]$. If individual i has died or been censored before time t, then there is no chance of observing a death in the interval $[t, t + \mathrm{d}t]$, so $\alpha_i(t) = 0$. Otherwise $\alpha_i(t) = \lambda(t|\mathbf{Z}_i)$ by the definition of the hazard function. Hence in general $\alpha_i(t) = Y_i(t)\lambda(t|\mathbf{Z}_i)$.

Using the new notation, we define the log partial likelihood using information up to time u as

$$l(\boldsymbol{\beta}, u) = \int_0^u \sum_{i=1}^n \left(\boldsymbol{\beta}' \mathbf{Z}_i(t)\,\mathrm{d}N_i(t) - \log\left\{ \sum_{j=1}^n Y_j(t) \exp[\boldsymbol{\beta}' \mathbf{Z}_j(t)] \right\} \mathrm{d}N_i(t) \right).$$

Note that $\mathrm{d}N_i(t)$ is equal to either 0 or 1, because N_i is a counting process. Thus integration with respect to $\mathrm{d}N_i(t)$ is simple: in the classical Cox model $\int f(t)\,\mathrm{d}N_i(t) = D_i f(T_i)$. Differentiate l with respect to $\boldsymbol{\beta}$ to get the score process

$$\mathbf{U}(\boldsymbol{\beta}, u) = \int_0^u \sum_{i=1}^n [\mathbf{Z}_i(t) - \mathbf{E}(\boldsymbol{\beta}, t)]\,\mathrm{d}N_i(t),$$

where

$$\mathbf{E}(\boldsymbol{\beta}, t) = \frac{\sum_{j=1}^n Y_j(t) \mathbf{Z}_j(t) \exp[\boldsymbol{\beta}' \mathbf{Z}_j(t)]}{\sum_{j=1}^n Y_j(t) \exp[\boldsymbol{\beta}' \mathbf{Z}_j(t)]}. \quad (10)$$

It is easy to show that at the true $\boldsymbol{\beta}$, integration with respect to the intensity process is identically zero (for all u). Hence, at $\boldsymbol{\beta}_0$, one may replace $\mathrm{d}N_i(t)$ by $\mathrm{d}M_i(t)$:

$$\mathbf{U}(\boldsymbol{\beta}_0, t) = \int_0^u \sum_{i=1}^n [\mathbf{Z}_i(t) - \mathbf{E}(\boldsymbol{\beta}_0, t)]\,\mathrm{d}M_i(t).$$

It follows from the theory of martingale transforms that $\mathbf{U}(\boldsymbol{\beta}_0, \cdot)$ is a martingale since the integrand $[\mathbf{Z}_i(t) - \mathbf{E}(\boldsymbol{\beta}_0, t)]$ is predictable (i.e. its value is known just prior to t). Under mild regularity conditions [5] one can apply a martingale central limit theorem to show that $n^{-1/2}\mathbf{U}(\boldsymbol{\beta}_0, \cdot)$ converges in distribution to a Gaussian process.

Extending the counting process notation in the obvious way to permit strata, so that, for instance, $Y_{si}(u)$ indicates whether individual i is at risk in

stratum s at time u, the Breslow estimator is

$$\hat{\Lambda}_{s0}(t) = \int_0^t \frac{\sum_{i=1}^{n} \mathrm{d}N_{si}(u)}{\sum_{i=1}^{n} Y_{si}(u) \exp[\hat{\boldsymbol{\beta}}' \mathbf{Z}_i(u)]}$$

$$= \int_0^t \sum_{i=1}^{n} \mathrm{d}N_{si}(u) / S_s^{(0)}(\hat{\boldsymbol{\beta}}, u)$$

Let $J_s(t) = I\{\sum_{i=1}^{n} Y_{si}(t)\} > 0$. Then

$$\int_0^t J_s(u)\, \mathrm{d}[\hat{\Lambda}_{s0}(u) - \Lambda_{s0}(u)] = \int_0^t \frac{J_s(u)}{S_s^{(0)}(\hat{\boldsymbol{\beta}}, u)}$$

$$\times \sum_{i=1}^{n} \{\mathrm{d}N_{si}(u) - Y_{si}(u) \exp[\boldsymbol{\beta}_0' \mathbf{Z}_i(u)]\, \mathrm{d}\Lambda_{s0}(u)\}$$

$$= \int_0^t \frac{J_s(u)}{S_s^{(0)}(\hat{\boldsymbol{\beta}}, u)} \sum_{i=1}^{n} \mathrm{d}M_{si}(u).$$

Thus, once again, the asymptotics can be proved using a martingale central limit theorem.

Time-Dependent Explanatory Variables

The possibility of including explanatory variables that change with time was realized by Cox in his original article [21]. There it is suggested that the inclusion of a user-defined variable $Z_2(t) = tZ_1$ might be used as a test of the proportional hazards assumption. Other authors have included explanatory variables that change value at possibly random times. The classical example of this sort of covariate is one that indicates whether a patient has received a heart transplant before time t [25]. The uses and interpretations of these two types of time-dependent variables are quite different. In this section they will be discussed relying heavily on the ideas presented by Kalbfleisch & Prentice [50].

External or Ancillary Variables

An external variable is one that is not affected by the failure process. The simplest sort of external variable is a fixed or time-independent one. A second type is a defined variable such as $Z_2(t) = tZ_1$. Although Z_2 is not fixed, its entire path is known from the outset. A more general example of an external variable is a measure of air pollution as a predictor of severe asthma attacks. Although the level of air pollution is not known in advance, it is "external" to the individuals in the study. Furthermore, the marginal distribution of the variable does not involve the parameters of the failure time model. The whole history of an external variable can be included in $\mathcal{F}_0$ and the hazard or intensity process can be related to the survival function $\Pr(T \geq t|\mathcal{F}_0)$ in the usual way.

Internal Variables

An internal explanatory variable is the output of a **stochastic process** that is generated by the individual under study and so is observed only so long as the individual survives and is uncensored [50]. An example might be the level of β-2 microglobulin in a patient's sera. In practice, the actual level at any given time will be unknown. Instead one uses the level as measured in the most recent blood sample. Typically blood will be taken at most a dozen times during a trial. In such circumstances, the term "updated" may be preferred to "time-dependent".

The key point is that although one may include the history of an internal process up to time t in the filtration $\mathcal{F}_t$ and so define the hazard or intensity function, the intensity function is itself a random process and is not simply a function of the survival function. In general survival from u to t depends on $\{Z(s) : u \leq s \leq t\}$ and this is unknown at u. Furthermore, if Z is only observed when an individual is alive, then $\Pr(T \geq t|Z(t)$ is not missing$) = 1$. Thus it is not possible to make predictions of survival from models that include internal explanatory variables. To do that one must jointly model the survival process and the explanatory variable trajectory.

In a clinical trial with primary focus on a treatment which is fixed by randomization at time 0, internal variables may change in response to treatment. If the effect of treatment is predominantly reflected in the changing value of the explanatory variable, a Cox model of survival that includes both treatment and the updated measurements of the explanatory variable will show little or no treatment differences. Clearly, then, one must be very careful when interpreting the output of a Cox model that includes an internal explanatory variable. Treatment differences in a

model that includes the values of explanatory variables only at time 0 may be inferred to be causative (because of **randomization**). When a large treatment difference is attenuated by inclusion of updated measurements of an internal variable, one may gain useful insights into the mechanism through which the treatment is effective. In such circumstances, it is sensible to also explore the effect of treatment on the internal variable directly.

As with censoring, the value of a variable may depend on the history of the trial so far, without depending on the history of a given individual. Thus, for instance, one might decide to change the environment of a controlled experiment after every 15 deaths. Such a variable is neither internal nor external, but for the purpose of making inference it is closer to an external process.

Computing with Time-Dependent Variables

There are many practical issues in fitting models using time-varying regressors, such as how to deal with missing values, that are not discussed here [3].

The Cox model does not distinguish between a single individual who enters a trial at time 0 and dies at time T_i with fixed regressors $\mathbf{Z}_i$, from two individuals both with regressors $\mathbf{Z}_i$ one of whom enters at time 0 and is censored at time u and one of whom enters at u and dies at T_i. This may sound surprising, but it is true; the likelihood contributions from $[0, u]$ and $(u, T_i]$ are $\Pr(X > u|\mathbf{Z}_i)$, and

$$\frac{\Pr(T_i \le X < T_i + \mathrm{d}t | X > u, \mathbf{Z}_i)}{\mathrm{d}t} = \frac{\Pr(T_i \le X < T_i + \mathrm{d}t|\mathbf{Z}_i)/\mathrm{d}t}{\Pr(X > u|\mathbf{Z}_i)},$$

respectively. Furthermore, in the partial likelihood, all that matters is the $\mathbf{Z}$ values of the members of the risk set at each failure time, not whether a given individual happens to appear in several different risk sets. Thus, if $\mathbf{Z}(t)$ is only updated at a few times per person, it is simplest to treat each person as several "individuals" each with a time fixed covariate. Let the vector $(T_0, T, D, \mathbf{Z})$ denote the entry and exit times, the censoring indicator, and the value of $\mathbf{Z}(t)$ for $t \in (T_0, T]$, respectively. Then an individual who enters a trial at time 0 with $Z(t) = -2$ for $0 \le t \le 1$, $Z(t) = -3$ for $1 < t \le 2$, $Z(t) = 2.5$ for $2 < t \le 3$, and $Z(t) = 2$ for $3 < t \le 3.6$ and dies at $T = 3.6$ is represented by the four data points (0, 1, 0, −2), (1, 2, 0, −3), (2, 3, 0, 2.5), and (3, 3.6, 1, 2).

When computing the likelihood with fixed regressors, it makes sense to use an updating formula. As one moves from one time point to the next, the risk set changes slightly due to the entry or the exit (due to death or censoring) of "individuals". The values for those "individuals" who remain in the risk set do not change and need not be recalculated. In this way the calculation is kept to order n (albeit $4n$ if each individual is treated as four because of changing covariate values).

By contrast, when using continuously varying regressors, one has no choice but to recalculate the partial likelihood contribution from each time point from scratch. This makes the calculation order n^2.

Many software packages that will handle updated regressors will not (easily) handle continuously varying regressors. It is difficult to fit models with user-defined variables such as $Z_2(t) = tZ_1$ using such packages. One might wish to compare the models with hazards $\lambda_0(t)\exp(\beta_1 Z_1)$ and $\lambda_0(t)\exp(\beta_1 Z_1 + \beta_2 t Z_1)$. Of course, for the purpose of testing $\beta_2 = 0$, it is not necessary to fit the latter model. Instead, one may calculate the score statistic for $\beta_2 = 0$ evaluated at the maximum partial likelihood estimate of β_1 from the model with the single (fixed) regressor.

Model Checking

An important aspect of modeling any set of data is assessing the adequacy of the fit and checking to see that the resulting inference is not unduly influenced by a few observations. In general the iterative process of model building and checking may be considered an art rather than a science. Here we review some of the tools available to the statistical artisan analyzing survival data by means of a Cox model.

The simplest form of graphical check comes from dividing the data into groups based on some explanatory variable and fitting a stratified Cox model. If the explanatory variable "$Z = s$" is well modeled by the Cox model, one has $\Lambda_{s0} = \Lambda_0 \exp(\gamma s)$, say. Thus, plotting the logarithm of the cumulative hazard estimate from each strata should reveal parallel curves. That is, the vertical distance between the two curves $\log \Lambda_{r0}(t)$ and $\log \Lambda_{s0}(t)$ should be the same for all t. The common distance should be $\gamma(r - s)$. In practice, such graphics, while intuitively appealing, are not particularly useful.

A closely related, but rather more useful, graph for two strata is obtained by plotting one cumulative hazard $\Lambda_{r0}(t)$ against the other $\Lambda_{s0}(t)$ for all or some selected values of t. Under proportional hazards, such an H–H plot should approximate a straight line through the origin with slope $\exp(\gamma s)$ [6, Section VII.3.1]. The method is easily extended to multiple strata. The disadvantages of the H–H plot are that they do not record the actual time t, and that, if the proportional hazards assumption is seen to be violated, it is difficult to know how to modify the proportional hazards model other than by using a stratified model. Hess [42] reviews a number of variants on these two simple graphical checks of proportional hazards and compares eight graphical methods on each of three data sets. He recommends smoothed plots of scaled Schoenfeld residuals. These are described in the subsection on residuals.

Goodness-of-Fit Tests

Several authors have developed formal goodness-of-fit tests. These can be divided into those designed to be able to detect global alternatives and those with greater power at detecting some specified alternative. Virtually all the tests are asymptotically equivalent to tests based on a defined time-dependent explanatory variable. We saw earlier that the first such tests were proposed by Cox himself [21]. One may add an additional regressor $Z_*(t) = Zg(t)$ for some function $g(t)$. Common choices for g included the identity function $g(t) = t$ and its logarithmic transform $g(t) = \log t$. Other authors use step functions that may jump at either a fixed or a random (but predictable) time. If the partial likelihood is maximized with $Z(t)$, then the partial likelihood ratio test is the statistic of choice. But for testing the goodness of fit, the score test is simpler to compute because it does not require fitting a model with a time-dependent regressor.

Gill & Schumacher [34] proposed a family of tests of the proportional hazards assumption between two samples, A and B. Their tests are motivated by comparing two different estimates of the relative hazard between the two samples. Under proportional hazards the two estimates will be similar, but they need not be in general. The estimates of relative hazard used are derived from **linear rank tests**, which are themselves equivalent to score tests from the Cox partial likelihood with specially defined time-dependent regressors [33]. The family of tests proposed by Gill & Schumacher [34] are thus similar in spirit to those proposed by Breslow et al. [14]. The latter consider the score test for $\beta_2 = 0$ in the model

$$\lambda_B(t) = \lambda_A(t) \exp[\beta_1 + \beta_2 g(t)],$$

corresponding to covariates $Z_1 = I(B)$ and $Z_2(t) = I(B)g(t)$. A popular choice is $g(t) = \hat{S}(t)$, the Kaplan–Meier estimate of survival in the combined sample at t. O'Quigley & Pessione [62] suggest using a step function for $g(t)$. For a one degree of freedom test, one must choose both the cut points and the values of the step function. For a more general alternative hypothesis, one could partition the time axis into J intervals. The null hypothesis is that the relative hazards $\exp \beta_j$ in all $j = 1, \ldots, J$ intervals are the same, and this can be tested with $J - 1$ degrees of freedom. Wei [85] proposes an omnibus goodness-of-fit test for the two-sample problem based on the supremum of the score statistic $\sup_t |U(\hat{\beta}, t)|$.

Schoenfeld [75] was interested in a more general goodness-of-fit test for the Cox model. He suggested embedding a Cox model with regressor Z in a much larger model with regressors Z and $\mathbf{Z}_*(t)$, where the $\mathbf{Z}_*(t)$ are a set of indicator variables that partition the regressor–time space. Thus, for instance, one might divide the time axis into three parts and the covariate space into four, and form the Cartesian product with 12 cells. In addition to the score test for the coefficients of $\mathbf{Z}_*$ being all zero, one can examine the "residuals", i.e. the difference between the observed and expected (under the basic model with covariate Z) number of events in each of the 12 cells. Lin et al. [58] avoid the need for an arbitrary partition of the space by deriving a supremum test based on the cumulative sum

$$W(t, z) = \sum_{Z_i \le z} [O_i(t) - E_i(t)],$$

where $O_i(t) = N_i(t)$ and $E_i(t) = \int_0^t Y_i(u)\, \mathrm{d}\hat{\Lambda}_i(t)$ are, respectively, the observed and expected number of events in individual i, by time t.

Residuals

There have been numerous attempts to define residuals and to propose diagnostic plots for the Cox model

(*see* **Diagnostics**). The situation is complicated by both the **semiparametric model** and the presence of censoring. Some of the proposed techniques are decidedly less useful than one might have hoped. In particular, attempts to define residuals that (under the Cox model) look like a random sample from a specified distribution, so that $Q-Q$ plots can be drawn (*see* **Normal Scores**), have failed. Graphical assessment of the functional form of a covariate and of the constancy of the regression parameters over time have been more successful.

An early definition of residual for the Cox model was the estimated cumulative intensity for each individual:

$$\hat{A}_i(\infty) = \int_0^\infty Y_i(u)\,\mathrm{d}\hat{\Lambda}_i(u) = \int_0^\infty Y_i(u)\exp[\hat{\boldsymbol{\beta}}'\mathbf{z}_i(u)]\,\mathrm{d}\hat{\Lambda}_0(u) \quad (11)$$

[if $Y_i(u) = I(T_i \geq u)$ and $\mathbf{z}_i(u) = \mathbf{z}_i$, then $\hat{A}_i(\infty) = \hat{\Lambda}_i(T_i) = \exp(\hat{\boldsymbol{\beta}}'\mathbf{z}_i)\hat{\Lambda}_0(T_i)$] [24, 52]. Later authors made an adjustment to the residual depending on whether the individual was censored or not. The resulting residual $r_i = D_i - \hat{A}_i(\infty)$ is called the martingale residual and is a special case of the general family of residual processes defined by

$$\int_0^t H_i(u)\,\mathrm{d}\hat{M}_i(t), \quad (12)$$

where $\hat{M}_i(t) = N_i(t) - \int_0^t Y_i(u)\,\mathrm{d}\hat{\Lambda}_i(u)$ and H_i is a predictable process [8, 81]. Thus r_i is the estimated martingale transform, (12), with $H_i = 1$ and $t = \infty$. The martingale residual may be thought of as the difference between the observed and the expected number of events for the ith individual. The distribution of martingale residuals in a survival setting is very skewed since they have mean zero (under the true model) but range from 1 (for someone who fails at time 0) to minus a very large number (for someone who survives much longer than "expected"). Summing over individuals with similar covariate values $\{i : \mathbf{z}_i \in \mathcal{Z}\}$, say, one obtains the residual number of events for individuals with $\mathbf{z} \in \mathcal{Z}$. Thus, smoothing the martingale residuals against a regressor (or a potential regressor) gives an indication as to how well the model fits the data. Systematic departures from zero indicate that there is an excess (or deficit) in the modeled hazard for that group of individuals. Heuristically one has

$$\mathbf{E}\{N_i(\infty)|\mathbf{z},z^*\} = A(\infty|\mathbf{z}, z^*) \approx \hat{A}(\infty|\mathbf{z}) + \text{smooth}(r_i|z^*).$$

More recently, Grambsch et al. [36] have considered the model

$$\lambda(t|\mathbf{z},z^*) = \lambda_0(t)\exp[\boldsymbol{\beta}'\mathbf{z} + f(z^*)]. \quad (13)$$

They propose fitting the Cox model with prognostic index $\boldsymbol{\beta}'\mathbf{z} + \gamma z^*$ and plotting $\log\{\text{smooth}[N_i(\infty)]\} - \log\{\text{smooth}\,[\hat{A}_i(\infty)]\} + \hat{\gamma}z^*$ vs. z^*. The smooth curve will approximate $f(z^*)$ to first order. In practice, the approximation seems to work well even when Z^* is correlated with the other regressors $\mathbf{Z}$.

The martingale residuals were defined by integrating the martingale difference array $\mathrm{d}\hat{M}_i(t)$ over the time axis to give a single residual per individual. To examine the proportional hazards assumption, one is more interested in obtaining a separate residual for each failure time. This can be done by summing the martingale differences, at a given time, over all individuals. Now $\Sigma_i\,\mathrm{d}\hat{M}_i(t) = 0$ for all t by the definition of the Breslow estimator $\hat{\Lambda}_0$. Nevertheless, one can use the martingale transform, (12), with $\mathbf{H}_i = \mathbf{Z}_i$. Then at each failure time one is comparing the observed value of $\mathbf{Z}$ in the individual that fails with its expected value. Such a residual,

$$\mathbf{r}^*(T_j) = \sum_i \mathbf{Z}_i(T_j)[\,\mathrm{d}N_i(T_j) - Y_i(T_j)\,\mathrm{d}\hat{\Lambda}_i(T_j)] = \mathbf{S}_j - d_j\frac{\mathbf{S}^{(1)}(\hat{\boldsymbol{\beta}}, T_j)}{\mathbf{S}^{(0)}(\hat{\boldsymbol{\beta}}, T_j)},$$

was first proposed by Schoenfeld [76]. It is seen that the sum of the Schoenfeld residuals evaluated at $\boldsymbol{\beta}$ is equal to the score $\mathbf{U}(\boldsymbol{\beta})$. It is not difficult to show that, even under the model

$$\lambda(t|\mathbf{z}) = \lambda_0(t)\exp[\boldsymbol{\beta}(t)'\mathbf{z}], \quad (14)$$

$\mathbf{S}^{(1)}\,[\boldsymbol{\beta}(t), t]/\boldsymbol{S}^{(0)}\,[\boldsymbol{\beta}(t), t] \rightarrow \mathbf{E}(\mathbf{Z}|T = t,\ D = 1)$. Thus, using a one-step Taylor series expansion about $\boldsymbol{\beta}(t) = \hat{\boldsymbol{\beta}}$, one has

$$\boldsymbol{\beta}(t) \approx \hat{\boldsymbol{\beta}} + \hat{\mathbf{V}}(t)^{-1}\mathbf{r}^*(t),$$

where

$$\hat{\mathbf{V}}(t) = \frac{\mathbf{S}^{(2)}(\hat{\boldsymbol{\beta}}, t)}{\mathbf{S}^{(0)}(\hat{\boldsymbol{\beta}}, t)} - \left(\frac{\mathbf{S}^{(1)}(\hat{\boldsymbol{\beta}}, t)}{\mathbf{S}^{(0)}(\hat{\boldsymbol{\beta}}, t)}\right)^{\otimes 2}.$$

Hence, Grambsch & Therneau [35] have proposed plotting a smooth of $\hat{\boldsymbol{\beta}} + \hat{\mathbf{V}}(t)^{-1}\mathbf{r}^*(t)$ against t in order to get a feel of $\boldsymbol{\beta}(t)$. Often $\mathbf{V}(t) = \lim_{n\to\infty} \hat{\mathbf{V}}(t)$ does not vary much as a function of t, so for exploratory purposes it may be enough to use $\mathbf{I}(\hat{\beta})/\Sigma N_i(\infty)$ in place of $\hat{\mathbf{V}}(t)$. This has the advantage of not having to store and invert a different covariance matrix at each failure time. In practice, $\mathbf{V}(t)$ will vary most when a variable Z has a skewed distribution and those in the tail are at greatest risk. In all cases it will be difficult to estimate $\hat{\mathbf{V}}(t)$ if the risk set is small at time t, and it is also for large values of t that the $V(t)$ is most likely to be substantially different from its average value.

Influence Diagnostics

Various measures of influential observations have been suggested for the Cox model. The influence **diagnostic** is intended to approximate the amount by which the regression estimate $\hat{\boldsymbol{\beta}}$ would change if the ith individual were removed from the data set [69]. One such approximation is the infinitesimal **jackknife**, first proposed by Cain & Lange [17]. Their residuals are equal to the components of the scaled efficient score statistic. This can be written as a martingale transform residual with $\mathbf{H}_i(t) = \mathbf{Z}_i - \mathbf{E}(\hat{\boldsymbol{\beta}}, t)$. The scaling is done by $\mathbf{I}(\hat{\boldsymbol{\beta}})^{-1}$. One has

$$\tilde{\mathbf{r}}_i = I(\hat{\boldsymbol{\beta}})^{-1} \int_0^\infty [\mathbf{z}_i - \mathbf{E}(\hat{\boldsymbol{\beta}}, t)]\, \mathrm{d}\hat{M}_i(t).$$

An alternative estimate of the influence of an individual is given by Storer & Crowley [79].

Alternatives and Extensions

We have already discussed many extensions of the basic Cox model. We have permitted nonproportional hazards through the stratified Cox model and through user-defined time-dependent variables. We have considered diagnostics to detect data that appear to come from more nonparametric models, such as the additive Cox model $\lambda(t|\mathbf{z}) = \lambda_0(t)\exp[\sum_k f_k(z_k)]$, in which some of the functions f_k may be assumed to be linear while others are left unspecified [32, 37, 39, 70], and the multiplicative hazards model $\lambda(t|\mathbf{z}) = \lambda_0(t)\exp[\boldsymbol{\beta}(t)'\mathbf{z}]$ [30, 40, 41, 86, 84].

We have also seen how the model that was originally perceived for survival data can be generalized quite naturally to event data in which a single individual may have multiple events. The events need not even all be of the same type. They may represent competing risks or more generally the various states in a multistate model. In the classic heart transplant situation, for example, one might use Cox regression to model the transition from identification as a potential recipient (state 0) to transplant (state 1); from state 0 to death (state 2); and from state 1 to death [26]. Three state models in which transitions from state 1 (diseased) back to state 0 (healthy) are possible are also common (see, for example, Andersen et al. [6, Example VII.2.10]). The study of (i) acute graft-vs.-host disease, (ii) chronic graft-vs.-host disease, (iii) leukemia relapse, and (iv) death following bone marrow transplantation (state 0) is also considered by Andersen et al. [6, Example VII.2.18].

