FIGURE 3. Seizure discharge of the depressed brain in the left temporal region occurring in the EEG of a 2-day-old, 38-week gestational age female infant with hypoxic–ischemic encephalopathy. The EEG background is depressed and undifferentiated. No clinical seizures ac-companied the electrical seizure activity. From Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures*. Philadelphia: Lippincott-Raven: 1998:181, with permission.[118]

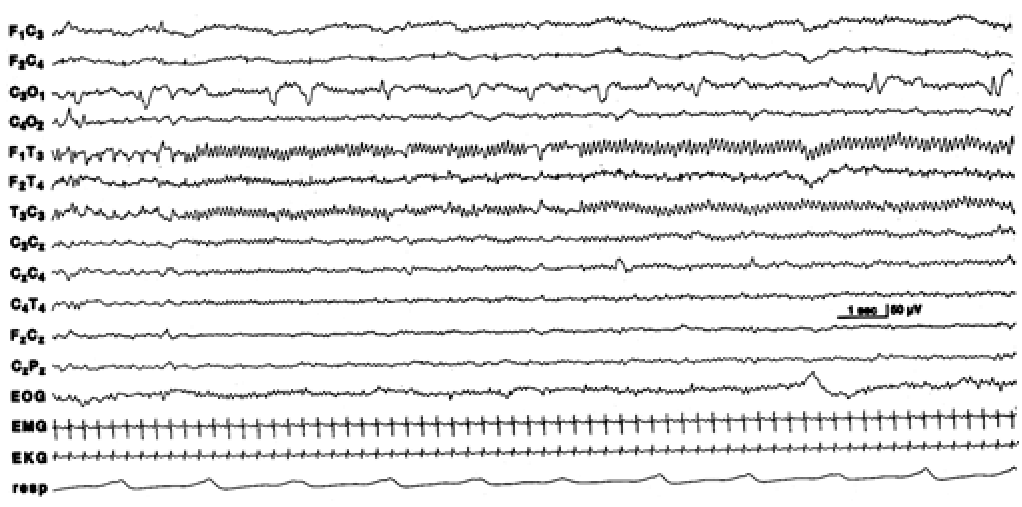

FIGURE 4. α-Seizure discharge in the left temporal region is characterized by sinusoidal 10- to 11-Hz rhythmic activity that evolved from rhythmic sharp-wave activity. There is also an independent, repetitive, slow, sharp transient in the left occipital region. The EEG background activity is depressed and undifferentiated. This EEG is recorded from a 4-week-old, 38-week gestational age male infant with pneumococcal meningitis. No clinical seizures occurred with these electrical seizure discharges. From Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures*. Philadelphia: Lippincott-Raven: 1998:181, with permission.[118]

Diagnostic Considerations

Etiology

The occurrence of neonatal seizures indicates the presence of CNS disease and, in clinical practice, prompts a thorough evaluation for etiology and, if found, the institution of etiologic-specific therapy. A large number of potential causes exist for neonatal seizures. This, coupled with the susceptibility of the immature brain to injury may account for the high incidence of acute neonatal seizures and chronic postnatal epilepsy in this population. Although the list of potential etiologies is extensive,[118] most causes can be broadly categorized as hypoxia–ischemia, metabolic disturbances, CNS or systemic infections, and structural brain lesions. Table 4 lists the most

P.645

P.646

frequently identified etiologies of neonatal seizures in the order of their relative occurrence.

Symptomatic Neonatal Seizures

The presence of hypoxic–ischemic encephalopathy (HIE) can be difficult to establish because diagnostic criteria have not been uniformly established or accepted. In addition, some proposed criteria have been so restrictive that infants with encephalopathy may not meet all of them but still carry the diagnosis of “suspected HIE.” In other proposed schemes, the criteria are too lenient and may not predict the occurrence of long-term neurologic sequelae.[123,134] The American College of Obstetricians and Gynecologists, in association with the American Academy of Pediatrics, have provided guidelines for HIE diagnosis.[34] At some centers, current practice is directed toward identification of measures of asphyxia that have predictive value in the occurrence of long-term sequelae.[137] This strategy has resulted in less restrictive criteria for HIE. Both approaches, however, include the tabulation of delivery room Apgar scores, blood gases, need for resuscitation, recognition of clinical aspects of encephalopathy including seizures, and confirmation of multisystem involvement. There is also an emerging discussion of the use of computer-assisted analysis of EEG, including aEEG, to aid in the staging of the severity of HIE,[163] although this is still considered investigational.

Metabolic disturbances ranging from electrolyte imbalances to inborn errors of metabolism may also be associated with neonatal seizures. This category of etiologies represents an important group of potentially treatable disorders and include hypocalcemia, hypomagnesemia, and hypoglycemia. Much less frequent is the finding of an inborn error of metabolism, such as an aminoaciduria, urea cycle defect, or organic aciduria. Other rare causes of medically refractory neonatal seizures that are potentially treatable include pyridoxine and biotinidase deficiency and others.

FIGURE 5. Interictal and ictal seizure activity associated with focal cortical dysplasia. **A:** Interictal high-voltage sharp waves are present in the left central region of this recording of a 1-month-old infant. **B:** Four sequential and continuous segments of the EEG from the same infant in **A** demonstrating, in the first panel, the transition from interictal to ictal seizure activity and then the evolution of the electrical seizure all confined to the left central region. (Note in this example post-ictal depression of the EEG occurs, a relatively unusual finding in neonatal seizures). From Lortie A, Plouin P, Chiron C, et al. *Epilepsy Res*. 2002;51(1–2):133–145, with permission.[97]

Both bacterial and viral agents can be causes of CNS infection in the neonate that are associated with seizures, to the extent that almost all neonates with new-onset seizures are investigated for such infection. Some viral infections, such as herpes simplex encephalitis, may be treated empirically at clinical presentation prior to confirmation of the diagnosis. In addition, prenatal *t*oxoplasmosis, *o*ther agents, *r*ubella, *c*ytomegalovirus, *h*erpes simplex (TORCH) infections can be risk factors for neonatal seizures.

Structural brain conditions associated with neonatal seizures include acquired conditions such as stroke or hemorrhage and developmental anomalies of the brain. Congenital brain malformations may range from highly localized focal dysplasias to catastrophic defects such as holoprosencephaly. Some malformations, such as lissencephaly, are associated with specific genetic disorders.

Special circumstances also arise in which neonates may be at risk for seizures, providing opportunities for increased

surveillance and development of preventative therapies. Clancy et al.[30] prospectively studied neonates undergoing cardiac surgery that required deep hypothermic circulatory arrest. They found that 19% of all infants with nonhypoplastic left heart syndrome experienced a postoperative acute neurologic event, including seizures and coma.

Table 4 Most frequently occurring etiologies of neonatal seizures

- Hypoxia–ischemia
- Intracranial hemorrhage
  - Intracerebral
  - Intraventricular
  - Subarachnoid
  - Subdural
- Infection—CNS
  - Encephalitis
  - Intrauterine
  - Meningitis
- Infarction
- Metabolic
  - Hypocalcemia
  - Hypoglycemia
  - Hypomagnesemia
- Chromosomal anomalies
- Congenital abnormalities of the brain
- Neurodegenerative disorders
- Inborn errors of metabolism
- Benign neonatal convulsions
- Benign familial neonatal convulsions
- Drug withdrawal or intoxication

Main categories are listed in relative order of frequency (subcategories listed alphabetically). Not listed is “unknown” etiology, which is encountered in approximately 10% of cases (although some in this category may be benign neonatal convulsions). From Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures*. Philadelphia: Lippincott-Raven; 1998:181, with permission.[118]

Prognosis

In clinical practice, the long-term outcome of neonates with seizures is predominantly determined by the etiology underlying seizure onset. However, two other specific issues frequently arise in discussion of prognosis: The possibility that the seizures themselves contribute harm to the developing brain, and the possibility that AED administration may adversely affect the neonate.

Adverse Effects of Seizures on the Developing Brain

For many years, it was believed that, even though the immature brain was more likely to develop seizures in response to injury than was the more mature brain, the immature brain was either more resistant to seizure-induced injury or that any seizure-related alterations were either transient or not clinically significant. However, emerging evidence suggests that seizures in early life result in permanent anatomic and functional

P.648

alterations and enhanced epileptogenicity. However, a full understanding of the mechanisms of these seizure-induced dysfunctions has not been clearly delineated.[69,71,180,192,195]

A number of mechanisms of seizure-induced injury have been investigated. Seizures may cause direct neuronal injury through the sustained release of glutamate receptors,[170] even though this type of injury is age-dependent, with the immature brain less vulnerable than the mature one.[175,184] Although the otherwise healthy immature brain may be relatively resistant to glutamatergic excitotoxicity, seizures may cause a greater degree of neuronal damage in previously immature abnormal brains, thus raising the possibility that a recurrence of seizures after neonatal seizures may be associated with cell death. This so-called “double-hit” clinical scenario may be common in neonates.

It has also been hypothesized that seizures in the immature brain impair subsequent brain growth. Experimental data suggest that prolonged seizures may uncouple energy production and utilization; decreased energy supply eventually depletes energy stores which, in turn, inhibits DNA and protein synthesis and dissociates polysomes. However, these findings appear transiently and are followed by a period of “catch-up” brain growth.[75,99,108,194]

Seizures may have an adverse effect on the structure and function of the hippocampus, resulting in an increased susceptibility to seizures and perhaps, chronic epilepsy.[22,23] It has been hypothesized that, in mature animals, hippocampal damage caused by seizures is manifested by synaptic reorganization and selective cell death through a number of proposed mechanisms including: (a) the “sprouting” hypothesis, (b) seizure-induced cell death, (c) aberrant growth of axons and reorganization of excitatory synapses,[178] and (d) the “dormant interneuron” hypothesis, based on the suggestion that seizures lead to dysfunction of γ-aminobutyric acid (GABA)-containing cells, rendering them nonfunctional or dormant, and thus contribute to a state of decreased inhibition.[169] All these effects may be age-dependent, with the immature brain more resistant than the mature brain. In addition, seizures in the immature brain may alter synaptic connectivity during brain development, alter the morphology of individual pyramidal cells, and alter ion channel subunit composition. Collectively, these disturbances promote hyperexcitability.[35,106,180,183]

Epileptic activity may adversely impact the immature brain and the subsequent development of CNS networks and pathways. To achieve precise patterns of connections within the normal mature brain, axons typically grow toward an established synaptic contact with their appropriate target; this is achieved first by the establishment of a relatively imprecise projection pattern, followed by a process of “fine-tuning.” This depends on normal electrical patterns of neuronal activity.[79,161,164] Grigoinis and Murphy[61] investigated the effect, in immature animals, of epileptic activity on the visual system, including occipital cortex and associated corpus callosal projections. Epileptic activity in the occipital cortex early in life stabilized immature projections that were normally eliminated during development, suggesting that epileptic-induced maintenance of such immature projections in the eventually mature brain may interfere with normal cortical functions later in life. Thus, seizures may create artificial functional pathways that interfere with the intended and necessary pruning of neuronal networks.

Recent findings indicate that seizures in immature animals do not, in the immediate post-seizure period, result in significant alterations of learning, memory, or activity levels. However, when animals who had been exposed to seizures early in life were compared with those exposed when mature, the immature animals demonstrated impairments and alterations in learning and behavior.[70,72,124,171,174] Adverse effects of seizures are more apparent when animals exposed to prolonged seizures early in life are then exposed to seizures when mature.[81,155] Lado et al.[85] suggest that subtle age-specific changes are present following the initial bout of prolonged seizures, but manifestations of actual symptomatic damage and behavioral effects required a second insult for expression. Holmes et al.[68,69] note that prolonged seizures in immature animals result in minimal behavioral consequences when the animals are studied later in life and are associated with minimal morphologic changes. However, in describing the "two-hit" hypothesis, they report that early-onset seizures result in changes in the brain that make it more vulnerable to the development of cognitive impairment when animals are exposed to post-neonatal seizures.

Table 5 Outcome at 24 months of Term and Near-term Neonate with Seizures

Study population	
Number enrolled	207
Number of survivors	149
Number of survivors evaluated at 24 months	127 (84.7%)
Outcome	**Percent**
Death	28.0
Abnormal neurologic examination*	42.7
MDI <80*	55.2
PDI <80	49.6
Post-neonatal epilepsy**	26.0

From Mizrahi EM, Clancy RR, Dunn JK, et al. Neurologic impairment, developmental delay and postnatal seizures 2 years after EEG-video documented seizures in near-term and term neonates: Report of the clinical research centers for neonatal seizures. *Epilepsia*. 2001;42:102, with permission.[115]

*Outcome for survivors 2 years following neonatal seizures: Standard neurologic examination, Bayley Developmental Assessment of Mental Development Index (MDI), and Psychomotor Developmental Index (PDI).

Clinical Considerations in Prognosis

The outcome of infants with neonatal seizures has been assessed in terms of survival, neurologic disability, developmental delay, and post-neonatal epilepsy. Ortibus et al.[130] reported that 28% of those with neonatal seizures died, 22% of survivors were neurologically normal at an average of 17 months of age, 14% had mild abnormalities, and 36% had severe abnormalities. In a prospective study of full-term infants 2 years following neonatal seizures, Mizrahi et al.[115*] found that 28% died; in survivors, 42.7% had abnormal neurologic examinations, 55.2% had a Bayley Developmental Assessment of Mental Development Index score of less than 80, 49.6% had a Bayley Developmental Assessment of Psychomotor Developmental Index score of less than 80, and 26% had post-neonatal epilepsy[115*] (Table 5). Brunquell et al.[19] found that 30% of those with neonatal seizures died and 59% of survivors had abnormal neurologic examinations, 40% were mentally retarded, 43% had cerebral palsy, and 21% had post-neonatal epilepsy when

followed up to a mean of 3.5 years. Most recently, Tekgul et al.[181] found that 7% of neonates who had experienced seizures died and, of the survivors, 28% had a poor outcome.

Ellenberg et al.[50] studied post-neonatal epilepsy in more detail. They found that approximately 20% of those who survived neonatal seizures experienced one or more seizures within 7 years of age, and that nearly two-thirds occurred within the first 6 months of life. Similar rates were found by Scher et al.[158] (17%–30%), Ortibus et al.[130] (28%), Bye et al.[21] (21%), Mizrahi et al.[115] (26%), Brunquell et al.[19] (21%), and, most recently, Da Silva et al.[37] (22% at 12-month follow-up and 33.8% within 48 months). Clancy and Legido[29] found a much higher rate of post-neonatal epilepsy. However, entry into this study required that at least one EEG seizure be captured on a brief, routine EEG examination. It is thus likely that many of these patients actually had numerous seizures or status epilepticus, which is known to further increase the rate of subsequent epilepsy. Seizure types that characterize post-neonatal epilepsy include both partial and generalized. Watanabe et al.[198] considered in detail a selected population of infants with neonatal seizures that persisted beyond the neonatal period and that could be classified as epilepsy of neonatal onset. For most of those infants with severe encephalopathy syndromes such as EIEE and EME, their initial epileptic syndrome evolved to West syndrome, with a fewer number evolving to symptomatic localization-related epilepsy.

The management of neonatal seizures includes accurate diagnosis, expeditious determination of etiology, rapid administration of etiologic-specific therapy, and successful AED treatment. The goal is to improve long-term outcome and prevent adverse sequelae. However, it is not clear which of these management components is critical to achieving the goal of maximizing outcome. It may appear that seizure duration may influence outcome, because infants who experience brief and infrequent seizures may have relatively good long-term outcomes, whereas those with prolonged seizures may not do as well. However, easily controlled seizures or self-limited seizures may be the result of transient, or more benign CNS disorders, whereas medically refractory neonatal seizures may be the result of more sustained, refractory, or more severe brain disorders. Recently, McBride et al.[105] demonstrated that a relation exists in infants with perinatal asphyxia between a greater amount of EEG seizure activity and subsequent relative increased mortality and morbidity. Other investigators, utilizing proton magnetic resonance spectroscopy in neonates, found an association between scores of seizure severity and impaired cerebral metabolism measured by lactate/choline and compromised neuronal integrity measured by *N*-acetylaspartate/choline. These investigators suggested this as evidence of brain injury not limited to structural damage detected by magnetic resonance imaging (MRI).[110]

Table 6 Prognosis of neonatal seizures according to neurologic disorder

Neurologic disorder	Normal development (%)(a)
Hypoxic–ischemic encephalopathy	50
Intraventricular hemorrhage (b)	10
Primary subarachnoid hemorrhage	90

Hypocalcemia	
Early onset	50(c)
Late onset	100
Hypoglycemia	50
Bacterial meningitis	50
Developmental brain defect	0

Prognosis is for those with the stated neurologic disease when seizures manifest (thus, value usually differs from overall prognosis).
(a) Values are rounded to the nearly 5%.
(b) Usually severe intraventricular hemorrhage associated with major periventricular hemorrhagic infarction.
(c) Represents primarily the prognosis of complicating illness; prognosis approaches that of later onset hypocalcemia if no or only minor neurologic illness present.
From Volpe JJ. Neurology of the Newborn. In: *Neonatal Seizures*.
Philadelphia: WB Saunders, 2001, with permission.[191]

However, it is currently thought that the dominant variable that predicts neurodevelopmental outcome may be the underlying cause of the seizures, rather than the presence, duration, or degree of brain involvement of the seizures themselves. Mizrahi and Kellaway[118] analyzed a number of clinical studies indicating that normal outcomes occurred with increasing frequency in association with the following etiologies: HIE, infection, hemorrhage, hypoglycemia, and hypocalcemia.[10,78,95,103,107,150] In discussing prognosis, Volpe[191] emphasized gestational age and etiology on outcome (Table 6). Mortality increases with the greater degree of prematurity, and specific etiologies are associated with varying degrees of developmental delay. Most recently, Tekgul et al.[181] suggested that seizure etiology and background EEG patterns remain powerful prognostic factors.

It has been suggested that clinical seizure type may also predict outcome,[117] although this too may reflect etiology or the degree of associated brain dysfunction at the onset of seizures. Focal clonic and focal tonic seizures were associated with a relatively good outcome primarily because these seizure types are typically associated with relatively confined, nondiffuse brain injury and significantly spared CNS function. Generalized tonic posturing and motor automatisms were associated with a poor outcome because they are associated with diffuse CNS dysfunction. Recently Brunquell et al.[19] demonstrated similar findings in long-term studies.

Multivariant analyses factors that were considered as predictors of outcome have included features of the interictal EEG from one or serial recordings, the ictal EEG, the neurologic examination at the time of seizures, the character or duration of the seizures, etiology, findings on neuroimaging, conceptional

P.650

age, and birth weight. Multiple, rather than single factors, appear to be most accurate in predicting outcome. For example, Ortibus et al.[130] found that the predicted outcome is less reliable when based solely on EEG variables from a single recording obtained at seizure onset than when based on a combination of imaging findings and clinical and EEG data. Pisani et al.[139] also considered several different independent variables and found the character of the EEG background activity predictive of developmental outcome. However, in these studies, all variables related to a single factor: The degree of brain injury at the time of seizure occurrence, and this, in turn, related to etiology.

Differential Diagnosis

The differential diagnosis of generic clinical "seizures" is diverse and ranges from normal movements to abnormal, but nonseizure, activity. Normal movements of neonates may at times appear "paroxysmal," such as abrupt stretching of the extremities or trunk, squirming, sucking, and sudden jerking movements, which may occur during sleep. Infants may also experience spasmodic coughing and hiccups. Jitteriness and tremor may also occur in normal infants, although they may also be present in abnormal newborns. Unforeseen changes in the parameters of autonomic dysfunction such as heart rate, respirations, and blood pressure have been described as features of neonatal seizures. However, more often these changes are nonseizure in origin —physiologic changes that can be present in normal neonates or abnormalities related to the systems themselves. Some abnormal, nonseizure movements may be age-dependent. For example, the extreme premature infant may experience random, erratic movements resembling fragmentary myoclonus. The clinical significance of these movements is not clear.

Specific Very–Early-Onset Epilepsy Syndromes

Epileptic seizure syndromes are characterized by recognizable constellations of clinical signs, symptoms, and laboratory findings. These features include seizure type, age of onset, etiology, anatomy (including neuroimaging findings), precipitating factors, severity, ictal and interictal EEG, duration of the seizure disorder, associated clinical features, chronicity, diurnal and circadian cycling, response to AEDs, and prognosis.[48] In its Classification of Epilepsies and Epileptic Syndromes, the ILAE has designated only a few syndromes in the neonatal period,[33,200] although their recognition in clinical practice is important. These syndromes are benign neonatal convulsions, benign neonatal familial convulsions, early myoclonic encephalopathy and early infantile epileptic encephalopathy. These have been reviewed by Mizrahi and Clancy.[114] The first two are associated with a relatively good prognosis, whereas the others suggest a poor outcome and have been included among the catastrophic pediatric epilepsy syndromes.[86]

Benign Neonatal Convulsions

The syndrome of benign neonatal convulsions has also been referred to as "benign idiopathic neonatal convulsions," because of the lack of an identifiable etiology,[140] and "fifth day fits," because of their timing of onset.[41] This syndrome is characterized by focal clonic seizures or, rarely, focal tonic seizures in an otherwise normal neonate. There is no family history of neonatal seizures. Infants are typically full term with a history of an uncomplicated, normal pregnancy, labor, and delivery. Seizures usually occur between the fourth and sixth day of life and are typically brief (1 to 3 minutes) although, rarely, the seizures can be prolonged. The seizure disorder is self-limited in that seizures may recur during a 24- to 48-hour period after onset, although, rarely, seizure disorder can also be prolonged. The clinical seizures are usually unifocal clonic and may be associated with apnea. The infants are neurologically normal prior to, between, and after the occurrence of seizures.[141] A critical feature for diagnosis is that no etiology for the seizures can be identified. In the past, this disorder has been associated with a finding of rotavirus in stool but not in cerebrospinal fluid (CSF)[65] and with acute zinc deficiency in CSF.[57] These findings are now considered of doubtful etiologic relevance. The ictal EEG is characterized by focal, rhythmic, recurrent sharp wave or spike activity that is closely correlated with the clinical seizures. The background EEG is typically normal, although it has also been reported that, in up to 60% of neonates with this syndrome, the interictal EEG pattern referred to as *θ pointu alternant* may be present.[141] This is characterized as a discontinuous nonreactive background with rhythmic (4 to 7 Hz) θ-wave activity within the bursts, which may be mixed with sharp waves that alternate between hemispheres. More recently, this pattern has not been considered diagnostic for this disorder.[143] Although the clinical seizures may spontaneously resolve within a short period, it has been reported that the θ pointu alternant EEG pattern may persist for up to 2 weeks.

This syndrome is a diagnosis of exclusion, because the initial clinical presentation may resemble that of infants with symptomatic focal clonic seizures. Thus, a thorough evaluation for an etiology is conducted to identify a potentially treatable cause of seizures, even though the diagnosis of benign neonatal convulsions may be considered at the onset. Plouin[141,142,143] has proposed the following diagnostic criteria for the disorder: Normal pregnancy and delivery, full-term gestation, appropriate for gestational age birth weight, Apgar score greater than 7 at 1 minute, typical interval between birth and seizure onset (4–6 days), normal neurologic examination before seizures and interictally, normal laboratory findings (including, but not limited to metabolic studies, neuroimaging, and lumbar puncture), and no family history of either neonatal seizures or post-neonatal epilepsy.

Treatment for this disorder is controversial. Most frequently, the seizures are treated with phenobarbital. However, because the seizures tend to be brief and infrequent, it can also be argued that AED therapy may not be needed. If AEDs are used, they are typically discontinued once the seizures subside.

The prognosis for infants with benign neonatal convulsions is considered to be generally good.[142,143] However, one group of investigators has found transient psychomotor delays in infants[41]; another found neurodevelopmental deficits at 2 years of age in 50% of those with this syndrome, and the incidence of post-neonatal epilepsy—0.5% of patients—is slightly higher than in the population of those without neonatal seizures.[142,143]

Benign Neonatal Familial Convulsions

This syndrome is characterized by early-onset focal clonic or focal tonic seizures in a neonate with a family history of neonatal seizures and with no other neurologic findings.[20,66,138] There is an autosomal dominant pattern of inheritance with incomplete penetrance,[36] with two known chromosomal loci: One on chromosome 20q13[89,90] and one on chromosome 8q.[92,151,177] All the families with benign neonatal familial convulsions provide sufficient data for linkage to chromosome 20q; only one family has provided data for linkage to chromosome 8q. Recently, the genes for this disorder have been identified. These are potassium channel genes, referred to as *KCNQ2* for the

P.651

chromosome 20q gene[11,25,168] and *KCNQ3* for the chromosome 8q gene.[177] It has been suggested that the KCNQ2/3 channels might be the molecular basis of the M-current, a slowly activating and deactivating potassium conductance channel that may play a critical role in determining the subthreshold electrical excitability of neurons.[11,193] Only a slight loss of channel activity will lead to neuronal hyperexcitability and resultant seizures.[193] A novel mutation in *KCNQ2* has been reported that is associated with the diagnosis of benign neonatal familial convulsions, but also with drug-resistant epilepsy and mental retardation.[14]

The clinical seizures are best characterized as focal clonic or focal tonic. Seizure onset is between the first few days and 1 week of life,[145] although there have been reports of onset as late as the second month of life. The various ages of onset may be developmentally determined, because infants who are born prematurely with this disorder will have seizure onset at an older chronologic age than will infants born at term. The seizures may be brief, but can recur up to 2 to 3 months of age, when they will remit spontaneously. The interictal EEG is typically normal, although θ pointu alternans pattern has also been reported to occur in these infants. Although the outcome is generally good, there is a higher incidence of post-neonatal seizures in affected infants later in life, ranging from 11% to 16%.[141,149] It has been reported that phenobarbital therapy is successful, although some investigators use valproate as an alternative.[142,143]

Early Myoclonic Encephalopathy

Early myoclonic encephalopathy is a relatively rare syndrome characterized by the onset of erratic, fragmentary myoclonus in the first month of life and with the eventual development of both focal seizures (originally described as partial motor seizure) and infantile spasms.[1,4,5] The associated EEG is characterized as a periodic, suppression-burst pattern.[102] This syndrome has also been referred to as neonatal myoclonic encephalopathy,[187] myoclonic encephalopathy with neonatal onset,[24] neonatal epileptic encephalopathy with periodic EEG bursts,[104] and early epileptic encephalopathy.[39,40]

Aicardi[1,4] reviewed in detail the clinical expression of the ictal events in 39 cases. These seizure types included fragmentary or partial erratic myoclonus; massive (or generalized) myoclonus, simple partial (or focal) seizures; and infantile spasms with a sustained tonic component. These clinical events were not all present at onset of the disorder. Typically, the erratic myoclonus appeared first, sometimes within the first few hours of life. Myoclonic movements could involve very circumscribed regions of the limbs or face; they are typically repetitive or virtually continuous, shift persistently from one body region to another in an anarchic and asynchronous manner, and may persist in sleep. Either with the onset of erratic myoclonus or shortly thereafter, generalized myoclonus and partial seizures may develop. The generalized myoclonus may involve all extremities synchronously and bilaterally, or may involve axial musculature. The partial seizures have been reported to consist of deviation of the eyes associated with limb or face clonic activity, or autonomic phenomena such as flushing or apnea. Although the appearance of general myoclonus and partial seizures may occur early with, or shortly after, the onset of erratic myoclonus, infantile spasms typically develop later in the course of the disorder, usually between 3 and 4 months of age.

The EEG is characteristic and considered an essential criteria for the diagnosis of this syndrome. The background activity is a suppression-burst pattern. The bursts occur periodically and are characterized by generalized and multifocal, high-voltage spikes and sharp and slow wave complexes (Fig. 3). (There are other disorders in which suppression-burst may be present; thus this finding alone is not diagnostic of early myoclonic encephalopathy.) The pattern usually persists during wakefulness and sleep. There is typically no specific EEG correlate to the fragmentary or erratic myoclonus, except that the myoclonus usually occurs during the burst periods of the EEG. When partial seizures occur, their EEG correlate is no different from other infants with focal seizures. When infantile spasms occur, they may eventually be associated with high-voltage, slow, sharp transients and/or episodes of generalized voltage attenuation. Over time, the suppression-burst pattern may take on features that may allow it to be characterized as atypical or modified hypsarrhythmia.

Aicardi[1,3] notes that the neurologic status of infants with early myoclonic encephalopathy is always abnormal either at birth or at the onset of clinical seizures. Most often, the infants are hypotonic and poorly responsive; this latter feature is consistent with the clinical diagnosis of an encephalopathy. This early onset of abnormal neurologic status makes further neurologic deterioration difficult to assess.

When the syndrome is encountered, a metabolic etiology is most often given initial consideration as an etiology, including nonketotic hyperglycinemia, propionic acidemia, D-glyceric acidemia, and methylmalonic acidemia.[18,38,60,96,188]

Therapy is typically symptomatic, directed toward the specific inborn error of metabolism, if present. AEDs or hormonal therapy typically utilized for infantile spasms are often tried, with little success.

The outcome for infants with early myoclonic encephalopathy has been consistently reported as poor. There is a high incidence of death within the first few years of life. Some survivors have been reported to remain in a vegetative state, and others show significant developmental delay. As noted, there is some debate concerning the course of neurologic impairment. Some suggest that there is a gradual deterioration or arrest of development with onset of the disorder,[39,40] whereas others suggest that, because of the severity of impairment at onset, subsequent development cannot be quantified.[1,4,5]

There has been an ongoing discussion concerning the relationship of early myoclonic encephalopathy and the syndrome of early infantile epileptic encephalopathy, described by Ohtahara et al.[4,126,127] and discussed below. Kellaway et al.[73] suggested that these syndromes represented a continuum of a single disorder. Aicardi[1] indicated that the two syndromes "have too many points in common to assume that they are completely different syndromes, and they may, at least in some cases, simply be two different aspects of a single basic process." However, others suggest that these represent two distinct syndromes.[128,160] The syndromes are compared in Table 7.

Table 7 Comparison* of early myoclonic encephalopathy (EME) and early infantile epileptic encephalopathy (EIEE)

	EME	EIEE
Age of onset	Neonatal period	Within first 3 months

Neurologic status at onset	Abnormal at birth or at seizure onset	Always abnormal even prior to seizure onset
Characteristic seizure type	Erratic or fragmentary myoclonus	Tonic spasm
Additional seizure types	Massive myoclonus, simple partial seizures, infantile spasms (tonic)	Focal motor seizures hemiconvulsions, Generalized seizures
Background EEG	Suppression-burst	Suppression-burst
Etiology	Cryptogenic, inborn errors of metabolism, familial	Cerebral dysgenesis, anoxia, cryptogenic
Natural course	Progressive impairment	Static impairment
Incidence of death	Very high, occurring in infancy	High, occurring in infancy, childhood, or adolescence
Status of survivors	Vegetative state	Severe mental retardation, quadriplegia, and bedridden
Long-term seizure evolution	Infantile spasms	West syndrome, Lennox-Gastaut syndrome

Neonatal seizures: Early-onset seizure syndromes and their consequences for development. *Ment Retard Dev Dis Res Rev*. 6;2000:229–241, with permission.[114]

Early Infantile Epileptic Encephalopathy

Cases of early infantile epileptic encephalopathy were first reported by Ohtahara et al., with additional cases reported by that group beginning a short time later.[125,126,127,128] In addition, they proposed that the syndrome of early infantile epileptic encephalopathy represents one of three so-called "age-dependent epilepsy encephalopathy syndromes," which also included West syndrome and Lennox-Gastaut syndrome.[125,128,129,202] The characteristics of early infantile epileptic encephalopathy include onset in early infancy (neonatal period through the first few months of life), tonic spasms (brief tonic seizures) as the predominant seizure type, suppression-burst EEG background, severe psychomotor retardation, medically intractable seizures, poor prognosis, no single etiology characteristic for the disorder, and evolution to West syndrome (i.e., infantile spasms, retardation, hypsarrhythmia on EEG).[4,128,129]

The predominant seizure type is described as a tonic spasm. These are brief episodes of limb and axial stiffening, with each event lasting longer than a general myoclonic event, but shorter than a typical tonic seizure. Tonic spasms may occur in clusters, but in some may be solitary events. In most patients, they occur during wakefulness or sleep, and their daily frequency may be very high. In addition to tonic spasms, about a third also experience other seizure types including focal motor seizures, hemiconvulsions, alternating hemiconvulsions, and generalized seizures.

As previously noted, the EEG is also characterized by a suppression-burst pattern that is not modulated by wake–sleep cycles. This distinguishes its pattern from other hypsarrhythmic EEG variants that feature suppression burst. During a clinical spasm, the EEG is characterized by generalized voltage attenuation.

A number of etiologic factors have been associated with this syndrome. In a series of 15 cases, Ohtahara et al. reported cryptogenic factors in four and symptomatic factors in 11. The symptomatic patients included four with HIE; two with Aicardi syndrome; and porencephaly, cerebral atrophy, or dysgenesis in the remaining subjects. None had a recognized metabolic disorder.

These infants are often treated with hormonal therapy (typically adrenocorticotropic hormone [ACTH]). However, this therapy is considered less effective for early infantile epileptic encephalopathy. In addition, other AEDs have been utilized, also with limited success, including clonazepam, nitrazepam, valproate, and pyridoxine.[128]

The prognosis for early infantile epileptic encephalopathy is poor. In a series by Ohtahara et al.,[128] seven of 15 infants died between 6 months and 11 years (with four deaths occurring within the first 2 years of life). All survivors were characterized as severely mentally and physically disabled when last evaluated between 4 and 17 years of age All but two were described as quadriplegic and bedridden. In six of the eight survivors, seizures were either controlled or resolved. In a surviving 7-year-old, tonic seizures persisted; focal motor seizures continued in a 14-year-old. The degree of both mental and physical impairment appears to be static over time.

Table 8 Etiology-specific therapy for neonatal seizures of metabolic origin

	Acute therapy	Maintenance therapy
Glucose, 10% solution	2 mL/kg, IV	Up to 8 mg/kg/min IV
Calcium gluconate, 10% solution (9.4 mg of elemental Ca/mL)	2 mL/kg IV over 10 min (18 mg of elemental Ca/kg)	8 mg/kg/day IV* (75 mg of elemental Ca/kg/day)
Magnesium sulfate, 50% solution (50 mg of elemental Mg/mL)	0.25 mL/kg IM	.25 mL/kg IM repeated every 12 hrs until normomagnesemia
Pyridoxine	100 mg IV	

*After restoration of normocalcemia, tapering dosage may help prevent rebound hypocalcemia. Diagnosis of hypoglycemia, hypocalcemia, and hypomagnesia may vary between laboratories and is dependent on neonate's gestational age (with preterm infants tending to tolerate lower physiologic levels). Administration of metabolic correcting solutions requires careful monitoring of infant's systemic homeostasis, including EKG monitoring during administration of calcium.[76,83] From Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures*. Philadelphia: Lippincott-Raven; 1998:181, with permission.[118]

Although there was a high incidence of death in the series by Ohtahara et al.,[128] their data from all patients formed the basis for an interesting discussion and the development of hypotheses concerning the evolution of seizure types and syndromes and their relationships to brain development. They note that, for many patients, an evolution of the EEG occurs from a suppression-burst pattern, to a hypsarrhythmic pattern, then to that of diffuse slow-spike and slow-wave activity. They propose that this evolution follows brain development, with periods of transition characterized by the emerging pattern when the infant is awake and the resolving pattern persisting in sleep. The evolution of the EEG is an objective marker of and parallels the sequential emergence of the age-dependent epileptic encephalopathies: Early infantile epileptic encephalopathy (associated with suppression-burst activity), West syndrome (associated with hypsarrhythmia), and Lennox-Gastaut syndrome (associated with generalized slow-spike and slow-wave activity). In general, this complete evolutionary development occurs in only a very small number of infants, because the occurrence of early infantile epileptic encephalopathy is rare. Thus, while this sequence may be observed in those with early infantile epileptic encephalopathy, the vast majority of those with West

P.653

syndrome or Lennox-Gastaut syndrome do not experience an antecedent early infantile epileptic encephalopathy.

Epilepsy in Focal Cortical Dysplasia in Infancy

Epilepsy in focal cortical dysplasia (FCD) in infancy is not currently recognized as a specific syndrome by ILAE, although it falls into the broad category of symptomatic neonatal seizures. However, emerging data suggest that infants with this disorder have a fairly characteristic constellation of features. Lortie et al.[97] reviewed the features of 28 infants with FCD presenting at two specialized centers. Semiology depended on the topography of the dysplasia (for example, abnormal eye movements in all cases of posterior FCD). Almost half the infants eventually developed infantile spasms, mainly asymmetric. All but one patient in the series exhibited abnormal neurodevelopmental findings. Of those studied, 15 patients underwent surgery; eight became seizure free and in seven, their neuro-developmental status improved. It was suggested that the early identification of this disorder may prompt early surgery and improved outcome.

Response to Treatment

The basic principles of general medical management of the critically ill infant are naturally relevant to the comprehensive therapy of neonatal seizures because in some, both seizures and acute AED administration may be associated with depression of respirations, heart rate, and blood pressure. Ensuring airway patency and access to the circulatory system are considered critical early in the course of treatment.

Assessment of the cause of seizures is often conducted in parallel to the initial phase of AED therapy. If remediable causes of seizures are identified for which specific treatments are available, this therapy is initiated. This may be essential in management because it not only may directly treat the underlying disorder but also because some seizures may not be controlled effectively with AEDs unless the underlying cause is treated. This is particularly evident when seizures are caused by metabolic disturbances such as hypocalcemia, hypomagnesemia, and hypoglycemia. Etiologic-specific therapies for these disorders are listed in Table 8. Although treatment of some etiologies may not immediately affect seizure occurrence, therapy is still critical because it may limit the degree of CNS injury.

Decision to Initiate AED Therapy

The decision to initiate AED therapy should be based on several considerations. Because AEDs are utilized to treat neonatal seizures of epileptic origin, initial considerations are given to the clinical and EEG features of the events. When EEG examinations are available, electroclinical seizures and "electrical only" seizures are clearly candidates for AED therapy. When clinical observation alone is the basis for management, AED treatment should be considered for those clinical seizures that are most likely coupled to EEG seizures. These primarily include focal clonic and tonic seizures. In contrast, clinical events characterized as generalized tonic seizures and motor automatisms (provoked by stimulation and suppressed by restraint) are considered nonepileptic in origin and unlikely to require or respond to AED administration.

Table 9 Dosages of first-line, second-line AEDs in the treatment of neonatal seizures

Drug	Dose: Loading	Dose: Maintenance	Average therapeutic range	Apparent half-life
Diazepam	0.25 mg/IV (bolus), 0.5 mg/kg (rectal)	May be repeated 1–2 times		31–54 h
Lorazepam	0.05 mg/kg (IV) (over 2–5 min)	May be repeated		31–54 h
Phenobarbital	20 mg/kg IV (up to 40 mg)	3–4 mg/kg in 2 doses	20–40 μg/L	100 h after day 5–7
Phenytoin	20 mg/kg IV (over 30–45 min)	3–4 mg/kg in 2–4 doses	15–25 μg/L	100 h (40–200)

International Review of Child Neurology Series. New York: Raven; 1994:217[2]; and Volpe JJ. Neurology of the Newborn. In: *Neonatal Seizures*. Philadelphia: WB Saunders, 2001.[191]
Table from Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures*. Philadelphia: Lippincott-Raven; 1998:181, with permission.[118]

There has also been discussion concerning the need to treat all neonatal seizures of epileptic origin because some are brief, infrequent and self-limited, occurring only in reaction to an acute CNS insult. In these instances, AEDs may not be warranted, and the infant need not be exposed to acute and chronic AED therapy. On the other hand, some neonatal epileptic seizures are long in duration, frequent, and not self-limited. These should be treated acutely and vigorously with AEDs. It is difficult to predict at the onset of seizures which infants will have self-limited, frequent, or prolonged events. Clinical difficulties arise in the management of those infants whose seizures have characteristics that fall between these two extremes. In clinical practice, almost all neonatal epileptic seizures within this intermediate category are treated.

Initial AED Therapy for Acute Seizures

First-line AEDs and dosing schedules are listed in Table 9. The pharmacology of some of some these individual drugs has been well studied in neonates, particularly phenobarbital and phenytoin. However, few comprehensive clinical trials have been conducted to determine the most effective regimen for the treatment of neonatal seizures.[26] The most established strategy is

to acutely treat seizures with an AED that can be subsequently given as maintenance therapy; most often this is phenobarbital. It is given first as a loading dose then with additional boluses titrated to response until the maximum tolerated dose or serum levels in the high therapeutic range are reached. Boylan et al. prospectively assessed the efficacy of phenobarbital utilizing video-EEG monitoring[17] and found that only four of 14 infants completely responded with a cessation of all electroclinical seizures. The others experienced a reduction in electroclinical or clinical seizures, but continued electrical seizures.

After phenobarbital, phenytoin is the AED most often used, now typically initiated with fosphenytoin because of reports of reduced adverse effects with acute administration.[136] Again, as with phenobarbital, phenytoin administration is increased to the maximum tolerated dose or high therapeutic serum levels. Painter et al.[133] compared the relative efficacy of the acute administration of phenobarbital and phenytoin in seizure control and found no significant difference between the two medications. However, neither drug proved as efficacious as generally hoped or believed.

An alternative strategy of acute seizure management is the intravenous administration of benzodiazepines (midazolam, diazepam or lorazepam) until seizures are controlled, thus avoiding chronic AED therapy.

When the clinician begins AED therapy, this should be accompanied by establishment of criteria to determine whether acute therapy has been successful. Control of the clinical and electrical seizures is ideal, but often difficult to determine or unattainable. A typical response by electroclinical seizures to acute AED therapy is the initial control of the clinical seizures with the persistence of the electrical seizure activity, referred to as "uncoupling."[117] With additional doses, the electrical seizures may be controlled.[157] However, there are common instances in which the EEG seizures cannot be controlled despite increasing doses of the initial AED and addition of other AEDs.

Current practice usually consists of acute AED administration (most commonly, phenobarbital) until clinical seizures are controlled. This often requires the achievement of serum levels in the high therapeutic range or maximum tolerated dose followed by a second drug if needed (commonly phenytoin or a benzodiazepine). If EEG is utilized, the same AED strategy is followed, although the AEDs are ideally titrated to eliminate the electrographic seizures. Since the electrical seizure discharges are often acutely resistant to AED therapy, additional drugs are administered cautiously to avoid adverse effects without significant benefit.

Some aspects of the pharmacology of phenobarbital and phenytoin in the neonate are useful to consider in the treatment of neonatal seizures because pathologic conditions can alter the availability of active drug given at standard doses in sick neonates.[43,91,100,131] Because phenobarbital is a weak acid and is protein bound, infants with acidosis may have less active AED available. Those with hypoalbuminemia may have greater unbound or active drug available. Both conditions may be found in sick neonates. Phenobarbital is eliminated by the liver and kidney, so that infants with impaired hepatic or renal function, including those with HIE, may have a reduced rate of elimination and, therefore a potential for unexpectedly high serum levels and clinical toxicity using standard dosing. Phenobarbital has a longer half-life in preterm compared with term infants and, in term infants, it is reduced during the first month of life. Thus, in preterm infants there exists a potential for higher serum levels with standard doses and the potential for toxicity; as the infant becomes older, there is the potential for identical doses to result in lower serum levels, thus creating the potential for breakthrough seizures with no other change in the infant's clinical condition. Overall, monitoring serum level trends, rather than day-to-day fluctuations, is more useful in the management of phenobarbital therapy.[47,55,132,191]

Important pharmacologic characteristics of phenytoin include nonlinear pharmacokinetics,[15,46] a variable rate of hepatic metabolism, a decrease in elimination rates during the first weeks of life, and a variable bioavailability of the drug in various generic preparations. In addition, a redistribution of the AED occurs after the initial dose, resulting in a drop in brain concentrations after the first dose. These pharmacologic characteristics indicate that phenytoin use requires individualization of dosing after the initiation of therapy.

Adjuvant AED Therapy for Acute Seizures

The use of so-called second-line, or adjuvant, AEDs falls into two categories: Those agents used to control acute seizures and those administered for otherwise medically refractory seizures. Agents in both classes have been utilized either intravenously or orally with variable success. Those given intravenously and primarily as alternatives to acute therapy include clonazepam,[8] lidocaine,[64,186] midazolam,[74,167] and paraldehyde (not available in the United States).[84] One recent study reported success with continuous midazolam infusion in the treatment of otherwise uncontrolled neonatal seizures,[74] although infants experienced treatment-related hypotension that required medical management. Lidocaine is another medication that has been the topic of renewed interest. Boylan et al.[16] reported limited success with lidocaine in refractory neonatal seizures. Another recent investigation reported that, during the use of lidocaine (initial loading dose of 2 mg/kg over 10 minutes followed by a

continuous infusion of 6 mg/kg per hour), 4.8% of infants experienced a cardiac arrhythmia but all responded to lidocaine discontinuation.[186] Other agents, which are given orally to control medically refractory seizures, include carbamazepine,[101] primidone,[154] valproate,[54] vigabatrin,[6] and lamotrigine.[109] The success of this latter group of AEDs is difficult to assess because they have been used in conjunction with other AEDs and well into the course of illness.

Chronic AED Therapy

The use of chronic AED therapy for neonates after the acute seizures have been controlled is not well studied or standardized. There are no well-defined criteria for maintenance AED treatment. When chronic therapy is considered, either phenobarbital or phenytoin is given in maintenance doses of 3 to 5 mg/kg/day and serum levels are monitored. There are also no well-established criteria for discontinuation of maintenance AED therapy. Reported schedules range from 1 week up to 12 months after the last seizure,[13] although a currently utilized and successful schedule is to withdraw AEDs 2 weeks after the infant's last seizure.[52] At some centers, an EEG is also performed at the end of this 2-week period to assess for electrical seizure activity not associated with clinical seizures.

Potential Adverse Effect of AED Therapy

There has been much concern about the potential adverse effects of AEDs on the developing brain. Early animal experiments suggested alteration in cell growth and energy substrate utilization,[9,45] although the applicability of these findings to humans has been called into question.[191] There have been few studies of clinically significant adverse effects of acute AED therapy. However, over vigorous acute AED administration can result in transient CNS depression, hypotension, bradycardia, and respiratory depression. Any of these clinical events represent a risk for secondary CNS hypoxia or ischemia.

More recently, Ikonomidou et al. assessed the effect of phenytoin, phenobarbital, diazepam, clonazepam, vigabatrin, and valproate on apoptotic neurodegeneration in the developing rat brain in plasma concentrations relevant for seizure control in humans. The basis of their study was the consideration that AEDs work via three mechanisms: Limitation of sustained repetitive neuronal firing via blockade of voltage-dependent sodium channels, enhancement of GABA-mediated inhibition, and blockade of glutamatergic excitatory neurotransmission. However, they hypothesized that these blocked mechanisms are also features of an endogenous neuroprotective system in the brain that is crucial for neuronal survival during development. They concluded that AEDs may impair survival-promoting signals and an imbalance between neuroprotective and neurodestructive mechanisms in the brain, which, during a developmental period of ongoing programmed neuronal death, will promote apoptotic neurodegeneration. However, the proapoptotic effects of these AEDs appears to be species specific in research animals, and it is unclear if these results can be extrapolated to human newborn infants. In addition, recent data from the same group show that another AED, topiramate, lacks the toxicity seen with the other drugs.[56]

Summary and Conclusions

The occurrence of seizures in a newborn infant strongly indicates the presence of a CNS disorder. Clinical management is based on accurate characterization and classification of the clinical events and, if available, appropriate correlation of the interictal and ictal EEG. Etiologic factors are wide-ranging, although, hypoxic–ischemic encephalopathy continues to be a prominent cause. Etiology-specific therapy is critical to minimizing any adverse effects of the seizures. Although a number of potential AED regimens exist, phenobarbital and benzodiazepines are used most consistently. There are only a few well-defined, specific neonatal epileptic syndromes including benign neonatal seizures, benign familial neonatal seizures, early myoclonic encephalopathy, and early infantile epileptic encephalopathy. The prognosis of neonatal seizure is generally associated with the nature and severity of the underlying etiology, but this may be modulated by the burden of associated neonatal seizures and possibly the administration of the AEDs themselves, both fertile areas for future research.