We briefly mention a few alternatives to the semiparametric Cox model for regression analysis of censored survival data. Naturally one can try to adapt estimation in any parametric regression model to cope with right censored data. Loglinear models with **Weibull** or **Gamma** errors [50, Section 3.6] tend to be more popular in reliability (engineering) than in biostatistics. Particularly in epidemiology, one sometimes has a known population mortality rate that one wants to use in place of the baseline hazard function. The hazard for individual i is given by

$$\lambda_i(t) = \mu_i(t)\exp[\boldsymbol{\beta}'\mathbf{Z}_i(t)],$$

where μ_i is the population mortality corresponding to individual i [7, 15]. Fully parametric models have been studied using counting process techniques by Borgan [12]. Another Cox-like model that uses a known rate is the proportional excess hazards model [73] (*see* **Excess Risk**),

$$\lambda_i(t) = \mu_i(t) + \lambda_0(t)\exp[\boldsymbol{\beta}'\mathbf{Z}_i(t)],$$

in which the excess mortality is modeled by a Cox model.

A general family, known as the **accelerated failure-time model**, is a linear regression model for

the logarithm of the survival time,

$$\log X = \boldsymbol{\beta}'\mathbf{Z} + \varepsilon,$$

where the error ε may be either from a specified distribution or from an unknown distribution. Gaussian errors and no censoring simply correspond to linear regression of $\log X$. If the errors are Weibull, then the model is also a proportional hazards model. Theoretical attention has focused on the semiparametric model with unknown error distribution. Another family of models that include the Cox model as a special case are the transformation models in which an unknown monotone transformation of the survival time is assumed to have a linear regression:

$$\psi(X) = \boldsymbol{\beta}'\mathbf{Z} + \varepsilon.$$

If the error distribution is **extreme value** ($\exp\varepsilon$ distributed exponential with mean 1), then the transformation model is a Cox model with cumulative baseline hazard given by $\exp[\psi(t)]$ and regression parameter $s - \boldsymbol{\beta}$.

The Cox model is a multiplicative hazards model. Aalen [2] introduced an additive hazards model (*see* **Aalen's Additive Regression Model**). A semiparametric version of the model [61] is given by

$$\lambda(t|\mathbf{Z}_1, \mathbf{Z}_2) = \boldsymbol{\theta}_1(t)'\mathbf{Z}_1(t) + \boldsymbol{\theta}_2'\mathbf{Z}_2(t).$$

If the variables $\mathbf{Z}_1$ include a constant, then we may pull out a baseline hazard and write the first term on the right of the equation as $\lambda_0(t) + \alpha_{11}(t)Z_{11}(t) + \cdots + \alpha_{1p}(t)Z_{1p}(t)$. The cumulative components of hazard $A_{1j}(t) = \int_0^t \alpha_{1j}(u)\,\mathrm{d}u$ can be estimated at parametric rates, and these must be smoothed to estimate the $\alpha_{1j}(u)$. The model extends naturally to the more general counting process formulation.

Several authors have considered "special" Cox models. These include models for matched pairs [38, 44] (*see* **Matching**), and for **interval censored** survival data [46], a model for periodic data [64] (*see* **Seasonal Time Series**), and a model for **case–cohort** data [66, 77]. **Bayesian analysis** of the Cox model was first considered by Kalbfleisch [49; [50], Section 8.4] and later by Hjort [43].

There has been relatively little written about robust estimation in the Cox model (*see* **Robustness**). Estimators that maximize a weighted partial likelihood have been proposed independently at least three times [56, 71, 72, 74]. The weights may be random and may depend on the regressors $\mathbf{Z}$, but they should be predictable (or at least asymptotically equivalent to predictable weights). A slightly different estimator which essentially corresponds to the efficient score function from a weighted full likelihood has also been studied [10].

Consideration of the Cox estimator for $\hat{\boldsymbol{\beta}}$ when the data do not come from a Cox model leads naturally to adoption of the sandwich estimator of the variance of $\hat{\boldsymbol{\beta}}$ [57, 69]. This is the usual infinitesimal jackknife estimator that can be obtained from the influence residuals

$$\tilde{\mathrm{var}}(\hat{\boldsymbol{\beta}}) = \sum_i \tilde{r}_i \tilde{r}_i'.$$

The estimator is perhaps most useful when the data are clustered (*see* **Clustering**). Suppose that $\tilde{\mathbf{r}}_{ki}$ is the influence residual from individual i in cluster k. Then define $\tilde{\mathbf{r}}_k = \Sigma_i \tilde{\mathbf{r}}_{ki}$ and estimate the variance of $\hat{\boldsymbol{\beta}}$ by $\Sigma_k \tilde{\mathbf{r}}_k^{\otimes 2}$ [55]. This may be a simple technique for adjusting inference when using the Cox model with multivariate survival data. For instance, if each person could have several events, then one might wish to treat the person as a cluster. In another example, the clusters might be formed from survival data on individuals within families.

Another approach adapting the Cox model to multivariate data is through latent variables or **frailties**. The idea is that, conditionally on an unobserved variable or frailty, the survival times follow a Cox model. The value of the frailty W_i is assumed to be the same for all survival times within a cluster. Two frailty distributions have received the most attention: Clayton & Cuzick [19] considered the hazard model $\lambda_0(t)\exp(\boldsymbol{\beta}'\mathbf{Z} + W)$ in which $\exp W$ has a gamma distribution; Hougaard [45] favors using the positive stable distribution, as this is the only choice that yields proportional hazards both marginally (integrating over the unobserved variable) and conditionally.

PETER SASIENI

Cox, Gertrude Mary

Born: January 13, 1900, in Dayton, Iowa.
Died: October 17, 1978, in Durham, North Carolina.

Gertrude Mary Cox was one of the twentieth century's pioneers in statistics. She wrote the following notes on her early years:

> I was raised on a farm where I had several years for roaming in the woods by the river and over the hills. I learnt from my mother the value and joy of doing for other people. She nursed the sick and raised us to be active church workers. There were four of us, two boys and two girls. We had responsibilities at home. I liked best making the homemade bread for our family because I was allowed to sell one pan of biscuits. My main ambition was to help others so after high school, I took a two-year special social service course of study and worked two years as housemother for 16 little orphan boys in Montana.

The Cox family moved to Perry, Iowa, where Gertrude graduated from high school; her major interests were in arithmetic and mathematics. The social service and orphanage work were in preparation to become a deaconess in the Methodist Episcopal church; however, she finally decided that academic training was more to her liking. She enrolled at Iowa State College (ISC) where she majored in mathematics, but elected courses in psychology, sociology, and craft work and did computing to help pay school expenses, receiving a B.S. degree in 1929.

Gertrude secured a master's degree in statistics from ISC in 1931 (supervised by **George Snedecor**), which was the first in statistics at that institution. She then began work on a Ph.D. in psychological statistics at the University of California at Berkeley; she gave up the latter in 1933 to return to Iowa State to direct the Computing Laboratory of the newly created Statistical Laboratory under Professor Snedecor. She became interested in the design of experiments, in which she developed and taught graduate courses. Her courses were built around a collection of real-life examples in a variety of experimental areas. She taught from mimeographed materials, which formed part of the famous *Experimental Designs* by **W.G. Cochran** and her [4]. She had three major principles in setting up an experiment: (i) the experimenter should clearly set forth his or her objectives before proceeding; (ii) the experiment should be described in detail; and (iii) an outline of the analysis should be drawn up before the experiment is started. She emphasized the role of **randomization** and stressed the need to ascertain if the size of the experiment was sufficient to demonstrate treatment differences if they existed (*see* **Sample Size Determination**).

In 1940, Snedecor responded to a request for suggestions on possible candidates to head the new Department of Experimental Statistics in the School of Agriculture at North Carolina State College (in Raleigh); upon seeing his list of all males, Miss Cox asked why he had not included her name. He then inserted a footnote which stated that if a woman could be considered, he recommended her. This footnote has become a statistical landmark, because Miss Cox was selected. She started staffing her department with statisticians who had majors or strong minors in applied fields. In 1944 the President of the Consolidated University of North Carolina established an all-University Institute of Statistics with Gertrude Cox as head, and in 1945 she obtained funds from the General Education board to establish graduate programs at North Carolina State and in 1946 a new Mathematical Statistics Department at Chapel Hill.

In 1949, Gertrude Cox gave up the Headship at North Carolina State to devote full time to the Institute, including the development of strong statistics programs throughout the South. This latter development was augmented by an arrangement with the Southern Regional Education Board to establish a Committee on Statistics. From 1954 to 1973 the Committee sponsored a continuing series of six-week summer sessions and is now co-sponsoring (with the **American Statistical Association**) a Summer Research Conference.

Of special interest to biostatistics was the founding in 1949 of the Department of Biostatistics in the School of Public Health at UNC, Chapel Hill, chaired by **B.G. Greenberg**. In 1953, the Statistics Section of the **American Public Health Association** and the Biostatistics Department sponsored a Biostatistics Conference on procedures to provide field training for health statisticians.

One of Gertrude Cox's strongest points was her ability to obtain outside financial support. The Rockefeller Foundation supported a strong program in statistical genetics (*see* **Genetic Epidemiology**) at North Carolina State and the Ford Foundation supported one in dynamic economics. She was a strong advocate of the development of powerful computer

programs; North Carolina State was a leader in the use of high-speed computers, especially the IBM650 and the initial SAS programs (*see* **Software, Biostatistical**).

Iowa State bestowed on her an honorary Doctorate of Science in 1958 as a

> stimulating leader in experimental statistics... outstanding teacher, researcher, leader, and administrator... Her influence is worldwide, contributing to the development of national and international organizations, publications, and councils of her field.

Starting in 1958, Dr Cox and other members of the North Carolina State statistics faculty developed procedures to establish a Statistical Division in the not-for-profit Research Triangle Institute (RTI) in the Research Triangle Park (RTP) between Raleigh, Chapel Hill, and Durham; Gertrude Cox retired from the University in 1960 to direct this division. She retired from RTI in 1965, but continued to teach at North Carolina State and consult on research projects. RTP has developed into a world-recognized research park.

Dr Gertrude Cox was a consultant before and after retirement to many organizations, including the **World Health Organization**, the US. Public Health Service, and the government of Thailand, and on a number of US Government committees for the Bureau of the Budget, **National Institutes of Health**, National Science Foundation, Census Bureau, and Agricultural Department. She was a founding member of the **International Biometric Society** in 1947 for which she served as President in 1968–69, Council three times, and first editor of its journal, ***Biometrics***. She was an active member of the **International Statistical Institute** and was President of the American Statistical Association in 1956. Her Presidential address in 1957, "Statistical frontiers", was an affirmation of her ethical concepts of moral uprightness and hard work [5]. She emphasized that

> The fact that you, as an individual, are classified as a statistician does not free you from obligations and responsibilities toward other human beings. You have an obligation to clarify the foundations of your techniques and methods for your clients. I want you young statisticians not to become men of success but rather become men of value.

In 1970, North Carolina State University designated the building in which statistics was housed as Cox Hall, and in 1977 a Gertrude M. Cox Fellowship Fund was established for outstanding graduate students in statistics. Her election to the National Academy of Sciences in 1975 was a treasured recognition of her many contributions.

In 1976 Gertrude learned that she had leukemia but remained sure that she would conquer it up to the end. She even continued construction of a new house, unfortunately not completed until a week after her death. While under treatment at Duke University Hospital she kept detailed records of her progress, and her doctor often referred to them. With characteristic testy humor she called herself "the experimental unit", and died as she had lived, fighting to the end. To those who were fortunate to be with her through so many years, Raleigh will never be the same.

There are published obituaries and biographies of Gertrude Cox [1–3].

Cox's Test of Randomness

There are occasions when it is necessary to determine whether a series of events has occurred at random. Barnard [1] provides a simple test using the result that if the series is random, then the instants of occurrence of events in a finite interval constitute a random sample from a rectangular distribution. Cox [3] gives a test of randomness against the alternative that the series has some trend in the rate of occurrence of the events. Let n events occur at times $t_1, \ldots, t_n$ in the interval $(0, T)$ and assume that Pr[an event occurs in $(t, t + \delta t)] = \lambda(t) + o(\delta t)$, where δt is a small interval of time. Cox demonstrated that, if $\lambda(t) = \alpha \exp(\beta t)$, then an appropriate statistic to test $H_0 : \beta = 0$ against the alternative $H_1 : \beta \neq 0$ is $\hat{\beta} = \sum_{i=1}^{n} t_i / nT$. The probability distribution of this statistic under H_0 is the Irwin–Hall distribution with mean $\frac{1}{2}$ and variance $1/12n$. Bartholomew [2] shows that for $n \geq 20$ the distribution of $\hat{\beta}$ tends rapidly to normality, and calculates the power function of the test for $n = 5$. Mansfield [4] gives further power function values for $n = 20(10)80, 100, 200$, for both one- and two-tailed tests. Details of test statistics that can be used to detect other types of nonrandomness are given in [3]. For example, a statistic is given for the case where successive intervals between events are assumed to be correlated.

Cramér–Rao Inequality

The Cramér–Rao inequality provides a lower bound for the variance of any **unbiased** estimator of a one-dimensional parameter θ in the probability density function (pdf) of the observed **random variable** or, more generally, of a given parametric function $g(\theta)$. The following regularity assumptions are made:

Assumption 1

The relation $\int p(x,\theta)\,\mathrm{d}x = 1$ for the pdf $p(\cdot,\theta)$ of random variable X can be differentiated twice with respect to θ under the integral sign.

Assumption 2

The relation $\int t(x)p(x,\theta)\,\mathrm{d}x = g(\theta)$ for any unbiased estimator $T = t(X)$ of $g(\theta)$ can be differentiated with respect to θ under the integral sign.

Assumption 1 requires that the support of the distribution (i.e. the range of the random variable X) does not depend on θ. If the random variable X above happens to be multi-dimensional, say $(X_1, X_2, \ldots, X_n)$, of continuous components, then the integral in Assumptions 1 and 2 has to be interpreted as an n-dimensional integral. However if X, or its components X_i, are discrete random variables, then the integral in Assumptions 1 and 2 is to be replaced by the summation symbol.

For the unbiased estimator $T = t(X)$ of $g(\theta)$ the basic form of the Cramér–Rao inequality is

$$\mathrm{var}_\theta(T) \geq \frac{[g'(\theta)]^2}{I(\theta)}, \tag{1}$$

due to Cramér [4] and Rao [7]; the lower bound on the right-hand side of the inequality is usually referred to as the *Cramér–Rao lower bound (CRLB)* for the variance of the unbiased estimator of $g(\theta)$. In (1), $g'(\theta)$ is the first derivative of g, and $I(\theta)$ is the Fisher **information** in (the pdf of) X, defined by

$$I(\theta) = \mathrm{E}_\theta\left[\frac{\partial \log p(X,\theta)}{\partial\theta}\right]^2. \tag{2}$$

In the special case $X = (X_1, \ldots, X_n)$, when we have independent and identically distributed components X_i in the *random sample* X, each with pdf $f(\cdot,\theta)$, $I(\theta) = ni(\theta)$, where

$$i(\theta) = \mathrm{E}_\theta\left[\frac{\partial \log f(X_1,\theta)}{\partial\theta}\right]^2, \tag{3}$$

the Cramér–Rao inequality (1) reduces to the form

$$\mathrm{var}_\theta(T) \geq \frac{[g'(\theta)]^2}{ni(\theta)}. \tag{4}$$

The Cramér–Rao inequality (1), and its special form (4), sometimes have been referred to as the information inequality, and the CRLB as the information bound. For the particular case $g(\theta) = \theta$, the numerator on the right-hand sides of both (1) and (4) reduces to 1.

The Cramér–Rao inequality has been generalized in a number of directions. Of special interest is the generalization for the case of d-dimensional parameter $\boldsymbol{\theta}$ with components θ_j, $j = 1, \ldots, d$ for $d \geq 1$. The regularity assumptions (Assumptions 1 and 2 above) are now needed with respect to elements θ_j of $\boldsymbol{\theta}$ for unbiased estimators $T_i = t_i(X)$ of the parametric function $g_i(\boldsymbol{\theta})$, $i = 1, 2, \ldots, r$.

Let $\mathbf{I}(\boldsymbol{\theta})$ be the $(d \times d)$ *Fisher information matrix* with elements

$$I_{jk}(\boldsymbol{\theta}) = \mathrm{E}_{\boldsymbol{\theta}}\left[\frac{\partial \log p(X,\boldsymbol{\theta})}{\partial\theta_j}\,\frac{\partial \log p(X,\boldsymbol{\theta})}{\partial\theta_k}\right],$$

for $j, k = 1, \ldots, d$, and $\mathbf{G}(\boldsymbol{\theta})$ the $r \times d$ matrix of partial derivatives

$$G_{ij}(\boldsymbol{\theta}) = \frac{\partial g_i(\boldsymbol{\theta})}{\partial\theta_j}, \quad i = 1, \ldots, r; j = 1, \ldots, d.$$

In addition to generalized versions of the regularity assumptions (Assumptions 1 and 2) we now need also the following:

Assumption 3

The information matrix $\mathbf{I}(\boldsymbol{\theta})$ is positive-definite.

The generalized form of the Cramér–Rao inequality (1) is (see, for example, [8])

$$\mathrm{cov}_{\boldsymbol{\theta}}[\mathbf{T}] \geq \mathbf{G}(\boldsymbol{\theta})\mathbf{I}^{-1}(\boldsymbol{\theta})\mathbf{G}'(\boldsymbol{\theta}). \tag{5}$$

Here $\mathbf{T}$ is the vector of unbiased estimators T_i of $g_i(\boldsymbol{\theta})$, $i = 1, \ldots, r$, and the notation $\mathbf{A} \geq \mathbf{B}$ for any two nonnegative-definite matrices means that the matrix $\mathbf{A} - \mathbf{B}$ is nonnegative-definite.

For the special case $r = d$ with $\boldsymbol{g}(\boldsymbol{\theta}) = \boldsymbol{\theta}$, the matrix inequality (5) reduces to the simpler form

$$\mathrm{cov}_\theta(\mathbf{T}) \geq \mathbf{I}^{-1}(\boldsymbol{\theta}), \tag{6}$$

for the covariance matrix $\mathbf{T}$ of unbiased estimators of $\boldsymbol{\theta}$.

When equality is attained for the two sides of inequality (1) for some unbiased estimator T of $g(\theta)$, it then follows that T is indeed the uniformly **minimum variance unbiased estimator** (UMVUE) of $g(\theta)$. Furthermore, under the regularity conditions (Assumptions 1 and 2), and some further technical conditions, it can be shown that the pdf of X has to belong to the one-parameter **exponential family** of the form

$$p(x, \theta) = \exp[a(\theta)T(x) + b(\theta) + c(x)], \tag{7}$$

for some real-valued functions $a(\cdot)$, $b(\cdot)$ of θ, and $c(\cdot)$ of x.

It should be noted that, when the form (7) holds for the pdf $p(\cdot, \theta)$, the equality is attained for the two sides in (1) only for the statistic T in (7) or its linear transforms $T^*(x) = c_1T(x) + c_2$, for some constants c_1 and c_2. Thus, the CRLB is attained only for unbiased estimation of parametric functions of the form $g(\theta) = c_1\mathrm{E}_\theta[T(X)] + c_2$, when X has pdf (7).

It has to be emphasized, however, that UMVUE estimates $T = T(X)$ can exist for unbiased estimation of $g(\theta)$ without attaining the CRLB; thus, the two sides of (1) might not be equal even when the pdf $p(\cdot, \theta)$ satisfies the form (7).

An analog of the Cramér–Rao inequality, when the regularity assumptions (Assumptions 1 and 2) are not necessarily met, is given by Chapman & Robbins [3], while Wolfowitz [9] has given the extension to sequential sampling situations. Bhattacharya [2] has given a more stringent inequality, using higher-order derivatives along with the first-order derivative of log $p(\cdot, \theta)$ used in the basic inequality (1). Similarly, for estimation of functions of parameters of interest $\boldsymbol{\theta}_1$, of d_1 dimensions, in the presence of unknown nuisance parameters $\boldsymbol{\theta}_2$, of d_2 dimensions, Bhapkar & Srinivasan [1] have given a more stringent inequality than (5) for the general case $d_1 \geq 1$, $r \leq d_1$ with $d_2 \geq 1$; the special case $r = d_1 = 1$ follows from the generalized information function developed by Godambe [6]. Gart [5] has given an extension of the inequality when the parameters $\boldsymbol{\theta}$ are themselves random variables.

Critical Care

Over the last three decades, critical care has emerged as one of the most important and expensive aspects of medicine. There are over 6000 intensive care units (ICUs) in the United States today, caring for 55 000 patients per day [15]. The cost of this care is approximately 180 billion dollars, or almost 1% of the United States gross domestic product. The randomized controlled trial (RCT) has become the "gold" standard for clinical research (*see* **Clinical Trials, Overview**). This is also true for research in critical care; however, the complex nature of critical illness has made the design and conduct of RCTs difficult. Historically this has led to clinical decision based on **observational studies** or poorly controlled clinical trials. A recent review of RCTs published in a prominent critical care journal in the two decades up to 2000 found that only 25% of 173 trials could be considered adequate [9]. Over the last several years, several large well-designed RCTs have been published, which have resulted in major therapeutic advances in the treatment of the critically ill.

Research in critically ill patients presents unique challenges [7]. The disease processes are often not well defined but are described as a constellation of clinical findings, or syndrome. As such, definitions are often imprecise and variable. There are also multiple therapeutic interventions being administered and the disease processes themselves often have a variable clinical course. Finally, **outcome** selection is a challenge, mortality (short or long) versus nonmortality outcomes. These latter decisions have a major impact on ultimate determination of efficacy or effectiveness (*see* **Pharmacoepidemiology, Adverse and Beneficial Effects**).

Adding to the difficulty in conducting studies in the critically ill is the identification and enrollment of patients. To answer many of the clinical questions in critical care, large numbers of patients are required. While a particular clinical syndrome may be common in critically ill patients in general, often no single institution has enough patients to achieve a study of adequate size. Therefore, it is uncommon for any single center to be able to recruit patients in sufficient numbers within a reasonable time frame. This has led to a trend to large **multicenter studies**. In addition to improving the ability to recruit patients, multicenter trials potentially have greater generalizability as they account for practice difference across ICUs. A final issue is the difficulty in obtaining informed consent (*see* **Ethics of Randomized Trials**). This issue contributes to increasing difficulty in conducting research in a critically ill patient population [4, 11]. Regulations governing who can serve as a surrogate to provide consent for participation in a research study in those circumstances when patients are unable to give consent for themselves are becoming stricter. This is a particularly important issue for research in the ICU where patients often are not able to provide consent for themselves.

The last few years have seen the publication of the results of five RCTs that have had a major impact on the practice of critical care. These trials are notable in that they have all demonstrated mortality benefit for large populations of critically ill and in four of the five trials, the intervention involved simple changes in clinical practice rather than novel therapeutic agents.

Blood Transfusion

Critically ill patients are often anemic and as a result receive a large number of red blood cell (RBC) transfusions [5, 17]. However, over recent years, questions have arisen over both the safety and efficacy of RBC transfusion. Hebert and colleagues [8] compared two transfusion strategies: a restrictive strategy, maintaining a hemoglobin level between 7 and 9 $g\,dL^{-1}$ with a transfusion threshold of 7 $g\,dL^{-1}$; and a liberal strategy, maintaining a hemoglobin level between 10 and 12 $g\,dL^{-1}$ with a transfusion threshold of 10 $g\,dL^{-1}$. Because the entry criteria for the study specified a hemoglobin $\leq 9\,g\,dL^{-1}$, all patients in the latter group received an RBC transfusion. Patients in the restrictive group received 50% less RBC transfusions. All results favored the restrictive group, and in those patients who were younger ($\leq$55 years of age) and less sick (APACHE score $<$20), a liberal strategy resulted in a significant increase in mortality. The conclusion from this study was that a restrictive transfusion strategy was at least equivalent and in some patients superior to a more liberal transfusion strategy. This study has challenged long-standing beliefs regarding transfusion thresholds and transfusion practice.

Goal-directed Resuscitation

There is a long history of attempting to target resuscitation to physiologic endpoints in the critically ill patient with sepsis. The rationale for this is that there is an imbalance at the tissue level between oxygen delivery and demand and that by "optimizing" delivery, end organ damage could be prevented and survival thereby improved [2]. Unfortunately, these efforts have met with little success. Rivers and colleagues [14] in an RCT evaluated the efficacy of early goal-directed therapy initiated in the emergency room, prior to their ICU admission. As compared to "standard" therapy, early goal-directed therapy resulted in a significant reduction in mortality and organ failure (30.5% versus 46.5%, $p < 0.009$). The results from this study have major implications for the practice of critical care. The study highlights the importance of early identification of critically ill patients and early initiation of appropriate therapy, including initiation of therapy prior to arrival into the ICU.