Chapter 57

Febrile Seizures

Carol S. Camfield

Peter R. Camfield

Brian G. Neville

Introduction

Febrile seizures are the most common convulsive disorder through the lifecycle. In the United States and Western Europe, about 4% of children under the age of 5 years experience a febrile seizure[47,65]; the frequency has been reported to be higher in some Asian populations (8% in Japan and 14% in Guam).[58,64] Febrile seizures are characterized by their benign prognosis.

Historical Perspectives

Until the mid-19th century, febrile seizures were not recognized as distinct from other seizures. Before that time, infantile convulsions were thought to be the result of irritation of the central nervous system (CNS). Presumed causes included gastrointestinal irritation, teething, improper diet, and fever. Treatment was nonspecific and focused on relieving the symptoms. By the mid-19th century, this began to change, and treatment was directed at underlying causes rather than symptoms. Beginning in the latter part of the 19th century, fever came to be regarded as a primary factor in producing infantile convulsions. This emphasis on fever may have been related to the introduction of the thermometer into clinical use around this time.[26]

Throughout the late 19th and early 20th centuries, any infantile convulsion was considered to be serious and potentially fatal. This was because of a failure to separate febrile from neonatal and other symptomatic seizures.

By the turn of the century, as it was gradually understood that seizures were a symptom and not a disease, treatment of the underlying cause became important. Unfortunately, very few effective treatments were available.

In the mid-20th century, studies focused on febrile seizures were published by Lennox[40] and Livingston.[41] These investigators found that a benign outcome was predicted by onset between 1 and 3 years, generalized seizure of short duration, single or few episodes, family history positive for febrile convulsions, male sex, and normal findings on the electroencephalogram (EEG). Increased likelihood of later epilepsy was associated with onset before 1 year of age, prolonged or partial convulsions, multiple seizures, abnormal birth history, family history of epilepsy, female sex, and abnormal EEG findings. Subsequent studies have confirmed many of these factors as predictive, albeit not very accurate predictors.

By the 1970s, three large population-based studies had been published that demonstrated a much lower risk for epilepsy following febrile seizures than previously proposed. These studies had very similar results, and formed the foundation for our current understanding of febrile convulsions. In their study of 18,500 children, van den Berg found a 2% incidence of febrile seizures with a 3% rate of later epilepsy.[65] In 1976, the National Institute of Neurological Disorders and Stroke (NINDS) Collaborative Perinatal Project, which followed 54,000 infants prospectively, found an incidence of almost 4% for febrile seizures.[47] The developmental outcome was unaffected, and the overall incidence of later epilepsy was relatively small (2%). Verity followed a British cohort of 14,676 children.[70] The incidence of at least one febrile seizure was 2.7%, and 2.3% of those with febrile seizures later developed epilepsy.

Definitions

In 1980, the National Institutes of Health (NIH) Consensus Panel defined febrile seizures as "An event in infancy or early childhood, usually occurring between three months and five years of age, associated with fever but without evidence of intracranial infection or defined cause. Seizures with fever in children who have suffered a previous nonfebrile seizure are excluded. Febrile seizures are to be distinguished from epilepsy, which is characterized by recurrent nonfebrile seizures."[21]

This definition excludes any seizure that occurs in the presence of neurologic illness, such as encephalitis, meningitis, or toxic encephalopathy. The prognosis for such seizures is different from that of febrile seizures, because the underlying illnesses can potentially cause CNS sequelae. Seizures caused by mild encephalopathies may be included within this definition, such as those associated with *Shigella*, a bacterium that produces a neurotoxin. Febrile seizures are difficult to define in malaria-endemic areas where all children are infected from time to time, many have elevated temperatures, and the severity of brain involvement is often measured by severity of the seizure disorder as well as level of consciousness.[48]

Simple febrile seizures are those that last less than 15 minutes and are generalized. Complex febrile seizures are prolonged, multiple within 24 hours, or partial. Seizures in either of these subgroups may be accompanied by a pre-existing neurologic abnormality or a family history of either febrile or afebrile seizures.

Febrile status epilepticus follows the usual definition of 30 minutes of continuous or intermittent convulsive phenomena without the return of consciousness.

Discussion remains about the age range used in the NIH Consensus Panel definition. Many experts feel that ages between 3 and 6 months is rather young for the onset of a first febrile seizure. In fact, it may herald the onset of Dravet syndrome, a recently described epilepsy syndrome. As well, children have febrile seizures beyond the fifth birthday, and it has been suggested that the upper age limit be the sixth birthday. Another area of contention is a standard definition of "fever" and how a child's temperature should be measured (i.e., oral, rectal, axillary, or tympanic measurement). Based on the childhood vaccine trial literature, our definition of an elevated temperature is 38°C per rectum or 38.5°C orally. However, we recognize that such accuracy is not always available.

Seizures are not considered to be "febrile seizures" when they occur with fever but in the context of exposure to proconvulsant drugs such as diphenhydramine, tricyclic antidepressants, amphetamines, and cocaine.

Table 1 Predictive Factors in Febrile Seizures

- **For a first febrile seizure**
  - Family history of febrile seizures
  - Low plasma ferritin level
  - Slow development
  - Day care
  - Higher temperature
  - Delayed neonatal discharge
- **For recurrences**
  - "Complex" first febrile seizures
  - Family history of febrile seizures
  - High number of febrile episodes
  - Low fever
  - Short duration of fever before seizure
- **For epilepsy**

- Young age at onset
- Abnormal development before first seizure
- Family history of epilepsy

It has been suggested that febrile seizures should be categorized as acute symptomatic because of the coincident febrile

P.660

illness. We feel this is misleading. It is our opinion that fever is a systemic trigger that provokes the seizure, as contrasted to the underlying severe brain dysfunction found in most conditions included in the acute symptomatic category. In addition, the outcome for febrile seizures is so much better than for seizures associated with many acute symptomatic causes that it is misleading to lump them together.

Epidemiology

In the United States, South America, and Western Europe, febrile seizures are experienced by 2% to 5% of all children before the age of 5 years.[28,47] They are reported to be even more common in certain Asian countries.[58,64]

The first febrile seizure is complex (lasting more than 15 minutes, partial, or multiple within 24 hours) in about 30% to 40% of cases.[69] The peak incidence is in the second year of life, with the average age of onset between 18 and 22 months. Febrile seizures are slightly more common in boys.

Risk factors for a first febrile seizure have been studied in comparison to febrile controls without seizures (Table 1). A higher temperature was a risk factor for febrile seizures in two studies,[9,52] and a history of febrile seizures in the immediate family was noted in another study.[15] Low plasma ferritin, reflecting poor iron status, also increased the risk. When both febrile and afebrile children were used as controls, in addition to a family history of febrile seizures, neonatal discharge at 28 days or later, parental report of slow development, and day care attendance were also risk factors.[16]

Approximately 40% of children with a first febrile seizure will experience one or more recurrences. The risk of a second seizure after a first is about the same as a third febrile seizure after a second. Most recurrences (75%) are within 1 year of the first febrile seizure. Four major risk factors for recurrence have been identified: (a) a young age (<12–18 months)[17,69]; (b) a family history of febrile seizures[16,52,66]; (c) a low temperature at the time of seizure[12]; and (d) a short duration of fever before the first seizure.[12] The recurrence risk for those with none of the four factors was 14%, with one factor 23%, with two 32%, with three 62%, and with all four 76%.[13] In a meta-analysis, young age of onset and a family history of febrile convulsions were the strongest predictors of recurrence[11] (see Table 1). A family history of afebrile seizures has inconsistently been associated with risk for recurrence.[12,47,49,69] "Complex" febrile convulsions and neurologic dysfunction do not influence the chance of febrile recurrences.[12,47,69]

Genetics

There is an important genetic predisposition for febrile seizures, and genetic factors exist that may be either causative or protective. It is natural to consider the possibility of a genetic propensity for the occurrence of a febrile seizure; however, there may also be protective gene(s) in those who never experience a febrile seizure. These protective gene(s) might raise the seizure threshold.

Although the exact mode of inheritance is not known, febrile seizures tend to run in families. An autosomal recessive mode of inheritance is not likely, because there is an excess of affected parents and the risk to siblings is less than 25%. Either a polygenic mode of inheritance or dominance with incomplete penetrance is more likely.[3,63] Afebrile seizures or epilepsy may be more common in families of children with febrile seizures, but the evidence is controversial. When a child has a first febrile seizure, the risk for younger siblings is in the range of 10% to 20% and even higher if a parent reports having had a febrile convulsion.[6]

Two unique epilepsy syndromes always include seizures with fever: generalized epilepsy with febrile seizures plus (GEFS+)[54] and Dravet syndrome (severe myoclonic epilepsy of infancy).[22] GEFS+ is an autosomal dominant epilepsy syndrome with 80% penetrance and is associated with heterogeneous clinical phenotypes (see Chapter 257).[20] In a given family, about one third of those affected have one or more febrile seizures that often persist beyond the usual age of 5 years. About one third have febrile seizures and then afebrile generalized tonic–clonic seizures in adolescence that usually remit. A final third have other epilepsy syndromes, usually, but not always, generalized syndromes (myoclonic-astatic epilepsy, typical childhood absence, and even Dravet syndrome). Several gene mutations have been identified involving voltage-gated sodium channels of *SCN1A* and the γ2 subunit of ligated-γ-aminobutyric acid (GABA)-2 receptor.[20]

Dravet syndrome (Chapter 230) begins in the first year of life with prolonged, often unilateral febrile seizures precipitated by relatively low-grade fever. Development stagnates or regresses around 1 year of age, when other seizure types develop (myoclonic, atypical absence, or partial). Ataxia and important behavior problems (hyperactivity) are very common. Dravet syndrome may occur within families with GEFS+ and with the identical gene defect, but in approximately 50% of cases, no de novo missense or truncating mutations of the *SCN1A* subunit are present.[20]

The complete genetic story of febrile seizures is still incomplete. More than seven chromosome linkage sites have been associated with febrile seizures, suggesting locus heterogeneity. In addition, at least five genes have been identified as causal for epilepsy syndromes that include febrile seizures, including GEFS+.[73] These findings may provide insights into the biology of age-limited temperature-dependent seizure susceptibility.

Etiology and Basic Mechanisms

"Everyday" infections, such as tonsillitis, upper respiratory infections, otitis media, roseola infantum, or *Shigella* gastroenteritis are often implicated as the cause of fever in children with febrile seizures. Unfortunately, there are no recent studies of the epidemiology of these infections, since vaccines against *Haemophilus influenzae*, varicella, pneumococcus, meningococcus and influenza are in widespread use and have likely

P.661

changed the panorama of childhood febrile illness. Seizures occurring soon after immunization with whole-cell diphtheria-pertussis-tetanus (DPT) and measles vaccines should not be regarded as a direct adverse effect of the vaccine.[30] Such seizures are believed to be "ordinary febrile seizures" triggered by fever induced by the vaccine. Their subsequent clinical course is identical to other febrile seizures,[29] with no increased risk for subsequent afebrile seizures or abnormal neurologic development.[7] The frequency of febrile seizures after DPT or measles vaccination is six to nine, and 24 to 25 per 100,000 children vaccinated, respectively. Newer acellular pertussis vaccines rarely induce a febrile reaction and, since their introduction in Canada, there has been a 79% decrease in hospital admissions for DPT vaccine related febrile seizures.[38]

The pathophysiology of febrile seizures is unknown. The role of activation of the cytokine network is presently being studied. There appears to be increased susceptibility to febrile seizures associated with specific interleukin alleles.[36,43,62,71] Circulating toxins, immune reaction products, and viral or bacterial invasion of the CNS have been implicated, together with relative lack of myelination in the immature brain and increased oxygen consumption during the febrile episode.[30] Immaturity of thermoregulation and a limited capacity to increase cellular energy metabolism at elevated temperatures have been suggested as contributory factors.[32]

Recent reports indicate that human herpes virus type 6 (HHV6), which causes roseola, is strongly associated with febrile seizures.[8] HHV6 infection was identified in eight of 42 children with a first febrile seizure.[60] In children with multiple febrile seizures, HHV-6 DNA was detected in the cerebrospinal fluid, but not in controls without febrile seizures. It was postulated that viral invasion of the brain might occur during roseola, with reactivation by fever during subsequent illnesses, thus provoking recurrent febrile seizures.

In a survey of general practitioners throughout the Netherlands, a significant relationship was noted between recurrent febrile seizures and influenza A[67]; therefore, vaccination against influenza A may be considered after a first febrile seizure as a strategy to reduce the risk of recurrences.

Clinical Presentation

A febrile seizure is often the first sign that a child is ill, and it usually occurs early in the course of a febrile illness.[69] It is commonly assumed that a rapid rise in temperature is an important trigger, but this has not been proven.[9] The most common seizure type is tonic–clonic, but the seizure may be partial or atonic, having the appearance of a sudden collapse. Prolonged febrile seizures are often focal, and a Todd paresis may follow a partial seizure.

Other possible seizure types are described as staring accompanied by stiffness or limpness, rhythmic jerking movements without prior stiffening, or focal stiffness or jerking only. Most seizures do not last beyond 6 minutes; in a large study, fewer than 8% were longer than 15 minutes.[47] Therefore, the child with a febrile seizure is usually not brought to medical attention until after the seizure has ended.

Febrile seizures are generally divided into either simple (single, brief, and generalized) and complex (partial, prolonged, or repeated in the same illness). About 60% to 70% of febrile seizures are simple, and 30% to 40% are complex.[10,47] A Todd paresis occurs in 0.4%.[47] In a prospective cohort study of first febrile seizures, 35% of 428 children had one or more features of a complex febrile seizure.[10] A retrospective study reported similar findings.[39] Postictal unconsciousness lasting more than 30 minutes, although rare, has been associated with seizures that are focal and/or last longer than 5 minutes.[50]

Diagnostic Evaluation

As soon as the child is brought to medical attention following an apparent febrile convulsion, it is important to identify whether any medical condition is present that requires treatment. The history should include possible symptoms of infectious illness, trauma, medication taken, exposure to toxins, developmental level, and any previous or family history of seizures, either febrile or afebrile. Whenever possible, a complete description of the seizure from start to finish should be obtained from an eyewitness. This history may be unreliable because caretakers are often very frightened by the seizure.

A general physical examination should note the level of consciousness and presence or absence of meningismus, tense or bulging fontanelle, Kernig or Brudzinski signs, and focal differences or abnormality in muscle strength and tone. Urgent attention must be given to exclude the presence of meningitis and status epilepticus.

For children with many febrile seizures, it is important to consider a chronic infection or immune deficiency.

Two practice parameters prepared for the American Academy of Pediatrics, based on peer-reviewed publications about simple febrile seizures,[4,5] have concluded that very little investigation is warranted.

Routine Blood Work

Routine blood work has not been shown to be of value. Two studies have suggested that low serum sodium after a first febrile seizure is associated with a significant risk of a recurrent febrile seizure within that illness[33,37]; however, another more robust study failed to confirm this association.[61] Because rates of bacteremia (2%) and other serious bacterial illnesses are low (2%), blood cultures and complete blood count are not routinely necessary.

Lumbar Puncture

The main controversy in the evaluation of febrile seizures continues to be the lumbar puncture (LP). About 15% of children with meningitis will have seizures, but virtually none are neurologically normal shortly after the seizure.[27] Once a febrile seizure has stopped, excluding meningitis/encephalitis becomes a critical task for the physician.

A LP is indicated if meningitis is suspected clinically, even if a source of infection outside the CNS has been found, such as otitis media. If the infant has been receiving antibiotics, partially treated meningitis should be considered.

In infants younger than 12 to 18 months, clinical signs of meningitis may be absent, and a LP should be strongly considered.[72] However, this clinical truism has not been critically assessed. The American Academy of Pediatrics Committee on Quality Improvement Committee practice parameter states: “The clinical evaluation of young febrile children requires skills that vary among examiners. In all children younger than 12 months, performance of a lumbar puncture should be strongly considered.”[5] In the slightly older child, the practice parameter maintains: "In a child between 12 to 18 months of age, a LP should be considered because clinical signs and symptoms of meningitis may be subtle."

The LP should not be omitted solely on the basis of age or family history, and it should be considered even in a child who has had several previous febrile seizures. If increased intracranial pressure is suspected, the decision to perform a LP should be made by an experienced physician who is able to weigh the

P.662

risk of delaying a possible diagnosis of meningitis against the risk of LP.

It is clear that meningitis is incredibly unlikely if a child older than 18 months of age appears well shortly after the seizure. The American Academy of Pediatrics Committee on Quality Improvement Committee stated, "In a child older than 18 months, although a lumbar puncture is not routinely warranted, it is recommended in the presence of meningeal signs and symptoms. In addition, if the child has previously been treated with antibiotics, the clinician should be aware that the signs and symptoms of CNS infection may become masked, and lumbar puncture should be strongly considered in such cases."[5]

In one series, of 503 children with meningitis, none had a simple febrile seizure.[27] Offringa studied 309 children who had an LP after presenting to an emergency department with a seizure associated with fever.[49] Ten cases had meningitis (bacterial or viral), and all had major signs pointing to serious illness. Six other children had the same signs but did not have meningitis. Therefore, only 16 of 309 "needed" an LP to exclude a CNS infection. An older study by Lorber suggested that an experienced pediatrician could avoid many LPs without missing cases of meningitis.[42] Such a selective approach implies that the physician assessing the child is experienced with the kinds of symptoms that are associated with meningitis in children. This judgment seems to be based on "the child appeared more ill than the physical signs suggested; had photophobia, neck stiffness, or a positive Kernig sign; had continuing pyrexia without obvious cause; or deteriorated in hospital."[49] The contention that "lack of experience by junior doctors does not justify routine lumbar puncture" must be tempered by what is realistically possible.[42] We suggest following the practice parameter recommendation (noted earlier) to perform a LP if the child is less than 12 months of age, unless an experienced pediatrician is available to assist.

Neuroimaging

The published evidence indicates no proven benefit for neuroimaging in children with either simple or complex febrile seizures. Neuroimaging would appear justified only when special evidence points to an underlying structural lesion such as focal neurologic abnormalities, significant developmental delay, neurocutaneous lesions or abnormal head circumference.[5] Anxiety about complex febrile seizures does not justify routine imaging, especially considering that this group involves 30% to 40% of all first febrile seizures. No abnormalities were found in one study of computed tomography (CT) scans in 44 hospitalized febrile seizure patients.[46]

Electroencephalograph

Routine electroencephalography (EEG) is not justified after a first simple febrile seizure, either at the time of presentation or within the following month.[5] Even though EEG is often requested, no consistent evidence suggests that routine EEG predicts febrile seizure recurrence or subsequent epilepsy.[45,57] Furthermore, studies of children with complex febrile seizures have not shown the EEG to be predictive of the development of epilepsy.

The one special feature of the EEG and febrile seizures is hypnagogic spike-wave. This discharge consists of short bursts of irregular high-voltage δ-waves with a few buried spikes as the child drifts off to sleep. It has a peak expression at about 3 to 4 years of age—long after the peak age of febrile seizures—and apparently may be seen in the majority of children with febrile seizures.[2,56,63] Many authorities view hypnagogic spike-wave as an expression or marker of the febrile seizure tendency but, in any case, it carries no long-term negative connotations. The value of EEG in children with repeated febrile seizures has apparently not been extensively studied.

Differential Diagnosis

Rigors due to fever, febrile myoclonus, breath-holding, and syncope triggered by illness must be differentiated from febrile seizures.[51,59] It is possible that many febrile seizures are febrile syncope, a diagnosis that should be suspected on the semiology of reflex asystolic attacks accompanied by sudden pallor and atonic collapse or tonic extension.

A new scenario of an afebrile seizure associated with minor infection was described by Lee.[39] The age group is similar to those with febrile seizures, and a high prevalence of family history of febrile seizures is noted. Children with this disorder frequently have febrile seizures on other occasions. The seizures occur in children who are afebrile (temperature <37.8°C), have definite signs or symptoms of illnesses (cough, coryza, vomiting, or diarrhea), and have normal metabolic and cerebrospinal fluid findings and no other obvious cause for seizures. Nearly 25% of the 125 children had more than one recurrent seizure within the next 24 hours. After a follow-up of 6 years, the risk of recurrence of an afebrile seizure was 7.8%, as compared with 1.6% followed having a first unprovoked (regular) febrile seizure. There is an overlap in presentation between febrile and illness-provoked seizures. We are not convinced that including them within the acute symptomatic group is appropriate, as mentioned previously. The appropriate initial evaluation for cause of seizures is similar, as is the supportive care, counseling, and long-term management. The "afebrile-febrile seizure" scenario was also noted in a recent study of 39 children from Seattle, Washington.[74]

Long-Term Prognosis

Risk for Epilepsy

A population-based study and a large case series determined that febrile seizures precede 15% of all cases of childhood-onset epilepsy.[14,17] The majority of these children had experienced simple, generalized febrile seizures. On the other hand, epilepsy develops in fewer than 5% of all children with febrile seizures.[53] The reported rate of epilepsy after a febrile seizure is higher in populations from selected sources, such as patients admitted to hospitals or referred to specialists.[47]

The number of recurrent febrile seizures does not increase a child's risk for later afebrile seizures.[47] Factors that increase the risk for one or more afebrile seizures are history of abnormal development before the first febrile seizure, abnormal findings on neurologic examination, a history of afebrile seizures in a parent or sibling, or a "complex" first febrile seizure (see Table 1).[3,47] In a large prospective study, 66% of children with febrile seizures had none of these risk factors ("simple febrile seizures"), and only 2% of those with simple febrile seizures had an afebrile seizure by the age of 7 years. Of the 34% with one risk factor, one or more afebrile seizures occurred in 3%, and if a child had two or more risk factors, the afebrile seizure rate was 13%. Therefore, most children with risk factors do not develop epilepsy. Identification of a risk factor for subsequent afebrile seizures generally does not mandate a change in long-term management.

Annegers in Rochester, Minnesota, noted that, when epilepsy follows a simple febrile seizure, it is usually generalized epilepsy. In the 2% to 4% of children who develop subsequent epilepsy after a complex febrile seizure, partial epilepsies

P.663

tend to follow.[3] The significance of these observations must be tempered somewhat because these conclusions are only based on a long follow-up of 687 children with febrile seizures of whom only 32 developed epilepsy (or at least one unprovoked seizure) following a febrile seizure. Again, the clinician following a child with a complex febrile seizure must remember that the vast majority never develop epilepsy. Even those with a partial, prolonged febrile seizure repeating within the same illness have only a 15% chance of developing epilepsy.[47]

The Sequence of Prolonged Febrile Seizures Followed by Intractable Temporal Lobe Epilepsy Secondary to Mesial Temporal Sclerosis

Although it has been argued that febrile seizures may predispose a child to the later development of partial seizures of temporal lobe origin, the evidence for a cause-and-effect relationship remains controversial. Studies of patients with intractable complex partial seizures who have a history of prolonged febrile convulsions show an increased rate of mesial temporal sclerosis.[18] However, population-based studies find this sequence to be rare—about 1 in 150,000 children.[17]

The initial observations of Falconer, based on a series of 100 children having surgery for intractable temporal lobe epilepsy (TLE), suggested two main ideas.[25] First, the etiology of TLE often appeared to be mesial temporal sclerosis (MTS); in 41 of his 100 cases, it was the only pathology. Second, a 30% of those with mesial temporal sclerosis had preceding prolonged febrile seizures (compared with 6% in the group with other pathologies). A cause-and-effect relationship was postulated, and further confirmation came from work with status epilepticus in adolescent baboons, in which very severe status caused damage to the mesial temporal structures.[44] It is likely that these baboons were too mature to accurately reflect the human circumstance (see Chapter 39). Recent evidence in rats suggests that a prolonged febrile seizure may not be sufficient to cause later epilepsy by itself, but rather may permanently lower the seizure threshold, which in turn allows the expression of a second independent injury.[23]

In many cases, at the time of surgery "dual pathology" is found in the temporal lobe; for example, a small area of malformation plus mesial temporal sclerosis.[31] A single published magnetic resonance imaging (MRI) study documents two completely normal children with no perinatal difficulties who had febrile status with initial unilateral hippocampal swelling and then volume loss in mesial temporal structures.[68] More frequently, investigators have found bilateral hippocampal swelling following febrile status, which usually resolves completely.[55] No prospective studies document a normal MRI, then a prolonged febrile seizure, then unilateral hippocampal swelling, followed by mesial temporal sclerosis and intractable TLE. Additional longitudinal prospective studies are presently underway that will help to answer this question.

The link between a very common condition causing a significant problem is very difficult to demonstrate prospectively. We have estimated that the sequence of febrile status followed by mesial temporal sclerosis and intractable TLE occurs in only 1 of 75,000 to 150,000 children.[17] However, regardless of how rare or complicated, the syndrome of prolonged febrile seizures associated with unilateral mesial temporal sclerosis and intractable TLE has an excellent surgical outcome in 80% to 90% of cases (see Chapter 247 for further discussion).[1,34,35]

Intellectual Development

Two large cohort studies have firmly established that febrile seizures do not affect later intellectual ability. The National Perinatal Collaborative Study followed more than 54,000 babies identified prenatally to age 7 years.[47] There were 1,706 with at least one febrile seizure. Of these, 431 children had a sibling without febrile seizures. At age 7, the intelligence and school performance of those with febrile seizures was the same as their unaffected siblings.[24] Of the 16,163 children in the British National Birth Cohort Study, 381 with a history of febrile convulsions were no different from other children with regard to behavior, height, head circumference, or academic progress, behavior, or performance on simple intellectual tests.[69] In two other large prospective studies, academic performance was not impaired in children of school age with a history of febrile seizures.[47,53]

Chang utilized a prospective, population-based, case-control method to assess the learning, spatial, and sequential working memory of 87 school-aged children with a previous febrile seizure and 87 randomly selected age-matched control subjects.[19] The febrile seizure group performed significantly and consistently better than control subjects on mnemonic capacity and had more flexible mental processing abilities than their age-matched controls.

Summary and Conclusions

Febrile seizures are essentially benign. They are determined by genetic factors and an age-related susceptibility to fever that is outgrown by about 6 years of age. Although febrile seizures may be extremely frightening to parents, they resolve without appreciable risk of sequelae. There is no later effect on intellectual or behavioral ability. Epilepsy later develops in only a small minority of children with febrile seizures and, unless the seizure is exceedingly long, there is no evidence of any risk for neurologic consequences in the future. The most important determinant of neurologic status after a febrile seizure is the child's neurologic status before any seizure occurred. Although the sequence of prolonged febrile seizures followed by intractable TLE secondary to mesial temporal sclerosis occurs, this appears to be an infrequent event.

Chapter 58

Generalized Convulsive Status Epilepticus

David M. Treiman

Introduction

Generalized convulsive status epilepticus (GCSE) is the most common and most dangerous type of SE. The earliest mention of SE in the medical literature—in a Babylonian medical text from the first millennium before the Common Era[165]—referred to what we now know as *generalized tonic-clonic SE*,[109] *major motor SE*,[110] *generalized status epilepticus*,[74] *GCSE*,[135] or *grand mal status epilepticus*.[101] The first modern description of GCSE was provided by Calmeil in 1824,[17] who wrote, "There are cases where, as soon as one attack is barely over, another begins, so that there is a succession of up to as many as 40 or 60 uninterrupted attacks. This is what the patients amongst themselves call *etat de mal*. The danger is urgent; many patients die." Detailed descriptions of GCSE subsequently were provided by Bourneville,[12] Trousseau,[152,153] and Clark and Prout.[25,26,27] However, it was not until the Marseilles Conference[42] that GCSE was clearly distinguished from other types of SE. In 1984, Treiman et al.[143] introduced the term *subtle GCSE* to describe a late and subtle presentation of GCSE. At that time, subtle GCSE was not generally recognized, although Bourneville[12] and later Clark and Prout[25,26,27] had recognized the dynamic character of GCSE as a disorder with "progressive clinical stages."

Definitions

Generalized convulsive SE classically has been defined as recurrent generalized convulsions without full and complete recovery of consciousness between seizures or as a single prolonged convulsion without the characteristic evolution of a single discrete seizure. Thus, recurrent primarily and secondarily generalized tonic–clonic seizures without recovery of consciousness between seizures are both forms of GCSE. However, it is now recognized that at least secondarily GCSE is a dynamic state[137,138,139,141] (evidence for dynamic changes during primarily generalized convulsions is sparse). If recurrent convulsions are allowed to persist without treatment or with inadequate treatment, a progressive diminution of convulsive activity occurs, so that the motor manifestations of GCSE become increasingly subtle.[33] Subtle GCSE is defined as a condition in which a patient exhibits profound coma, convulsive activity consists of only subtle twitches of the extremities or trunk or nystagmoid movement of the eyes, and bilateral (although frequently quite asymmetric) ictal discharges are present on the electroencephalogram (EEG).[137] Although the clinical and EEG characteristics of GCSE are different in early (usually overt) GCSE and late (usually subtle) GCSE, there is a continuum between these two presentations, and subtle GCSE may progress to complete cessation of motor activity, even though ictal discharges continue on the EEG. Treiman[141] termed this presentation of GCSE electrical GCSE and suggested that this represents the final stage in the progression from overt GCSE. Electrical GCSE, sometimes following more overt GCSE, has also been reported by others.[33,34] Many investigators have used the term *nonconvulsive SE* for such profoundly comatose and severely ill patients.[13,33,102,160] Treiman[137] suggested that what others have called *myoclonic SE* (in patients with anoxic or other severe encephalopathies) is really subtle GCSE, even though there may be only one or two (or occasionally no) generalized convulsions before the appearance of signs and symptoms of subtle GCSE. This is an area of controversy, and some epileptologists are not convinced that the subtle convulsive activity and periodic epileptiform discharges sometimes seen in severe hypoxic encephalopathy should be considered SE.

The definition presented also distinguishes subtle GCSE from true nonconvulsive SE (a category that includes both complex partial SE and absence SE), in which the characteristic clinical feature is an epileptic twilight state, although, as noted, the increasingly common use of the term nonconvulsive SE in comatose patients adds confusion to the literature. A progression from overt to subtle motor activity has not yet been described for primarily GCSE.

The definition of GCSE must also deal with generalized convulsive activity that occurs as a single prolonged episode rather than as repeated discrete behavioral seizures. Such a situation is common in the later stages of GCSE, when convulsive movements tend to be subtle, but it may also occur early in an episode of GCSE, especially in children. Here the convulsive movements are more likely to be overt. Most authors have suggested that seizure activity should persist for at least 30 minutes before the diagnosis of SE is made. However, data from Theodore et al.[130] confirming the widely held clinical impression that single convulsions that are not part of an episode of SE do not last >2 minutes (discussed later) suggest that 30 minutes of continuous convulsive activity is far too long to be a good operational criterion for the diagnosis of GCSE. For practical clinical purposes, 10 minutes of continuous behavioral or electrical seizure activity, without the evolution of the ictal discharges typical of a discrete generalized convulsion, is a more realistic criterion. Lowenstein et al.[75] suggested 5 minutes' duration as the definition of SE, but this may be too short, especially because discrete generalized convulsions in children may persist for >5 minutes.

Epidemiology

Generalized convulsive SE is the most common type of SE, especially when subtle presentations of GCSE are included. However, in many older reports, GCSE is not clearly distinguished from other types of SE. Hauser[47] suggested that there are approximately 65,000 cases of SE in children and adults in the United States each year. However, DeLorenzo et al.[32] estimated that there are approximately 150,000 cases of SE in the United States each year, based on extrapolation of data from their community-based study in Richmond, Virginia. About 70%

of both adults and children in the Richmond series exhibited GCSE. Shorvon,[118] on the basis of a careful review of hospital-, clinic-, and population-based studies, estimated an annual incidence of GCSE of 180 to 280 per million persons in the United States and the United Kingdom. He emphasized that this probably represents an underestimate of the true incidence of GCSE, which almost certainly is still higher in developing countries. In the last decade, eight major population studies of the epidemiology of status epilepticus have been reported, six of which were reviewed by Chin et al.[22] Data from all eight studies are summarized in Table 1. Five included all ages,[28,32,48,63,166] two included only adults,[157,158] and one included only children.[21] Six covered all types of status epilepticus; two only included convulsive SE.[21,166] Overall, the reported incidence of status epilepticus ranges from 10.3 to $61/10^5$, but the incidence is much higher in the very young (<1 year: 135–$156/10^5$) and the elderly (>60 or 65 years: 14.6–$86/10^5$). Generalized convulsive status epilepticus (including both primarily and secondarily generalized convulsions) accounted for 33.3% to 71% of the cases when all types of SE were included. These numbers can be extrapolated to give an estimate of at least 2 million cases of GCSE in the world each year.

Etiology

Older series of cases of SE that tabulated etiologies usually included all varieties of status, but the majority of such cases were GCSE. A summary of these data is provided in the first edition of this book.[140] However, even when newer studies are reviewed, the etiology of GCSE has not changed substantially. Ten case series in the last decade have been limited to generalized convulsive status epilepticus (Table 2). Most of these studies used variations on a classification of etiology that includes acute symptomatic and remote symptomatic causes, prolonged febrile seizures, and de novo epilepsy. Hauser[47] suggested that 12% of patients with new-onset epilepsy will present in status epilepticus. Over the last decade, 10, mostly prospective, studies of the etiology of GCSE have been reported (Table 2). The etiology of GCSE is quite variable, depending on age and whether the patient has a previous history of epilepsy, as are events precipitating specific episodes of SE. In adults, the most common causes are remote symptomatic, and discontinuation of antiepileptic drugs is the most common cause of SE in patients with chronic epilepsy. Head trauma, central nervous system infection, and cerebral infarction or hemorrhage are frequent causes of SE occurring de novo. In the one series of patients with subtle GCSE,[148] life-threatening medical illnesses, including hypoxic encephalopathy, accounted for more than half of the cases. In children, prolonged febrile seizures account for up to 40% of the cases.

Pathophysiology

Most convulsive seizures are of short duration, and the convulsive activity almost always terminates within 2 minutes. Theodore et al.[130] studied the convulsive portion of 120 generalized tonic–clonic seizures recorded in a monitoring unit at the National Institutes of Health. The mean duration of the generalized tonic–clonic phase was 62.2 seconds, with a range of 16 to 108 seconds. Thus, mechanisms exist that terminate isolated epileptic seizures within a short period of time. Furthermore, in many patients there is a refractory period lasting for minutes, hours, or days before another seizure occurs. However, under some circumstances, seizure-terminating mechanisms fail and seizure activity either persists or recurs before full recovery of physiologic and neurochemical homeostasis. This, in physiologic terms, is the operational definition of SE. Neuronal inhibitory mechanisms that may contribute to seizure termination include Ca^{2+}-dependent K^+ currents, blockade of *N*-methyl-D-aspartate (NMDA) channels by Mg^{2+}, and the inhibitory effects of adenosine, opioid peptides, and γ-aminobutyric acid (GABA). Kapur et al.,[59] using a paired-pulse technique in an electrogenic model of experimental SE, showed that a marked deterioration of GABA-mediated inhibition occurs during continuous hippocampal stimulation, and Treiman et al.[151] reported similar findings in hippocampal slices obtained during various EEG stages in lithium/pilocarpine-induced SE. Furthermore, NMDA receptors become activated during continuous hippocampal stimulation,[8] and NMDA antagonists block the deterioration of GABA-mediated inhibition.[58] Wasterlain and colleagues reported a 50% reduction in synaptic $GABA_A$ receptors and increase in synaptic NMDA receptors per granule cell synapse after 1 hour of experimental SE.[20,88] On the basis of these observations they propose that alterations in receptor trafficking can explain the transition from isolated seizures to SE and the progressive refractoriness of ongoing GCSE to treatment, especially with GABAergic drugs such as benzodiazepines and barbiturates.

Although it is frequently difficult to sort out cause and effect, there is abundant evidence for profound neuropathologic changes occurring as a consequence of GCSE, starting with Pfleger's detailed pathologic study of a patient dying in SE.[100] Neuronal damage, involving principally the neocortex, hippocampus, thalamus, and cerebellum, has been observed in brains of children and adults dying shortly after an episode of SE.[29,40,92,116,167] However, neuronal damage observed after SE could be caused by the initial insult to the central nervous system that precipitated the episode of status rather than by the SE seizure activity itself. DeGiorgio et al.[31] attempted to test this possibility with a case-matched control study. These authors studied hippocampal neuronal density in the brains of five adult patients who died shortly after an episode of GCSE; five patients who were as closely matched as possible for parameters such as age, underlying central nervous system insult, and underlying medical conditions, including epilepsy, but who had not had an episode of GCSE; and five age-matched controls with no history of central nervous system insult or epilepsy. In five regions of the hippocampus, the patients with SE had the lowest neuronal counts, the case-matched controls the next lowest, and the central nervous system controls the highest.

Animal studies also provide evidence for SE-induced neuronal damage in previously normal subjects, even when the animals are paralyzed and artificially ventilated.[83] Observation of neuronal changes in well-ventilated animals in which adequate glucose levels have been maintained suggest that although systemic complications such as hypoxia, hypoglycemia, lactic acidosis, and especially hyperpyrexia may exacerbate the neuronal damage occurring as a result of sustained seizure activity,[9,76,83,120,126] the ongoing seizure activity itself substantially contributes to the neuronal damage.[30,43,54,70,89,90,93,154,155] Fujikawa[41] detected neuronal damage after only 20 minutes of ongoing pilocarpine-induced experimental SE. There was a progression of distribution and intensity over the 3 hours of observation. Both animal and human studies have shown that the immature brain may be less susceptible to seizure-induced neuronal damage, although it is more susceptible to seizures.

Clinical Features

Generalized convulsive SE is characterized by paroxysmal or continuous motor activity. The motor activity may be of the tonic or clonic type or a combination of both; it may be symmetric or asymmetric, and overt or subtle. However, it is always associated with a marked impairment of consciousness

P.667

P.668

P.669

and with bilateral (although frequently asymmetric) ictal EEG discharges.[137] In what Treiman et al.[148] called *overt GCSE* the episode usually begins with a series of discrete generalized convulsions in which tonic or clonic motor activity, or a combination thereof, is associated with EEG discharges that evolve during the course of the convulsion. At this stage, the clonic phase of a discrete generalized convulsion stops abruptly, coincident with the end of the electrographic seizure. Typically, there is a gradual recovery of consciousness following each convulsion, but if the patient has not recovered fully to baseline—usually a fully alert state with no residual confusion or other neurologic symptomatology—before the next convulsion occurs, the patient is considered to be in GCSE. If GCSE is not treated or is inadequately treated, the motor manifestations become increasingly subtle as the episode of SE persists.[137] Eventually, only subtle twitching of the fingers, abdominal muscles, or face or nystagmoid jerks of the eyes may be seen. Finally, if GCSE continues for a prolonged period of time, all motor activity may cease, although ictal discharges on the EEG persist. This condition is then called *electrical GCSE*. Such a term is not an oxymoron because GCSE is a dynamic state in which the clinical and electrical manifestations change with time, as discussed in the Definition section. Thus, the evolution of untreated or undertreated GCSE is usually from overt GCSE to subtle GCSE to electrical GCSE. However, in some patients the encephalopathic insult is so severe (e.g., anoxic encephalopathy) that only one or two generalized convulsions (or sometimes even none) occur before subtle convulsive activity develops or the patient progresses to electrical GCSE.[24,156]

Interictal symptomatology depends on the stage to which GCSE has progressed. Discrete seizures typically evolve from initial generalized tonic stiffening to clonic jerks, which increase in amplitude and decrease in frequency until further clonic activity ceases abruptly and completely. At this point, the patient remains comatose and motionless. If the patient is truly in an interictal state, low-voltage slow activity without epileptiform discharges are seen on the EEG. Following a discrete seizure the comatose state lightens gradually and the EEG gradually normalizes. However, even though the patient may largely recover to a full state of alertness, if the behavior and the EEG do not return completely to the preictal baseline before the next seizure, the patient operationally is considered to be in GCSE. As GCSE evolves from overt to increasingly subtle motor manifestations, the EEG and associated behavioral abnormalities progressively become continuous and the patient no longer exhibits any periods that can be considered interictal.

A number of physiologic changes occur during the course of GCSE. Physiologic changes during SE have been summarized recently by Simon[121] and Young.[167] Meldrum,[79] Brown and Hussain,[14,15] and Walton[161] emphasized the importance of differentiating between early and late physiologic changes during SE. The initial physiologic response is a massive release of epinephrine and norepinephrine into the circulation.[7,123] This increase in circulating catecholamines results in increased systemic, pulmonary, and left atrial blood pressure, heart rate, and plasma glucose concentration[7,9,10,11,19,50,53,66,67,81,82] and an increase in cardiac arrhythmias.[39,68,81] Several investigators have suggested, on the basis of experimental evidence from animal studies, that hyperglycemia may exacerbate SE-induced neuronal damage.[9,103,131] Therefore, glucose administration during SE should be avoided unless true hypoglycemia has been established.[131]

Respiratory function is frequently impaired in early SE.[6,98] Pulmonary edema is a common finding in experimental[60,122] and clinical[39] SE and has also been seen at autopsy following clinical episodes of SE.[94] Acidosis is seen frequently during GCSE, both in animal models[56,81,124] and in human patients.[1,35,163] Much of the acidosis is caused by a combination of respiratory failure and release of systemic lactate during generalized convulsive activity. However, some degree of acidosis is present even in paralyzed and artificially ventilated animals.[83,124]

It has long been recognized that of all the systemic physiologic changes occurring during early SE,[12,25,26,27] hyperpyrexia is the most important cause of poor outcome following an episode of SE.[1] In their studies of bicuculline-induced SE in baboons, Meldrum and colleagues[80,83] reported that cerebellar damage following status occurred exclusively in animals whose core temperatures remained >40°C for prolonged periods. Temperature elevations >41°C cause hippocampal epileptic damage in rats and hypothermia protects against damage.[76] Hyperthermia lowers the seizure threshold to kainic acid, and prolonged seizures result in greater brain damage.[71] Sustained hyperpyrexia during GCSE also has been shown to produce permanent cerebral damage in humans.[120]

White blood cell counts may also be elevated in GCSE.[2,35,129] When patients also exhibit hyperthermia, clinicians may mistakenly presume an infectious etiology for the episode of status when no such infection exists. A low-grade pleocytosis in the cerebrospinal fluid (CSF) may also be observed following an episode of GCSE.[1,3,114] Barry and Hauser,[3] however, recently reported that the CSF white blood cell count in their study of 138 episodes of SE was never >30/mm^3 unless there was another cause for the CSF pleocytosis.

In late GCSE (usually after ≥30 minutes of seizure activity), many physiologic parameters return to baseline values or even drop below baseline. After an initial period of hypertension, blood pressure begins to decline after 15 to 30 minutes of experimental SE and may be markedly low after 2 hours of continuous seizure activity.[7,54,81,82] Plasma glucose concentrations may also decline to hypoglycemic levels.[11,38,84] Renal failure may develop as a result of rhabdomyolysis with resultant myoglobinuria[44,62,113,125] but has also been reported to be caused by intense vasoconstriction, even without myoglobinuria.[99]

Increased intracranial pressure occurs, at least transiently, with all epileptic seizures. However, if increased intracranial pressure persists when blood pressure drops during late SE, generalized cerebral edema may develop, especially in children.[14] Focal cerebral edema may also occur in GCSE and may be mistaken for other pathologies on cerebral imaging studies.[5,65,108,112] One recent report found evidence of hippocampal edema associated with prolonged febrile seizures but not in nonfebrile generalized SE.[117] Two recent reports[69,127] suggested, on the basis of MRI acute and chronic data, that mesial temporal sclerosis (MTS) may follow prolonged febrile convulsions, but other contributing factors for MTS, including genetic predisposition, have also been proposed.[18]

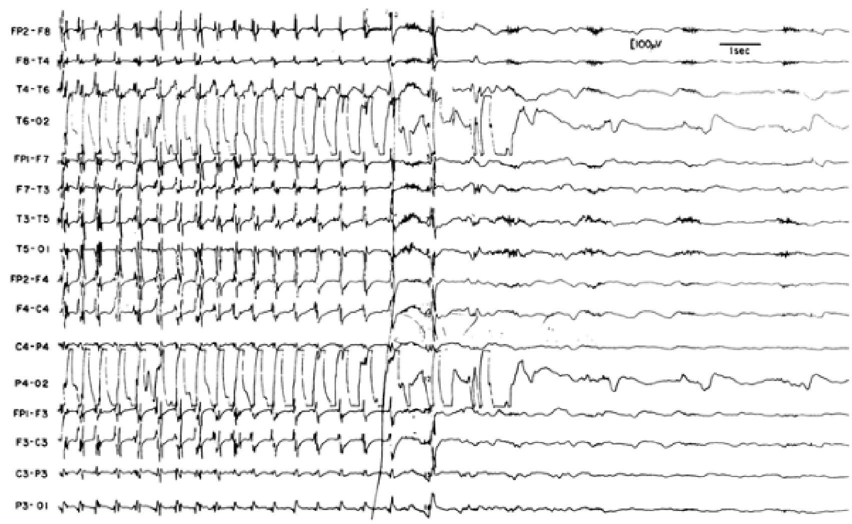

FIGURE 1. Discrete generalized tonic–clonic seizures with interictal slowing, recorded before treatment in a 39-year-old man. The example shows the end of the clonic phase of the seizure and the appearance of postictal slowing. (From Treiman DM, Walton NY, Kendrick C. A progressive sequence of electroencephalographic changes during generalized convulsive status epilepticus. *Epilepsy Res*. 1990;5:49–60; with permission.)

Diagnosis

Overt GCSE is operationally defined as two or more generalized convulsions without full recovery of consciousness between seizures or as a single prolonged convulsion. The diagnosis of overt GCSE is not difficult when recurrent convulsions occur, but a common error is to fail to diagnose SE because the patient appears to be recovering consciousness before the next seizure occurs. Any residual impairment of consciousness—any state short of full alertness—is an indicator that seizure-induced pathophysiologic changes persist and that therefore, by definition, the patient is in SE when seizure activity recurs under such circumstances. Furthermore, the clinical presentation of GCSE and the ictal patterns observed on the EEG may be asymmetric. Physicians might erroneously make a diagnosis of focal motor (simple partial) SE when a patient with impaired consciousness exhibits only unilateral convulsive movements. Such patients

P.670

should be considered to be in GCSE with an asymmetric or unilateral presentation unless they are fully alert during the motor convulsions.