Insulin Therapy

Hyperglycemia is common in critically ill patients, whether or not patients have a history of diabetes. Although it has been suggested that hyperglycemia may be associated with an increase in complications, there is little data on the impact of glucose control on clinical outcomes in the critically ill [12]. Van den Berghe et al. [16] in an RCT of patients receiving mechanical ventilation compared intensive insulin therapy (to maintain blood glucose between 80 and 110 $\mathrm{mg\,dL^{-1}}$) with standard therapy (insulin infusion for blood glucose $>215\,\mathrm{mg\,dL^{-1}}$ with maintenance between 180 and 200 $\mathrm{mg\,dL^{-1}}$). Intensive insulin therapy was associated with reduced mortality versus standard therapy (4.6% versus 8.0%, $p < 0.04$). This was a result of the mortality benefit in patients who remained in the ICU for more than five days (10.6% versus 20.2%, $p < 0.005$). This study demonstrates that normalization of blood glucose with insulin therapy resulted in a dramatic improvement in morbidity and mortality.

Acute Respiratory Distress Syndrome

Mortality for patients with acute respiratory distress syndrome (ARDS) is 40 to 50% [6]. The traditional approach to mechanical ventilation in these patients has involved the use of tidal volumes of 10 to 15 $\mathrm{ml\,kg^{-1}}$. However, it has been suggested that mechanical ventilation with tidal volumes in this range may in fact exacerbate lung injury. The ARDS Network conducted an RCT in patients with ARDS comparing a low tidal volume strategy with traditional mechanical ventilation [1]. This trial was terminated early because of mortality reduction in the lower tidal volume group (31% versus 39.8%, $p < 0.007$). In addition, patients in the low tidal volume group increased the number of days without ventilator use.

Sepsis

In the United States, 750 000 cases of sepsis occur each year of which 225 000 are fatal [10]. Over the last two decades, over 20 clinical trials have been conducted on therapeutic agents for sepsis [13]. These trials have failed to demonstrate any clinical benefit. Bernard et al. [3] performed an RCT evaluating the efficacy of activated protein C in severe sepsis. Activated protein C has antithrombotic, anti-inflammatory, and profibrinolytic properties. The mortality rate in the **placebo** group was 30.8% as compared to 24.7% with activated protein C. This was the first trial to demonstrate a benefit to therapeutic interventions directed towards interrupting the pathologic cascade initiated by sepsis.

HOWARD L. CORWIN

Critical Region

To test a statistical hypothesis, one must define a rule for determining when to "accept" or "reject" the specified hypothesis (*see* **Hypothesis Testing**). This rule is usually, but not always, based upon observed data. The set of observations that corresponds to the rejection of the specified hypothesis is said to be the *critical region* of the test. The steps for performing a test for a given statistical hypothesis are straightforward. First, one observes a *random sample* of data. Next, one determines whether this observed random sample is contained in a predefined critical region. This is usually done by calculating a statistic (e.g. the sample mean) based on the observed data and determining whether the statistic is contained within the critical region. If the sample (i.e. statistic) is in the critical region, then one rejects the hypothesis. The *size* of the critical region is also referred to as the size of the test (which is often denoted by α; *see* **Level of a Test**). The size of the test is the probability that the observed data would have fallen into the critical region if the hypothesis were true. It is important to note that there may be several possible critical regions for a fixed size of a test. For instance, for the normal distribution, if one chooses the size of the test equal to 0.05, then the following critical regions are all possible:

1. values of the statistic either larger than 1.96 or smaller than -1.96 (a two-tailed test)
2. values of the statistic larger than 1.645 (a one-tailed test; *see* **Alternative Hypothesis**)
3. values of the statistic larger than 1.75 or smaller than -2.326 (a two-tailed test with asymmetric cutpoints).

In all three examples, the critical region is different, and yet the size of the critical region (size of the test) is the same. Figure 1 shows three plots illustrating these three different critical regions.

Consider the following example. We wish to test the hypotheses as to whether the population mean, μ, for some normally distributed random variable is equal to μ_0 (some specified value) or whether it is larger than μ_0. We can write these hypotheses as $H_0 : \mu = \mu_0$ (the **null hypothesis**) and $H_a : \mu > \mu_0$ (the *alternative hypothesis*). Next, we define a rule for determining when to accept or reject the null hypothesis for a specified level of significance α. One rule may be that we reject the hypothesis if the mean of the observed data, $\overline{x}$, is larger than a specified value C. A common choice of C in this setting would be $C = \mu_0 + z_\alpha(\sigma/n^{1/2})$, where σ is the known standard deviation of the variable being studied, n is the sample size of the observed data, μ_0 is the hypothesized value of μ, and z_α is the value from a standard normal distribution which has α area above it and $1 - \alpha$ area below (i.e. for $\alpha = 0.05$, $z_\alpha = 1.645$ since the area above 1.645 in the standard normal distribution is 0.05 and the area below 1.645 is 0.95). One would then collect data, $X_1, \ldots, X_n$, and if the observed mean of these data, $\overline{x}$, was larger than C, then the null hypothesis would be rejected. For this example, the set of values of the test statistic $\overline{x}$ that leads to the rejection of the null hypothesis is the critical region.

Cronbach's Alpha

Cronbach's alpha, or coefficient alpha, is widely used to assess the internal consistency or reliability of multiple-item instruments. A multiple-item instrument, also called a multiple-item scale, measuring an underlying construct, or latent variable, is internally consistent if its items are highly intercorrelated. Cronbach's alpha measures this internal consistency [1].

The relationship between the latent variable and the actual responses to the items is known as the measurement model. The classical measurement model assumptions are that measurement errors for each item are random, are not correlated with one another, and are not correlated with the true score, or latent variable. Two additional assumptions called the parallel test assumptions are that the latent variable affects all items equally and that there is equal measurement error in each item. Coefficient alpha is defined as the proportion of variance attributable to the true score of the latent variable [2].

An equivalent model is generated by assuming that items cannot be measured without error, and that the total variation in the items can be partitioned into the true, or common, variation and the error variation [4]. The true variation is the variation in latent score values across the subjects. Coefficient alpha can then be viewed as the ratio of the true variation to the total variation.

We now present the derivation of coefficient alpha. Consider a latent variable which is measured by k distinct items $x_1, x_2, \ldots, x_k$. The x_is are observed data measured on a sample of n subjects. The variance–**covariance matrix** of the k items is

$$\mathbf{\Sigma} = \begin{bmatrix} \sigma_1^2 & \sigma_{12} & \ldots & \sigma_{1k} \\ \sigma_{21} & \sigma_2^2 & \ldots & \sigma_{2k} \\ \vdots & \vdots & \ldots & \vdots \\ \sigma_{k1} & \sigma_{k2} & \ldots & \sigma_k^2 \end{bmatrix}.$$

We assume that each observed item, x_i, can be used to estimate the latent variable Y. A better estimate of the latent variable is produced by summing the responses over the set of observed items. Let Y denote the summed rating scale $Y = \sum_{i=1}^{k} x_i$. The total variation in Y is the sum of the elements of $\mathbf{\Sigma}$: $\text{var}(Y) = \sigma_Y^2 = \sum_{j=1}^{k} \sum_{i=1}^{k} \sigma_{ij}$, where $\sigma_{ii} = \sigma_i^2$. The unique variation is the sum of the diagonal elements of $\mathbf{\Sigma}$, or $\sum_{i=1}^{k} \sigma_i^2$. The ratio of the unique, or noncommon, variation to the total variation in Y is given by $\sum_{i=1}^{k} \sigma_i^2/\sigma_Y^2$. The proportion of common variation, or true score variation, in Y is defined as: $1 - \sum_{i=1}^{k} \sigma_i^2/\sigma_Y^2$. Coefficient alpha is based on this proportion of common or true score variation, and is adjusted to reduce dependency on the number of items, k, as follows:

$$\alpha = \frac{k}{k-1}\left(1 - \left[\frac{\sum_{i=1}^{k} \sigma_i^2}{\sigma_Y^2}\right]\right).$$

As the proportion of true score variation accounted for by the observed items increases, the reliability increases. Higher reliability indicates less effect of random errors in the model.

Researchers interested in measuring an underlying construct or latent variable generally use either existing items (i.e. manifest or observed variables with known psychometric properties) or develop new items which relate to the underlying construct. For example, suppose a health maintenance organization (HMO) wishes to measure whether its patients are satisfied with their medical office visits. The underlying construct or latent variable is patient satisfaction. Suppose five items are created to measure patient satisfaction, one of which might be: "How satisfied are you with your physician's willingness to answer all of your questions during your office visits?" The response options for each item could be a **Likert scale**, as shown in Table 1.

Suppose the items are administered by questionnaire to a random sample of patients from the HMO. To evaluate whether a reliable, multiple-item satisfaction measure exists (i.e. whether the five items are consistently measuring the underlying construct, satisfaction) requires a series of, sometimes iterative, analyses. First, all of the items must be scored in the same direction (e.g. higher scores indicate more patient satisfaction for every item). Then the distributional properties of the items must be evaluated. Specifically, the means and standard deviations

Table 1

Not satisfied	Somewhat satisfied	Neither satisfied nor unsatisfied	Satisfied	Very satisfied
1	2	3	4	5

should be approximately equal (parallel tests assumption). If the distributional properties of the items are similar, then coefficient alpha is computed according to the formula shown above. The value of coefficient alpha is then evaluated (see guidelines below). If coefficient alpha is in the acceptable range, then a multiple-item scale is constructed. If coefficient alpha is not in the acceptable range, investigators should examine individual items carefully (see below and [3] for examples).

The theoretical range of coefficient alpha is 0 to 1. Suggested guidelines for interpreting coefficient alpha are: <0.60 unacceptable, 0.60–0.65 undesirable, 0.65–0.70 minimally acceptable, 0.70–0.80 respectable, 0.80–0.90 very good, and >0.90 consider shortening the scale by reducing the number of items [2].

Suppose, in our example, that the five items are highly consistent, with an observed coefficient alpha of 0.80. Here, each item has responses ranging from 1 to 5. The summed rating scale is computed by summing the five item responses for each patient. The theoretical minimum and maximum values for the satisfaction scale are 5 and 25, respectively.

Summed rating scales should not be created when items are not internally consistent (i.e. have a low alpha coefficient). If a set of items produces a low alpha coefficient, either there are too few items or the items have little in common. To assess the latter, the item–total correlations, which are the correlations between each individual item and the sum of the remaining items that constitute the scale, should be investigated. If a particular item has a low item–total correlation, it should be dropped from the scale and coefficient alpha should be recomputed.

Cronbach's alpha is also used for split-half **reliability** assessment. In split-half reliability assessment a set of k items is randomly split into equal halves of $k/2$ items each. Scores based on the two halves are computed (e.g. $Y_1 = \sum_{i=1}^{k/2} x_i$ and $Y_2 = \sum_{i=k/2+1}^{k} x_i$) and correlated. Let r_{12} denote the correlation between Y_1 and Y_2. There are many ways to split the items into the two halves. Cronbach's alpha (as defined above) is equivalent to the lower bound on the correlation between scores derived on sets of $k/2$ items (i.e. Cronbach's $\alpha < r_{12}$ over all possible r_{12}).

Alternative formulas for coefficient alpha are the Kuder Richardson Formula 20 (KR-20), which is primarily used to assess the reliability of measures based on dichotomous items, and the Spearman–Brown prophecy formula which is based on the average interitem **correlations**, as opposed to covariances. The respective formulas are:

$$\alpha = \frac{k}{k-1}\left(1 - \left[\frac{\sum pq}{\sigma_Y^2}\right]\right),$$

where $p = \Pr$ (affirmative response in each dichotomous item),

$$q = 1 - p,$$

and

$$\alpha = \frac{k\overline{r}}{1 + (k-1)\overline{r}},$$

where $\overline{r}$ = the average interitem correlation coefficient.

Crossover Designs

Crossover trials are sometimes referred to as change-over or repeated measures designs, although the latter term is better reserved for the more general field of which crossovers form a part. They have been defined as follows: a crossover trial is one in which individual subjects are given sequences of treatments with the object of studying differences between individual treatments (or subsequences of treatments) [44].

Example 1

Graff-Lonnevig et al. [18] reported a crossover trial in asthma comparing single inhaled doses of 12 μg formoterol with a single inhaled dose of 200 μg salbutamol. Fourteen children with asthma were allocated at random to one of two sequences: formoterol followed by salbutamol or salbutamol followed by formoterol, and had their peak expiratory flow (PEF) measured at various times after treatment. One child (number 8) failed to complete both periods of treatment. PEF readings 8 h after treatment for the 13 other children for the two periods are given in Table 1, the last two columns of which need not concern us for the moment.

This is an example of the most studied type of crossover design, sometimes referred to as the two-period crossover and sometimes as the two-treatment, two-period crossover, but perhaps better designated, referring explicitly to the sequences employed, as the AB/BA design. (In this example we have A as formoterol and B as salbutamol or vice versa.) A schematic representation of such crossover trials is given in Figure 1.

Example 2

A crossover trial in migraine compared two doses (D1 and D2) of the potassium salt of diclofenac, a nonsteroidal anti-inflammatory drug, with placebo (P). Patients were allocated at random to one of six possible sequences of treatment: D1 D2 P, P D2 D1, D2 D1 P, D2 P D1, D1 P D2, and P D1 D2 [44].

In both of the above examples patients crossed over from one treatment to another, and this stratagem gives the design its name. In more complicated designs, however, not all patients cross over to all treatments and the essential feature is that which we have tried to capture in our definition. In both of the

		PEF			
Sequence	Patient number	Period 1	Period 2	Basic estimator	Two period totals
Formoterol/Salbutamol	1	310	270	40	580
	4	310	260	50	570
	6	370	300	70	670
	7	410	390	20	800
	10	250	210	40	460
	11	380	350	30	730
	14	330	365	−35	695
Formoterol/Salbutamol	2	370	385	15	755
	3	310	400	90	710
	5	380	410	30	790
	9	290	320	30	610
	12	260	340	80	600
	13	90	220	130	310

designs above the number of treatments equals the number of periods, but **incomplete block designs** in which the number of periods is inferior to the number of treatments are not uncommon, as in Example 3.

Example 3

A parallel assay comparing beta-agonists in asthma was run in seven treatments (three doses of a reference formulation, three doses of an experimental formulation, and placebo) and five periods [48]. The trial was planned to have 126 patients allocated in equal numbers to 21 sequences. In the end, 161 patients were recruited in 15 centers and four countries with an average of about seven and a half patients per sequence but with at least six patients on every sequence.

Designs in which the number of periods exceeds the number of treatments have also been studied extensively, if rarely applied. An example is provided by Ebbut [6], and these designs are discussed below.

Crossover trials are commonly used in drug development for various indications where the disease is chronic and relatively stable – asthma, hypertension, sleep disturbance, angina, diabetes, migraine, rheumatism, and epilepsy are examples. They are not suitable for life-threatening diseases, for the obvious reason that the patient may die and be unavailable for further study and, conversely, they are generally unsuitable for conditions in which a permanent cure may be affected.

The main advantage of the crossover trial is its extreme efficiency. Because each patient forms his or her own control (a feature which makes such designs intuitively attractive to the physician), an important source of variability present in parallel group trials (*see* **Clinical Trials, Overview**), the variability between patients, is eliminated. As a consequence, fewer patients are generally needed to form an adequate conclusion. A further potential advantage is that individuals' reactions to treatment may be studied (although to do this adequately requires crossover trials in which patients are repeatedly allocated to the same treatments). Crossover trials place a heavier burden of participation on the individual patient, however, whose time in the trial will be much longer than for a comparable parallel group trial and, therefore, the danger that patients will drop out is increased (as for patient 8 in Example 1). The total time to conclude a crossover trial may be longer, although this is rarely the case, since the recruitment phase is what dominates most trials and since fewer patients are required. The analysis of crossover trials is also more complex and controversial than for parallel group trials and, as noted above, the design is suitable only for certain indications. A potential problem with crossover trials, which is dealt with in detail below, is that of carry-over.

As a consequence of these potential advantages and disadvantages, crossover trials are more extensively used in **Phase I** and **Phase II trials** than in the long-term therapeutic studies which characterize phase III. They are by far the most popular choice of design for **bioequivalence**. For the indications in which they may be used, they are generally much better at dose finding than are parallel group trials [49], the latter suffering from the fact that they require group averages to study effects which operate on the individual level. They are more likely to be used for single-dose pharmacodynamic studies of an explanatory nature (*see* **Pharmacokinetics and Pharmacodynamics**) than for multiple-dose therapeutic trials of a pragmatic nature. They are the design of choice for studying individual reactions to treatment [44]. Because of the potential problem of carry-over, they are generally viewed with suspicion by drug regulatory agencies. However, they are extremely popular in certain indications as independent physician-initiated trials, for the simple reason that they are often the only trials that have adequate **power** when run in a single center.

Carry-Over

A standard assumption in the design and analysis of experiments is that there is no interference between units or treatments given to units – for example, that crops growing in one part of a field and treated with a given fertilizer do not affect the growth of crops treated in another plot with an alternative fertilizer. In many medical investigations this assumption is often (and generally safely) ignored, but there are cases where it could conceivably break down. For example, if depressive patients in a trial are together on one ward, affecting the mental state of some may have an indirect effect on others. Similarly, a trial of prophylactic education of homosexual men regarding transmission of human immunodeficiency virus (HIV) may reduce the chance of infection

amongst those not selected to receive such education, either by reducing infection amongst potential sexual contacts or by an indirect spread of the relevant knowledge. In crossover trials, the experimental units are *episodes* of treatment rather than patients (*see* **Unit of Analysis**). If the treatment given in one period continues to affect the patient when subsequently treated, then this *carry-over* of the treatment effect is an example of interference between units. It can have serious consequences for the interpretation of treatment effects because we may imagine that we are studying the response to a single treatment, when in fact we are also observing a residual effect of a previous treatment. Carry-over is regarded by many commentators as being the outstanding problem of crossover trials and, indeed, having been evoked, it will continue to have a residual effect throughout the rest of this article.

Different types of carry-over can be envisaged. However, for reasons to be explained, we shall make the following restrictions on carry-over. First, we assume that it cannot disturb the conclusions of a trial unless there is a genuine difference between treatments, and secondly that a carry-over is a true residual effect of a treatment. These may seem to be an unrealistic restrictions. For example, we can surely envisage cases where otherwise similar but synergistic drugs (*see* **Synergy of Exposure Effects**) may have unequal persistence. In that case, where the shorter persisting drug is given second, it will benefit from an **interaction** which will be denied to the longer persisting drug when it is given second. The reason for ignoring such exotic cases is that similar problems can also be envisaged as affecting parallel group trials. Consider our Example 1. Salbutamol is a standard treatment for asthma developed in the 1960s, whereas formoterol is a newer treatment first registered in the UK in the 1990s and (at the time of writing) not yet available in the US. Most patients recruited to trials of formoterol had been taking salbutamol for many years. Thus a parallel group design would really be as illustrated in Figure 2. There are thus two ways at least in which carry-over could affect parallel group trials comparing formoterol to salbutamol. First, given some persistence of the effects of salbutamol beyond whatever wash-out period was instituted, there could be a salbutamol–formoterol synergy from which patients in the formoterol group could benefit but which those in the salbutamol group would be denied. Secondly, patients recruited could have tachyphilaxis to salbutamol and be no longer capable of showing the same effect with that drug. Both of these phenomena are extremely unlikely to be important, and since they would also be extraordinarily difficult to guard against, there is no point in organizing parallel group trials to deal with them. But, by the same token, we must not saddle crossover trials with these problems either. This is not to say that interactions between carry-over and treatments are necessarily unimportant (where carry-over is appreciable they may be), but that it is pointless to attempt to deal with the problem of carry-over for the case where there is no treatment effect at all. As a consequence, whereas carry-over may affect the power of a test of the effect of treatment, we shall assume that it cannot affect its size.

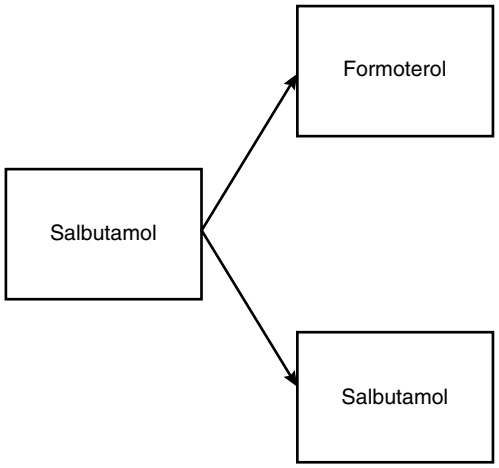

Figure 2 Illustration of the likely position in any parallel group trial in asthma comparing formoterol with salbutamol

Similarly, we shall not consider the related problem of period by treatment interaction. A comparable problem also affects parallel group trials. For example, three-month parallel group trials in asthma are commonly employed to support the registration of drugs, which may be then be taken by patients for a lifetime. This extrapolation requires an assumption about time-by-treatment interaction which, although not identical to period by treatment interaction (see below), is analogous. (The difference is essentially that in a parallel group trial a patient's time on the trial is, largely, time on the treatment.)

Periods

The word *period* is commonly used in the literature on crossover trials to describe the different occasions on which patients are treated. As we shall see, period effects are also commonly fitted in the models used to analyze crossovers. Two points are worth noting in this respect. First, the patients on clinical trials are rarely recruited at the same time, and crossover designs are no exceptions. Thus, one patient's period 2 may actually occur before another's period 1. Secondly, for multiple-dose crossover trials, in which the object is to study the steady-state effect of treatment, the trialist must determine the length of the period. The relevant primitive design constraint for such trials is likely to be the total length of time for which it is considered reasonable to have a patient on the trial. The number of periods is then a derived design constraint given the estimated time it takes for a patient to reach the steady state. This point has been misunderstood in much of the literature on optimal design of multiperiod crossovers, in which it has been implicitly assumed that the number of periods available is an absolute constraint, within which one must produce designs and associated analyses which guard against carry-over. In fact, by increasing the length of a period at the cost of reducing the number of periods, the trialist may reduce the risk of carry-over. The sort of assumptions necessary are no different in kind from the one commonly made that carry-over lasts for one period only. Obviously if this is true and the periods are made twice as long, carry-over can be eliminated completely.

Wash-Out

In designing crossover trials, precautions are commonly taken to attempt to eliminate carry-over. A period in which the residual effect of a treatment is presumed to disappear is known as a wash-out, although this is often a rather arbitrary label. In single-dose pharmacodynamic trials, the object of a crossover is to study onset of action as well as duration. The trialist has to determine how long after the previous treatment was given the next should be administered. The distinction between wash-out and treatment period is then essentially arbitrary. The treatment period is deemed to end once the trialist stops measuring the effect of a drug and the next treatment period starts once the next treatment is administered. The difference between the two is a wash-out, but essentially the trialist is faced with the task of determining the minimum *total* time interval between treatments. (In many trials the period varies from patient to patient, subject only to the constraint of a predetermined minimum, and the patient will take his or her regular treatment for at least some of the time between trial treatments. Both of these points are regularly overlooked.) For multiple-dose trials, where the object is to study the steady state, an active wash-out may be instituted: the effect of a previous treatment is presumed to wear off gradually during the period in which the following treatment is applied. For the purpose of analysis, measurements from the latter part of a period only are used. Thus the trialist's task is to determine the minimum total time between application of the first treatment and measurement of the effect of the second. A third case is where we have multiple-dose studies but wish to study onset of action as well. In this case there is little choice but to disrupt the rhythm of regular treatment and have a true wash-out in which no treatment is given at all. This is often considered to be a practical obstacle to running crossover trials, but it should be noted that it only arises from the need to study the onset of action and that, if this is the purpose, the need for a wash-out period will arise in a parallel group trial also, the difference being that the patient in a crossover trial will have at least two periods of wash-out rather than just one.

A Brief Historical Note

As with many experimental designs, crossover trials received an early application in agricultural research. Jones & Kenward [25] describe an experiment carried out in the nineteenth century over a long series of years at Rothamsted by John Lawes, in which each member of a pair of plots was treated either with minerals or ammonia. In clinical crossover trials, the main source of variability is usually patients rather than periods. In Lawes' experiment it would be years (owing to the weather) rather than plots. From one point of view, therefore, Lawes' experiment is an AB/BA crossover with plots taking the place reserved for periods in clinical crossovers and years being used for replication in the way that patients are. (If the plots were neighboring, the carry-over could occur both down the years and from plot to plot!)

An early crossover trial in medicine is the investigation published in 1905 by Cushny & Peebles [5] of the hypnotic effects of optical isomers. The data were used for illustrative purposes by Student (*see* **Gosset, William Sealy**) in his famous paper [11, 40, 47, 51]. Simpson's 1938 paper [50] provides an example of their use in studies of nutrition. Crossover trials are also covered in **Cochran** & **Cox's** famous book, although the applications considered are not medical [4]. Finney's 1956 paper [10] is important and considers the design of crossover trials for use in bioassay (*see* **Biological Assay, Overview**), a topic which had been considered with particular relevance to insulin assay earlier by **Irwin** [24] in 1937 and Fieller [9] in 1940, and even earlier by Marks in 1925 in the medical literature [35]. A burst of methodological investigation into the AB/BA crossover was initiated in the 1960s by the papers by Chassan [2] and Grizzle [22], the latter being extremely influential in its proposal of a two-stage approach to the analysis of such trials. This approach was endorsed with some hesitancy by an influential paper by Hills & Armitage [23], but was eventually shown to be potentially extremely misleading by Freeman [16], whose paper has set the agenda for current research into the AB/BA design. **Bayesian** approaches in bioequivalence were proposed by Selwyn et al. [43] in 1981, and an alternative method for crossover trials in general has been developed by Grieve [19–21, 41] in a series of papers starting in 1985. Koch [29] proposed a **nonparametric** approach for analysis in 1972. Early papers considering multiperiod designs are those of Simpson [50] (mentioned above) and **Yates** [54], also from 1938. Williams [53] in 1949 explicitly proposed designs for balancing the residual effects of treatment. Other influential papers will be mentioned in appropriate Sections below.