Although the initial diagnosis of GCSE is usually based on clinical criteria, the EEG has an important role in the diagnosis and management of GCSE. A predictable sequence of five patterns of EEG discharges has been reported by Treiman and colleagues in human patients (Figs. 1,2,3,4,5) and six experimental models of SE in the rat.[46,61,145,150] Subsequent to Treiman et al.'s initial description[144] the same sequence also has been observed in four additional models of experimental SE.[64,73,86,104] Initially, the EEG exhibits discrete electrographic seizures associated with overt generalized convulsions. If GCSE is allowed to progress without adequate treatment, the discrete seizures merge to form a waxing and waning pattern of rhythmic ictal discharges that ultimately become monomorphic and continuous. This continuous seizure activity, which may take the form of continuous spike or spike-and-wave patterns, rhythmic sharp waves, or rhythmic slow waves, is then punctuated by periods of relative flattening that become progressively longer as the ictal discharges shorten. Finally, the patient exhibits periodic epileptiform discharges on a flat background. Recognition of any of these ictal patterns in a comatose patient should lead to the diagnosis of GCSE, even in the presence of extremely subtle convulsive movements. However, some investigators continue to question whether such patterns as periodic epileptiform discharges should be considered as electrographic evidence of status epilepticus.[13]

There is a growing consensus that most cases of SE should be managed using simultaneous EEG recording, although initiation of treatment should never be delayed while the physician is waiting for the EEG. However, not all neurologists share this view. Certainly, if clinical seizure activity stops and the patient clearly is recovering consciousness, EEG monitoring is not necessary. However, if after convulsive movements have stopped the patient does not rapidly regain consciousness, cessation of all electrical seizure activity should be verified by EEG. Furthermore, if a patient has a single convulsion but fails to recover consciousness, emergency EEG recording is essential. Such a patient is likely to be in subtle GCSE following the single convulsion.

Subsequent diagnostic evaluation after the initial treatment of GCSE should be directed toward determining the cause of the episode. In patients in whom GCSE develops as a complication of a preexisting seizure disorder, the precipitating cause of the episode—low serum concentrations of antiepileptic drugs, intercurrent infection, progressive neurologic insult—should be determined by obtaining blood for serum chemistries, complete blood cell count, and assays for toxic agents. A history of intracranial mass may require magnetic resonance cerebral imaging to detect recurrence or enlargement. If the episode of GCSE is a first seizure, the patient should be evaluated for causes of new-onset epilepsy or for the possibility of an underlying systemic illness or encephalopathy that has been complicated by the development of GCSE. Depending on age, central nervous system infection, cerebral infarction or mass lesion, systemic metabolic disorder, or substance abuse or presence of other toxins must be considered.

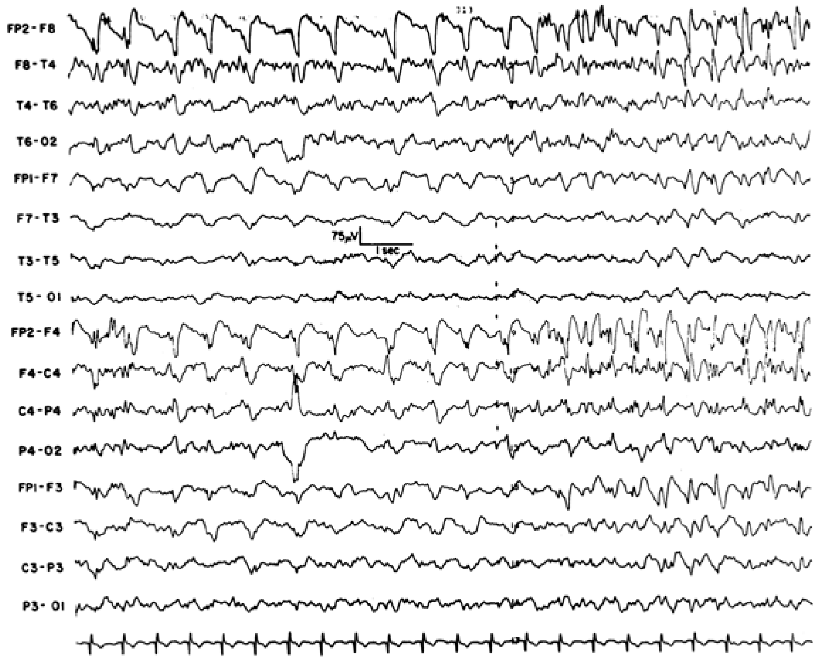

FIGURE 2. Merging of discrete seizures, recorded before treatment in a 64-year-old man. Ictal discharges are continuous but exhibit waxing and waning of frequency and amplitude. An increase in frequency and amplitude can be seen beginning on the right side of the recording. (From Treiman DM, Walton NY, Kendrick C. A progressive sequence of electroencephalographic changes during generalized convulsive status epilepticus. *Epilepsy Res*. 1990;5:49–60; with permission.)

Differential Diagnosis

Although psychogenic SE is not common, it has been described by a number of investigators in adults and children.[4,16,36,45,49,51,55,95,96,97,106,107,119,128,132,164] Psychogenic SE is seen frequently in some epilepsy-monitoring units. Some

P.671

patients who exhibit psychogenic seizures, even in the context of SE, can be extremely convincing. Four characteristics of genuine epileptic seizures are helpful in the identification of psychogenic seizures[23,136,137]: (a) evolution of behavior during the seizure, (b) stereotyped seizures, (c) sustained convulsive activity without pauses, and (d) eyes open during the seizure. Typically, generalized convulsive seizures exhibit a stereotypic evolution of first tonic and then clonic movements. Overt clonic jerks followed by tonic stiffening and then cessation of convulsive activity is never seen in a true epileptic seizure, although some patients may exhibit mild clonic jerks at the onset of a clonic–tonic–clonic seizure. Clonic jerks at the end of a clonic seizure, a typical tonic–clonic seizure, or a clonic–tonic–clonic seizure tend to decrease in frequency but increase in amplitude as the seizure progresses, and they usually stop abruptly. When motor seizure activity spreads in seizures of partial onset, the pattern of spread should be consistent with the organization of the homunculus on the motor cortex. If a seizure does not evolve in a typical pattern, this raises the question of a possible psychogenic seizure. However, some convulsions, particularly those of frontal lobe origin, may involve bizarre behavior, including strange vocalizations, flailing of the arms, head jerking from side to side, and sexually suggestive pelvic thrusting. If such seizures are stereotypic in their behavioral manifestations, it is likely they are true epileptic seizures despite their bizarre presentation. Psychogenic seizures, on the other hand, may exhibit variable behavior patterns from event to event. Furthermore, motor activity during a psychogenic event is likely to be punctuated by pauses for brief periods of rest, whereas during true epileptic convulsions, tonic, clonic, or tonic–clonic activity is usually sustained without pauses until the end of the seizure. A conscious patient having psychogenic generalized tonic–clonic seizures cannot ordinarily sustain continuous intense clonic or even tonic muscle contractions without at least brief periods of rest.

Ultimately, the EEG recording is the definitive way to differentiate between epileptic seizures and psychogenic seizures.[139] Well-modulated alpha activity in the posterior regions during or immediately following apparent seizure activity is good evidence for psychogenic seizures. After true generalized convulsions, there should be postictal slowing, at least initially, although patients with seizures of frontal lobe origin rapidly recover consciousness and their EEGs rapidly normalize.

Response to Treatment

Response to treatment in GCSE is largely determined by the duration, EEG pattern, and clinical presentation at the time treatment is initiated and by the underlying etiology. The longer an episode of status is allowed to persist, the more refractory to treatment it will be.[37,78,146,148] In both experimental SE[57,162] and human GCSE,[149] the later the EEG stage, the less responsive is the subject. In a Veterans Administration (VA) cooperative study that compared the efficacy of four treatments of GCSE, overall only 56% of patients with overt GCSE and only 15% with subtle GCSE responded to the initial treatment.[148]

P.672

P.673

There was little further response to a second or third treatment. Only intravenous general anesthesia exhibited efficacy in a substantial number of patients who failed the first drug. The outcome of this study is discussed in more detail in Chapter 126.

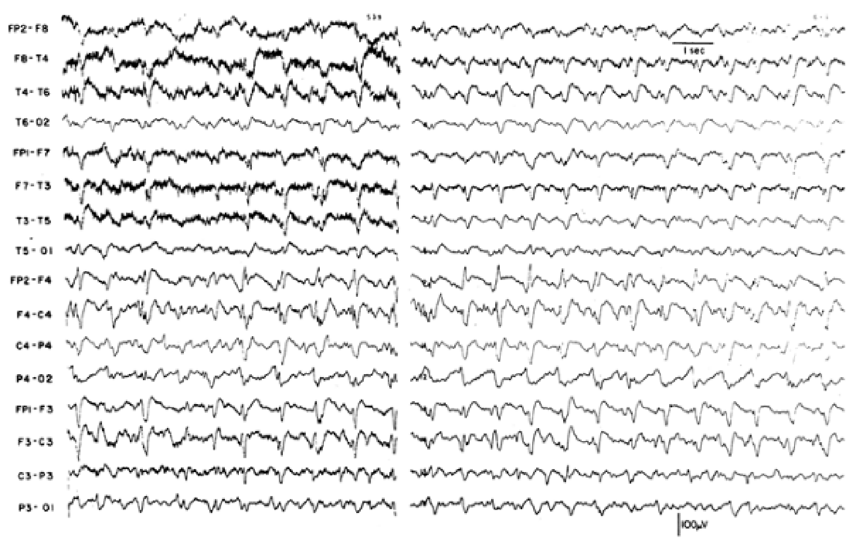

FIGURE 3. Continuous ictal discharges recorded before treatment in a 68-year-old man. Examples are 16 minutes apart. Continuous ictal activity persisted for 101 minutes, stopping only after phenytoin infusion was completed and 4 minutes after the end of lorazepam infusion. (From Treiman DM, Walton NY, Kendrick C. A progressive sequence of electroencephalographic changes during generalized convulsive status epilepticus. *Epilepsy Res*. 1990;5:49–60; with permission.)

FIGURE 4. Continuous ictal discharges with flat periods recorded before treatment in a 68-year-old man. The seizure focus is clearly in the left hemisphere, but the spread of ictal activity to the right hemisphere can be seen as well. (From Treiman DM, Walton NY, Kendrick C. A progressive sequence of electroencephalographic changes during generalized convulsive status epilepticus. *Epilepsy Res*. 1990;5:49–60; with permission.)

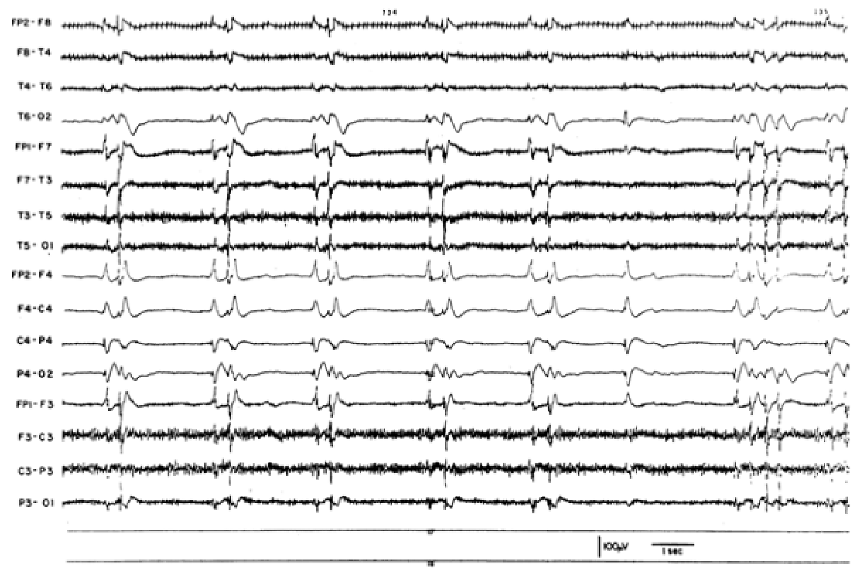

FIGURE 5. Periodic epileptiform discharges on a flat background recorded before treatment in a 64-year-old man. (From Treiman DM, Walton NY, Kendrick C. A progressive sequence of electroencephalographic changes during generalized convulsive status epilepticus. *Epilepsy Res*. 1990;5:49–60; with permission.)

Consequences

Morbidity and mortality in GCSE are largely determined by the underlying etiology of the episode, but they may be substantially increased by inadequate treatment. When treatment is delayed or inadequate, prolonged duration of GCSE is associated with a high morbidity and mortality.[35,77,148] However, in a systematic review of the outcome of pediatric convulsive SE, Raspall-Chaure et al. found the etiology is the main determinant of outcome and the effect of age or duration is difficult to separate from the underlying cause.[105] In fact, Hauser[47] suggested that mortality directly caused by SE itself occurs in no more than 1% to 2% of SE cases, even though recent series have reported mortality rates of 10% to 12%. Mortality rates of 5% to 50% have been reported.[142] Morbidity and mortality rates are substantially higher in hospital-based studies than in community-based studies. For instance, in the VA study mentioned earlier, the percentage of patients dying within 30 days of the episode of status was 26.8% for overt GCSE and 64.9% for subtle GCSE.[148] In this study, several predictors of mortality were identified. Both acute central nervous system insult and severe systemic disorder predicted poor outcome, whereas a remote central nervous system insult, whether or not an acute insult also occurred at the time of GCSE, predicted a better outcome.[147] In a community-based study in Richmond, Virginia, mortality was also defined as death occurring within 30 days following the episode of SE. Towne et al.[134] reported a mortality rate of 21% in patients with generalized SE, most of whom had GCSE. In Rochester, Minnesota, acute mortality after SE was 19%.[72] Table 2 summarizes mortality data from recent series of GCSE.

Summary and Conclusions

Generalized convulsive SE has been recognized since Babylonian times. This presentation of SE is characterized by recurrent or prolonged generalized convulsions, profound impairment of consciousness, and ictal discharges on the EEG. More than 150,000 cases of SE occur in the United States each year, most of which are cases of GCSE. Generalized convulsive SE is a dynamic state, and a predictable progression from overt to increasingly subtle motor manifestations occurs if GCSE persists without treatment or with inadequate treatment. A predictable sequence of progressive EEG changes also occurs from the beginning to the end of GCSE. Generalized convulsive SE includes what is sometimes mistakenly called *focal motor status* when motor activity is markedly asymmetric in a comatose patient. Psychogenic SE is not common but can be suspected by variability of seizure presentations during an episode, brief pauses for rest occurring during tonic or clonic motor activity, or persistent eye closure. Generalized convulsive SE must be treated early to achieve the greatest probability of success. The later the episode, the subtler the presentation, and the later the EEG stage, the more refractory to treatment the episode will be. Morbidity and mortality are largely determined by underlying etiology, but poor treatment further worsens a poor prognosis.

Chapter 59

Complex Partial Status Epilepticus

Peter D. Williamson

Introduction

Nonconvulsive status epilepticus (SE) is divided into two categories: absence SE (ASE) (spike-wave stupor, petit mal status) and complex partial SE (CPSE).[4,71,102,114,117] ASE is discussed in detail in the following chapter (see Chapter 60). ASE will be examined here only in comparison to CPSE. Until relatively recently, CPSE has been considered very rare. Twenty-three years ago, Ballenger[4] reviewed the literature and concluded that there were only 17 well-documented cases of CPSE. Subsequently and certainly related to the exponential growth in epilepsy centers, there has been a significant increase in reports critically examining nonconvulsive SE and CPSE.[14,18,44,62,91,114,115,116,127,129,133] This includes several studies in which CPSE was studied using intracranial electrodes.[53,129,133] Even so, the limits and definitions of nonconvulsive SE in general, and CPSE in particular are still imprecise.[125] Consequently, controversies over several important issues persist. As will be discussed, differentiating the two types of nonconvulsive SE is often difficult and sometimes not possible at the time of initial clinical presentation.

The term “complex partial” has recently been called into question by the ILAE Task Force on Classification and Terminology.[9] This was largely based on the difficulty encountered when trying to define consciousness. The term “dyscognitive” was suggested to replace “complex partial.” Dyscognitive SE would greatly simplify the condition and overlook many of the complicated and complex characteristics of the condition. This is even further confounded by a recent recommendation of a new classification of SE in which dyscognitive status is further subdivided into three subcategories.[93] For the purposes of this discussion, the term CPSE will be retained in the hopes of avoiding confusion. This is consistent with the recommendations of the ILAE task force.

History

CPSE with electroencephalographic (EEG) documentation was first reported by Gastaut et al.[38] in 1956. Almost 70 years earlier, however, during his Tuesday lectures, Charcot provided a fascinating and colorful account of a patient he had examined who had multiple, prolonged, ambulatory fugue states.[16,41] Charcot was convinced that this form of poriomania was indeed an example of epileptic fugue and, as such, would now be considered a type of nonconvulsive SE. Although an argument has been presented implying Charcot's case was an example of ASE,[41] an equally strong case could be made for CPSE. Jackson[50] also described cases of prolonged twilight states presumed to be epileptic. Whether these and other descriptions found in scholarly writings from ancient times up to Gastaut's report in 1956 are examples of nonconvulsive SE can only be conjectural, since most modern authorities would agree that EEG criteria are needed to make the diagnosis.[14,17,30,45,53,91,114,115,124]

SE of any type was only rarely described before the 19th century,[110] but as reviewed by Shorvon,[102] isolated early descriptions of fatal convulsive SE date from the neo-Babylonian era. In ancient times, it can be assumed that most nonconvulsive varieties of SE were not recognized as epilepsy. For example, a patient with probable nonconvulsive SE is described in *The Sacred Illness* written by an unknown student of Hippocrates, but this manifestation was specifically excluded as a form of epilepsy.[110] Hunter[49] made the ironic observation that descriptions of SE increased with the introduction of bromide therapy, implying a causal relationship between the introduction of effective antiepileptic drug (AEDs) and the increased frequency of SE, presumably a consequence of withdrawal of medication.

Definitions

SE is defined as "a condition characterized by epileptic seizures that are sufficiently prolonged or repeated at sufficiently brief intervals so as to produce an unvarying and enduring epileptic condition."[36] Although this definition is generally accepted, it has some definite drawbacks and limitations. What constitutes "enduring"? Time constraints were suggested only after the definition was proposed and have since generated considerable debate and controversy. Although the duration of convulsive SE may have prognostic significance, it is of much less importance in most cases of nonconvulsive SE, even in extreme examples.[18,77,133] In a study of patients with CPSE reported from the Yale epilepsy program,[133] several patients had repeated flurries of partial seizures, some lasting for less than 30 minutes and others lasting for hours. No fundamental difference was noted between the longer and the shorter episodes in terms of clinical seizure manifestations or intracranial electrographic findings. Are patients with prolonged postictal confusion examples of SE? The answer to this question depends on specific circumstances. Most examples of prolonged postictal states following complex partial seizures are exactly that—prolonged nonepileptic disturbances of cortical function following a discrete seizure. As such, this should not be considered SE. Occasionally, however, prolonged "postictal" states are due to continued seizure activity, either localized or diffuse, following a typical discrete complex partial seizure[53] (see patient 2 in case descriptions). This latter possibility clearly constitutes an enduring seizure state and is a form of SE.

Similarly, "unvarying" in the definition of SE is misleading. Some examples of nonconvulsive SE are very unvarying, whereas others present with widely variable clinical features. Some patients within a single episode of CPSE have stereotyped as well as highly variable clinical and electrographic manifestations.[127,129,133] The definition of SE therefore must be less restrictive to encompass a wide variety of types.

Shorvon[102] reviewed the limitations and proposed the following definition: "SE is a condition in which epileptic activity persists for 30 minutes or more, causing a wide spectrum of clinical symptoms, and with a highly variable patho-physiological, anatomical, and aetiological [sic] basis."

Although this avoids most of the limitations of the traditional definition of SE, there have been objections to the time constraints for nonconvulsive SE, for the reasons cited earlier. Also, this definition implies continuous seizure activity which is clearly not true in many examples of SE. Recently, the recommendations for minimal seizure duration in nonconvulsive SE have been 10 minutes.[103] This seems in much better agreement with clinical observations.

Gastaut[37] stated that there are as many types of status as there are types of epileptic seizures. The traditional separation of nonconvulsive SE into ASE and CPSE has, however, been questioned.[102,114,115] The definition of CPSE must be re-examined, and this will be done when describing clinical and electrographic seizure activity.

Epidemiology

Considering that the concept of CPSE is evolving and has yet to be defined precisely, the fact that there are no good epidemiologic studies of the condition should come as no surprise.[125] Although earlier studies concluded that CPSE was very rare, almost a medical curiosity,[4,71,74,117] more recent investigations report that CPSE is under-reported and more common than previously thought.[18,102,114,115,133] The current belief that CPSE is not rare is undoubtedly related to improved methods of detection, particularly through the use of intensive monitoring.[45] Although it is admittedly a crude approximation, Shorvon[102] estimates that CPSE occurs in 35 per 1,000,000 persons in the general population. Nonconvulsive status in the mentally handicapped population was similarly calculated at 100 to 200 per 1,000,000 persons.[102] In one hospital-based population study, an incidence of nonconvulsive SE was 1.5 per 100,000 per year.[114] Approximately half of these patients were thought to have CPSE. Two studies found that 19% to 25% of all types of SE were nonconvulsive, but the majority were considered ASE.[15,25] DeLorenzo et al.[24] attempted a prospective study of all types of SE. CPSE was very uncommon. This is not in agreement with other recent reports, which indicate that it can no longer be considered rare.[114,116,133] Treiman[116] notes that over 200 well-documented cases of CPSE have been reported. Furthermore, CPSE is probably even more common if, as suspected, the condition is under-reported.[14,24,56,102,114,133] Finally, as discussed later, many examples of what appear to be ASE occur in patients with localization-related epilepsy and are therefore examples of CPSE.[49,91,102,115,116,117] Nonconvulsive SE, in general, is estimated to comprise one third of all types of SE.[133] A PubMed search of "complex partial SE" from 2000 to present yielded 666 citations.

Etiology

The etiologies of CPSE are many and varied. Approximately one third to one half of patients with CPSE are initially seen without an antecedent history of epilepsy.[102,114] In one study of nonconvulsive SE that included CPSE, the most common precipitants were generalized tonic–clonic (GTC) seizures and changes in AEDs, either due to noncompliance or under medical direction.[114] A recent study related CPSE to increased levels of carbamazepine-10,11-epoxide secondary to comedication.[108] Other causes of CPSE include various acute diseases of the nervous system, including encephalitis and stroke.[62] A case of alcohol-induced CPSE has been reported.[35] Nonconvulsive SE has also been precipitated by intrathecal metrizamide during myelography and electroconvulsive therapy.[122,123] CPSE has been described in several reports of patients with presumed benign childhood rolandic epilepsy.[19,32,54] A type of autonomic status is characteristic of Panayiotopoulos syndrome,[59,66,81] and recurrent refractory CPSE is a component of the ring chromosome childhood epilepsy syndrome.[3] Over 30 reports relate tiagabine with the development of new CPSE.[58] CPSE has even been reported to occur after temporal lobectomy,[12] but this may have been in a patient with two separate types of epilepsy.

The causes of CPSE in patients with known focal seizures are the same as the causes of localization-related epilepsy. These include gliotic scars, tumors, vascular malformations, cerebrovascular disease, hamartomas, and congenital malformations. Precipitants include drug and alcohol withdrawal, physical and emotional stress, sleep deprivation, and metabolic disturbances. CPSE can produce transient abnormalities on neuroimaging studies that may or may not have etiologic and localizing significance.[5,61,96,109,113]

The anatomic site of seizure origin may be important in the development of SE. Until recently, CPSE was equated with temporal lobe SE.[30,37,74,98,102] In many cases, temporal lobe seizure origin was diagnosed on the basis of interictal scalp recording or simply implied because of clinical seizure characteristics. However, except for the four cases described by Wieser,[127,129] and several patients who have benefited from temporal lobectomy,[18,48] there have been very few well-documented examples of CPSE of temporal lobe origin (also see patients 1 and 3 in case descriptions). In one report, CPSE was recorded in eight of 87 patients with medically intractable localization-related epilepsy who were undergoing presurgical evaluations with intracranial electrodes.[133] Seizure origin was extratemporal in these eight patients, whereas CPSE developed in none of the 60 patients from this series with seizure origin in the medial temporal lobe. Extratemporal seizure origin and CPSE has been observed by others.[73,102] The association of frontal lobe epilepsy and convulsive SE has been the subject of several reports.[15,51,85] A similar association of nonconvulsive SE and frontal lobe seizure origin has also been reported.[7,10,13,41,114,115,130,134] In conclusion, CPSE is not analogous to temporal lobe SE, but is often related to extratemporal seizure origin, possibly with a frontal lobe preponderance.