The AB/BA Crossover

The Basics of Analysis

This is the simplest of all crossover designs for the purpose of comparing two treatments, and is illustrated in Example 1. The fact that there is an extensive literature associated with such an apparently simple design may come as a surprise to those unfamiliar with the field. The reason has to do with carry-over. To discuss the effect of carry-over in detail it is necessary to introduce a model for the AB/BA design. However, since, given an assumption that carry-over has *not* taken place, a very simple analysis of such a design is possible, and which has some claims to being as good, if not better, than any other, it is perhaps worth postponing the model until this analysis has been explained. The method has been clearly described by Hills & Armitage [23].

The first step is to calculate for each patient what has been referred to as a *basic estimator* [44] or crossover difference [29]. This is the difference for a given patient between the two treatments and is what we should be constrained to use as our estimate of the treatment effect, τ, were we to have data only on the given patient. The basic estimator for each patient is reproduced in the last column of Table 1. It has been calculated as the reading under formoterol minus that under salbutamol. Thus, for patients of the first sequence it is the period 1 value minus the period 2 value, whereas for patients in the second sequence it is the converse. Once the basic estimators have been calculated, there are then two standard approaches to analysis. One is to ignore the distinctions between sequences, treat the values as a single sample of data, and calculate estimates, ***P* values**, and confidence intervals accordingly. A parametric approach uses the (matched pairs) t test (*see* **Student's *t* Distribution**), and the nonparametric equivalent is the **Wilcoxon signed-ranks test**, or even the **sign test**. For a **randomization**-based mode of inference (*see* **Randomization Tests**), these methods are compatible with a design in which patients have been allocated completely at random to the two sequences [44]. If the matched-pairs t test is applied to the basic estimators here, it will be found that the mean basic estimator is 45.4 l/min, its estimated standard error on 12 degrees of freedom is 11.3 l/min, the observed t ratio is 4.03, the critical values at the 5% level two-sided are ± 2.18, the 95% confidence limits are 21 l/min and 70 l/min, and the P value (two-tailed) is 0.0017.

The approach we shall concentrate on, however, *does* recognize the distinction between sequences. The first step is to calculate a separate mean of the basic estimators for each sequence. These two sequence means are 30.7 and 62.5. The difference between them is probably due to chance, but might conceivably be due to a period effect. For example, if there were a secular tendency for second period values to be higher, this would diminish basic estimators in the first sequence and increase them in the

second. This would have two consequences. First, conditional upon a given unbalanced allocation to the two sequences, a straightforward average of the basic estimators would be **biased**. (Of course, in a randomized design, over all possible allocations, it would not be biased.) A simple way of dealing with this is to block the design (*see* **Blocking**) so that there are equal numbers of patients per sequence, but this does not deal with the second difficulty, namely that under such circumstances the variance of the basic estimators calculated by treating them all as coming from a single sample will be inflated by a component due to the effect of the periods.

A simple solution which deals with both problems is to stratify on the sequences and take an unweighted average of the two sequence means. In this case, the unweighted average, which we denote $\hat{\tau}$, is 46.6 l/min. In general if the two sequences have n_1 and n_2 patients, respectively, then such a contrast will have a **variance** of $q\sigma^2/4$, where σ^2 is the variance of a basic estimator and $q = (1/n_1 + 1/n_2)$. The variance of a basic estimator may in turn be *estimated* using the standard approach of pooling within group sums of squares, familiar from the two-independent-samples t test, using

$$\hat{\sigma}^2 = \frac{(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2}{n_1 + n_2 - 2},$$

where S_1^2 and S_2^2 are the unbiased estimates of σ^2 from sequence groups 1 and 2, respectively. Putting this together, we may calculate a t statistic with indexed degrees of freedom as

$$t_{n_1+n_2-2} = \frac{\hat{\tau} - \tau}{(\hat{\sigma}/2)\sqrt{q}}. \qquad (1)$$

If we take τ as the value provided by some **null hypothesis** of interest (typically that $\tau = 0$), then we may use (1) in a significance or hypothesis test in the usual way (*see* **Hypothesis Testing**). Alternatively, by setting the left-hand side of (1) equal to some percentage point and treating τ as unknown, we may calculate a confidence limit for τ. For this example, $S_1^2 = 1086.9$, $S_2^2 = 1997.5$, and hence $\hat{\sigma} =$ 38.7 l/min. For $\tau = 0$, the t statistic is 46.6/10.8 = 4.3 and the P value is 0.0012. Alternately, since the critical values for a test at the 5% level (two-sided) on 11 degrees of freedom are $\pm$ 2.2, the 95% confidence limits are 23 l/min and 70 l/min.

An equivalent analysis to the above is to work with period differences rather than basic estimators. The difference between periods is then calculated in the same direction in each group so that the period differences in the second sequence group are simply the negative of the basic estimators. The semidifference between the two sequence means, rather than their average, now reflects the treatment effect. In fact, if all that is wanted is to test for the treatment effect, a two-sample t test may be used. Alternatively, if the semiperiod differences are calculated on the subjects in the first place, then a confidence interval may be calculated for τ using the two-sample t. The equivalent nonparametric approach is to use a **Wilcoxon–Mann–Whitney test** as proposed by Koch [29]. Alternatively, **Fisher's exact test** using the signs of the period differences or an adapted Brown–Mood median test may be used [44].

A Model for The AB/BA Design

The above analysis, most commentators would agree, adjusts the treatment effect adequately for any difference due to periods and also validly eliminates the effect of individual patients from the estimate of the standard error of the treatment effect. If, however, carry-over is present, then the estimator of τ is biased. This is not, necessarily, a compelling reason for abandoning this approach [44], but the possible bias has led statisticians to look at the problem of carry-over in depth. To follow these arguments we now introduce a model for carry-over as follows.

Let Y_{ijk} be the response of subject j, $j = 1, \ldots, n_1$ or n_2, of sequence $i, i = 1, 2$, in period $k, k = 1, 2$. (Thus both i and j are necessary to identify a given subject.) Then let

$$Y_{ijk} = \alpha_{ik} + s_{ij} + \varepsilon_{ijk}, \qquad (2)$$

where α_{ik} is an effect common to all subjects in a given sequence in a given period, s_{ij} is an effect due to the given subject which may, according to the circumstance, be treated as either fixed or random, and ε_{ijk} is a random error term. The ε_{ijk} are assumed to be independent with constant variance γ^2 and, where the s_{ij} are treated as random (*see* **Random Effects**), they are taken to be independently distributed both of each other and the ε_{ijk}, with constant variance ϕ^2. (Note that σ^2, as previously defined, is $2\gamma^2$.) This is a components of variance

(*see* **Variance Components**) approach which is commonly used. An alternative formulation of the random effects model [22], which is more general, is to model a combined error term ξ_{ijk} with a block diagonal form for variances and covariances so that **correlations** between observations on the same patient are equal to ρ and correlations of observations between different patients are zero. Such a formulation allows for the theoretically possible, but unlikely, case where the correlation between observations on the same patient is negative. If, however, the components of variance model is correct, then since $\xi_{ijk} = s_{ij} + \varepsilon_{ijk}$ we have $\rho = \phi^2/(\phi^2 + \gamma^2)$, which can never be negative. We continue with the components of variance approach.

The next step is to model the α_{ik} terms. A possible parameterization is given in Table 2, with treatment effect τ indexed by the treatment labels A and B, period effects, π indexed 1 and 2, and carry-over effects λ indexed by engendering and perturbed treatment and general level μ. The object of the crossover trial is then to make inferences about the contrast $\tau_A - \tau_B$, equivalent to τ in our previous formulation. Also given in Table 2 are four cell means, each of which is an unbiased estimate of the combination of parameters in the same cell. Three linear combinations of these cell means have been much studied in the literature and, together with their expectations, are given in Table 3. The names of the contrasts are as used by Freeman [16] and Senn [45].

The first of these, CROS (for crossover), is nothing less than the simple estimate, $\hat{\tau}$, of the treatment effect we encountered above. This can now be seen to be a biased estimator of τ, except where the differential carry-over effect, $\lambda = \lambda_{AB} - \lambda_{BA}$, is zero. This will most plausibly be the case where both λ_{AB} and λ_{BA} are zero, i.e. when the wash-out has been successful in eliminating carry-over. In other cases, the estimator is biased downward by half the differential carry-over (hereafter simply referred to as the carry-over). As a consequence, where this occurs, there will be some loss of power associated with the test of the treatment effect.

The second linear combination, SEQ (differences between sequences), has an expectation equal to the carry-over, and the third, PAR (so called because it is a between-patient contrast using first-period data only and hence of the sort commonly used in a parallel group trial), is an unbiased estimator of the treatment effect. The three linear combinations have been presented in terms of the four cell means given in Table 2. Each corresponds, however, to the difference between the two sequence groups of the mean over all the patients in the group of a simple summary statistic calculated for each patient. For PAR (L_p), this summary statistic is simply the first period value. For SEQ (L_s), it is the total over two periods, and for CROS (L_c), as already discussed, it is the semidifference between the first and second period values. Note that these statistics are related by the

Table 2 Model for the AB/BA design

		Period 1 ($k = 1$)	Period 2 ($k = 2$)
Sequence	AB ($i = 1$)	$\mu + \tau_A + \pi_1$ $\overline{Y}_{1.1}$	$\mu + \tau_B + \pi_2 + \lambda_{AB}$ $\overline{Y}_{1.2}$
	BA ($i = 2$)	$\mu + \tau_B + \pi_1$ $\overline{Y}_{2.1}$	$\mu + \tau_A + \pi_2 + \lambda_{BA}$ $\overline{Y}_{2.2}$

Table 3 Linear combinations of the cell means

Name	Label	Definition	Expectation
CROS	L_c	$[(\overline{Y}_{1.1} - \overline{Y}_{1.2}) + (\overline{Y}_{2.2} - \overline{Y}_{2.1})]/2$	$(\tau_A - \tau_B) - (\lambda_{AB} - \lambda_{BA})/2$ $= \tau - \lambda/2$
SEQ	L_s	$(\overline{Y}_{1.1} + \overline{Y}_{1.2}) - (\overline{Y}_{2.2} + \overline{Y}_{2.1})$	$(\lambda_{AB} - \lambda_{BA})$ $= \lambda$
PAR	L_p	$\overline{Y}_{1.1} - \overline{Y}_{2.1}$	$(\tau_A - \tau_B)$ $= \tau$

relationship $L_p = L_c + L_s/2$. Of the three summary statistics, only CROS eliminates the subject effect given by s_{ij} in (2). Therefore, if we are interested only in this particular contrast, it is irrelevant whether the subject effect is assumed to be random or fixed since it is eliminated anyway. For the other two contrasts this is not the case, and it becomes necessary to treat the subject effects as random. (For the discussion that follows, this assumption is now made.) Given this assumption, the two-independent-samples t test may be used in connection with SEQ and PAR. If this is done for Example 1, then the means (estimated standard errors) are $L_s = 14.4(80.4)$ l/min and $L_p = 53.8(45.3)$ l/min, and the t statistics are 0.18 and 1.19, respectively, both on 11 degrees of freedom. Thus, if we are prepared to use the potentially biased estimate of the treatment effect for this example, then it is significant, but if we insist on using the unbiased estimate of the treatment effect, then it is not significant. The inconsistency of such inferences is not unusual and indeed is to be expected. Crossover trials are designed to be used with far fewer patients than parallel group designs, and one should not be surprised if an estimate which uses the within-patient structure of a trial is significant whereas one which discards half the data and is between-patient is not. The question then arises: can a reasonable choice be made between the two? For many years the accepted wisdom for crossover trials was that it could be. We now examine this procedure.

The Two-Stage Procedure

In Example 1, the estimate of the carry-over effect, L_s, is not significant, and this suggests no particular evidence that carry-over has occurred. Why not, therefore, use the within-patient estimator of the treatment effect, L_c? On the other hand, if L_s had been significant, it might seem to be more appropriate to use L_p. Grizzle [22] proposed a general strategy for testing crossover trials as follows (see Figure 3). First perform a test for carry-over. If this is not significant, perform the within-patient test of the treatment effect. However, if the test for carry-over is significant, use the between-patient estimator. Because the power of the preliminary test for carry-over is typically low, Grizzle suggested using a higher (less stringent) nominal level of significance of 10%. This general procedure came to be known as the *two-stage procedure*, and for many years was the accepted way of analyzing crossover trials.

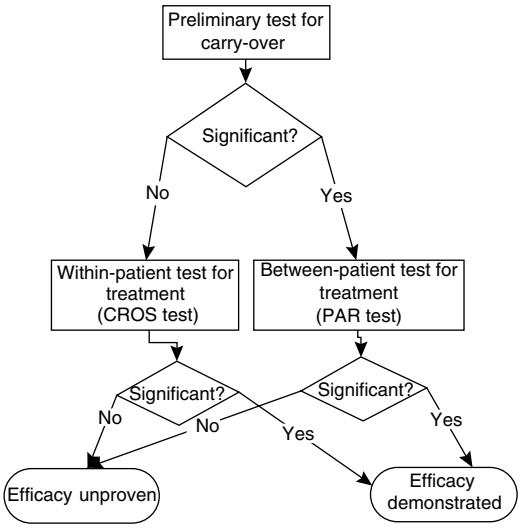

Figure 3 Schematic representation of the two-stage procedure

The fact that it now has few supporters amongst those researching in the field (for example, none of the three books devoted to crossover designs recommends it [25, 42, 44]) is due to the extremely important paper of Freeman's [16] which, analyzing the two-stage procedure as a whole, showed that it had a type I error rate of 7%–9.5% (depending on the correlation between successive measures, ρ for a claimed nominal level of 5%. (Note that, since we have claimed that carry-over cannot occur unless there is a treatment effect, a type I error can only be committed where there is no carry-over.) Freeman's result can be explained in a number of ways.

A simple explanation is that the test of carry-over, being a between-patient test, tends to show significance not only where there is genuine carry-over but also when, by chance, the patients in the two groups are very different. Under such circumstances, the last thing we should wish is to use a between-patient test of the effect of treatment, but this is precisely what the two-stage procedure leads us to do [44, 45]. An alternative explanation involves the variances of the contrasts. The argument for the two-stage procedure comes from considering the expectations of the contrasts, but considering their variances justifies the opposite procedure. As already discussed and as confirmed by the

main diagonal of the variance–**covariance matrix** given by Table 4, L_c has a much lower variance than that of L_p. Thus it is inevitable that they should often give very different answers. Furthermore, unless we should usually prefer the estimate given by L_c under the circumstance of their differing, there would be no point in using a crossover trial in the first place. However, $L_s = 2(L_p - L_c)$, so that, when the estimates differ, the contrast used for examining carry-over will tend to be large. Hence, based on the variances of the estimators, we should prefer CROS to PAR where SEQ is large, rather than vice versa.

A more formal explanation comes from considering the joint distribution of the three statistics. Table 4 gives not only the variances of the estimates but also their covariances. L_c and L_s are independent but L_p and L_s are highly correlated. The ratio of the covariance of L_p and L_s to the variance of L_s gives the **regression** of L_p on L_s, which is thus 1/2. In fact,

$$E[L_p|L_s] = \tau + \frac{L_s - \lambda}{2} \tag{3}$$

and the conditional variance is

$$\text{var}[L_p|L_s] = \frac{q\gamma^2}{2}. \tag{4}$$

Since L_c is independent of L_s, its expectation and variance are as given in Tables 3 and 4. We may note from (4), however, that conditional on L_s the variance of L_p is the same as that for L_c. This is, of course, an inevitable consequence of the fact that $L_p = L_c + L_s/2$. Furthermore, conditionally, L_p is not in general unbiased. Clearly, from (3) its bias is $(L_s - \lambda)/2$, and this is only zero where the carry-over is perfectly estimated. Of course, the expected value of $E[L_p|L_s]$ over the distribution of L_s is τ, but there are two objections to regarding this as having any relevance. The first is that in the two-stage procedure the use of L_p is *not* unconditional. Hence the unconditional expectation is irrelevant. Secondly, but for the possibility of carry-over, the value of L_s is a means of defining relevant subsets. Where such a relevant subset can be identified, one statistical viewpoint (that of Fisher [12] himself) is that the property of the set as a whole is irrelevant.

Table 4 Variance–covariance matrix for three contrasts

	CROS (L_c)	PAR (L_p)	SEQ (L_s)
CROS (L_c)	$q\gamma^2/2$		
PAR (L_p)	$q\gamma^2/2$	$q(\phi^2 + \gamma^2)$	
SEQ (L_s)	0	$q(2\phi^2 + \gamma^2)$	$q(4\phi^2 + 2\gamma^2)$

Whatever philosophical disagreements there may be about this point, however, the two-stage procedure as a whole has an inflated type I error rate because, whereas the conditional type I error rate of the CROS test (which will be used with probability 0.9) is 0.05 whatever the value of SEQ, that of the PAR test (which will be used with probability 0.1) is given by the integral over significant values of SEQ of the conditional type I error of PAR. This value lies between 0.25 and 0.5. The latter value arises if the within-patient variability is zero, so that $\gamma^2 = 0$. In that case there is a perfect correlation between L_p and L_s, the former being simply half the latter. Under such circumstances, the P value associated with PAR is the same as that with SEQ. Hence, since under the null hypothesis the P values have a **uniform distribution**, there is half a chance that a P value which is below 0.1 will be below 0.05. Hence if the P value for SEQ is significant at the 10% level, there is half a chance that the P value for PAR will be significant. Thus, the conditional type I error rate is 50%. Numerical integration produces the corresponding result for any combination of the values of γ^2 and ϕ^2, the other extreme being given where there is no between-patient error and $\phi^2 = 0$. This case gives a conditional type I error rate of 0.25. Putting these results together, the unconditional type I error rate for the two-stage procedure lies between $0.9 \times 0.05 + 0.1 \times 0.25 = 0.07$ and $0.9 \times 0.05 + 0.1 \times 0.5 = 0.095$. Further details are to be found in the paper by Freeman [16]. Although some commentators have since claimed that the two-stage analysis may be used after all [26], most regard it as no longer acceptable [42, 44, 45]. Tudor & Koch [52] have suggested performing the test for carry-over only if CROS is significant, and this, at least, would avoid the problem of the increase in type I error rate with the two-stage procedure. Note, however, that, when SEQ is significant, PAR and CROS will differ considerably, so that it is unwise to expect much comfort from a back-up test using PAR if the procedure is run this way round. Senn has shown how it is possible to correct the bias in the two-stage procedure by carrying out the PAR test (if used) at the 0.005 level rather than the 0.05 level but shows

that this has no power advantages over using CROS alone [46].

A Bayesian Approach

A very simple criticism of the two-stage analysis is possible from the Bayesian perspective (*see* **Bayesian Methods**). This is to note that the amount of information regarding carry-over is insufficient to resolve an initial genuine doubt as to its presence or not. Thus, first to pretest and then to behave either as if carry-over definitely is or is not present is incoherent. Grieve [19–21, 41], in a series of papers, has introduced an alternative Bayesian approach to the AB/BA design. This establishes the Bayesian posterior distribution of the treatment effect under the highly informative prior distribution that carry-over is zero (thus corresponding more or less to a CROS analysis) and also where the prior is uninformative (corresponding roughly to the PAR analysis). These posterior distributions can also be regarded as conditional distributions given particular models. However, the trialist can also express his prior belief in the validity of these two models, and this can be updated using evidence from the trial via a Bayes factor to produce posterior odds. The posterior odds can then be used to mix the two conditional posterior distributions to produce a single posterior. This technique has been extended by Grieve to cover the case with baselines also [20].

By permitting the adoption of intermediate positions, Grieve's approach is more flexible than the CROS analysis alone (which is a consistent Bayesian approach but corresponds to an extreme prior) whilst avoiding the pitfalls of the two-stage approach. However, it is not fully Bayesian since it does not model the dependence of belief in carry-over on belief in the effect of treatment (on which it must, in practice, depend strongly), and the appropriate prior weightings are a rather delicate matter. (It is necessary to give more prior weight to the case of no carry-over than would literally be believed to be true.)

Using Baseline Data

The difficulty in analyzing the AB/BA design is that there are not enough model **degrees of freedom** available to analyze the contrasts of interest whilst eliminating other parameters. One solution is to add information of a different type to the basic design. Such information may be provided by baseline information, i.e. measurements taken prior to treatment. As Ratkowsky et al. [42] point out, such measurements may be obtained before the first treatment period, at the end of the wash-out period which intervenes between the two treatment periods, and after wash-out at the end of the trial. The general scheme is illustrated in Figure 4. The third baseline value is most rarely taken and the first most commonly. The most common combination, however, especially in single-dose trials, is baselines 1 and 2. A cell mean parameterization corresponding to this latter case is given in Table 5.

Various authors have proposed various approaches to estimation of the treatment effect and its standard error [25, 39], depending upon which of the above baseline values are available and which of the following assumptions, if any, are made: (i) that the

Table 5 Cell mean expectations for baselines

		Period 1 ($k = 1$)	Period 2 ($k = 2$)
Sequence	AB ($i = 1$)	$\nu + \theta_1$ $\overline{X}_{1.1}$	$\nu + \theta_2 + \lambda_{A\_}$ $\overline{X}_{1.2}$
	BA ($i = 2$)	$\nu + \theta_1$ $\overline{X}_{2.1}$	$\nu + \theta_2 + \lambda_{B\_}$ $\overline{X}_{2.2}$

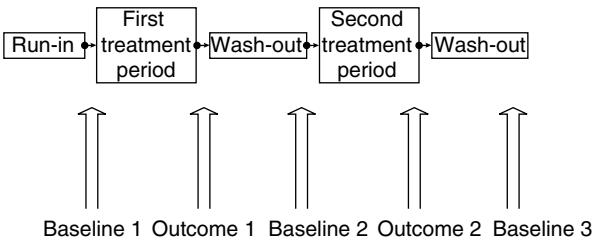

Figure 4 Schematic representation of outcome and baseline measurements in an AB/BA crossover trial

period effect applicable to a baseline measurement is the same as that which applies to the treatment which follows ($\theta_i = \pi_i$); (ii) that the effect of carry-over into a baseline value is the same as carry-over into a subsequent treatment ($\lambda_{A\_} = \lambda_{AB}$ and $\lambda_{B\_} = \lambda_{BA}$); and (iii) that baselines are measured on the same scale as outcomes and more particularly that the variances of outcomes and baselines are the same [var(X) = var(Y)]. (This latter assumption will not hold, for example, if some patients are placebo (*see* **Blinding or Masking**) responders and others are not.) Jones & Kenward [25] have pointed out, however, that assumptions (i) and (ii) are not necessarily reasonable and, indeed, one may also claim that assumption (iii) need not apply [44, 45].

In fact, it is probably fair to say that none of the solutions to the problem of carry-over by using baselines has achieved general assent. For example, if the carry-over into the baseline is assumed to be the same as that into the subsequent outcome, then the following within-patient estimator has expectation τ:

$$L_{bc} = \frac{\begin{bmatrix} (\overline{Y}_{11} - \overline{X}_{11}) - (\overline{Y}_{12} - \overline{X}_{12}) \\ +(\overline{Y}_{22} - \overline{X}_{22}) - (\overline{Y}_{21} - \overline{X}_{21}) \end{bmatrix}}{2}. \quad (5)$$

This is the same estimator as the conventional within-patient estimator CROS (L_c) associated with the design without baselines, but with the outcome values "corrected" by subtracting their respective baselines. However, unless the treatment period is short compared to the wash-out, then the condition that $\lambda_{A\_} = \lambda_{AB}$ and $\lambda_{B\_} = \lambda_{BA}$ is most unlikely to hold. Even then, the further assumption is required that carry-over of a treatment into a period where an active treatment is being given is the same (other things being equal) as carry-over into a period where no treatment is given. In fact, it is not hard to think of cases where either $\lambda_{A\_}$ or $\lambda_{B\_}$ would be large but (due to the longer time interval) λ_{AB} and λ_{BA} small. If that were the case, the bias in L_{bc} would be worse than the bias in L_c. For this reason Ratkowsky et al. [42] have proposed using the estimator

$$L_{bp} = (\overline{Y}_{11} - \overline{X}_{11}) - (\overline{Y}_{21} - \overline{X}_{21}), \quad (6)$$

but this is simply the standard PAR estimator, L_p, "corrected" for baselines. Hence, if this is used there is no point in carrying out a crossover trial unless the purpose is to study carry-over itself. (This would be an extremely wasteful use of the extra period.) Jones & Kenward [25] have proposed a complicated multistage testing process somewhat analogous to the Grizzle two-stage procedure, which uses the baselines to make the test for carry-over more powerful. This, however, may be criticized along rather similar lines to Freeman's criticism of the two-stage procedure and is not recommended.