Pathophysiology

Less is known about the pathophysiology of SE than of isolated seizures. Although the onset of isolated seizures and the initiation of an episode of SE are probably an expression of the same physiologic mechanisms, exactly how seizures start is not known. Even less is known about the mechanisms of seizure termination, but here is undoubtedly the key to understanding SE. It is known that the cessation of status per se is not due to energy failure, but presumably is related to the activation of those systems that stop single seizures.[33,34,86] The development of SE must represent failures of different systems, producing a cascade of neurophysiologic, neurochemical, and probably neuroanatomic changes that serve to perpetuate and prolong the epileptic process.[75,101] Self-sustaining feedback loops have been postulated in limbic status.[120,121] At the neurochemical level, depletion of γ-aminobutyric acid (GABA) during nonconvulsive status was reported,[126] but these results could not be duplicated in other studies.[105] Status-induced cell damage and the role of excitotoxins is discussed elsewhere in this volume, but the experimental evidence of CPSE-induced cell death must be described briefly because of its effects on long-term prognosis. In the kainic acid (KA) model of limbic SE, disseminated brain damage occurs, particularly in the hippocampus.[82] Pretreatment with diazepam abolishes this effect, thus demonstrating that cell damage is not due to the direct excitotoxic effect of KA.[6] Remote hippocampal damage occurs following prolonged perforant pathway stimulation.[104,106] Hippocampal cell damage does not occur following multiple (thousands of) single seizures.[8] How these observations relate to clinical CPSE is discussed in the sections on treatment and consequences.

Clinical Features

The initial descriptions of CPSE using EEG documentation defined two types: one with clinically apparent recurrent seizures, and another that exhibited a continuous seizure state.[30,39,69,74] Treiman and Delgado-Escueta,[117] after reviewing the literature and examining cases of their own, concluded that epileptic twilight states consisted of continuous and cyclic varieties of seizures, with CPSE being of the latter type—that is, all examples of CPSE consisted of recurrent complex partial seizures with incomplete clearing between episodes. The continuous type was thought to be ASE. This was in disagreement with previous reports (including one of their own), and is not supported by other studies. For example, Wieser[127] described a patient, studied using depth electrodes, who, during an episode of CPSE had continuous and discontinuous clinical and electrographic seizure activity. Subsequent reports of patients with CPSE, some studied using intracranial electrodes, confirmed the existence of both cyclic and continuous varieties, with some patients exhibiting both types of CPSE in single or different seizures.[14,92,114,115,129,133] Treiman,[116] in a recent communication, described CPSE presenting as a continuum between continuous altered conscious and recurrent discrete complex partial seizures, and he believed that CPSE originating in the medial temporal lobe structures was more likely to be of the cyclic variety, whereas frontal lobe CPSE was more likely to be continuous. However, this concept had been refuted by intracranial electrode studies.[129,133] Finally, variable or cyclic clinical patterns have been described in patients with ASE.[114,115] CPSE, therefore, does not always present with consistent or readily identifiable clinical characteristics, but rather is associated with a wide variety of clinical patterns, some of which may be indistinguishable from ASE. Others may mimic psychiatric disease.[53,91]

Recurrent focal EEG seizure activity was said to be typical and diagnostic of CPSE.[117] This pattern is said to exist at the onset of most, if not all, episodes of CPSE.[116] However, this has not been substantiated in patients who developed CPSE during intracranial electrode studies.[127,129,133] Cyclic and continuous ictal EEG activity can both occur in the same patient. Cyclic EEG activity has also been observed during intracranial recording without corresponding recurrent clinical activity.[133] Scalp EEG recording sometimes did not distinguish between cyclic and continuous seizure patterns in these same patients. When recurrent electrographic seizures occurred through episodes of CPSE, they tended to simplify with time, in terms of electrographic seizure discharge,[133] (see patient 2 in case descriptions). Finally, there are reports of patients with continuous diffuse spike-and-wave EEGs resembling ASE who have localization-related epilepsy.[7,40,44,114,115,116] Periodic lateralized epileptiform discharges (PLEDs) can be associated with prolonged but reversible alterations of neurologic function.[19,29,111] Some metabolic and single photon emission computed tomography (SPECT) studies indicate that PLEDs in some patients are a reflection of partial SE.[1,21,46] The EEG in patients who present with EEG patterns typical of ASE may have focal electrographic patterns only at the onset of the episode, thereby promoting diagnostic error[44,114,115] (also see patient 5 in case descriptions). Both scalp and intracranial EEG, analogous to the clinical seizure characteristics, can display a wide variety of different patterns during CPSE. The only diagnostic pattern would be clear, recurrent, localized electrographic seizures.

Given the many different clinical and EEG presentations, it is not surprising that clinical descriptions of CPSE cover a very broad range. By definition, impairment of consciousness must occur. This can vary from mild clouding of consciousness to unresponsive obtundation.[68,73,77,95,114,115] The accompanying behavior can range from bland confusion, either continuous or fluctuating, to agitated unresponsiveness with bizarre, almost psychotic activity.[37,79,91,133] Specific examples include prolonged reversible Wernicke aphasia,[60] recurrent unilateral atonic seizures in children with benign rolandic epilepsy,[54] and confusional states with PLEDs in the elderly.[46,111]

The concept of epileptic fugues lasting several days or longer has been disputed, with most such examples attributed to psychiatric disease.[76] Recent reports, however, describe well-documented examples of CPSE lasting months,[18,77,92,102] suggesting that prolonged fugues due to CPSE can occur. One of the earliest examples of prolonged nonconvulsive SE with EEG documentation is the frequently cited case of Henriksen.[48] A neurotic woman with well-established, discrete, complex partial seizures of presumed temporal lobe origin was described; she had a prolonged episode of recurrent auras of fear and a visceral sensation followed by acute anxiety with corresponding EEG changes. After 4 months, the episode was terminated with a left anterior temporal lobectomy. Because impairment of consciousness was not mentioned in the report, this would currently be classified as simple partial SE or aura continua.[97] Mikati et al.[77] describe a previously healthy 11-year-old boy who was first seen with several right focal motor and secondarily generalized convulsions; a protracted confusional state then developed, with EEG-documented recurrent localized seizures interspersed with acute psychotic behavior. While the recurrent electrographic seizures continued, he exhibited progressive obtundation that culminated in a catatonia-like state; eventually he required a gastrostomy feeding tube. AEDs were ineffective. After the third month of illness, he began to slowly improve. Nine months after illness onset, he was fully recovered and off all medications. An addendum to this report describes a similar case. Shorvon[102] mentions CPSE lasting 2 years in one of his patients, but does not provide further information. CPSE lasting 18 months is included in a report of recurrent CPSE.[18]

The following brief descriptions are selected from the author's series to illustrate some of the points made in this section:

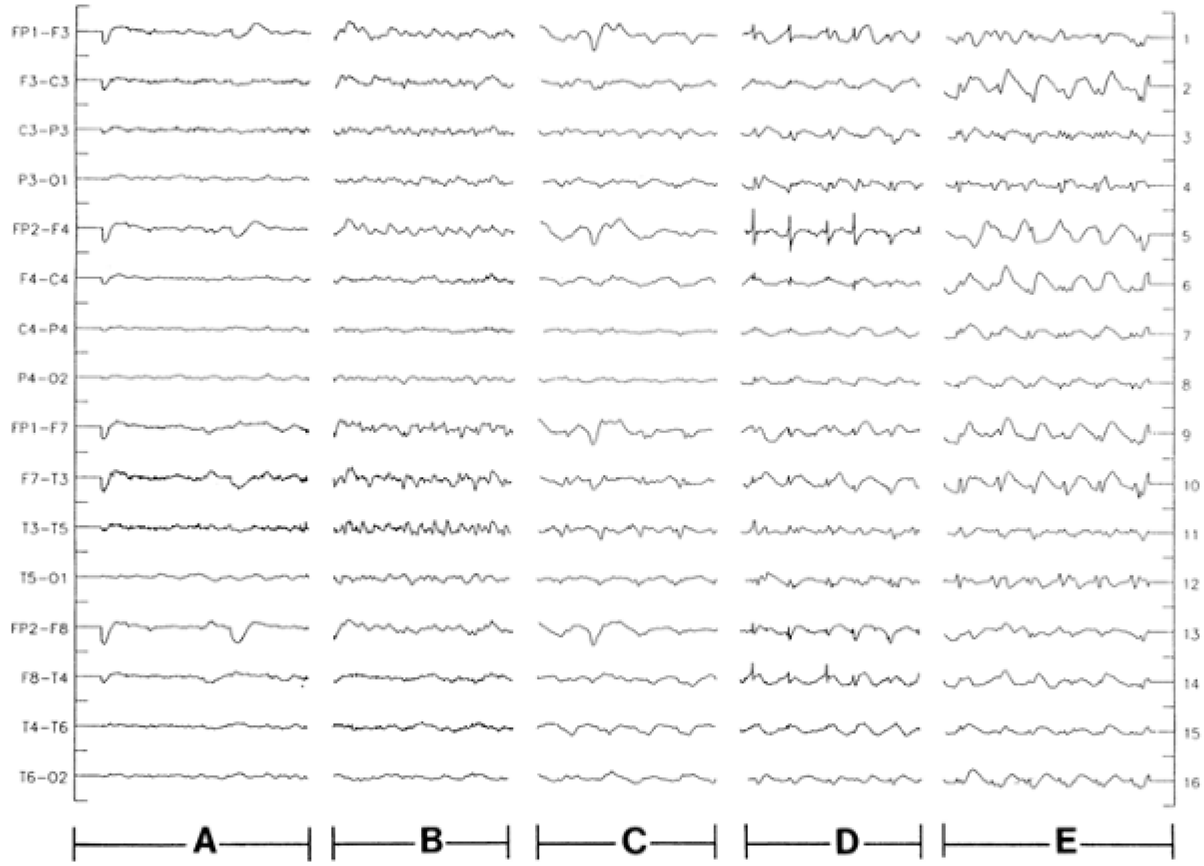

FIGURE 1. Patient No. 1. Segments of scalp EEG during prolonged, continuous seizure. **A:** Clinical seizure onset; no EEG changes. **B:** Rhythmic sharp wave buildup over left mid temporal region. **C,D:** Transition from localized to generalized seizure pattern, culminating in diffuse sharp-slow activity **(E)**.

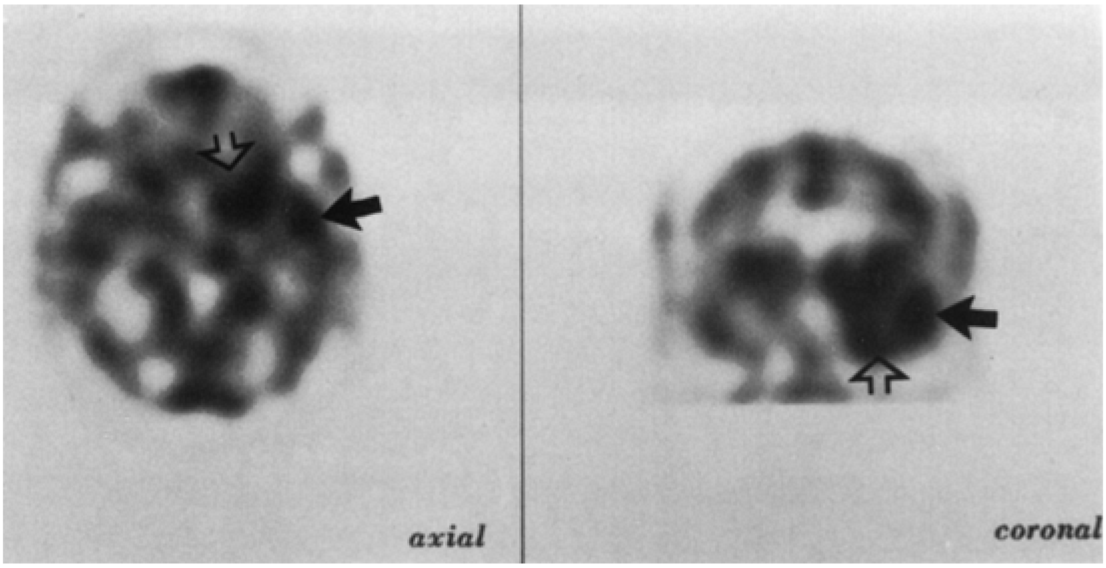

FIGURE 2. Patient No. 1. Ictal SPECT. Axial and coronal views showing increased activity in left medial (*open arrows*) and lateral (*closed arrows*) temporal lobe.

Case Study: Patient1

This 23-year-old man began having seizures at age 7. They consisted of several minutes of confusion and abnormal behavior. After 6 years of control, seizures became refractory to all antiepileptic medications, alone or in combination. Seizures occurred in a very cyclic fashion every 3 to 4 weeks. Typically, he would awaken in the morning, experience a salty taste in his mouth, and the smell of a sea breeze. He would utter "I am not going to make it! I am going to die!" and then lose contact and utter nonsense speech. He would continue in a variably confused state, fading in and out of contact throughout the rest of the day. He would then remain well for 3 to 4 weeks and have another day-long episode of recurrent seizures.

The patient was admitted for video and EEG monitoring. Medications were withheld to precipitate seizures. Interictal recording revealed left anterior temporal sharp-slow complexes and very infrequent left frontal sharp and slow complexes. He had recurrent seizures over a 74-minute period. The EEG progressed through a series of localized and generalized ictal patterns (Fig. 1). Approximately 30 minutes after onset, the entire process repeated itself, and was followed by a third similar cycle.

Clinically, during the first cycle, he initially appeared alert but was confused and unable to respond. He gradually became more responsive but did not return to baseline. His head and eyes then deviated to the extreme right, after which a tonic–clonic seizure ensued. The second cycle consisted primarily of unresponsiveness followed by brief, complete clearing, during

P.680

which the EEG transiently normalized. This was followed by repetition of the same clinical and EEG sequence seen in the first cycle.

Findings on magnetic resonance imaging (MRI) were normal, but ictal SPECT obtained during one of his habitual flurries demonstrated increased signal in the left anterior lateral and medial temporal lobe (Fig. 2).

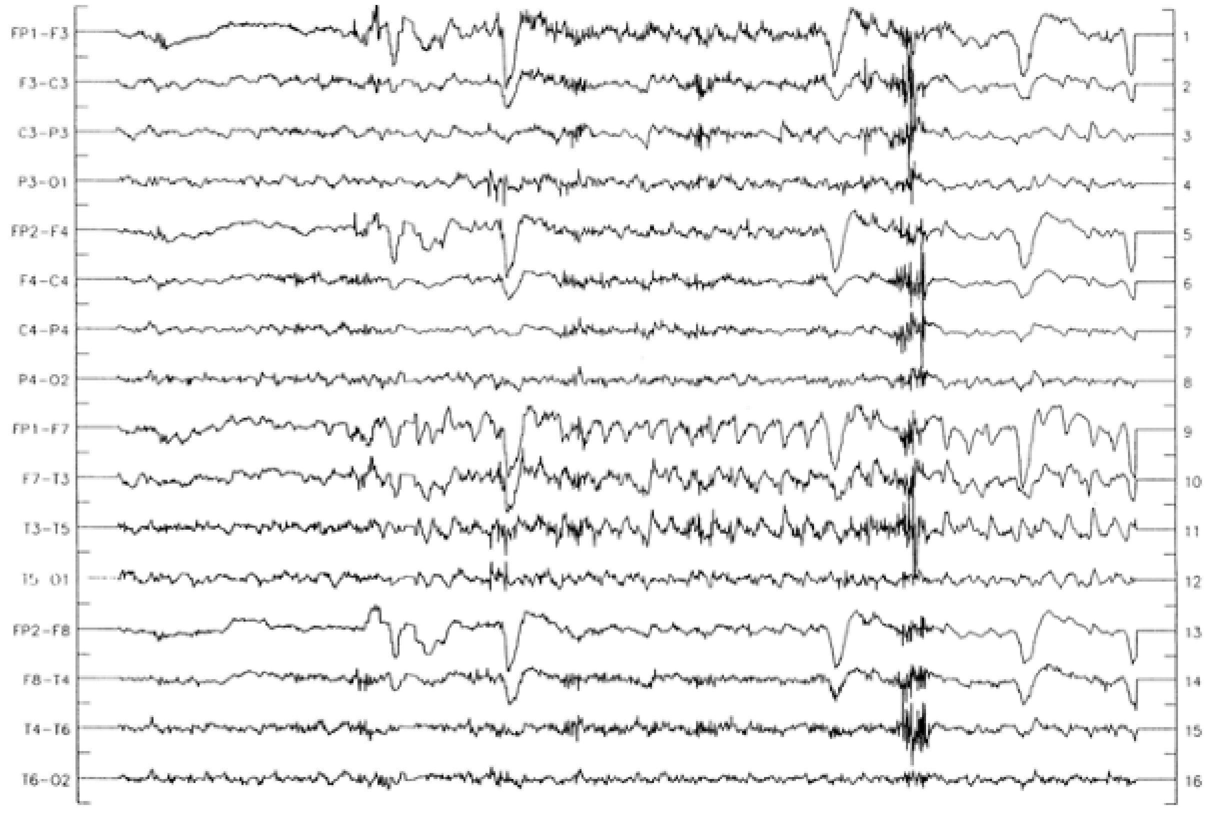

FIGURE 3. Patient No. 1. Scalp EEG during serial seizures showing rhythmic buildup over left midtemporal to anterior temporal region.

He was subsequently readmitted during one of his habitual seizure flurries, but this time while taking therapeutic doses of AEDs. Ten serial seizures were recorded. Clinically, they

P.681

were repeated episodes of receptive aphasia. The EEG demonstrated left midtemporal buildup of seizure activity during each episode (Fig. 3). Anticipating seizure origin in the lateral temporal neocortex, subdural electrode grids were placed over the left frontal convexity and left lateral temporal lobe. Additional subdural strip electrodes were placed subtemporally on the left and over the right lateral temporal and frontal lobes. Habitual seizures occurred with seizure build-up in the anterior portion of the left lateral temporal lobe followed by posterior spread, but without a clear localized onset. The first EEG changes were subtle rhythmic changes in the subtemporal strip electrode placed over the uncus. A multicontact depth electrode was then stereotactically placed to sample the length of the left hippocampus. Subsequent recorded seizures had a clear hippocampal onset that preceded EEG changes elsewhere by over 20 seconds (Fig. 4). He underwent a selective hippocampectomy. Pathologic examination revealed mesial temporal sclerosis. He remained completely seizure-free 12 months following surgery. Then he began to have very infrequent dysphasic seizures without loss of consciousness, usually related to noncompliance or sleep deprivation.

Comment

This is an example of both clinical and electrographic features suggesting ASE and CPSE in the same patient. During the first admission, the episodes, recorded after he had been taken off medications, had more generalized than partial features, whereas the reverse was true in the second monitoring admission during a habitual seizure flurry when he was on antiepileptic medication. It is also a demonstration of the potential utility of ictal SPECT during CPSE. Finally, what was thought to be an example of temporal neocortical seizure origin proved to be unexpected hippocampal seizure origin.

FIGURE 4. Patient No. 1. Segments of depth and subdural electrode recording of typical seizure showing onset and spread pattern. **A:** Ictal EEG onset in left hippocampus (depth electrode contacts *LTD 2 to 6*). **B:** Twenty-eight seconds later, ictal pattern continues in left hippocampus and rhythmic activity first occurs in subdural recording over left uncus (*LPS 2*). **C:** After another 20 seconds, seizure activity spreads to anterior left lateral temporal neocortex subdural contacts (*LTG 1 to 32*; lower numbers in each of four rows of eight contacts more anteriorly situated) and left subtemporal subdural contacts (*LAS 1 to 4* and *LPS 1 to 4*) but does not spread to frontal subdural contacts (*LFG 1 to 32*) or to right side (*RFS 1 to 8* and *RTS 1 to 8*).

Case Study: Patient 2

This 17-year-old man had several brief tonic–clonic febrile seizures beginning at 1 year of age. Afebrile seizures with tonic stiffening and falling backward began at 6 years of age. His parents thought his early seizures began with right arm stiffening and head deviation to the right, but they were not certain. After puberty, seizures increased in frequency, occurring weekly, with a nocturnal preponderance of up to ten seizures per night. He claimed to be fully awake during seizures, but was unable to speak or control his muscles. Seizures were preceded by a brief aura of a floating, “spacey” feeling.

Medications failed to control seizures, and he was evaluated for epilepsy surgery. MRI was normal. Interictal scalp EEG had rare right frontal spikes and bilateral frontal polar spike-and-wave activity. Ictal EEGs revealed some mild bifrontal slowing but were mostly obscured by muscle artifact. Clinical seizure characteristics consisted of shouted expletives and the sudden assumption of an extreme tonic posture with fists clenched, arms flexed, and legs extended. His head initially deviated to the right in several seizures, but most seizures were symmetrically tonic with some superimposed vibratory tremulousness. They lasted about 45 seconds, and stopped as suddenly as they started. He was mentally clear within several seconds. An ictal SPECT revealed increased activity on the left posterior high frontal convexity. Subdural grids were implanted

interhemispherically to cover both supplementary motor areas (SMAs). Additional subdural electrodes were placed to cover the frontal convexities and frontal polar regions.

He had a series of seizures spanning an 8-hour period. The first seizure was a typical habitual seizure. The next three seizures were typical seizures that secondarily generalized into tonic–clonic convulsions. They occurred 1 hour apart, with complete clearing in between. Similar seizures began to occur more frequently without clearing between episodes. They gradually became less symmetric, culminating in a CPSE consisting of first left and then bilateral supplementary motor area ictal EEG activity occurring repeatedly for over an hour (Fig. 5). During and between seizures, the patient was unresponsive. He would elevate his right arm with each brief electrographic seizure. Status was terminated with 400 mg of intravenous phenobarbital. Other isolated habitual seizures had bilateral SMA ictal EEG activity without consistent lateralization, but cumulative findings from the entire evaluation favored left SMA seizure origin. He underwent a selective left SMA resection. Pathologic examination of the resected cortex was unremarkable. During the first 3 months following surgery, he had several flurries of very brief tonic seizures, but then became and has remained seizure-free for 12 years.

Comment

This is an example of secondarily generalized convulsive seizures evolving first into convulsive SE and then CPSE. It is also an example of the progressive simplification of electrographic and clinical seizures in a patient having recurrent partial seizures.

Case Study: Patient 3

This 15-year-old girl had her first febrile seizures at 9 months of age. These consisted of three to four separate 15-minute episodes. Three similar febrile seizure clusters occurred during the next 6 months. Seizures without fevers began at age 2, and have persisted. Seizures consist of an aura of a “butterfly” feeling in her epigastrium and a tingling feeling in her scalp, followed by partial loss of contact and automatisms. She could remain confused for up to an hour. When seizures proved medically intractable, she was evaluated for surgery. Right hippocampal atrophy was revealed by MRI (Fig. 6).

Six typical seizures were recorded during video-EEG (V-EEG) monitoring. They all started with her aura; prominent lip-smacking was then followed by dystonic posturing of her left hand and arm. She remained partially responsive throughout this part of the seizure, which lasted approximately 1 minute. One typical seizure appeared to end clinically, but she remained only partially responsive for the next 15 minutes. During this time, repeated brief left head and eye deviation was noted. At the end of the seizure, left head and eye deviation progressed into a left-sided tonic–clonic seizure followed by a dense left Todd paresis. The EEG demonstrated no change during her aura, and then went through the progression of ictal changes illustrated in FIGURE 7. Another seizure was almost identical, but ended after 20 minutes without focal motor seizure activity. At the completion of the evaluation, right medial temporal seizure origin seemed established, and she underwent a right anterior temporal lobectomy and hippocampectomy. Pathologic examination showed mesial temporal sclerosis. During the first 2 postoperative weeks, she had several focal motor seizures, but then became and has remained seizure-free for 3 years before being lost to follow-up.