In fact, considerations such as these suggest that, whilst there may be many cases where the AB/BA crossover may be safely analyzed by ignoring baselines altogether, there are not a few where attempting to use them would introduce problems with carry-over which could otherwise be avoided, and rather few where the problems with carry-over could be eliminated by resorting to baselines. This does not mean that baselines are useless, however. If patients are subjected to individual time trends, then trends in baseline values may be correlated with trends in outcome values. If carry-over is not a problem, then **analysis of covariance** using the baselines may bring a considerable reduction in variance. The estimator is of the form

$$L_{bc} = \frac{\begin{bmatrix} (\overline{Y}_{11} - \hat{\beta}\overline{X}_{11}) - (\overline{Y}_{12} - \hat{\beta}\overline{X}_{12}) \\ +(\overline{Y}_{22} - \hat{\beta}\overline{X}_{22}) - (\overline{Y}_{21} - \hat{\beta}\overline{X}_{21}) \end{bmatrix}}{2}, \quad (7)$$

where $\hat{\beta}$ is chosen so as to minimize the variance of L_{bc} and hence corresponds to the partial regression of outcomes on baselines. Details of the implicit error structure are covered by Jones & Kenward [25], the properties of this and other estimators are clearly reviewed by Koch [30], and further discussion and details of fitting are given by Senn [44, 45]. Although this estimator does require the assumption that neither baselines nor outcomes are subject to carry-over, it does not require the assumption that outcomes and baselines be measured on the same scale, nor that period effects for baselines are the same as for their corresponding outcomes.

Two-Treatment Designs in Three or More Periods

n-of-1 Trials

Adding further periods to the crossover design permits one to study further types of effect. One which is potentially important but which has received little attention is that of treatment by patient interaction.

The fact that a given patient receives the same treatment more than once may permit one to divide "within-patient" variation in the AB/BA design into two further sources: pure random variation from period to period and a personal response to treatment. The individual sequences which patients receive are sometimes referred to as "*n*-of-1 trials", and these are often performed with the object of analyzing each patient's results independently. However, if these trials are analyzed as a sequence using a random effects model, then the whole can be referred to as a multiperiod crossover design [44].

The Simple Carry-Over Model

By adding more periods to the AB/BA design, more model degrees of freedom are obtained and these may be used to estimate or eliminate the carry-over effect, provided that restrictive assumptions are made about its nature. The most popular set of assumptions are associated with the so-called simple carry-over model, namely, that carry-over will last for one period only and depends only on the engendering and not the perturbed treatment. Much investigation of optimality has been reported using this model [25, 28, 32, 36]. At one time this model appeared to have acquired an importance in the literature on the design of crossover trials which practical consideration did not justify; in more recent years it has come under heavy criticism [13, 14, 44]. For example, the model implies that the effect of a treatment reaches the steady state after two periods (and not after one or three periods). This, in turn, implies that the trialist has misjudged the length of a period, making it too short and that if, for example, a parallel group trial were used as an alternative, only the one-period direct effect of treatment would be captured, rather than the more relevant sum of the direct and the residual or carry-over effects. On the other hand, the much criticized AB/BA design, but with treatment periods twice as long, would capture the relevant treatment effect perfectly!

Dual Balanced Designs in Two Sequences

A dual sequence is obtained from another by interchanging the A and B treatment labels. So, for example, BA is the dual of AB and vice versa, and BAA is the dual of ABB, and so forth. Designs consisting only of such pairs and in which the two members of a pair appear equally are often referred to as dual-balanced. A particularly simple analysis is possible for designs consisting of a single balanced pair [25].

For example, a three-period design might allocate patients in equal numbers to the two sequences ABB and BAA. A four-period design might use the sequences ABBA and BAAB. Such designs can be analyzed using the two-sample t test as follows. Contrasts are found which, when compared between sequences, will eliminate subject, period and carry-over effects whilst estimating the treatment contrast of interest. For example, Table 6 shows cell means parameterizations for the AABB/BBAA design corresponding to four different models of carry-over. (The cells have been numbered so that

Table 6 Cell means representations of a two-treatment four-period design in two sequences for four different types of carry-over

Sequence and type of carry-over	Period			
	1	2	3	4
AABB	1	2	3	4
Simple	$\mu+\tau_A+\pi_1$	$\mu+\tau_A+\pi_2+\lambda_A$	$\mu+\tau_B+\pi_3+\lambda_A$	$\mu+\tau_B+\pi_4+\lambda_B$
Steady-state	$\mu+\tau_A+\pi_1$	$\mu+\tau_A+\pi_2$	$\mu+\tau_B+\pi_3+\lambda_{AB}$	$\mu+\tau_B+\pi_4$
Both	$\mu+\tau_A+\pi_1$	$\mu+\tau_A+\pi_2+\lambda_{AA}$	$\mu+\tau_B+\pi_3+\lambda_{AB}$	$\mu+\tau_B+\pi_4+\lambda_{BB}$
Neither	$\mu+\tau_A+\pi_1$	$\mu+\tau_A+\pi_2$	$\mu+\tau_B+\pi_3$	$\mu+\tau_B+\pi_4$
BBAA	5	6	7	8
Simple	$\mu+\tau_B+\pi_1$	$\mu+\tau_B+\pi_2+\lambda_B$	$\mu+\tau_A+\pi_3+\lambda_B$	$\mu+\tau_A+\pi_4+\lambda_A$
Steady-state	$\mu+\tau_B+\pi_1$	$\mu+\tau_B+\pi_2$	$\mu+\tau_A+\pi_3+\lambda_{BA}$	$\mu+\tau_A+\pi_4$
Both	$\mu+\tau_B+\pi_1$	$\mu+\tau_B+\pi_2+\lambda_{BB}$	$\mu+\tau_A+\pi_3+\lambda_{BA}$	$\mu+\tau_A+\pi_4+\lambda_{AA}$
Neither	$\mu+\tau_B+\pi_1$	$\mu+\tau_B+\pi_2$	$\mu+\tau_A+\pi_3$	$\mu+\tau_A+\pi_4$

they may be referred to subsequently.) If we let Y_{ijk} be the response for period k for subject j of sequence i and we calculate the linear combination $C_{ij} = \sum_{k=1}^{4} W_k Y_{ijk}$, where $w_1 = 6/20$, $w_2 = 4/20$, $w_3 = -7/20$, and $w_4 = -3/20$, then since $\sum_{k=1}^{4} W_k = 0$, C_{ij} has the subject effect eliminated from it. Furthermore, as may be seen by studying Table 6, if such a linear combination is calculated for a patient chosen at random from sequence 2 and subtracted from the corresponding contrast calculated from a patient in sequence 1, and simple carry-over applies, the expectation of the result is simply $\tau_A - \tau_B$. Thus a comparison of the means from the two sequences produces the contrast of interest and may be tested using the two-sample t test. A nonparametric approach would be to use the Wilcoxon–Mann–Whitney test [29].

The weakness of the simple carry-over model, however, is easily illustrated using this design, which is one of two supposedly optimal designs in four periods and two sequences. Suppose that B is a placebo but that A is an active treatment. The elimination of λ_A, the carry-over due to A, relies on the fact that 4/20 − 7/20 + 3/20 = 0, these being the weights which will be associated with cell means 2, 3, and 8. (Note that, in the construction of the final treatment estimate, weights for the cell means in the second sequence are the negative of those in the first.) However, **pharmacokinetic and pharmacodynamic** considerations might suggest that, if carry-over is important, it will have much more of an effect on cell mean 3, which measures the effect of a placebo after a double period of active treatment, than anywhere else in the design. Yet this is the mean which attracts the greatest weight. If the steady-state carry-over model applies instead, therefore, this scheme of weights will be seen to be quite undesirable.

With the steady-state carry-over model, the one-period assumption is retained, but it is assumed that a treatment will show no carry-over into itself. The relevant weights for this model are $w_1 = 1/4$, $w_2 = 1/4$, $w_3 = 0$, and $w_4 = -1/2$. On the other hand, to produce an estimator which guards against both kinds of carry-over, then $w_1 = 1$, $w_2 = -1/2$, $w_3 = 0$, and $w_4 = -1/2$. If the problem of carry-over is ignored altogether, then the weights are $w_1 = 1/4$, $w_2 = 1/4$, $w_3 = -1/4$, and $w_4 = -1/4$. Yet another possibility is to suppose that both kinds of carry-over apply but that we wish to estimate the total effect (direct + carry-over) of the treatments. Suitable weights would then be $w_1 = 0$, $w_2 = 1/2$, $w_3 = 0$, and $w_4 = -1/2$. However, since periods one and three are ignored altogether, the estimator is then identical to that which would be produced for an AB/BA crossover with periods twice as long. This illustrates the problem nicely, showing that, although more complicated designs appear to open up the possibility of eliminating carry-over, the reliance on assumptions is not easily banished.

In indexing the efficiency of the designs, it is often assumed that the within-patient errors are uncorrelated. Although some work has been done on the more general case where there is **autocorrelation**, it has been assumed either that there is no carry-over or only simple carry-over [31, 36]. Where standard assumptions of independence and homoscedasticity (*see* **Scedasticity**) apply, then the efficiency of a design/model combination is proportional to the sum of the squares of the weights associated with the cell means. Table 7 gives the variances of three possible designs in four periods. (These are three designs based on a single dual pair for which each patient receives each treatment twice. Such designs are sometimes referred to as being *uniform on the patients*. In the absence of carry-over they are more efficient than designs in which patients receive one treatment three times and the other once.) The Table gives the variance of the estimate for the treatment effect for each of four carry-over models as a ratio of the variance for the case where no carry-over is fitted.

As can be seen, if either the simple carry-over model is used, or the steady-state model is used, the first and third designs are the most efficient, the

Table 7 Variances of estimated treatment effects for three designs and four models as a ratio of the case where carry-over is not fitted

Design	Simple	Steady-state	Both	Neither	Cumulative
AABB/BBAA	1.1	1.5	6	1	2
ABAB/BABA	5.5	5.5	5.5	1	
ABBA/BAAB	1.1	2	6	1	

second being much more inefficient. However, if both forms of carry-over are to be eliminated, then the second design is most efficient. On the other hand, if the total or cumulative effect under the steady state is of interest, the first design is the only possibility.

More Complicated Designs

There is no need to restrict the treatment sequences to a single dual pair, and designs based on the use of four sequences can prove superior. As above, however, the optimality of a design depends on the carry-over model. In nearly all of the literature the simple carry-over model is assumed with no investigation of its suitability, and, indeed, in the purely medical literature, such designs are hardly ever applied. To drug developers, the steady-state model will seem at least as plausible as the simple model.

Where a more general model for the correlation structure applies, identifying "optimal" designs becomes quite complex. There have been a number of extensive investigations. However, quite apart from the difficulties with carry-over described above, there is the added problem that optimal designs depend on the correlation structure, and this will not be known in advance nor with any certainty even after running the trial. Matthews [37] covers the estimation of dispersion parameters.

Another paper of Matthews [38] gives a good general review of the field. Fleiss [13, 14] and Senn [44] have provided critical attacks on this general topic. Jones & Kenward [25] and Ratkowsky et al. [42] give further details of models and fitting. An alternate approach to modeling carry-over has come from the field of pharmacokinetic and pharmacodynamic (PK/PD) modeling, where residual effects and direct effects are treated in one comprehensive PK/PD model. Sheiner et al. [49] have used this to investigate the relative performance of crossover, dose-escalation, and parallel group studies in dose-finding.

Designs for Three or More Treatments in the Same Number of Periods

It is not uncommon to run crossover trials in three or more periods. Indeed, in drug development, contrary to popular opinion, except in the field of bioequivalence, such designs are more common than the AB/BA design. For example, they are very popular in certain fields as dose-finding studies, using designs comparing several doses to a placebo. A very common way of designing such trials is to choose sequences which, taken together, form one or more **Latin squares**. Example 2 described such a design, comparing two doses of diclofenac to placebo using six sequences, or two Latin squares. A four-treatments crossover trial comparing treatments A, B, C, and D might allocate patients in equal numbers to sequences such as

A C D B,

B D C A,

C B A D, and

D A B C.

Such a design is not only uniform on the periods (each treatment appears equally often in every period), as is any Latin square, but it is sometimes called *balanced*, since each treatment appears an equal number of times (in this case once) after every other. (This is, however, a rather confusing term since balance is used generally by medical statisticians in a different and less specialized sense, and is given a similar but nonetheless somewhat different meaning in describing **incomplete blocks**.) Such balanced Latin squares are known as Williams squares, and are more efficient if the simple carry-over model is being fitted [53]. However, this does not necessarily make them the best choice for dealing with carry-over (for similar reasons to those discussed above) [44].

Some alternative Latin squares may also be preferable for certain types of analysis. Consider, for example, the square

A B C D,

B A D C,

C D A B,

D C B A.

By ignoring treatments D and C and pairing off sequences 1 & 2 and then again 3 & 4, this design can be reduced to two AB/BA crossovers. On the other hand, for the purpose of comparing the treatments A and C, treatments B & D could be ignored and sequences 1 & 3, and 2 & 4 can be paired, and so on. This means that any technique which is available

for analyzing the AB/BA design (nonparametric, for **binary** data, and so forth) can be used to analyze contrasts for such a design. The results from the two subdesigns thus formed can be pooled using standard **meta-analytic** techniques.

Designs for Three or More Treatments in Fewer Periods

Occasionally it is of interest to study more treatments than can realistically be given to a single patient. Incomplete blocks designs are then an option, as discussed in Example 3. This design is uniform on the periods and balanced in the sense of incomplete blocks designs (i.e. each of the 21 possible pairs of treatments is given equally frequently to the patients). However, the design is not balanced in the carry-over sense since each treatment does not follow every other equally frequently. However, in this example, wash-out was adequate and carry-over was not adjusted for.

If, as was the case in this example, balancing for carry-over is ignored, then such designs are simply examples of incomplete blocks designs, about which there is an extensive literature. If it is desired to balance for simple carry-over, then added complications are involved. In principle, it is also possible to recover interblock information for such designs. (In fact even for complete blocks (*see* **Randomized Complete Block Designs**), if carry-over is fitted, since this induces some non**orthogonality**, there is some interblock information available [3].) In practice it seems common to ignore this refinement and, indeed, some see advantages in having pure within-patient estimators, as distributional assumptions regarding patient effects are then irrelevant.

Computer Analysis

With the help of modern statistical packages (*see* **Software, Biostatistical**), the analysis of continuous outcomes for crossover designs is relatively straightforward. An approach using SAS® is as follows. Suppose we have a design where a number of treatments A, B, C, D, etc. are being compared. First of all the outcome data (OUTCOME) are arranged into an $n \times k$ vector, where n is the number of patients and k is the number of periods. For each such observation the corresponding patient number (PATIENT), period (PERIOD), and treatment (TREAT) are recorded as categorical variables. The analysis via ordinary **least squares** can then be carried out with the help of proc glm® as follows:

```
proc glm;
class PATIENT PERIOD TREAT;
model OUTCOME = PATIENT PERIOD TREAT;
estimate "A−B" TREAT 1   −1    0   0 (etc.);
estimate "A−C" TREAT 1    0   −1   0 (etc.);
etc.
run;
```

If it is desired to fit simple carry-over, then this can be done by defining an additional variable CARRY which has one more level than the number of treatments. This is then coded A, B, etc., depending on the treatment given in the previous period. An extra code, say Z, can be used whenever the particular observation is at the beginning of a sequence. The "class" and "model" statements then need to include this term.

It should be noted, however, that for designs in more than two periods, the analysis using ordinary least squares produces residual degrees of freedom for error in excess of the number of patients. This is an indication that strong assumptions are involved and, in the presence (say) of patient by treatment interaction, this analysis may be invalid [40, 44].

Further SAS® code for various types of analysis is given by Ratkowsky et al. [42] and Senn [44], who also covers alternatives to ordinary least squares as well as nonparametric approaches.

Other Outcomes

This survey has been entirely in terms of continuous outcomes. These have a much greater relative importance for crossover trials than for parallel group trials, where, unlike for crossover trials (but see below), **survival**, for example, can be an important outcome. Nevertheless, there is a growing body of work on binary and other outcomes (*see* **Categorical Data Analysis**). All that will be attempted here is a very brief summary of the literature.

We have also concentrated on the analysis of continuous outcomes using the general linear model. In fact, various nonparametric approaches have been

introduced following Koch's original paper [29]. Various simple strategies are discussed by Senn [44], and an authoritative review listing all the major approaches is given by Tudor & Koch [52]. In general, these techniques are really partially parametric since various linear manipulations of the data have to be undertaken before proceeding to the final "nonparametric" test. Confidence limits are also available for these approaches.

A simple test which may be used for binary outcomes in the AB/BA design is the Mainland–Gart test [17, 34]. The most important modern work in this field has been by Jones & Kenward [25], who applied **loglinear models** and who have since discussed both marginal and subject-specific models in great detail [27]. Ezzet & Whitehead [7] have introduced an alternative random effects **proportional-odds model** for **ordered categorical** (and hence also **binary**) data. Again some simple techniques are described by Senn [44].

Occasionally, survival-type data are obtained from crossover trials. For example, patients may be asked to undertake an exercise test, and such observations can then be **censored**. A model has been proposed by France et al. [15]. An alternative approach is given by Feingold & Gillespie [8].

The crossover trial also provides the possibility of examining directly patient preferences for treatment. An important reference is Baskerville et al. [1], and the subject has recently been treated by Lindsey & Jones [33].

Further Reading

Three books devoted to crossover designs have already been referred to [25, 42, 44]. A complete issue of *Statistical Methods in Medical Research* (Vol. 3, no. 4, 1994) was devoted to crossover designs, and provides review articles on the AB/BA design [45], binary and categorical data [27], nonparametric methods [52], multiperiod crossovers [38], and Bayesian approaches [21].

STEPHEN SENN

Cross-sectional Study

A cross-sectional study is a study to estimate the distribution of a quantity of interest (or joint distribution of several quantities) in a **target population**, at a certain moment in time. Ideally, this is accomplished by measurements from a **random** or **stratified random sample** of the target population, although convenience samples may also be used. A cross-sectional study is characterized by the fact that only one set of observations is taken from each subject, as opposed to a longitudinal study in which study participants provide observations at more than one point in time (*see* **Cohort Study**; **Panel Study**). Even if repeated or serial cross-sectional studies are conducted in the same population, the same individuals generally will not be sampled again except by chance.

Cross-sectional studies often have a **binary** variable as the quantity of primary interest, such as estimating the **prevalence** of a certain disease, risk factor, or health behavior. Continuous variables may also be of interest, for example the subject's weight or blood cholesterol level, although such data are often grouped or categorized in epidemiologic studies. One use of a cross-sectional study is to determine the association between an outcome variable and some **explanatory variables**, for example to estimate the prevalence of a disease, perhaps as a function of some explanatory variables. An association between outcomes and explanatory variables may suggest causality, although a causal link usually cannot be established from a single cross-sectional survey (*see* **Causation**; **Hill's Criteria for Causality**), because such studies give no information on the temporal ordering of possibly causal events. A second use of cross-sectional studies is to monitor changes in a population over time using a series of cross-sectional surveys; for example, the Monitoring the Future surveys [7] track drug use by teenagers over time in this way. Sometimes a better case for a causal link can be made with serial cross-sectional data; for example, Pirkle et al. [9] analyzed blood lead measurements from the second and third National Health and Nutrition Examination Surveys (NHANES), conducted in 1976–1980 and 1988–1991, respectively, to document a decline in blood lead levels in the US population that resulted from the gradual removal, since 1976, of most lead from gasoline. A third use of cross-sectional studies is to make some **inference** about disease incidence; this is harder to achieve, although some techniques for estimating incidence from a cross-sectional survey are discussed below.

As the distribution that is being estimated may be changing over time, the ideal cross-sectional study would be conducted instantaneously. However, a real study typically requires some time to conduct. In practice, the primary requirement is that the target distribution changes negligibly over the course of the study. In some situations this requirement is easily met: for example, a study of the prevalence of carpal tunnel syndrome can safely be conducted over an entire year; a study of the prevalence of varicella (chicken-pox) probably should be conducted within a week or two. In some situations cross-sectional surveys are conducted over a long period as a surveillance system (*see* **Surveillance of Diseases**). For example, the **Centers for Disease Control and Prevention (CDC)**, use ongoing **telephone surveys** to assess the prevalence of several chronic disease risk factors and tracks these over time [11]. These studies should be distinguished from incidence studies in which all new occurrences of a disease arising in a certain population in a given period are recorded; a defining characteristic of a cross-sectional survey is that subjects are sampled solely on the basis of their membership in a target population, not on the basis of a change in status. This distinction is somewhat blurred, however, in cross-sectional surveys that also collect retrospective data on duration of disease, since this type of data would allow identification of new cases.

Although a cross-sectional study can only measure a distribution at a single time point, interest is often centered on dynamic or time-dependent quantities; disease incidence is often the quantity of interest. One circumstance in which disease incidence can be measured from a cross-sectional survey occurs when an ephemeral state associated with recent onset can be identified. If the **mean** duration, w, of this state is known, then the prevalence of individuals in the ephemeral state can be converted into disease incidence using the relation prevalence$/w =$ incidence. For a disease of short duration, the ephemeral state can be the entire course of the disease. For this method to be valid, the time-scale over which the disease incidence changes must be longer than w. For example, the serologic testing algorithm for recent HIV seroconversion [6] estimates the incidence of HIV(human immunodeficiency virus) infection in a

population by identifying the proportion of individuals who test positive for HIV on a standard(sensitive) screening assay but who will still test negative on a less sensitive assay. Weinstock et al. [13] used this approach to estimate HIV incidence among patients at clinics for sexually transmitted diseases. Note that although this method is sensitive to the value of w, it is possible to test for or estimate trends in incidence in serial cross-sectional surveys by comparing the prevalence of individuals in the ephemeral state over time. For such a comparison to provide valid inference on trends in incidence, it is not necessary to know w; we need know only that it is small compared with the time between the surveys [12].

The methods described above are appropriate for situations in which the incidence is changing over time. In many situations the population may be considered homogeneous over time; in these situations, interest may focus on the age of onset or on age-specific incidences. Keiding [8] discussed a variety of assumptions that allow estimation of these quantities from a cross-sectional survey, and also discussed methods to estimate disease prevalence from incidence data (*see* **Incidence–Prevalence Relationships**). Some of these methods require either retrospective data or external data such as age-specific mortality for the general population or for people with the specific disease of interest. Additional information about population dynamics can sometimes be obtained if two or more cross-sectional studies are conducted in the same population at different times. For example, it is possible to estimate the incidence of a disease by comparing two measurements of disease prevalence taken at different times and accounting for the aging of the population. By comparing the proportion of 15-year-olds with 19-year-olds who have a positive ppd (purified protein derivative) TB test with the proportion five years later among 20- to 24-year-olds, one could estimate rates of infection with *M. tuberculosis*, in essence treating these two groups as members of the same "pseudo-cohort". Techniques are available for converting these "cohort infection rates" to age-specific period rates [10]. However, the validity of this calculation depends on the assumption that there is no differential loss of people with disease (i.e. mortality or migration caused by the disease); otherwise, external data on the these effects are necessary. In addition, for different age groups to be treated as members of the same pseudo-cohort, the distribution of important **covariates** must be the same across age groups, a condition that may pose a special challenge for **observational studies**. For example, in a study of childbearing women, the women aged 15–20 years may have markedly different demographic characteristics than those aged 20–25 years.

Conclusions about incidence can sometimes be drawn by comparing crude (i.e. not age-specific) prevalences from successive cross-sectional surveys. For example, HIV prevalence among injection drug-users in Bangkok, Thailand, jumped from 1% at the start of 1988 to 32%–43% by August–September 1988 [14], implying a remarkable incidence of HIV infection over this period, as well as illustrating the usefulness of cross-sectional surveys as a surveillance tool. However, in less dramatic situations, trends in prevalence may be difficult to interpret because they are the net result of new cases and death or the loss of old cases. As with analyses of age pseudo-cohorts, knowledge of or assumptions on the nature of the death or loss of prevalent cases are required before inference on incidence can be made. An unchanging crude prevalence also does not necessarily imply steady-state conditions; Batter et al. [1] report an example where crude prevalence was steady over time but the distribution of cases by age had shifted.

The line between cross-sectional studies and a wide variety of **retrospective studies** is blurred when retrospective **longitudinal data** are collected in a cross-sectional survey. Examples of such data include age at menarche, the number of months breast-fed, prevalence of diarrhea in the last two weeks, or conditions surrounding the death of a child. The validity of such retrospective data is dependent on the respondent's ability to recall accurately the events of interest for the time-period considered. For example, to examine the association between short birth intervals and the survival of the subsequent child, it is possible to use birth history reports of mothers [5]. This same type of data can also be used to estimate fertility and mortality patterns many years before the study for analysis of long-term trends.

Several major differences between cross-sectional studies and longitudinal (or cohort) studies determine when either should be used. **Cohort studies** measure the effect of risk factors on disease incidence in a defined population, whereas cross-sectional studies measure the effects of risk factors on disease prevalence. As a result, differences may arise when the same **associations** are studied by the two methods. Factors that affect both disease incidence and

mortality after disease will show a different association when measured cross-sectionally than when measured longitudinally. For example, a risk factor that is associated with both increased incidence and increased mortality among individuals with disease will show a smaller association with disease prevalence in a cross-sectional survey than with disease incidence in a longitudinal study, because the persons with the risk factor will be less likely to survive until the time of the cross-sectional study (*see* **Case–Control Study, Prevalent**). Even factors unrelated to disease incidence may show an association with disease prevalence if they affect the survival of individuals with disease differentially. Thus, if disease etiology is of primary interest, cohort studies or incident **case–control studies** are usually preferable, whereas prevalence studies may provide more useful information for characterization of a population for public health purposes.

Cross-sectional studies sample prevalent, rather than incident, cases; the selection requirement of survival to the date at which the survey is conducted results in differences between the population of prevalent cases and the population obtained by following incident cases over time. The likelihood of being observed in a certain transient stage in a cross-sectional survey is proportional to the time spent in that stage (*see* **Length Bias**). As a result of heterogeneity in the course of disease, individuals with longer survival times are more likely to be sampled in a cross-sectional study than those with shorter survival times. Similarly, the population of prevalent cases who have a given characteristic may differ from the population of those who have ever developed that characteristic. A cross-sectional estimate of the relative prevalence of two types of cancer (one virulent, the other less so) would not be equal to the relative incidences, as the relative incidence of the virulent type would be greater than its relative prevalence. Although the results of the cross-sectional study may properly reflect the distribution of survival times or disease subtypes among those individuals currently living with disease, these quantities must be interpreted as instantaneous pictures of a dynamic, open population and not necessarily as reflective of some other population, such as those with incident disease (*see* **Biased Sampling of Cohorts**; **Screening Benefit, Evaluation of**).

Another distinction between cross-sectional and longitudinal studies is that a cross-sectional study or series of cross-sectional studies can only address aggregate changes in the population; unless the appropriate retrospective data are available, it is not possible to measure change at the individual level. For example, two cross-sectional surveys may find approximately the same proportion of respondents used a condom during their last sexual contact; to plan a public health campaign to increase condom usage, we may want to know additionally whether some respondents always use condoms and some never do, or if all individuals sometimes use condoms. Such data are most reliably obtained from a longitudinal study. In some cases, however, the closed nature of the longitudinal study is a disadvantage. For example, studies of HIV incidence conducted longitudinally often find a decreasing incidence of new HIV infections which may not represent the trend in the general population but instead represent a depletion of high-risk individuals in the cohort, as well as a change in behavior among study participants, who receive counseling on how to reduce their risk of acquiring HIV infection.

Cost is often a deciding factor that favors cross-sectional studies over longitudinal studies. This is especially true for studies of rare diseases, where very large cohorts or long follow-up may be required to observe enough cases to obtain statistically significant results. A variety of split-panel designs combine elements of both cross-sectional and longitudinal studies. Further discussion of these designs, as well as a general discussion of what types of questions can be answered with a cross-sectional study and what questions require a longitudinal study, can be found in Curtin & Feinleib [3] and Dwyer & Feinleib [4].

Cross-validation

Cross-validation is one of several methods for error assessment of a statistical method. Alternatives include the **jackknife method**, the **bootstrap method**, Akaike's AIC (*see* **Akaike's Criteria**), and others.

The main ideas are simply illustrated by the statistical discrimination (also called classification) problem, discussed in detail in [5], for example. There one has, say, two populations, with "training samples" available from each, and it is desired to assign a new observation to one of the two populations. For a given discrimination scheme (which is based on the training data), the error rate, i.e. probability of misclassification, is a useful indicator of its performance (*see***Multivariate Classification Rules: Calibration and Discrimination**). Estimating the error rate by the proportion of misclassifications when the rule is used to classify the training data is usually inappropriate. This is because of an "optimistic bias", caused by the classification rule being fine-tuned for this particular realization of the data, which usually entails somewhat worse performance for a different realization from the same underlying distribution.

The idea behind the cross-validatory approach to this bias problem is to separate the data into two pieces, one of which is used to construct the classifier, and the other to "validate" or estimate the error rate of the classifier. Dependence on the particular dichotomy chosen is eliminated by averaging error rates over a large number of such dichotomies. The "cross" part of the name "cross-validation" comes from the fact that each data point is sometimes used for classifier construction, and at other times for validation.

A commonly used dichotomy is called "leave one out", where the validation set is a single observation, and the rest are used to construct the classification rule. In some situations, there is an advantage to using, say v, observations in the validation set (i.e. "leaving out v" in construction of the classifier). See Picard & Berk [9] for an interesting illustration of this point (in a different statistical setting). This form has been called "v-fold" cross-validation.

The ideas illustrated via the discrimination problem above apply to a wide variety of statistical problems. See [10] for a general formulation. See that paper and [1] for a good indication of the breadth of different contexts in which this principle applies, as well as for historical background. There was a period of very active research in the mid 1970s, but the method dates from well before.

An area where a large literature has developed around the cross-validation idea is in smoothing parameter (i.e. window width or bandwidth) selection for nonparametric curve estimation, i.e. smoothing methods. Rather different perceptions of the performance of cross-validatory methods have been developed, depending on the smoothing method used. Performance is viewed as "acceptable" by most of those who prefer smoothing splines (*see* **Spline Function**), and "unacceptable" by most of those who prefer kernel/local polynomial methods. The reason for this is unclear (because the essence of both smoothing methods is rather similar), but perhaps it is because spline researchers tend to work with "less noisy" data sets than kernel/local polynomial researchers.

In the context of smoothing splines, Wahba and co-workers have proposed, and demonstrated good properties of, a variation of cross-validation called "generalized cross-validation"; see [11], for example.

The deepest insights into the efficacy of cross-validation for smoothing parameter selection are available in the context of kernel density estimation; see [8] and references therein. Here the conclusion drawn by most researchers is that cross-validatory methods are "too variable", but this variability can be reduced to acceptable levels by alternative measures such as plug-in methods or the use of smoothed cross-validation. Similar ideas hold in kernel regression, as shown, for example, in [3, 6], and [7].

When data are dependent, cross-validation needs to be modified for use in smoothing parameter selection [4]. For deeper analysis, see [2].

J.S. MARRON

Crude Risk

Crude risk is the probability that an individual will develop a particular disease in a given time interval in the presence of other **competing risks** of death. For example, the probability that a 30-year-old woman will develop breast cancer between the ages of 30 and 60 is a crude risk. The crude risk is reduced by the fact that she may die of other diseases before she develops breast cancer. The term **absolute risk** is used synonymously with crude risk. Crude risk can be estimated without making special assumptions, such as the "independence" assumption used in competing risk analysis. Crude risk can be contrasted with the net risk in the theory of competing risks. Net risk refers to the probability of developing a particular disease if other competing risks are eliminated.

Crude risk is also used to describe the risk of disease in a heterogeneous population composed of different genders and age groups, for example. Crude risk is differentiated, in this context, from gender- and age-specific risks.

(*See also* **Aalen–Johansen Estimator**)

MITCHELL H. GAIL

Cumulative Hazard

The cumulative hazard on the interval $[0, t)$ is $\int_0^t \lambda(u)\,du$, where $\lambda(u)$ is the **hazard rate**. If $\lambda(u)$ is the hazard for total mortality, then the cumulative hazard is related to cumulative probability of death, $1 - \exp\left(-\int_0^t \lambda(u)\,du\right)$. If $\lambda(u)$ is a disease-specific **incidence rate** and if $\int_0^t \lambda(u)\,du$ is small, then the cumulative hazard approximates the "pure" probability of developing disease in the absence of other competing causes of death, provided that those other causes act independently of the cause of interest.

(*See also* **Competing Risks**; **Nelson–Aalen Estimator**; **Survival Analysis, Software**; **Survival Distributions and Their Characteristics**)

MITCHELL H. GAIL

Cumulative Incidence Rate

The cumulative **incidence rate** is a **cumulative hazard** and corresponds to the special case in which the hazard refers to the incidence rate for a specific disease. For small incidence rates, the cumulative incidence rate approximates the "pure" probability of developing the disease in the absence of competing causes of death (*see* **Competing Risks**) and should be distinguished from the crude probability of developing the disease in the presence of competing causes of death (*see* **Absolute Risk**; **Crude Risk**).

MITCHELL H. GAIL

Cumulative Incidence Ratio

The cumulative incidence ratio is the ratio of the **cumulative incidence** in an exposed cohort to that in an unexposed cohort over the same time period. The cumulative incidence ratio is the same as the **relative risk**.

(*See also* **Cohort Study**)

MITCHELL H. GAIL

Cumulative Incidence

Cumulative incidence is the proportion of individuals in a cohort initially free of a given disease who develop that disease in a defined age or time interval. Cumulative incidence is a **crude risk** and is synonymous with the terms cumulative risk, **risk**, and absolute risk. Sometimes cumulative incidence refers to the number, rather than the proportion, of individuals in a cohort initially free of a given disease who develop the disease in a given age or time interval.

MITCHELL H. GAIL

Cure Models

Most approaches to the analysis of survival, or time to event, data implicitly assume that, with sufficient follow-up, all subjects would experience the event of interest. However, there are situations when it is expected that a fraction of subjects will not experience the event. In the clinical setting, this often corresponds to the assumption that a fraction of patients treated for a disease will be cured of the disease under treatment, whereas the rest will experience a recurrence or adverse event of some sort.

Early work on models for data arising in such situations was done by Boag [2], Berkson & Gage [1], and Haybittle [12]. More recently, interest in such models has focused on the incorporation of **covariates**, or **explanatory variables**, into such models. The models can be characterized by defining a binary variable Y, where $Y = 1$ indicates that a subject will experience the event of interest and $Y = 0$ otherwise (*see* **Dummy Variables**). If $\mathbf{X}$ corresponds to a vector of explanatory variables, with x_i representing the observed values for the ith subject, then $p(x_i)$ can represent the probability of the event occurring for the ith subject, i.e. $\Pr(Y = 1|x_i)$, and $f(t|Y = 1, x_i)$ can represent the probability density function for the random variable T, which specifies the time of the event if it occurs. It is convenient also to specify the corresponding survivor function $S(t|Y = 1, x_i) = \Pr(T > t|Y = 1, x_i)$.

If the functions p and f have specified parametric forms, then **maximum likelihood** estimation of unknown parameters is possible. The **likelihood** is a product of contributions of the form $p(x_i)f(t|Y = 1, x_i)$ from individuals who experience the event, $1 - p(x_i) + p(x_i)S(t|Y = 1, x_i)$ from individuals observed to time t without experiencing the event, and, in some cases, $1 - p(x_i)$ if an individual is known not to have experienced the event. The latter contributions exist only if follow-up has continued past a time point before which it is known that the event must occur if it is to occur.

A variety of parametric forms have been considered. To incorporate covariates, the logistic model

$$p(x_i) = \exp(\alpha + x_i\boldsymbol{\beta})/[1 + \exp(\alpha + x_i\boldsymbol{\beta})],$$

where $\boldsymbol{\beta}$ is an appropriately defined vector of regression coefficients and α is a scalar location parameter, is convenient (*see* **Logistic Regression**). Farewell [4, 5] combined this with a *Weibull* regression model for f, but other choices are possible. For example, Larson & Dinse [14], in a **competing risk** framework, used a **proportional hazards** model with a step function for the baseline hazard, and Yamaguchi [22] used a class of **accelerated failure-time models**. Some specific results for **exponential** models were given by Ghitany and coauthors [9, 10].

In many situations, this mixture model approach to time-to-event data has a natural appeal. Some special considerations arise, however. There is an **identifiability** problem, since there can be a high **correlation** between the intercept term of the logistic model and any shape parameters in the model for f [6, 15]. This manifests itself in a nonquadratic and relatively flat **profile likelihood** function for α [6]. The extent of the problem depends on the generality of the model for f, but is minimized if there are a sizable number of censored observations at times well past the period when most events occur. A formal specification of this requirement was considered by Maller & Zhou [17]. Also, tests for the existence of a population with $Y = 0$, perhaps of particular interest when it would correspond to a "cured fraction" of patients or the presence of individuals in a population immune from some disease, involves nonstandard maximum likelihood theory as the null hypothesis lies on the boundary of the parameter space [23]. A conservative approach is to restrict the use of the models to situations in which there is external evidence for the existence of two populations. This is quite restrictive, however, and a general recommendation for caution in their use is perhaps sufficient to enable a wider application. For example, the models have been used to establish, in an informal manner, that there is little evidence for separate populations under plausible parametric assumptions [8, 19].

Recently, there has been interest in relaxing the parametric dependence of these models. Maller & Zhou [16] examined the estimator defined by the "flattening out" level of a **Kaplan–Meier** estimated survivor curve. This has been compared with parametric models [11]. Kuk & Chen [13] combined a logistic regression model for p with a proportional hazards model for f. Their approach estimates

the regression parameters of the proportional hazards model through an approximation to a marginal rank likelihood and then obtains an estimate of the baseline hazard function. Taylor [20] used an **EM algorithm** approach, as developed by Larson & Dinse [14], to replace the parametric event time distribution by a Kaplan–Meier type estimator. Although this work was not extended to include covariates in the event time distribution, it was shown to be quite efficient compared with a parametric alternative. Taylor [20] recommended that the survivor function S be forced to zero beyond the last event. Some such restriction is helpful to avoid nonidentifiability problems which will be potentially more acute with nonparametric approaches. It is not too restrictive when a mixture model is plausible and some follow-up is available at times in the upper tail of the event time distribution. Taylor [20] suggested that, if these conditions do not prevail, then the suitability of the model might be questioned in any event.

Comparisons of the use of a mixture model to the application of the commonly used relative risk regression model of Cox [3] have been made [5, 21]. Advantages associated with the mixture model relate to prediction [21] and to a simpler specification of covariate effects [5]. From an empirical point of view, the usual regression models for survival data will be useful even when a mixture model is appropriate. However, if only a subset of a population is expected to experience the event, the adoption of a formal mixture model may be more realistic and, through separate modeling of the probability of the event and the time to the event, more informative.

A comprehensive discussion of survival data with long-term survivors is provided by Maller & Zhou [18]. The general framework corresponding to "cure" models can also be applied to other types of data – for example, when noncure is evidenced by the observation of a nonzero count variable [7].

VERN T. FAREWELL

Cutler, Sidney Joshua

Born: April 13, 1917, in Odessa, Russia.
Died: October 21, 1993, in Silver Spring, Maryland.

Cutler immigrated to the US in 1923, graduated from City College of New York in 1938, received a master's degree in sociology from Columbia University in 1941, and a doctorate in epidemiology from the University of Pittsburgh in 1961. During World War II he served with the US Army in Europe.

A major part of Cutler's career as a biostatistician and epidemiologist, from 1948 to 1975, was with the National Cancer Institute, **National Institutes of Health** in Bethesda, Maryland. In the early 1950s Cutler authored a series of reports, including a monograph [5] on the 1947–48 incidence of and mortality from cancer in 10 metropolitan areas of the US. Twenty years later he was to direct a similar follow-up study. In 1954–55, nine years before the landmark US Surgeon General's Report *Smoking and Health* [7], Cutler published an overview of the strong epidemiologic evidence linking cigarette smoking to lung cancer [1] (*see* **Smoking and Health**), and, with Donald Loveland, an assessment of a smoker's lifetime probability of developing lung cancer, including the probable age of lung cancer onset [3].

In the late 1950s Cutler organized and became director of the End Results Evaluation program of the National Cancer Institute, a reporting system to which a number of cancer registries in the US contributed, on an ongoing basis, uniformly defined data on individual cases of cancer and their survival. The purpose of the program, later to become the SEER Program (Surveillance, Epidemiology, and End Results), was to develop data on population rates of incidence, mortality, and survival from cancer, that would allow comparisons of the results of various forms of therapy, of various regions of the country, and time trends. At a meeting in Bethesda in 1959, chaired by Michael Shimkin, representatives of six national cancer registration programs organized an international cooperative effort in the evaluation of end results of cancer therapy and in the investigation of epidemiologic questions on the effects of climate, diet, and other environmental factors on cancer incidence. Results of this effort were reported at a symposium in Norway in 1963 [6]. One of the findings from the international comparisons was that survival rates from mammary tumors were about the same in England and the US, although the method of treatment differed: in England the treatment was limited surgery, in the US it was radical surgery. The use of radical mastectomy decreased in the US subsequently.

As an aid in the analysis of survival data, Cutler developed the *relative survival rate*, a method still in use in the 1990s, as a way of correcting the survival rate for normal mortality [4]. In 1958 Cutler, with Fred Ederer, published a paper that explained in a form understandable by nonstatisticians how to describe the survival experience of cancer patients, how to include **censored data** in this description, and why it is important to include censored data [2]. The paper became a standard tool in **teaching statistics to medical students**. In the first 20 years after its publication, it was referred to in the medical literature 530 times, for which it won a citation award. In the 1960s Cutler, together with a number of other statisticians from the National Institutes of Health **Jerome Cornfield**, William Haenszel, Nathan Mantel, and **Marvin Schneiderman**), taught a course on current problems in public health at the University of Pittsburgh. During that time Cutler, together with Schneiderman and Samuel Greenhouse, another statistician from the National Institutes of Health, designed the first randomized trial of a screening agent (*see* **Screening Trials**), a study to determine whether periodic mammographic screening prevents death from breast cancer; the conduct of the trial was led by Sam Shapiro of the Health Insurance Plan of Greater New York.

Cutler was a Fellow of the **American Statistical Association**.

FRED EDERER

Data Access, National and International

Data and information are fundamental ingredients of health situation analysis. A national health information system helps safeguard against deterioration of the health of the population, provides data for research to improve health, and provides information for management of the health care system. Additionally, the system supports and enhances understanding of how health and well-being impact on the economy and other social institutions. The data collected should be those which are needed for determining a population's health status, aiding medical research, preventing and controlling diseases, assisting in decision-making, framing health policies, organizing or reorganizing health services, and informing the population about their state of health. Indicators of mortality, natality, morbidity, health services, and resource availability are among those which are useful for this purpose. Additionally, special data needs have arisen in recent years due to the increased incidence of several diseases as well as the alarming appearance of new diseases such as Lyme disease and acquired immune deficiency syndrome (**AIDS**) resulting from human immunodeficiency virus (HIV). At the same time, interest in international comparisons of health data has increased (*see* **Mortality, International Comparisons**) and, therefore, gaining access to relevant and timely data has become an important health priority.

National Sources of Data

Vital statistics, hospital discharge data, and health manpower resource statistics are collected and disseminated in virtually all of the industrialized countries and many of the developing countries. Most countries collect and publish these data on an annual basis through government statistical agencies. Access to these data vary from country to country. Published annual or other periodic statistics reports are the most common form of dissemination; however, many countries have electronic files available for public use.

The US **National Center for Health Statistics (NCHS)** has developed an *International Health Data Reference Guide* [2] which provides information on the availability and sources of selected national vital statistics, hospital discharge data, health manpower resources, and population-based health survey statistics (*see* **Surveys, Health and Morbidity**). As of 1996, official agencies of 44 industrialized nations provided information about the availability of selected health data for their country. The names, addresses, and facsimile (fax) numbers of these agencies are listed in the *Guide* to facilitate requests for data. This publication is available upon request from the National Center for Health Statistics, 6525 Belcrest Road, Hyattsville, MD 20782, USA.

Countries publish health data in varying detail and scope, ranging from simple summary measures of births and deaths to complex tabulations and analyses of a wide range of health variables. In the US, for example, two major annual health statistics publications are prepared, in addition to many one-off or special topic reports:

1. *Health, US* – a comprehensive report on the health status of the nation. It presents national trend data health status and determinants, supply and utilization of health resources, health care resources, and health care expenditures [1].
2. *Vital Statistics of the US* – a compilation of mortality, natality, marriage, and divorce data with extensive demographic and geographic detail [4]. A monthly vital statistics report is available providing monthly and cumulative provisional data [3].

A few countries release data to the public through a combination of publications, public use electronic data files, and unpublished tabulations. An even smaller number of countries, including the US, make data available on floppy diskettes, CD-ROM, and the **Internet**.

International Sources of Data

In the early 1980s, the **World Health Organization (WHO)** launched the Global Strategy for Health for All by the Year 2000. The Strategy has the aim of making possible the attainment, by all citizens of the world by the year 2000, of a level of health that will permit them to lead a social and economically productive life. Through the need to change priorities of information support and the need to reflect progress in implementation as ascertained by

the monitoring and evaluation processes, the need for health data including international comparisons has increased considerably.

United Nations

The Statistical Division of the United Nations (UN) has supplied basic statistical data for demographers, economists, public-health workers, and sociologists for almost 50 years. A prime publication is the *Demographic Yearbook*, which is published annually [8].

The *Demographic Yearbook* is a comprehensive collection of international demographic statistics (*see* **Demography**) which features the results of population **censuses**. Through the cooperation of national statistical services, official demographic statistics are presented for about 233 countries or areas throughout the world. Tables are presented giving a world summary of basic demographic statistics, followed by tables presenting statistics on the size, distribution, and trends in population, natality, fetal mortality, **infant mortality**, **maternal mortality**, general mortality, marriages, and divorces.

The *Yearbook* is available in published format and on magnetic tape. A database known as the Demographic and Social Statistics Database containing data previously published in the *Yearbook* from 1950 is available on floppy disks for use on microcomputers. Contact may be made to the Director, Statistics Division, United Nations, New York, NY 10017, USA, for further information on purchasing data.

World Health Organization

The World Health Organization (WHO) is a specialized agency of the United Nations with primary responsibility for international health matters and public health. Through this organization, which was created in 1948, the health professionals of more than 180 countries exchange their knowledge and experience. As part of WHO's mandate to establish and maintain statistical services and to provide information in the field of health, they publish the *World Health Statistics Annual* [9].

The *Annual* provides a compilation of data reported by Member States on deaths by cause, age, and sex, detailed statistics on selected causes of death, information on cases of deaths from notifiable diseases, and other data of medical and public health interest. The *Annual* is available in published format, and the more detailed mortality databases are available electronically over the Internet. For further information, contact the World Health Organization, Geneva, Switzerland.

Pan American Health Organization

The Pan American Health Organization (PAHO) is a regional office of the World Health Organization that provides data and information about the countries of the Americas. An annual publication *Health Statistics from the Americas* complements the quadrennial publication of *Health Conditions in the Americas* [6, 7]. The *Health Statistics* publications present a mortality database, estimated sex–age-specific death rates by broad groups of causes, and historical summaries of reported cases of selected **communicable diseases**. The *Health Conditions* publication presents a regional overview of the health situation with an annex of health and development indicators and country reports summarizing some salient conditions and problems for each country.

These two sources of data are available in published format and electronically over the Internet. Contact may be made to the Pan American Health Organization, World Health Organization, 525 Twenty-third Street, NW, Washington, DC 20037, USA.

Organization for Economic Cooperation and Development

The Organization for Economic Cooperation and Development (OECD), Paris, France, has developed a set of health data files designed to facilitate macroeconomic analysis of health care systems in the 24 industrialized OECD member countries. The files entitled OECD HEALTH DATA cover data on expenditures, hospitalization, demography, **life expectancy**, death rates, socioeconomic environment, compensation of health care professionals, length of stays in hospitals by **diagnosis-related groups (DRG)**, frequency of selected medical procedures, and fee schedules [5].

The information in this data bank is available for analysis through a software package designed for use on microcomputers. The data are updated when national administrations release new statistics

or revise old ones, usually on an annual basis. Contact may be made to the Publications and Information Centres, Organization for Economic Cooperation and Development, 2 Rue André-Pascal, 75775 Paris Cedex 16, France.

While sources for health data for countries around the world are increasing, and interest grows in drawing conclusions about international differences, it is important to bear in mind that a number of factors must be carefully considered before deciding that health information from different countries is, in fact, comparable. Among these factors are:

1. completeness of the coverage and reliability of the data
2. lack of standardization of data collection methods and definitions of terms
3. base population differences, e.g. the noninstitutionalized population vs. the total resident population
4. coding and tabulation differences.

Data and Safety Monitoring

Phase III clinical trials (*see* **Clinical Trials, Overview**) usually have a (**DSMB**), with broad responsibility for monitoring the conduct of the trial. The responsibilities of the Board typically include insuring scientific integrity and patient safety, monitoring the occurrence of adverse events, and assessing efficacy. As the study progresses, the Board discusses these issues and makes recommendations to the study investigators regarding the conduct of the trial, possibly including a recommendation regarding early termination of the study.

To simplify the discussion of this monitoring activity we suppose that the trial is a randomized, double blind (*see* **Blinding or Masking**) study comparing an experimental treatment to either a placebo or a standard treatment. Initially, we also assume that efficacy is measured primarily by a single, univariate primary endpoint, allowing that numerous secondary measures may also be available (*see* **Oblimin Rotation**).

Monitoring the scientific integrity of the study involves reviewing information such as violations of the protocol, recommendations for modifying the protocol (*see* **Clinical Trials Protocols**), evaluations of data quality (for example, errors identified at data entry specific to each form, how many errors have been corrected and how many are outstanding) (*see* **Clinical Trials Audit and Quality Control**), recruitment, timeliness of follow-up, drop-outs and **Adjustment for Noncompliance**.