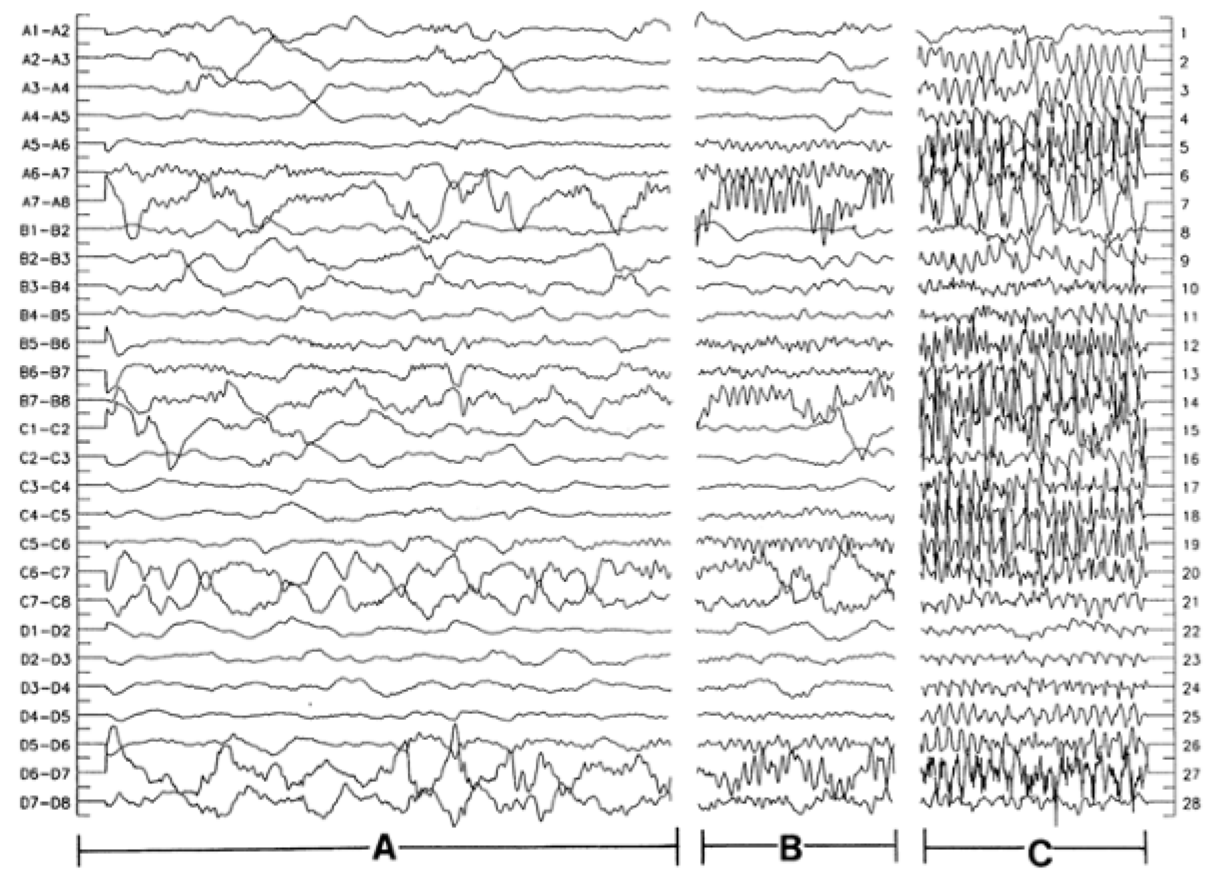

FIGURE 5. Patient No. 2. Segments of interhemispheric subdural recording of single event during CPSE.*A,B*: Contacts over left interhemispheric region. *C,D*: Contacts over right interhemispheric region.) **A:** Seizure begins with rhythmic activity in left SMA (*A7,B7*). **B:** Seizure spreads to right SMA (*C7,D7*). **C:** Seizure more extensively involves left and right interhemispheric regions. Left and right frontal convexity subdural contacts are not illustrated but were not involved in the seizure.

Comment

This is an example of what might have been considered prolonged postictal confusion following a typical right medial temporal lobe seizure. The EEG revealed continuous but variable ictal activity culminating in a lateralized spike-and-wave pattern. This case is an illustration of medial temporal lobe onset seizures leading to CPSE with continuous EEG ictal activity.

Case Study: Patient 4

This 39-year-old man with mild mental retardation has had seizures at least since age 2 years. Nothing is known about his birth and early development. He has lived in a sheltered and supervised environment all his life. Seizures occur on a daily basis and consist of loss of contact, with the sudden assumption of an asymmetrical tonic posture. This lasts for 30 to 40 seconds, after which he exhibits bimanual automatisms. The patient could have recurrent seizures of this type for hours.

He was evaluated for epilepsy surgery. Results of MRI revealed a large area of encephalomalacia in the left frontal lobe corresponding to the distribution of the anterior cerebral artery (Fig. 8). Neuropsychological testing documented IQ scores in the low 70s and diffuse moderate cognitive impairments. He had a very mild right hemiparesis.

During V-EEG monitoring, numerous seizures were recorded. There were isolated seizures and episodes of CPSE lasting up to 40 minutes. The CPSE consisted of asymmetrical tonic seizures followed by automatisms and confusion; these recurred repeatedly without clearing between episodes. Both the clinical and the electrographic seizures became progressively simpler and more subtle over time (Fig. 9). A subsequent study with subdural strip and grid electrodes over both frontal lobes failed to adequately lateralize frontal lobe seizure origin. An anterior two-thirds callosal section was done. Seizures recurred but were less frequent and less severe, but he remains disabled due to seizures.

Comment

This is an example of the relationship between frontal lobe epilepsy and CPSE. It also again demonstrates the simplification of electrographic and clinical seizures seen in some cyclic forms of CPSE. Anterior callosal section in patients with unlateralized frontal lobe seizures is an example of a not widely recognized indication for disconnection surgery.[88,131,132] Unfortunately, it did not prove very beneficial in this patient.

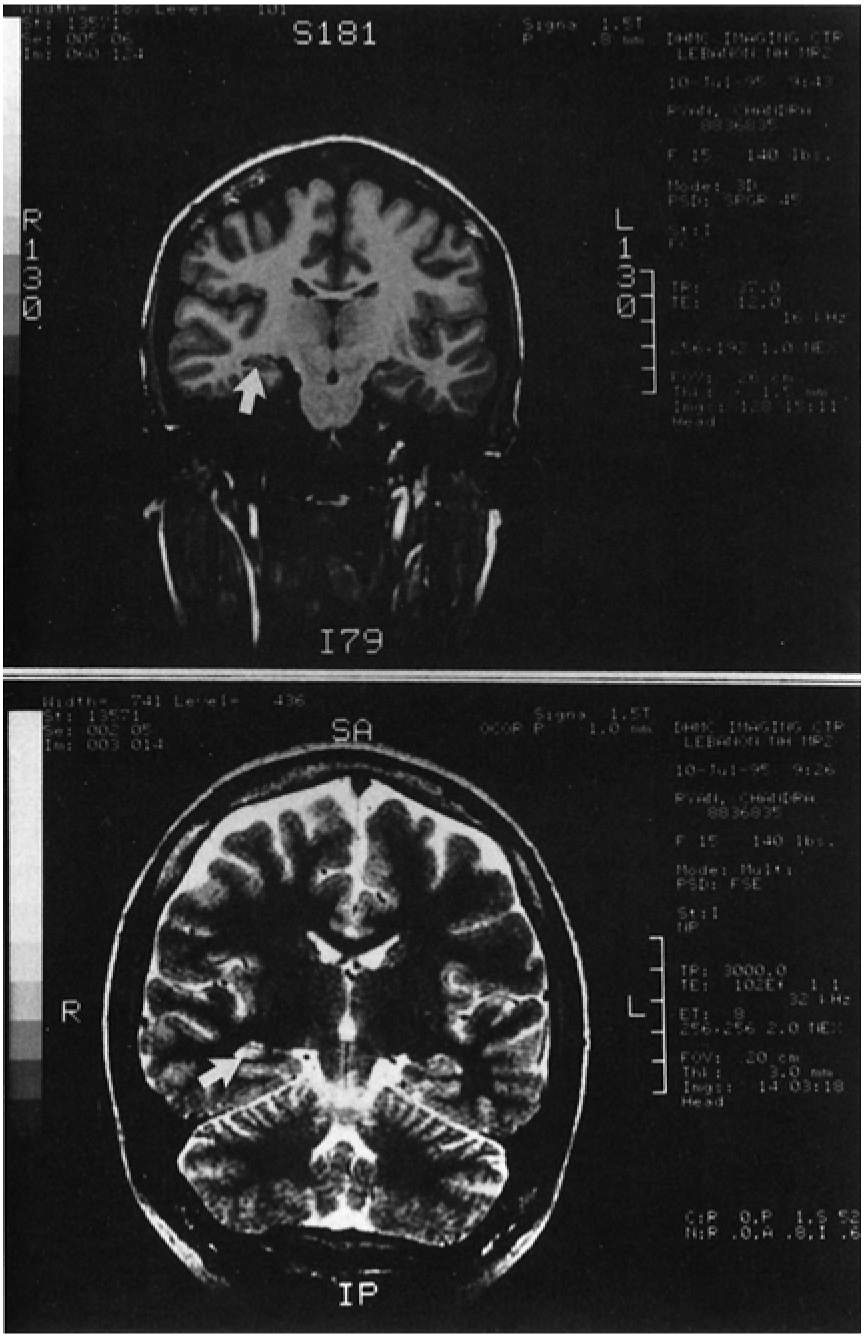

FIGURE 6. Patient No. 3. SPGR sequence (*top*) and T_2-weighted MRI (*bottom*) showing atrophy of right hippocampus and signal enhancement (*arrows*).

Case Study: Patient 5

This 41-year-old woman had epilepsy diagnosed when she was 33 years old. Prior to that time, she reported rare episodes of "blacking out" beginning at 8 years of age. Treatment with AEDs produced little benefit. She had "grand mal seizures" every 2 to 3 months, with as many as eight major motor seizures in 1 day. She also described episodes lasting several hours, during which she was observed behaving as if she were in a trance but responsive when questioned. She claimed total amnesia during these trance-like episodes. There were no risk factors for epilepsy. The results of neuroimaging studies and numerous EEGs were normal.

She was admitted for diagnostic monitoring with the impression she had psychogenic nonepileptic seizures. Medications were withdrawn to determine whether she had epilepsy. The results of the initial 24-hour EEG monitoring were normal. Subsequently, her EEG became progressively abnormal,

starting with rare right frontal spikes and culminating with a pattern suggesting spike-and-wave stupor (Fig. 10). Later episodes of nonconvulsive status later terminated with left adversion followed by convulsive seizures with increasing frequency, necessitating urgent medical treatment. Although she was not specifically examined when the EEG exhibited continuous spike-and-wave activity, she did respond appropriately on several occasions when the nurse questioned her. She later said she was totally amnestic during the 12-hour period when recurrent episodes of nonconvulsive status were occurring. Subsequent adjustment of medications resulted in complete seizure control.

Comment

This is an example of a patient in whom the diagnosis of epilepsy had been questioned; however, during the course of evaluation, she developed nonconvulsive SE. Unequivocal focal EEG features and adversive seizures established localized seizure origin. However, had she been evaluated with an EEG only during the portion of her nonconvulsive SE associated with generalized spike-and-wave discharges, a diagnosis of ASE would likely have been made.

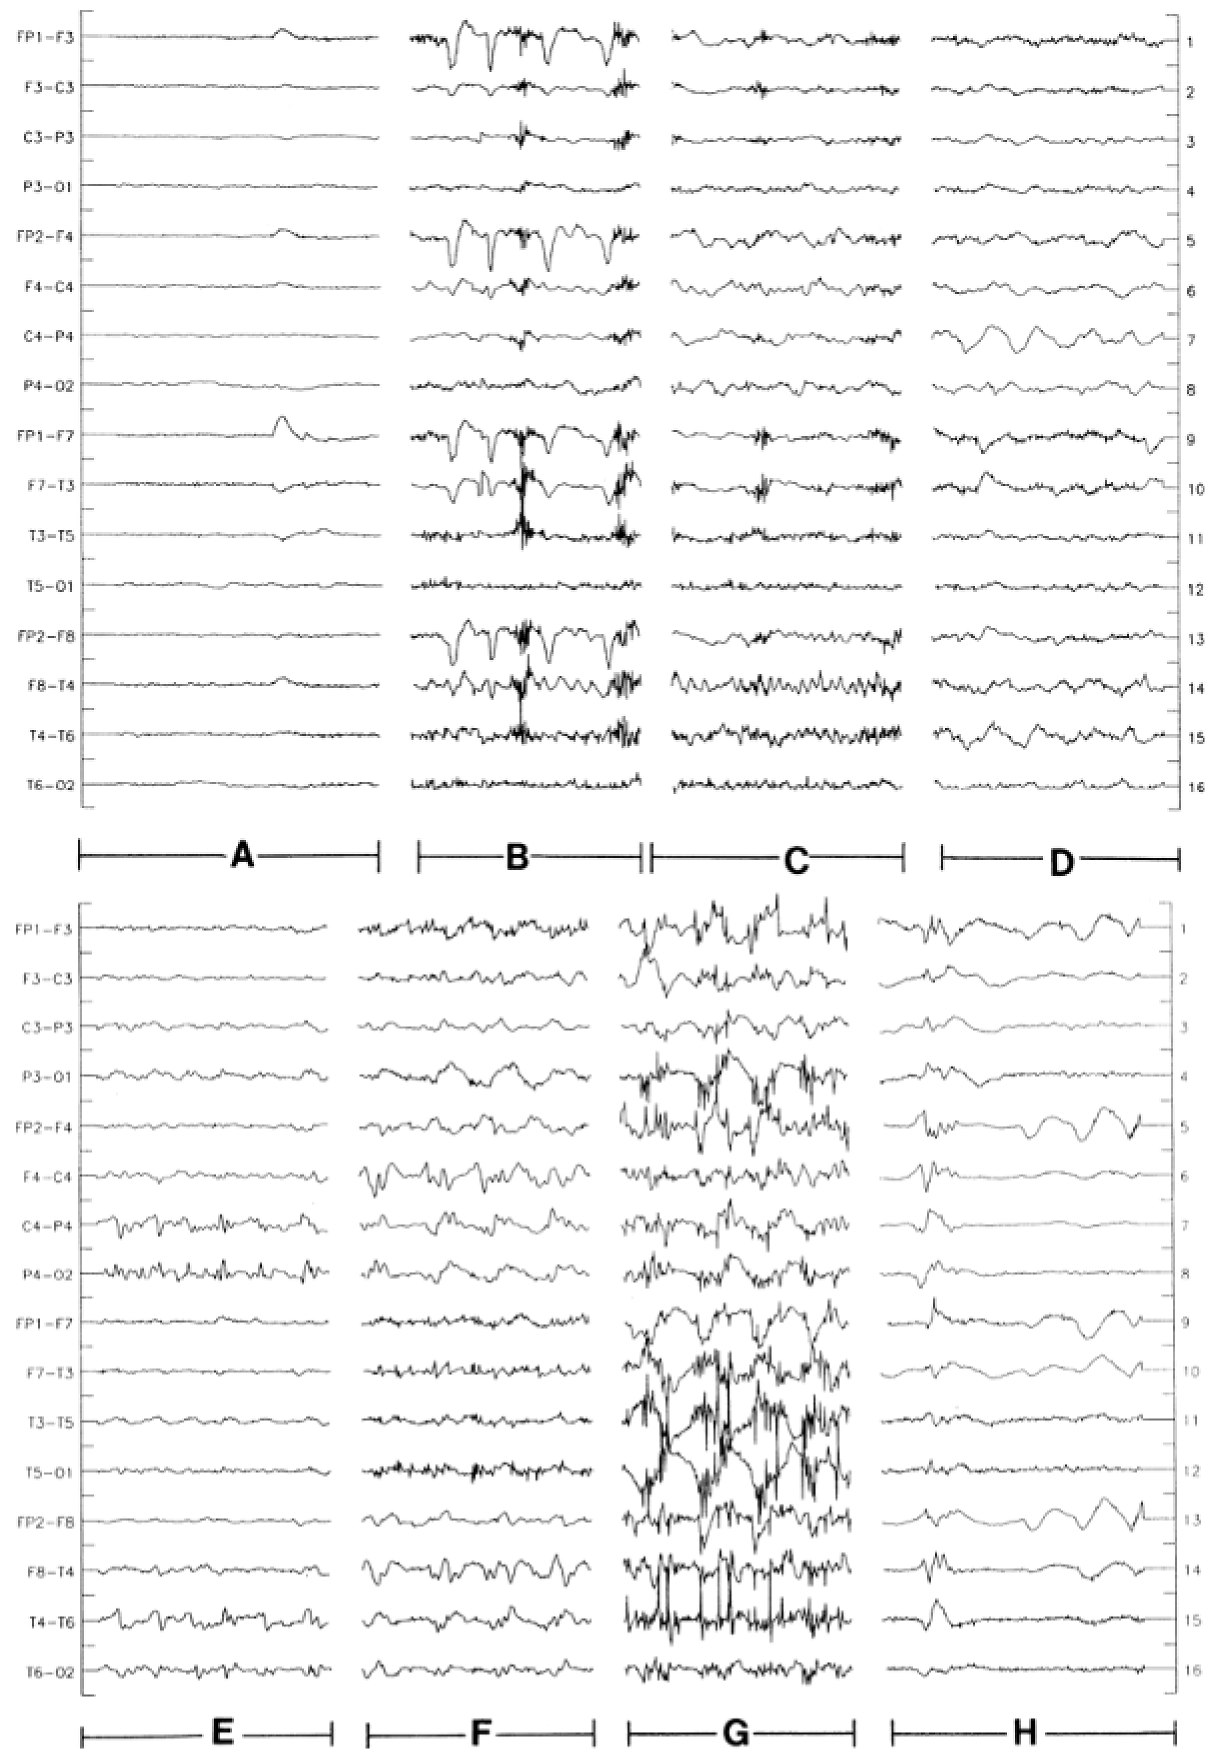

FIGURE 7. Patient No. 3. Segments of scalp recording during typical prolonged clinical seizure. **A:** Seizure onset with aura; no EEG changes. **B,C:** Starting at 20 seconds after clinical seizure onset, progressive buildup of right midtemporal to anterior temporal rhythmic activity. **D:** At end of typical temporal lobe seizure, there

is marked EEG slowing, most pronounced on right. At end of typical temporal lobe seizure, there is marked EEG slowing, most pronounced on right. This evolves into right posterior quadrant rhythmic sharp and polysharp activity. **(E,F). G:** At 18 minutes after seizure onset, right-sided activity becomes more diffuse and intense during tonic-clonic activity of left side of the body. **H:** At end of motor activity, diffuse right-sided rhythmic sharp activity develops on EEG before terminating 22 minutes after clinical seizure onset.

Diagnosis

Once the diagnosis of CPSE has been considered, an EEG should be obtained early in the course of the evaluation. Considering the rich variety of possible clinical presentations of CPSE, EEG confirmation and documentation is considered mandatory to make the diagnosis, except in the most obvious of cases.[14,30,114,115,117] Unexplained persistent alteration of mental status is one of the few relatively urgent indications for an EEG. The results usually have an immediate impact on further management. EEG findings are usually dramatic, varying from PLEDs to diffuse spike-and-wave patterns.[40,43,107,111] Only rarely will the EEG patterns in CPSE be subtle.[133] As discussed previously, however, the EEG findings in CPSE cover a wide range of abnormal patterns that, although indicative of an

P.686

epileptic basis for the problem, are not always able to differentiate between the two categories of nonconvulsive SE.[102,114,115]

After the diagnosis of nonconvulsive SE has been documented using EEG, further evaluation will depend on what is already known about the patient. If the patient has a previous diagnosis of epilepsy with partial seizures and a known lesion in one frontal lobe, it is entirely reasonable to assume that the diagnosis is CPSE, regardless of what particular pattern the EEG shows. Similarly, if an otherwise healthy young adult with known idiopathic generalized epilepsy exhibits confusion and a diffuse spike-and-wave pattern on EEG, the diagnosis is ASE. Between these two extremes are many diagnostic possibilities, a complete discussion of which is beyond the scope of this chapter. Suffice it to say that when information about a patient with possible CPSE is limited, diagnostic considerations include infections, metabolic disorders, toxic exposures, withdrawal conditions, and structural brain lesions, acute and chronic. Further diagnosis and management will depend on results of initial evaluations.

If a patient with clinical localization-related epilepsy presents with CPSE, and no acute, potentially hazardous, coexisting problems exist, a window of opportunity exists. This is particularly pertinent in the absence of known structural lesions. MRI or computed tomography (CT) during or shortly after CPSE can reveal transient signal abnormalities that might have diagnostic and localizing implications.[5,61,67,95,109,113,137] Ictal SPECT, a logistically difficult test to perform with isolated seizures, but with potentially localizing information not otherwise obtainable, can be done with relative ease during CPSE.[47,62,63,72,78,79,94] Because CPSE can masquerade as ASE, ictal SPECT could provide crucial diagnostic information in atypical cases.[34] CPSE also offers a unique opportunity to obtain an ictal positron emission tomography (PET) scan, which could provide localizing information in addition to research data.[28,46]

If the initial assessment suggests a deteriorating or urgent situation, such as a transition from nonconvulsive status to convulsive SE, treatment with intravenous AEDs should be initiated without delay. Because (with some exceptions, as discussed later) CPSE alone is usually not associated with enduring neurologic sequelae, treatment can usually be safely delayed to obtain important diagnostic tests.[18,57,62,77,82,109,133] Treatment itself can be diagnostic. Intravenous diazepam is said to control ASE rapidly in most cases, whereas CPSE responds more gradually.[102] Furthermore, intravenous diazepam may unmask focal EEG features in some patients with generalized ictal discharges.[44] One report also describes a diagnostic intracarotid sodium Amytal test in a patient with CPSE.[11]

Differential Diagnosis

CPSE is included in the differential diagnosis of the unresponsive or confused patient.[68,102] A critical step in the diagnosis of CPSE is to consider it in the appropriate clinical setting. Although this statement might seem self evident, doubtless CPSE is often not considered, and the diagnosis is therefore missed.[18,115,133] Unexplained obtundation during an acute

illness could be unrecognized CPSE.[107] Psychiatric disorders sometimes are erroneously diagnosed in patients with CPSE.[60,91,102,133] CPSE with very subtle alterations in consciousness and behavior can easily be missed.[73] Although CPSE is more common in the adult population between 20 and 40 years of age,[18,102,115] it can occur in the elderly or very young. ASE in the elderly has been associated with focal frontal onset, justifying the diagnosis of CPSE in some patients.[112] A diagnosis of CPSE should therefore be considered whenever there occurs the acute or subacute onset of persistent unexplained alteration of consciousness and behavior, regardless of the patient's age or whether a history of epilepsy is present.[91,124]

CPSE must be differentiated from true absence status because of different treatment strategies. When nonconvulsive status occurs in a patient with known idiopathic generalized epilepsy, the correct diagnosis is obvious. Clinically, however, the two types of status can be indistinguishable.[112,133] Even the EEG findings will not always separate the two. Therefore, in certain situations, additional clinical information will be needed to make the correct diagnosis.