A primary responsibility of the DSMB is to insure that the trial is sufficiently safe to warrant continued participation of the patients. This activity normally involves a qualitative review of adverse events. In view of the varied and somewhat unpredictable nature of the adverse events that may ultimately become of concern, formal stopping rules may be less helpful for assessing safety than for assessing efficacy. However, one might form a combined safety endpoint, such as the occurrence of any major adverse event (suitably defined), and then evaluate this endpoint in the context of a stopping boundary. At the least, such an approach might provide the DSMB insights as to the frequency with which an observed imbalance between groups would occur by chance, and this in turn might aid in arriving at a decision whether or not to terminate the study.

Formal stopping rules have found particular usefulness in assessing efficacy. A large number of approaches have been proposed. We will focus here on the commonly used group sequential methods, all of which assume a classical statistical framework. **Decision theoretic** approaches are also discussed. Before describing the mechanics of implementing interim analyses for efficacy, it is important to consider the larger context in which these analyses occur. There are numerous considerations that affect the decision to terminate a study early, and the crossing of a statistical boundary is only one. Thus, the actual decision may not be the same as the decision suggested by the statistical test.

Reasons for desiring early termination of a trial are rather obvious. Certainly, if the evidence in favor of an experimental therapy is overwhelming, there is an ethical need to stop the trial and provide the drug to all study participants as well as other patients (*see* **Ethics of Randomized Trials**). There is also a clear financial incentive to stopping early under these circumstances, both in terms of the costs of the study as well as revenues which may accrue from sales of a new drug or medical device. Early termination may also release patients for other trials, especially if the reason for terminating early is convincing evidence that the drug is ineffective. Finally, early termination because of overwhelming evidence of treatment efficacy may facilitate initiation of additional follow-up studies to understand further the nature of the treatment effect.

Thus, there are important reasons to consider stopping early. However, there are also arguments against early termination. The consequent reduction in sample size may prevent a definitive evaluation of important secondary endpoints or evaluation of subgroups, analyses which might shed important light on the nature of the treatment effect (*see* **Treatment-covariate Interaction**). When the primary endpoint is survival, or time to a specified event (*see* **Survival Analysis, Overview**), a dramatic early effect may prove to be transitory, with the survival curves eventually coming together or even crossing, and early termination may cause this phenomenon to go unobserved.

As we will discuss in greater detail, early termination introduces a **bias** into conventional estimates of

the magnitude of the treatment effect. Although statistical techniques are available to adjust estimates, they are complex, thus compounding the difficulty of explaining these issues and adjustments to a nonstatistical audience.

Group Sequential Tests

The desirability of performing tests on accumulating data while a study is ongoing has long been recognized. Early work on sequential methods (*see* **Sequential Analysis**) focused on procedures which called for testing after each observation was realized, and sequential probability ratio tests (SPRT) were a cornerstone of this approach. It consists of computing the ratio of the **likelihood** functions under the **null** and **alternative hypotheses** (both specified as simple hypotheses) and comparing this to upper and lower boundaries. Depending on which boundary is crossed, one accepts the corresponding hypothesis. Fully sequential designs with a **binary** outcome were proposed by Bross [9] and Armitage [4].

Although a large body of theory relating to fully sequential designs has been developed, these methods are infrequently used. One limiting feature is that there is typically no upper bound on the number of observations that may be required to reach a decision. An additional problem is the logistical impracticality of testing after each observation.

These limitations led to consideration of group sequential tests, where tests are performed only periodically during the course of the study. The idea for this approach dates back to Armitage et al. [5] and Samuel-Cahn [36, 37]. A simple strategy for performing group sequential tests was proposed independently by Haybittle [21] and by Peto et al. [32]. The approach is to perform interim tests at a very stringent level of significance, and then test at the nominal level at the end of the study if the trial was not terminated early. For example, one might test at the 0.01 level if only one or two interim tests are planned, or at the 0.001 if more than two are planned. Although the overall probability of type I error (*see* **Hypothesis Testing**) will exceed the nominal level, the excess should be small. More recently, methods have been developed which provide accurate control over the type I error rate, and which give the investigator a wide choice of boundary shapes.

Some Commonly Used Procedures

In describing the most commonly used group sequential tests, we start with the simplest situation, in which **normally distributed** endpoints are observable immediately after treatment, $K - 1$ interim tests are planned, and n subjects are recruited into each arm of the study between successive tests. Let X_{ij} represent the observation on the ith subject receiving placebo therapy during the jth period of recruitment (between the $j-1$ and jth tests), $i = 1, \ldots, n$, $j = 1, \ldots, K$. It is assumed that the X variables are independently distributed with a common normal distribution having mean μ_P and known variance σ^2. Similarly, let $Y_{ij}, i = 1, \ldots, n,\ j = 1, \ldots, K$, represent the observations on the experimentally treated patients, which are normally distributed with mean μ_E and variance σ^2.

For $k = 1, \ldots, K$, let T_k represent the usual t test statistic (*see* **Student's *t* Distribution**) based on the data available after the kth recruitment period:

$$T_k = \frac{\sum_{j=1}^{k} \left(\overline{Y}_{\cdot j} - \overline{X}_{\cdot j}\right) (n/2k)^{1/2}}{\sigma}.$$

The procedures described below can all be expressed in terms of boundaries depending on a set of constants determined by the choice of K and the overall type I error rate, $\alpha : C(1, \alpha), \ldots, C(K, \alpha)$. After collecting data up to the kth test ($k = 1, \ldots, K$) one computes T_k, and if the test statistic exceeds $C(k, \alpha)$ one concludes that the trial may be terminated with overall probability of type I error less than α.

Three of the most commonly used boundaries are listed below. For $k = 1, \ldots, K$:

1. Constant boundary (Pocock boundary [33]):

$$C(k, \alpha) = C_P(K, \alpha).$$

2. Monotone decreasing boundary (O'Brien and Fleming boundary [29]):

$$C(k, \alpha) = C_{OF}(K, \alpha) \left(\frac{K}{k}\right)^{1/2}.$$

3. Intermediate boundary (Fleming et al. [17]). Let π_k represent the probability of a type I error occurring at the kth test. $C_{FHO}(k, \alpha)$ is defined

such that $\pi_1 = \cdots = \pi_{K-1}$ and $\pi_1 + \cdots + \pi_K = \alpha$. Notice that the probability of a type I error occurring at each of the interim tests equals the nominal level of the first interim test.

As seen in Table 1, the Pocock (P) boundary offers the greatest opportunity for stopping at the first interim test. Conversely, it is the most stringent of the three boundaries at the final test if the study is not terminated early. This can result in an awkward situation for a DSMB, when the nominal P value at the end of the study is less than 0.05, but is not sufficiently small to achieve significance as defined by the group sequential boundary. For a fixed number of interim tests and equal sample sizes between each test, the P boundary gives the smallest average sample size among the three boundaries. However, for designs with equivalent maximal sample size, it gives the lowest **power**. Put differently, it requires the largest maximal sample size to achieve a specified power.

The O'Brien–Fleming (OF) boundary requires very strong evidence of an effect to terminate at the first interim test, whereas the criteria at the final test are rather close to those for a single sample design (that is, a design with no interim testing). This feature may be viewed as desirable in the sense that monitoring committees typically want very convincing evidence that a treatment effect is real before terminating a study very early (for all the reasons discussed previously), but desire a criterion close to the single sample test if early termination does not occur. However, the boundary at the first test is judged to be too extreme in some applications, particularly if the number of interim tests exceeds two. In this case, one may modify the decision rule to stop after the first test if $P < 0.001$. The effect of this modification on the overall type I error rate is negligible.

Table 1 Nominal P values for overall type I error of $0.05(\alpha = 0.05)$ Pocock, O'Brien–Fleming, and Fleming–Harrington–O'Brien boundaries

k	Pocock	O'Brien–Fleming[a]	Fleming–Harrington–O'Brien[b]
1	0.0294	0.0051	0.0150
2	0.0294	0.0415	0.0418
1	0.0221	0.0006 (0.001)	0.0050

3	0.0182	0.0184	0.0103
4	0.0182	0.0412	0.0403
1	0.0158	5×10^{-6} (0.001)	0.0038
2	0.0158	0.0013	0.0048
3	0.0158	0.0085	0.0053
4	0.0158	0.0228	0.0064
5	0.0158	0.0417	0.0432

[a]Use of 0.001 for the first test is recommended for the OF boundary with $K > 2$.

[b]Letting π_1 represent the probability of type I error occurring at the kth test, $\pi_1 = \cdots = \pi_{K-1}$ (where π_1 is the tabled entry for $k = 1$) and $\pi_K = \alpha - (K-1)\pi_1$.

The boundary proposed by Fleming, Harrington & O'Brien (FHO) occupies middle ground between the P and OF boundaries, but is closer in spirit to the OF boundary. The distinguishing characteristic of the FHO boundary is that the probability of a type I error is held constant for each interim test. Thus, the boundary is determined by specifying the number of interim tests and the probability of a type I error occurring at the final test. In the examples shown, this error rate has been chosen to be close to the overall type I error rate ($\alpha = 0.05$).

A different type of approach to group sequential testing has been proposed by Whitehead [40] and Whitehead & Stratton [41], using a triangular boundary. Conceptually, one plots an estimate of the treatment effect on the vertical axis and a measure (V) of the information contained in Z on the horizontal axis. The null or alternative hypothesis is accepted depending on whether the lower or upper of two lines are crossed. Since the lines are constructed to cross eventually for suitably large V, the test terminates with probability one.

Although the original formulation of these group sequential designs assumed normal distributions with known variances, simulation studies have shown that they provide accurate control over the overall type I error rate for other types of data. Thus, they are commonly used when variances are unknown, for binary endpoints, and survival data. Theoretical work indicates that independent increments of information accumulating between successive tests is an important underlying consideration relating to the joint distribution of the K test statistics.

The Alpha-spending Function Approach

Formally, the Pocock and O'Brien–Fleming boundaries require two assumptions which may be violated

in practice. First, one assumes that the number of interim tests which will be conducted is specified in advance. This may be problematic if a decision is made to extend the trial due to slower than anticipated accrual. Notice that this assumption is not required for the FHO boundary, since one can adjust the level of the final test to allow for an increase in the number of interim tests conducted.

A second assumption is that an equal number of subjects are recruited between each test, or in the case of survival-type studies, that the number of events occurring between each test is constant. This assumption is typically unrealistic, since meetings of the DSMB are usually determined according to calendar times. **Simulation** studies [13, 29] indicate that the effects on size and power resulting from using unequally spaced tests is negligible.

Thus far, we have assumed that modifications to the monitoring plan are not motivated by accruing data. For example, it might be tempting to schedule more frequent tests if it appears that the stopping boundary is being approached. Proschan et al. [34] considered a variety of data-driven strategies and found that the overall type I error rate can be severely inflated. Thus, these types of monitoring strategies should be avoided.

In view of the considerations discussed thus far, it appears that the Pocock and O'Brien–Fleming boundaries are quite flexible, and can be used without modification in monitoring trials in a wide range of circumstances. However, it is of interest to consider versions of stopping boundaries which are a continuous function of the percentage of the study completed. This approach was proposed by Lan & DeMets [26], and is illustrated in Figure 1. In this example, an FHO boundary is specified as in Table 1, with two interim tests performed at equally spaced time points, with $\alpha(t_1) = 0.0050$ and $\alpha(t_2) = 0.0100$.

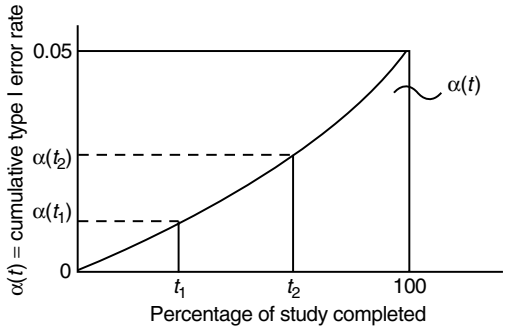

Figure 1 A spending function, $\alpha(t)$, expressing the cumulative type I error rate as a function of the percentage of the study completed

Notice that the times t_1 and t_2 need not have been specified in advance. For example, one might suppose that an FHO boundary had been selected, but the time of the first analysis (t_1) had not been planned. If t_1 corresponded to completion of 1/3 of the study as in the example, then $\alpha(t_1) = 0.0050$. However, if t_1 were some other time point, then the critical value would have been the point in the boundary corresponding to this time.

Continuous spending functions that correspond closely to the Pocock and O'Brien–Fleming boundaries have been identified by Lan & DeMets [26], and computing software has been developed in order to address the computational problems required to identify boundary points as a function of time.

Multiple Endpoints

Thus far, we have assumed that efficacy is defined by a single univariate endpoint. The situation actually encountered by a DSMB is often more complex. Of particular concern is the situation in which the primary endpoint is conceived as a single but multifaceted endpoint. For example, one might be evaluating the effects of an experimental therapy in improving the status of small nerve fibers in diabetic neuropathy. However, the status of small nerve fibers may be measured by performance on several neurologic tests, and it is the combined information from these tests which provides the definitive assessment of status (*see* **Multiplicity in Clinical Trials**).

Ideally, a clinically meaningful method for combining the various measures might be available. In this case, the resulting global score can be used, and the statistical issues associated with multiple endpoints do not arise. If such a score is not available, statistical algorithms for obtaining global scores can be used (see O'Brien [28]; and *see* **Multiple Endpoints, Multivariate Global Tests**).

A qualitatively different scenario which may be of concern to the DSMB is where multiple secondary endpoints, each of interest in its own right, are considered. The question may be asked if any of these endpoints have shown a response to therapy and, if so, which endpoints. Analyses directed at answering these questions may produce multiple statistical tests, in which case questions arise about what error rates

should be of interest (per comparison, experimentwise, or per experiment) and the best way to control them. An excellent review of these issues can be found in Hochberg & Tamhane [22]. The case against attempting to control experimentwise and per experiment error rates is discussed by Rothman [35].

It is perhaps unfortunate that discussion of testing multiple hypotheses tends to accept as a premise that one type of error rate is appropriate and the other not. An alternative approach would be to view the differing error rates as qualitatively different pieces of information, one or more of which might be helpful in any given instance.

Stochastic Curtailment

In comparing the different approaches for interim testing, it was observed that it is often desirable to stop only when the evidence for or against a treatment effect is overwhelming. Under these circumstances, the OF procedure has the desirable property that the probability of type I and type II errors are close to the error rates associated with a single sample test. Thus, one gains the opportunity to terminate early with little loss.

Stochastic curtailment follows this train of thought to its logical conclusion. One examines the data to see if the final result has already been determined with certainty [1, 2, 14, 19, 20, 27]. For example, if the data strongly suggest that treatment is efficacious, one can suppose that subsequent data will be the least favorable possible. If the **null hypothesis** would still be rejected under this assumption, then there would be no need to continue the trial, at least as far as the primary test for efficacy is concerned. Similarly, if the data indicate a lack of an effect, one could suppose that subsequent data will be the most favorable possible, and consider terminating the study if the null hypothesis would not be rejected under these circumstances.

Since it is unlikely that a trial will progress to the point that the outcome is completely determined, a DSMB is more typically concerned with the probability that a current trend might be reversed, so that statistical significance might be achieved despite an early negative trend, or vice versa. This approach is closely tied to the concept of conditional power. If the early trend is positive, one would compute the probability of achieving significance under the null hypothesis.

Conversely, if the trend is negative, one would compute the conditional power under a suitable alternative hypothesis. A natural alternative to consider is the one which was originally proposed in the study design and used for sample size calculations (*see* **Sample Size Determination for Clinical Trials**). This approach may be especially appropriate in studies in which the primary endpoint is time to an event, where one might suppose that lack of an effect initially may be due to a delayed onset of treatment effect.

In other applications, one might argue that, if the current data indicate that the originally hypothesized effect is implausible given the current data, one should consider an alternative which is both clinically meaningful and also plausible given the current data. Although some authors have proposed using the point estimate from current data as the alternative for computing conditional power, this reasoning seems somewhat circular.

The issues surrounding early stopping based on stochastic curtailment are similar in many respects to those described previously. In particular, any purely statistical algorithm will in practice be used by a DSMB as only part of the information to be considered in arriving at a decision whether or not to terminate the trial. However, a unique aspect of stochastic curtailment is that it typically does not allow one to say that statistical significance has occurred, or that it cannot occur. Rather, stochastic curtailment provides a mechanism for predicting whether or not significance will occur.

Point and Interval Estimation

When accumulating data are monitored during the course of a trial, one can expect that at times the results will appear overly encouraging. At other times, results may appear overly negative. When considering whether or not to terminate a trial early, a DSMB will need to account for this in evaluating the magnitude of treatment effects. Thus, there is a need to adjust point and interval estimates to account for interim monitoring, in much the same spirit that P values must be adjusted.

In formulating appropriate interval estimates, it is necessary to take into account that the sample space is two-dimensional, consisting of the number of tests undertaken ($k^* = 1, \ldots, K$) and the value of the test statistic at the last test (T^*). One must obtain

a univariate ordering of the sample space, and one way to do so is to order first according to k^*, then T^*. The ordering may be represented as a mapping from (k^*, T^*) to $Z(k^*, T^*)$. By inverting probability statements about $Z(k^*, T^*)$ and the parameter of interest (θ), one obtains confidence intervals for θ.

A detailed discussion of this approach appears in Tsiatis et al. [39]. A limitation is that the ordering of the sample space is somewhat arbitrary and may produce **confidence intervals** that may be counter-intuitive. For example, one would suppose that the need to adjust for overly optimistic data would be greatest for trials which terminate at the first interim test. However, using the ordering of the sample space described above, in this circumstance the adjusted confidence interval, is the same as the "naïve" single sample interval. This problem is discussed in Chang & O'Brien [11], who consider an ordering based on **maximum likelihood** criteria. However, there is no general agreement over the best ordering to use.

There is also the need to adjust point estimates of treatment effect. Methods for obtaining estimates which are unbiased in the usual sense are not generally available. An alternative approach is to use the confidence interval calculations described above, but to compute the 50% confidence interval, obtaining an estimate which may be described as "median unbiased" in the sense that the estimate will be greater than (and less than) the true value with probability 0.5.

The methods described above provide a means for adjusting point and interval estimates upon completion of a trial when the study has been terminated early. A conceptually different problem is to obtain repeated confidence intervals during the course of the study as an aid in judging the desirability of early stopping. This approach seems especially well suited to the way a DSMB works in practice, making assessments about the magnitude of effects which seem plausible, weighing this information with other considerations, and making a judgment about whether or not to continue.

Repeated confidence intervals are computed in a way to insure that all the intervals which may ultimately be computed will contain the true population parameter with a specified probability (e.g. 0.95). A method to accomplish this is to use the well known correspondence between interval estimation and hypothesis testing [23]. Since the probability statements pertain to all confidence intervals which may be computed, one could use the intersection of all intervals available at the time they are being considered. In practice, interest usually centers on the most recent interval.

One-sided Versus Two-sided Tests

Statisticians often disagree about whether tests should be one- or two-sided (*see* **Alternative Hypothesis**) [15, 16, 24, 25, 30, 31]. The issues involved are somewhat more complex in the context of monitoring a clinical trial. Careful consideration of these issues is worthwhile, because it provides important insights into the monitoring process itself. It is helpful first to consider the controversy in the more general context of **hypothesis testing**.

One argument is that a test should be two-sided if it is possible that an effect could go in either direction. Thus, if it is possible that a drug could be worse than placebo with respect to the primary endpoint, this view would imply that the test for efficacy should be two-sided. A second argument is that the test should be two-sided if the investigator would be interested in an effect in either direction. Since it is difficult to establish that a phenomenon is impossible (particularly when the effects of a drug are unknown), and since investigators are interested in any new information which might be gleaned from their study, these two arguments generally lead proponents to argue for two-sided tests.

A third point of view is that one must first determine what question the study is intended to answer. The translation of this question into corresponding null and alternative hypotheses then determines whether the test will be one-sided or two-sided. To illustrate, suppose the purpose of a study is to answer the question, "Is the experimental drug more efficacious than placebo?" The alternative hypothesis corresponding to this question is clearly one-sided, and the probability of a type I error (a claim of efficacy when in fact the drug is not more efficacious than placebo) is given by a one-sided ***P* value**. Although it might be possible that the drug effect is deleterious, and one would certainly be interested in such a finding, these are additional questions which, along with many others, would be an appropriate subject for secondary analyses. A qualitatively different situation occurs when one is comparing two competing therapies and the question motivating the study is, "Is one treatment superior to the other?"

This is a two-sided question, in which a difference in either direction will lead to an affirmative answer (and potentially a type I error).

These considerations become increasingly important in the context of monitoring a clinical trial. One might argue that, although the primary analysis at the end of the study addresses a one-sided question, the question during the monitoring phase is two-sided, since the DSMB will terminate the study if the evidence of a treatment effect is overwhelmingly positive or negative. Thus, one might argue for two-sided tests during the monitoring phase, but plan on a one-sided test at the final analysis for efficacy.

Another approach is for the DSMB to consider three distinct questions and target correspondingly distinct analyses towards each: (i) Is the drug efficacious? (ii) Is the drug safe? (iii) Is the probability of achieving statistical significance so remote that we might as well stop the trial now?

The first question is one-sided and might be addressed using a group sequential test or stochastic curtailment, using a one-sided test in either case. Similarly, the third question would be appropriately addressed using stochastic curtailment or conditional power based on a one-sided test.

The second question usually encompasses a wide range of potential hazards, and some of the dangers may only become apparent during the course of the trial. An adverse effect on the primary measure of efficacy may be only one of many such hazards, and is typically one of the least likely to materialize. In addition, the desirability of waiting until statistical significance is achieved, and the level of significance which is appropriate, may be quite different in assessing safety vs. efficacy. Thus, the implementation and interpretation of hypothesis testing in addressing safety may differ from assessments of efficacy.

Decision Theoretic Methods

Controling the overall type I error rate is a critical concern in monitoring clinical trials and in making judgments about the desirability of early termination. As indicated previously, this piece of information is combined with other factors, such as the estimated magnitude of the effect, in arriving at a decision. Although the **decision theoretic** approaches of the sort that we discuss next appear to be infrequently used by DSMBs, they might provide helpful additional information. In addition, **Bayesian methods** may be especially well suited to monitoring pilot studies in the drug development process prior to a large Phase III trial.

Maximizing the Number of Patients Receiving Better Treatment

Consider the total population of patients who will receive either the standard or experimental therapy in the future. One approach to the study design might be to attempt to maximize the number of patients who will ultimately receive the superior treatment. Specifically, let N represent the number of patients who might receive the new treatment. Among the number (n) who will be entered into the trial, let n_s and n_e represent the number who will be assigned to standard and experimental therapy, respectively. If we assume that the remaining $N - n$ will receive the drug selected at the end of the study and adopt a prior probability distribution that one treatment is superior to the other, then we can choose n_s and n_e to maximize the expected number of patients receiving superior treatment.

A fixed sample size test with equal numbers assigned to each treatment arm of the study, assuming that the study endpoint is dichotomous and immediately observable, was proposed by Canner [10]. The requirement of equal allocation between treatment arms was obviated in a method by Berry & Pearson [8]. Earlier work by Colton [12] considered procedures that are conceptually similar, using **minimax**, maximin, and Bayesian approaches focusing on the costs associated with a wrong treatment selection. Group sequential versions of these types of tests would be desirable for use by a DSMB.

A Bayesian Approach

In a sense, deciding that the evidence in favor of an experimental therapy is sufficient to justify terminating a trial and recommending the treatment for future patients is analogous to the decision a physician makes in choosing a new treatment for future patients [3, 6]. Furthermore, one might argue that, at least implicitly, physicians make these types of decisions based on a Bayesian probability; that "medical researchers ... act like Bayesians" [7].

This line of reasoning suggests a Bayesian decision rule rather than a classical group sequential

approach. A simple example of how such a rule might proceed is provided by Berger & Berry [6], who consider a randomized trial comparing experimental and standard therapies. They assume that patients are randomized in pairs and that a dichotomous response (success or failure) is immediately observable.

Let p represent the prior probability that there is no difference between drugs (H_0), and let θ represent the probability that E will be superior to S in a given pair, where the investigator must specify the constant p and the distribution for θ. In this case, we assume $p = 0.5$ and that θ follows a uniform distribution over the interval (0, 1).

Hypothetical data for the first 18 pairs are shown in Table 2, together with the posterior probability that E is superior to S. Based on these computations, it would appear that the evidence in favor of E was convincing well before the eighteenth pair.

It is of interest to consider how the monitoring of this trial might have proceeded using the classic group sequential approach, evaluating the data after every six pairs, supposing that a maximum of 18 pairs had been planned. The nominal P value for a one-sided test after 12 pairs is 0.019, slightly larger than the level required for the OF, but less than the level required by the P boundary.

Table 2 Results in 18 pairs of patients

Pair	Superior treatment	Cumulative preference for E	Posterior probability E better than S
1	E	1	0.750
2	S	0	0.500
3	E	1	0.687
4	E	2	0.812
5	E	3	0.891
6	S	2	0.773
7	E	3	0.855
8	E	4	0.910
9	E	5	0.945
10	E	6	0.967
11	E	7	0.981
12	E	8	0.989
13	E	9	0.994
14	S	8	0.982
15	E	9	0.989
16	E	10	0.994
17	E	11	0.996
18	E	12	0.998

Source: Berger & Berry [6].

This example provides some insights about the strengths and weaknesses of a Bayesian approach within the context of monitoring clinical trials. A subjective assessment may be especially useful for a pilot study in which the goal is to determine whether or not to proceed to the next step in drug development. On the other hand, for trials which are intended to provide a definitive answer about efficacy, the necessity to specify prior distributions may pose a difficulty for the Bayesian approach. Disagreement about priors may occur both within the DSMB as well as in the medical and scientific community.

Some ways to integrate Bayesian methods into a more traditional framework are: to compute the type I error rate for Bayesian stopping bounds; to adopt skeptical priors resulting in conservative stopping bounds; and to treat Bayesian analysis as a source of additional information complementing the information obtained from frequentist analyses. Excellent discussion of applied aspects of incorporating Bayesian methods in the monitoring of clinical trials is provided in Spiegelhalter et al. [38] and Freedman & Spiegelhalter [18].

Data Archives

Data archives are accessible and indexed compendia of data which can be accessed and utilized by researchers intending to perform secondary data analysis. Such archives have been in existence in the United States since the early 1960s and have spread internationally since then. An example is the Economic and Social Research Council (ESRC) data archive at the University of Essex, UK, established in 1967. Quantitative data from various governmental, administrative, and research sources are held in computer-readable forms. Qualitative data archives, including the ESRC QUALIDATA archive, are a more recent innovation.

Data archives preserve data against disposal or deterioration, provide indexing services, and can provide data in formats useful to secondary data analysts. There are several reasons why increasing accessibility of data, through the establishment of data archives, is beneficial to the research community [1]. Data collection is expensive, and the use of extant data to answer research questions which were not originally envisaged by the collectors of the data is an efficient use of resources. Study participants are protected from being overresearched by the multiple use of data. Archived data provide a rapid and inexpensive way of replicating the findings from other studies, and the interrogation of existing data at the time of the design of future studies is useful for the performance of **sample size determination**, evaluation of data collection instruments (*see* **Questionnaire Design**), and the exact formulation of research questions. Archived data can be linked to other data (*see* **Record Linkage**) if different sets of records on the same people exist, creating data sets which can be used to explore issues which cannot be examined in existing unlinked studies. The rapidly expanding field of **meta-analysis** also benefits from the ready availability of primary data. Statistical techniques can be applied to data which were collected when such methods of analysis had not been developed. Finally, the requirement to provide original data is one protection against the production of findings based on a particular statistical approach to the data – findings produced by what is commonly called "data torture" and the actual fraudulent invention of results.

Primary researchers may understandably view the provision of data to archives as threatening [1]. Guaranteed rights to initial publication, transfer of the costs of data preparation for archival storage to funding bodies or secondary analysts, and protection against the commercial exploitation of data by a recipient are all reasonable requests by primary data collectors. Criteria for the evaluation of secondary (including archived) data sources for use in epidemiologic research have been developed [2], and a formal appraisal of the value of secondary data analysis in relation to that of primary research would be valuable.

Data Management and Coordination

The term "data management" in **clinical trials** has become a very general term that covers the procedures both for the collection of data at clinical sites, and for the quality control of those data after they have been submitted to a central statistical or coordinating center (*see* **Clinical Trials Audit and Quality Control**). In both locations procedures should be established for managing the trial data, and steps taken to ensure that the quality of data is high throughout a trial. These steps and procedures are described in this article.

An individual who is responsible for the collection and quality control of data is known by various titles, including "data manager", "clinical research associate", "data coordinator" and "research assistant". For the sake of clarity, in this article the term "clinical research associate" (CRA) is used for an individual responsible for the abstraction of data and completion of forms at the participating institution, and the term "data manager" is used for an individual responsible for the quality control and computerization of the data at the statistical center. Usually, there is one clinician who has overall responsibility for the design and monitoring of the trial and, in this article, this person is referred to as the "study chair".

The importance of high-quality data cannot be overemphasized. The "end-product" of a clinical trial is the publication of its results in the scientific literature. To reach this point, trials have to be designed carefully, required data defined, forms developed, patients enrolled, data collected, data analyzed, and a manuscript prepared. The goal of the data management team is to collect complete and accurate data so that the results are correct. By "correct" results is meant true observations. Whether these are statistically or clinically significant is not the main concern of the data management team.

Trial Participants

Clinical trials can be single-institution or **multicenter trials**. A single-institution trial is conducted in one location with trial design, patient entry, data collection and analysis all being done at that institution. Multicenter trials are collaborations between investigators at multiple institutions. Study design is done as a team, patients are entered from all participating institutions and the data are usually sent to a central statistical center or coordinating center for quality control, computerization and analysis. Most large Phase III trials are done as multicenter trials, as few single institutions are able to accrue enough patients by themselves. In this article, the multicenter model is used for examples, but most of the discussion applies equally to small single-institution trials.

As well as the participating institutions and the statistical center, special reference centers (e.g. to review pathology slides, read x-rays and scans, or to do specialized laboratory testing not routinely available at the participating sites) may be used for specific trials. These reference centers usually generate data that become part of the database for the clinical trial, and therefore data management procedures need to be established to handle the collection and transfer of these data.

Another major participant in a trial is the sponsor. Most large trials have sponsors who provide funding or resources (such as drugs). The sponsor could be a government, a private agency that supports scientific research, or a company that manufacturers one of the treatment components. The sponsor may have special requirements for data management procedures, and it is important to discuss these during the design phase of the trial to be sure that they will be met.

Protocol and Forms Design

Data management input is important during all phases of a clinical trial, including the design phase. Data managers can contribute to the clarity, completeness, and consistency of a **clinical trial protocol** by providing feedback. In particular, they should review the eligibility section (*see* **Eligibility and Exclusion Criteria**), the section describing how patients will be entered, the treatment administration section, and the section describing the schedule for submitting required data forms. Data management review of each draft of the protocol can greatly improve the quality of the final protocol and make it easier to use. Reviewers should include both CRAs at sites that will enter patients and the data managers at the statistical center.

In parallel with the development of the protocol, there should be discussion about the data items

needed to meet the study objectives and monitor the progress of the trial (*see* **Data and Safety Monitoring**). The identification of the data items to be collected, and the subsequent design of the data collection instruments and the computer database (*see* **Database Systems**), are critical. These three activities are interrelated and are best performed in the order listed. The data collection instruments, whether paper forms or electronic screens, should be available prior to entry of the first patient. A trial should not be activated without data collection instruments.

Defining The Data Items

There are different types of data that may need to be collected, and it is important during the planning phase of a study to think through all the requirements for the trial. For example, besides the research data, it may be necessary to collect data to aid the administration of the trial and to document compliance with professional regulations and good clinical practice.

Identification Data. When forms are submitted they must be linked to the appropriate patient and also to the correct trial. Therefore, a form must have space for recording sufficient information for correct identification of the patient, the trial, and the local institution.

Research Data. The research data represent the information that is ultimately analyzed to address the study objectives. The required data should be identified during the protocol development phase, with input from all key members of the trial team, including the study chair statistician and data coordinator.

It is always tempting to collect data items "just in case" they turn out to be interesting when the data are analyzed. However, collecting large amounts of data on each individual can be detrimental to the study because, as the volume of data increases, the quality of the data can decrease. It is, therefore, important to limit data collection to those items that are truly necessary to answer the trial objectives and manage the trial. In assessing the data requirements, the team should distinguish between data that are needed for the clinical care of the patient and data that are needed to answer the research objectives. Data collection for the trial should be limited to those items related to the research objectives. In most trials, only a small fraction of the clinically relevant information is entered into the trial database.

Omissions at this stage will be very difficult to rectify once the trial has begun to accrue patients, as it is hard to collect data retrospectively. To help to ensure that all necessary data are collected, it is useful for the statistician and study chair to draft an analysis plan detailing the information to be included in the final report. Other members of the trial team can review this outline and provide input. Once this is done, it is easier to identify the required data items. At a minimum, the required data usually include key dates of events (such as date of entry to the trial), information about the treatment assigned and received, side effects of treatment, and the study endpoints (*see* **Outcome Measures in Clinical Trials**).

Administrative Data. It is usually necessary to collect administrative data to help with the management of the trial. An example is the recording of dates of dispatch of materials sent by the institutions to reference centers, and an inventory of the materials sent. The amount of administrative data depends on the size and complexity of the trial. In a small single-institution trial, much less information is needed than in a large multicenter trial, where data and materials are being shipped to various locations.

Regulatory Data. For some trials it may be necessary to collect documentation that shows compliance with local, national or international regulations (*see* **Drug Approval and Regulation**). This could include documentation of protocol approval (and periodic re-approval) by an ethics committee or institution review board prior to patient entry, consent of the patient prior to entry, and the professional qualifications of the personnel at a participating site. Normally, if the trial includes investigational treatments, then the statistical center needs to collect copies of these documents. For other trials, it may be sufficient to maintain a file of these at each participating site.

Design of Case Report Forms

Once the data items have been defined, case report forms (CRFs) should be developed. A CRF is a printed or electronic document that is designed to collect the required research, administrative, and regulatory data for a clinical trial. The measurement and

recording of the trial data are perhaps the most critical steps in the overall data management process, and it is, therefore, important that the CRFs be designed for clarity and ease of use. Forms should always be available before a trial is activated. Activating a trial without the CRFs available is likely to generate incomplete and inconsistent data; the urgency to activate a trial should, therefore, always be balanced by the need to have the forms in place. It is recommended that forms be piloted, to identify problems that can be corrected prior to starting the trial.

It is always useful to look at the data collected for other similar trials before designing new forms, and to take advantage of this prior experience. If there are existing forms that can be used for the new trial, it can eliminate much work. A book of more than 600 forms used in previous clinical trials is available [3] and may provide useful examples. If existing forms are used, it is important to check that these do, in fact, collect all the data needed for the new trial, and, conversely, do not collect data that are superfluous.

When designing forms for a trial, thought should be given to the following aspects.

Content and Organization of CRFs. The ultimate objective of the CRF is to collect the data needed to answer the trial's objectives. Once identified, it is necessary to decide how to organize the data items on the forms. It is not always best to minimize the number of CRFs by trying to fit as much as possible onto one form. It may be better to have more forms, each with a smaller amount of data. When designing CRFs, one should ask:

1. When will data be available?
2. Who will complete the forms?
3. Where will the data be collected?

As a first step, the *timing* of the collection of the different items should be established. For example, one should identify all of the data items that will be collected at the time that the patient is entered on the study. These normally include data on the patient's past medical history, data confirming the patient's eligibility, and results of baseline tests required by the protocol. Other relevant time points could be the different stages of the protocol treatment period, the end of treatment, and scheduled follow-up examinations after the treatment period. All of these are logical divisions and can help in deciding which data items belong on which forms.

As well as the timing of the data collection, it is also useful to identify *where* the data will be collected and *by whom*. These are also logical divisions that can help to decide which data should be collected on which form. For example, there may be baseline data that are gathered from the medical record by a CRA and other data that are completed by a medical specialist, such as a surgeon. Even though all the data are collected at the same time point, it is more efficient to have two different forms – one for the CRA and one for the surgeon. This allows each person to complete their part of the data collection in parallel, rather than one having to wait for the other to complete their part before passing the form on. Likewise, if some of the data are available in the cardiology department and some in the physical therapy department, two separate forms may work better.

Format of Questions and Coding Conventions. The goal of the CRFs is to collect complete and unambiguous data and to ensure standardization and consistency of data across participating clinics. The format of the CRFs should be designed with three functions in mind: (i) the completion of the form; (ii) the entry of the data onto computer; and (iii) the retrieval of data for analysis. The person completing the form should be able to answer the questions and record the answers in an efficient and effective way, minimizing the possibility of misinterpretation or transcription errors; the person entering the data onto computer should be able to transcribe values from the form to the keyboard with minimum effort in following the flow of responses and entering the data values; the person analyzing the data needs to be able to interface the data and the statistical **software** with minimal data conversion. Even if the data are not computerized, but are tabulated manually, it is important to design the forms with analysis in mind.

There are several ways to format questions on CRFs and there are conflicting ideas of the most effective format for collecting complete, accurate data. Because the goals of different trials and environments of data collection vary, it is recommended that the user develops forms in the format that best suits the research being done and the resources available. If several forms are developed for a trial, the most important criterion is to use a consistent format across forms, so that the users can become familiar with the format used. Page layouts should be similar

across forms, and the headers of the pages should be designed in the same way, collecting the same identification information. Coding conventions should also be consistent for all data items; for example, 1 = no, 2 = yes for all instances where "no" and "yes" are possible answers.

When designing the layout of the forms, the questions should be concise and unambiguous. The text should be contiguous to the box or space where the answer is to be written, and there should be adequate space for responding. Instructions should be clear and located next to the field to which they apply. Decisions need to be made about the codes to be used and the inclusion of values for "Unknown", "Other", "Not-Applicable" or "Not-Done" responses. It is often useful to leave clear space for the participants to enter comments using free text, as important information may be conveyed in this way.

Good forms design is a complex subject and cannot be discussed in detail here. Hosking et al. [1] summarize many of the issues involved in form design and their article is recommended for further reading (*see* **Questionnaire Design**).

Role of the CRA

The job description for a CRA varies from one institution to another, and can include many responsibilities, depending on the qualifications and training of the CRA. If the CRA is a nurse, the responsibilities can include patient care as well as those oriented towards data collection. The following responsibilities are usually part of the job description for a CRA.

Tracking Data Submission Requirements

At the participating institutions, particularly those participating in several trials simultaneously, it is important to develop systems to ensure submission of complete and accurate data according to the schedule defined in the protocol. Scheduling systems can be computer- or paper-based, and the system selected will depend on the local resources and skills, unless scheduling software is provided from a central office. A computer scheduling system usually requires the building of a database that contains information on each patient entered, information on the forms required for a trial, and the time frame for submission of the forms. Programs are needed to link these data and to generate calendars based on the patient's date of entry to the trial and any relevant events occurring during the trial. Forms can be required at fixed time frames (e.g. after each clinic visit), or after particular events (e.g. failure to respond, or toxicity). The system therefore requires the ongoing entry of relevant data to remind CRAs of forms submission requirements. Such a system normally requires programmer support in development and maintenance.

If computer support is not available at a location, a paper-based system can be developed, using tools such as a wall calendar or index cards. Entries are made for each patient by marking the date of entry on to the study. At each visit, or time of patient contact, the CRA completes and submits any required data. The CRA then calculates when the next form is due and, with the calendar system, makes an entry under that date indicating the form needed for that patient. The calendar needs to be checked regularly to see what forms are due each week or month. With the index card system, the CRA sets up a file with a section for every month or, if necessary, every week. There is a card for every patient, perhaps listing all the required forms. After a form is submitted for a patient, the date of submission is entered on the card to record that the data were sent; then the date that the next form is due is calculated, and the card is filed in the card system according to that date. The CRA pulls all cards in the relevant section each week or month, and makes sure that the required forms are submitted.

While a computer-based system allows more flexibility and eliminates the need for the CRA to calculate future due dates, a paper-based system can be equally effective, unless there are large numbers of patients to track or the trial is highly complex.

Data Recording

Another important responsibility of the CRA is to ensure the collection of complete and consistent data. This requires ensuring that all trial data are recorded in the patient's medical record and that all study parameters are followed. In a busy clinical environment, there may not always be sufficient time for a clinician or nurse to review a protocol and ensure that all tests are done and required data collected. Anything that a CRA can do to help with this process will improve the likelihood of complete data being recorded. The CRA can review the list of patients

attending clinic on a particular day, identify the protocol patients ahead of time, prepare a list of tests to be done at that visit, and place it in a prominent place in the patient's chart. This will help the clinical staff in ensuring protocol compliance.

If there are subjective data to be collected from the patient, or aspects of a physical examination (such as tumor measurements) that need to be recorded, the CRA can prepare a special internal data collection instrument for use by the clinical staff to ensure that they ask all the questions necessary. These data collection instruments can become part of the patient's trial record and used to complete the CRFs submitted to the statistical center, and are valuable for audit purposes.

Preparation for Audits

Many trials require complete or partial source verification by an outside organization, particularly if investigational treatments are involved, or if the data from the trial are likely to be used as part of a regulatory submission for approval of commercial use of the treatment. This monitoring is usually done by the sponsor or their designee. The primary goals of such a monitoring system are to verify that all regulatory requirements are being met, and that the data submitted to the statistical center are complete and can be substantiated by review of the original medical records of the patient. Maintaining complete and well-organized source documents can greatly facilitate this process. When an audit is scheduled, the CRA can assist the auditors by organizing the medical records and marking the relevant parts of the record. More details of the on-site monitoring process can be found in the article on **Clinical Trials Audit and Quality Control**.

Role of the Data Manager

The most important function of the data manager at the statistical center is quality control of the submitted data. Data need to be checked for completeness, clarity and consistency over time. If missing, unclear or inconsistent data are detected, the statistical center needs to query the responsible institution to resolve the issue and obtain the correct data values.

Quality control can be done by computer, visual review of the submitted data, or a combination of both of these. When planning a study, a quality control plan should be developed, defining the checks to be made. Once the trial is active and data are received and reviewed, the plan will probably need to be modified on an ongoing basis. It is important to follow the quality control plan and do consistent quality control checks on all data entered. Documentation should be maintained defining all the checks, and keeping a record of the type and timing of changes to the quality control plan.

Eligibility Check

There are several checks that should be done as part of the quality control process. A system should be developed to ensure that patients are registered in the trial prior to starting on protocol treatment. A check should be done to ensure that the patient is eligible for the trial. The institution can be solely responsible for ensuring that all eligibility criteria are met, or the statistical center can check eligibility by asking relevant questions at the time of registration (*see* **Eligibility and Exclusion Criteria**). It may also be important to check that all regulatory requirements have been met prior to entry, e.g. that informed consent has been given and that the protocol has ethics committee approval (*see* **Ethics of Randomized Trials**). Often, an eligibility checklist is prepared as part of the forms for a trial and is used by both the institution and the statistical center to confirm patient eligibility. The eligibility check should be repeated on review of the submitted data to ensure that the data given at the time of registration were accurate.

Logging Receipt of Forms

When data forms are received at the statistical center, they should first be checked to ensure that patient and trial identifiers are correct. For example, if patient initials are on the form, they can be checked with the initials given at the time of registration of the patient with that identifier, or the name of the institution can be checked. If there are any discrepancies, they will need to be checked with the institution that submitted the forms. The forms should then be logged in so that a record is kept of patient and trial identifiers, type of form and date of receipt. Depending on the size of the trial, this can be done manually or by computer. Bar code technology can be used to scan in this information. Logging receipt allows the statistical

center to know which forms have been received and which are overdue. It also allows tracking of timeliness of data submission.

Logical Checks

Submitted data need to be checked to ensure that the correct forms have been used, that patient identifiers are on each form, that the data are consistent over time and that the forms are complete. Logical checks can also be defined; for example, checks that dates are in logical sequence, or for consistency between associated data items. These types of checks can be done manually or by computer, and the statistical center should have a mechanism for sending queries back to the institutions when discrepancies are found.

Assessment of Compliance and Endpoints

There also need to be defined procedures for monitoring **compliance** to the protocol and evaluating the study endpoints for each patient, using the criteria specified in the protocol (*see* **Outcome Measures in Clinical Trials**). The design of the data collection forms and the level of data computerization determine whether these checks can be done by computer or need review by a data manager (or a combination of the two.) The checks usually require comparison of data over time or over different data forms. For example, in cancer trials, if there is a summary form that collects data on the best overall response to treatment and another form that collects tumor measurements over time, the measurements can be reviewed to confirm that the response assessment is correct. If the tumor measurements are not entered onto computer, then the check is done manually.

Clinical Review of Data

In many trials, data are also reviewed by the study chair or another designated clinician. This fulfills two primary purposes. First, it ensures that complex medical data are reviewed and assessed by someone with the appropriate training to detect any clinical nuances in the data. It also provides a quality control check on the assessments of the data manager at the statistical center. If clinical review is part of the trial procedures, then a system must be developed. This could involve copying all data as they are received and sending copies to the reviewer, or having the reviewer visit the statistical center on a regular basis to review the data on site. Normally, the results of the clinical review are compared with those of the data manager, and disagreements are discussed with the statistician in an attempt to reach consensus.

Coding Conventions

Conventions need to be developed and documented for dealing with problems such as **missing data** values, or tests not being done, with results consequently unavailable, or for flagging cases that still have unresolved questions. The statistician is normally closely involved in developing these rules and for ensuring that they are consistently applied.

Data Requests

It is important to ensure that data are collected and submitted in a timely way, and lists of overdue data should be sent to the institutions at frequent intervals. Often, bad news arrives early and the forms first received at the statistical center document study failures. Unless there is a balance to ensure that data are received on all cases according to the same schedule, there is a risk of overreacting to the bad news and drawing erroneous conclusions about the efficacy of the treatments under study.

Data Queries

A query to the institution can be generated at any time during the quality control process, when clarification is needed or missing data has been detected. Queries should be made in writing so that there is a record of both the query and the response. It is also advisable to keep track of dates that queries were sent so that the response can be tracked. When generating a query, it is important to provide sufficient information to the institution so that they understand the question. The patient and trial identifiers should be on the query, along with a clear statement of the question being asked. If the queries are generated by computer, it is important to avoid being cryptic in the text of the error message. Decisions need to be made about whether revised CRFs should be submitted, or whether the query can be answered with a note from the institution. If the latter is acceptable, the query

letter should have space for the institution to write a response and, when received at the statistical center, the returned query should be part of the patient's trial record.

Data Management Support for Analyses

When an interim or final analysis is being done, the data manager plays an important role. Normally, a cut-off date is selected, and all data that have been submitted by that date are quality controlled and entered into the trial database. It is important to try to recover as many responses to queries as possible. When the statisticians prepare for the analysis, they usually run programs to check the database, and inevitably detect further inconsistencies. It is the data manager's responsibility to resolve these discrepancies and make corrections to the database. For interim analyses, (*see* **Data and Safety Monitoring**) this is an ongoing process, and it is not necessary to have all issues resolved before the analysis is done. However, when the final analysis is being done in preparation for a manuscript, it is important to set enough lead time so that a final effort can be made to retrieve all missing data from the participants, to resolve all queries, to ensure that all follow-up is as up to date as possible, that clinical review (if being done) is complete, and that all database inconsistencies have been resolved. The data manager works closely with the statistician to ensure that this is done.

Computing Support

For all clinical trials except very small **Phase I** and **Phase II** studies, it is unlikely that data will be managed without the use of a computer for either quality control, data storage or statistical analysis. Decisions therefore need to be made about the computing system used.

Data Storage

Clinical trials data are usually managed by a database management system (DBMS) (*see* **Database Systems**). Choices are available for most types of computers. The most common type of DBMS in use for clinical trials is the relational database where data are stored in multiple tables that can be linked by the use of key fields [2]. Any database system is unlikely to provide all the functionality required for a clinical trials application, and it is usually necessary to develop application programs that meet the needs of the trial. Before embarking on the purchase of hardware or software, it is important that a detailed analysis of the requirements be done so that the system chosen is one that closely meets the needs of the trial. Mistakes can be costly, both in terms of purchases and in the time and effort expended to make the system work.

Whatever database management system is used, it is important that it provides an interface to the statistical software to be used. Many DBMS packages provide interfaces to the most commonly used statistical software packages, but if no interface is available, then one may need to be developed specifically. If the interface is developed locally, then it is important that it be rigorously tested to ensure that it produces complete and accurate data as input to the statistical software.

Data Entry

If data are collected on paper forms, they need to be entered onto the computer at the statistical center. Data entry is usually done by setting up computer screens that have a layout similar to the data forms being used. When data are keyed, range- and field-type checks are usually performed, and error messages appear if a value is out of range or of the wrong data type (e.g. alphabetic instead of numeric). Professional data entry operators are usually not trained to resolve these kinds of discrepancies, and are therefore required to mark the field that is causing the error and return the form to the data manager for resolution. The record is not entered into the database until the problem has been resolved. If a data manager is entering the data, he or she may be able to resolve the problem at the time of entry. Depending on the resources available, data may be entered and verified by double key entry. Data are keyed by one operator and then rekeyed by a second operator (or sometimes by the same operator after some specified time has elapsed). The two resulting files are compared and errors resolved. This type of system reduces the number of data entry errors but is considerably more expensive than single key entry.

Decisions need to be made about the software to be used for data entry. If the database for the trial

is being maintained on a mainframe computer or workstation, then there is usually an option to enter the data directly into the database, or to enter the data off-line (using a personal computer (PC)) and then transfer the data to the main computer for batch update. The decision depends on the programming resources available, as well as the types of computers. If a batch process is used, detailed checks can be done on the data prior to their entry into the trial database. If the data are entered directly into the database and checks are done while the data are being keyed, the data entry process will be slowed down as the operator deals with any error messages. With both systems, additional checks can be run against the entire database once the new data are in the database. An advantage of off-line data entry is that it can continue even if the database computer is unavailable.