Treatment and Outcome

How aggressive the management of CPSE should be is a controversial issue. During the past 20 years, most well-documented reports of CPSE describe favorable neurologic outcomes despite whether medical treatment is successful.[18,77,102,114,133] This appears to be true in extreme, very prolonged, medically refractory examples of CPSE lasting months.[18,77,92] Severe focal neurologic deficits and localized cerebral edema can occur after CPSE and may be long lasting, but completely reversible.[96] During an ictal PET study, a patient with CPSE had hypermetabolism in the occipital region and hypometabolism in the same region when seizures stopped.[28] After CPSE, a new homonymous hemianopsia was detected that gradually cleared over 15 months. Partial resolution of the hypometabolism corresponded with the neurologic improvement. Two often-cited earlier reports describe enduring neurologic deficits following CPSE.[20,96] These two studies report three patients with memory impairment after CPSE, but one patient also had convulsive status during the episode and another had a short follow-up. A study[49] of CPSE-related complications is flawed, because seven of the ten patients reported had acute systemic or neurologic disorders that could account for the morbidity and mortality. Three patients, however, with previously diagnosed epilepsy did develop mild-to-moderate cognitive impairments following CPSE. Another report describes a permanent hemiparesis following CPSE in a patient with frontal lobe epilepsy.[7] There have been several recent studies of nonconvulsive status in the critical care setting.[17,62,135] Reports of morbidity and mortality from acutely ill patients, not surprisingly, are associated with a poor prognosis. This can be misleading, because all such reports find that the poor prognosis is related to the underlying etiology of the serious medical condition present in the majority of patients. Only exceptionally was a poor outcome due to

epilepsy per se and, in at least some of these patients, it was due to complications of aggressive treatment.[56,101] In summary, CPSE is not associated with increased neurologic deficits in most patients.[55]

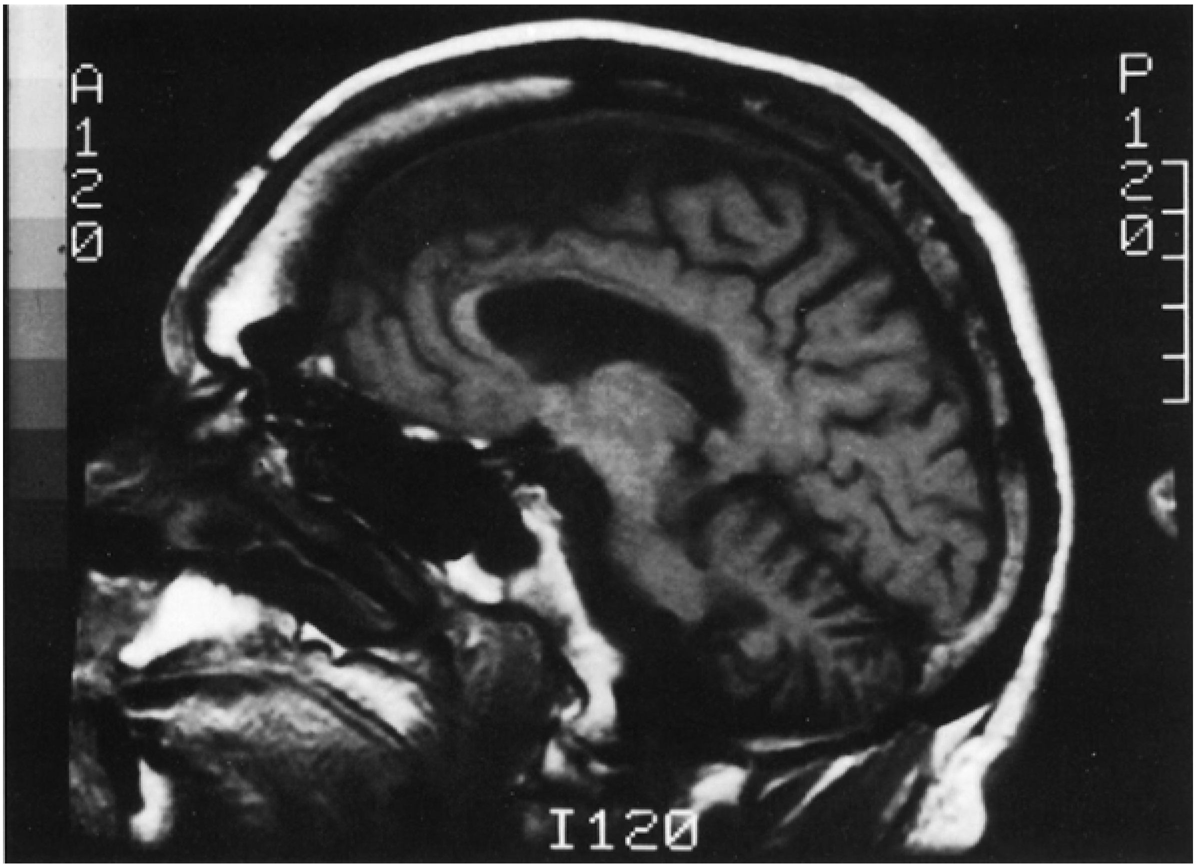

FIGURE 8. Patient No. 4. Midline sagittal MRI showing encephalomalacia in the left medial frontal region.

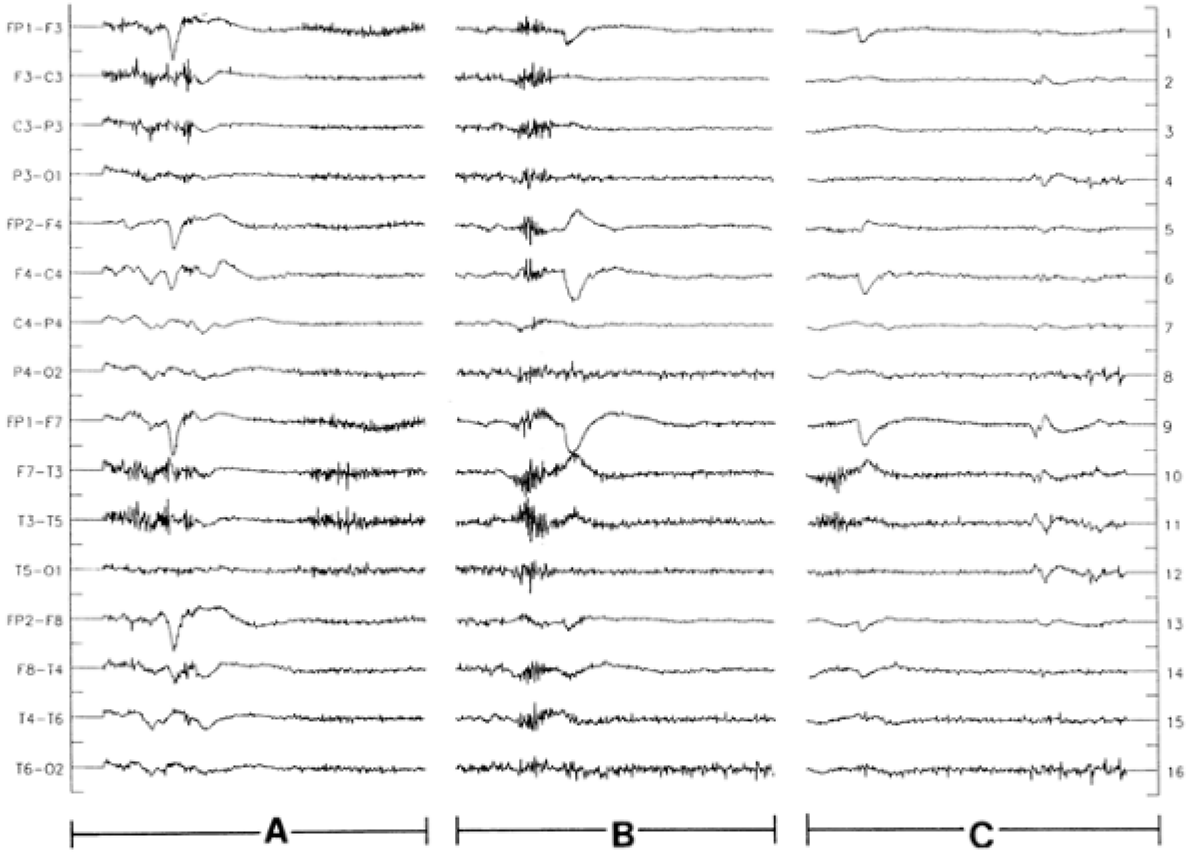

FIGURE 9. Patient No. 4. Scalp EEG of three separate asymmetric tonic seizures during an episode of CPSE. **A,B:** Onset only with voltage suppression of two seizures at beginning of CPSE. These seizures lasted 15 to 20 seconds. **C:** Entire seizure lasting under 3 seconds towards end of CPSE.

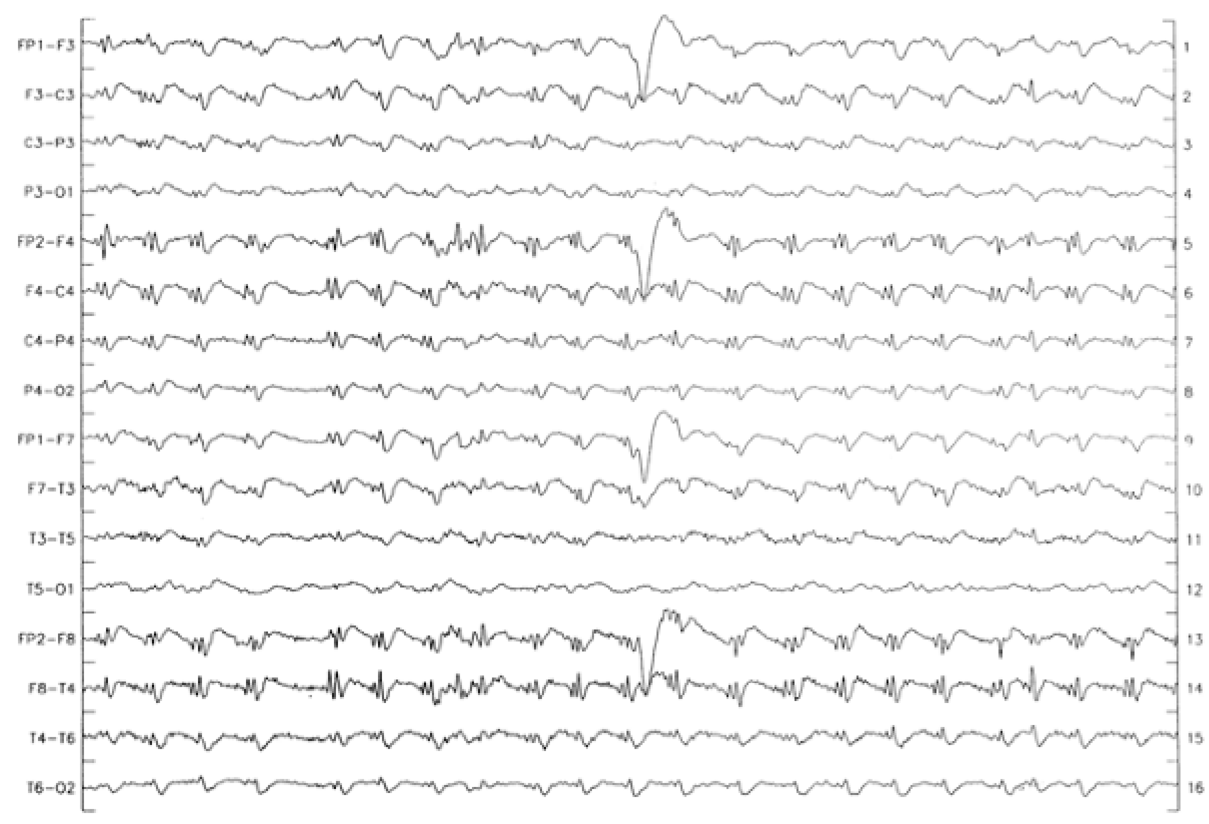

FIGURE 10. Patient No. 5. Scalp EEG during prolonged episode of diffuse sharp-slow activity.

This is in contrast to studies of partial SE in laboratory animals where, as discussed in the pathophysiology section and elsewhere in this volume, permanent brain damage is frequently observed. At present, no identified features predict an unfavorable neurologic outcome following CPSE except when it occurs during comorbid medical conditions.

CPSE is a disabling condition and, as such, it should be treated. The treatment of CPSE is no different than that for other varieties of SE. Drugs to treat CPSE should be given intravenously. Benzodiazepines, such as diazepam, lorazepam, or midazolam, are often first-line choices, followed by a longer-acting medication, such as phenytoin.[23] An alternative method is to use intravenous phenobarbital as the sole drug for treating CPSE. The only study comparing the efficacy of phenobarbital with diazepam/phenytoin for treating SE found phenobarbital superior.[99] Although the methodology used in this study was criticized,[84] the authors' reply satisfactorily addressed the criticisms.[100] Either treatment will be effective in most cases of CPSE, but the occasional patient with CPSE will be resistant to conventional therapy.[18,77,92] As discussed previously, the issue of aggressive medical therapy in CPSE is controversial. Although pentobarbital coma has been recommended for refractory cases of SE,[119] this can be associated with serious complications.[83,90,138] The same is true of intravenous anesthesia using propofol.[52,56,80] As suggested earlier, an alternative method for treating refractory CPSE is to initiate therapy with intravenous phenobarbital and continue with this drug. This approach has scientific rationale. In tests of antiepileptic efficacy, phenobarbital is many times more potent than pentobarbital.[2,70,89] Very high doses of phenobarbital, with serum levels exceeding 300 ng/mL, have been used to successfully treat refractory status in children.[20] The concerns related to profound sedation, respiratory depression, and hypotension are largely unfounded. If hypotension does occur, it can be treated with low doses of pressor drugs without major reductions in the dose or level of phenobarbital. A recent report emphasizes the efficacy and safety of phenobarbital in general.[65]

Most patients with CPSE have a prior history of epilepsy. Many will have medically intractable, localization-related epilepsy. These patients should be considered for surgical intervention, because it can be very beneficial.[18,27,42,48,128,133,134] A current review of the use of phenobarbital in SE provides favorable data in support of its use.[31]

Long-Term Prognosis

The long-term prognosis of CPSE is, to some extent, related to the cause. In many acute situations, such as intoxication and adverse drug reactions (e.g., to metrizamide, tiagabine),[58,87,123] the process is self-limited. In patients who develop CPSE in association with systemic disorders, the outcome is often determined by the course of the systemic disease and not the CPSE.[62] As noted previously, there are a few isolated reports of long-lasting neurologic deficits following CPSE,[10,26,30,62] but most patients suffer no ill effects; when neurologic deficits do occur, they are usually completely reversible.[18,56,95,96] Whether repeated episodes of CPSE can take a neurologic toll over time is not known, but it is probably unlikely. There are reports of full recovery following recurrent, prolonged, and incapacitating episodes of CPSE.[18,77] Patients, however, who present with unprovoked CPSE or have CPSE as part of their chronic epilepsy are very likely to have recurrence of CPSE.[18,92,102,115] Finally, as

P.690

noted previously, in patients with medically intractable partial epilepsy who have CPSE, successful surgical intervention can eliminate both.

Summary and Conclusions

Previous descriptions and definitions of CPSE have proven to be too restrictive. Broadening the definition of CPSE to include all cases of localization-related epilepsy with episodes of prolonged, continuous, or repetitive seizures during which consciousness is impaired will increase the numbers of patients in whom CPSE is diagnosed. By doing this, many patients with clinical and electrographic features of ASE will receive the correct diagnosis and treatment for CPSE. As a result of these concepts, coupled with vastly improved diagnostic capabilities, CPSE will become recognized as one of the more common types of SE.

The issue of enduring neurologic deficit following CPSE has not been resolved. The fact that most patients with CPSE, even when subject to prolonged CPSE, recover completely does not negate the occasional observations of permanent neurologic deficit following CPSE. Do these few examples of CPSE-induced deficit dictate aggressive, potentially hazardous management of those cases of CPSE who do not respond readily to standard medical management? Probably not, but there will be exceptions. Criteria defining these exceptions have yet to be identified. Fortunately, most cases of CPSE will respond to the intravenous administration of standard AEDs, without resorting to drug-induced coma.

Chapter 60

Absence Status Epilepticus

Pierre Thomas

O. Carter Snead III

Introduction

Status epilepticus (SE) may be classified for practical purposes into convulsive SE, which must be rapidly stopped to prevent death or neurologic sequelae, and nonconvulsive SE (NCSE) in which the diagnosis is not obvious and must be confirmed by urgent EEG recording. NCSE may be further classified into nonconfusional and confusional forms.[85] Nonconfusional NCSE is characterized by various somatosensory, visual, auditory, psychic, or vegetative symptoms that occur, by definition, with no impairment of consciousness. This is in contrast to confusional NCSE, which is characterized by some degree of clouding of consciousness. NCSE is also classically divided on the basis of the ictal EEG into absence SE (ASE) and complex partial SE (CPSE). CPSE is discussed in Chapter 59.

ASE, a diagnostic challenge, is a heterogeneous clinical and EEG condition that associates impaired consciousness and predominantly symmetrical bilaterally synchronous ictal discharges. On a historical perspective, Charcot, in one of his Tuesday lectures of January 1888, described a healthy 37-year-old delivery man with episodes of prolonged automatisms during which he walked from place to place throughout Paris. Charcot believed that this prolonged ambulatory fugue state was related to an epileptic breakdown of consciousness[28] and later proposed a trial of potassium bromide, an early antiepileptic drug (AED).

Concept of Absence Status, Definitions, and Classification

In 1938, W.G. Lennox recorded periods of continuous spike-and-wave discharges (SWDs) and altered level of consciousness after insulin-induced hypoglycemia in one of his cousins, a child with absence epilepsy. Lennox believed that this represented very brief absences in rapid succession without a return to the usual level of consciousness and, in 1945, suggested the term *petit mal status* to describe this condition.[99] This term implied a clinical picture limited to prolonged or serial typical absence attacks that were sufficiently close together to give rise to a prolonged disturbance of consciousness and an EEG pattern limited to the classic ictal 3-Hz spike-and-wave pattern on a syndromic absence-epilepsy background. However, it soon became clear that these forms of SE could occur in patients whose epilepsy was manifested by seizures other than absences and who had no history of idiopathic generalized epilepsy (IGE).

In the mid-1960s, Niedermeyer and Khalifeh,[116] then Lob[104] reported that, during ASE, the alteration of consciousness seemed to be less profound than that observed during typical absence attacks. Similarly, the EEG expression of ASE also was atypical, consisting of SWDs that were neither as regular nor as continuous as those of absence seizures. Also, these epileptic confusional states could appear in patients with severe epilepsy associated with mental retardation. These authors preferred the less specific and more descriptive term *spike-wave stupor* rather than petit mal status. The problems arising from the use of this latter term may explain the extraordinary development of new eponyms, described by Shorvon[144] as a "nosographic labyrinth" for what were very similar clinical entities (Table 1).

Typical and Absence Status Epilepticus

In 1970, in an attempt to unify the concept, the Classification and Terminology Commission of the International League Against Epilepsy retained the term *absence status,* which Gastaut had proposed in October 1962 during the tenth Marseilles Colloquium[60,61]: "a prolonged or repeated absence seizure, thus representing SE. Clinically, ASE is essentially or exclusively characterized by impairment of consciousness of varying intensity, persisting hours to days, occasionally leading to an epileptic fugue. The EEG findings exceptionally consist of continuous or discontinuous rhythmic 3-Hz SW discharges similar to those encountered in typical absence seizures; more often one finds more or less rhythmic SW or polyspike-wave (PSW) discharges sometimes interrupted by slow background activity".

In a further attempt at clarification, Gastaut suggested at the 1983 Santa Monica Colloquium a new classification of ASE,[62] distinguishing "typical" ASE as having an excellent prognosis, occurring in patients with IGE, and characterized by a simple confusional state with rhythmic 3-Hz SWDs; "atypical" ASE is characterized as occurring mainly in patients with symptomatic and/or cryptogenic generalized epilepsy. This atypical variety could be conceptualized as a transient exacerbation of the epileptic symptomatology superimposed on a chronic epileptogenic encephalopathy, such as the Lennox-Gastaut syndrome.[13] Episodes of atypical ASE were characterized by periods of confusion accompanied by more marked tonic or myoclonic manifestations, and associated with SWDs or PSW discharges slower than 3 Hz, with a variable rhythmicity and regularity.[62] Moreover, these atypical ASEs were clearly distinguishable from "typical" ASE by their associated clinical features, including pseudoataxia and/or pseudodementia, their prolonged duration (several days or several weeks), their tendency to recur, and their pronounced resistance to treatment—benzodiazepines (BZ) being usually ineffective.[25,40,57,122]

New Cases of Uncertain Classification

During the 1970s, newly reported cases that could not be correctly classified added yet further difficulties. These events were occasionally encountered in patients with localization-related epilepsy[123] and were characterized by electroencephalographic (EEG) patterns with focal features that were considered too

P.694

significant to justify their classification within the group of generalized epilepsies.[59,75,115] This "imperfectly generalized" ictal pattern was compared to the focal ictal discharges of CPSE and contributed to blur the margins between the two entities. New pathophysiologic mechanisms were discussed, mainly based on the works of Tükel and Jasper in Montreal, and on depth electrode studies by Bancaud and Talairach in Paris, who demonstrated that a single epileptic focus could give rise to secondary bilaterally synchronous discharges.[9,175]

Several authors had indeed emphasized the similarities between these ASE forms and CPSE of temporal or, especially, frontal origin.[3,59,137,168,171] These similarities are probably not fortuitous: Several reports show the transformation from CPSE with fronto-polar focal ictal discharges into an ASE with a perfectly bilateral and symmetric EEG pattern.[2,97,115,139,164,168] These occasional but well-documented reports may explain the development of ASE with "generalized" discharges during the course of an extratemporal localization-related epilepsy, particularly of frontal lobe origin.[97]

Table 1 Absence Status Epilepticus: Some Published Synonyms

Petit mal status[99]
Prolonged epileptic twilight state with almost continuous wave-spikes[192]
Prolonged alterations in behavior associated with a continuous EEG spike-and-dome abnormality[21]
Epilepsia minoris continua[56]
Simple epileptic confusional state[63]
Prolonged behavioral disturbance as ictal phenomena[67]
Spike-wave stupor[116]
Minor SE[23]
Centrencephalic condition of prolonged disturbance of consciousness[73]
Isolated petit mal status presenting de novo in middle age[141]

Borderline petit mal status[75]
Ictal psychosis[186]
Absence status with focal characteristics[115]
Prolonged confusion as an ictal state[48]
Senile petit mal epilepsy[119]
Acute prolonged ictal confusion[179]
De novo minor SE of late onset[11]
Toxic ictal confusion in middle age[177]
Generalized nonconvulsive SE[71]
De novo absence status of late onset[167]

De Novo Absence Status Epilepticus of Late Onset

A further group of patients was described in which ASE first occurred in elderly subjects with no previous history of seizures. In 1971, Schwartz and Scott[141] published reports on four patients with ASE appearing "de novo" in middle-aged or elderly adults. They suggested that these cases could represent the "the extreme end of a continuum of Petit Mal epilepsy extending from childhood to middle age."[141] However, later observations show that this is not usually so. Since 1971, about 100 such patients have been described in the literature; a review is available.[165] The average age of the patients is in the sixth decade, and there is a preponderance of women. Many of the subjects have preexisting psychiatric symptoms. In two thirds of the cases, the ASE occurs with a toxic or metabolic systemic disorder.[166,178] Among triggering factors, psychotropic drugs appear to be prominent and were present in a series of 79 such patients.[164] The ASE may occur with high doses of psychotropic drugs or with a sudden withdrawal of the medication: Several reports have emphasized the role of BZ withdrawal.[45,52,83,167] A combination of factors, such as a simultaneous toxic and metabolic encephalopathy, is characteristic. These data indicate that "de novo" ASE is more often an acute symptomatic epileptic event rather than the late resurgence of a childhood absence epilepsy, and is probably best designated as "situation-related SE."[31,177]

Electrographic Status Epilepticus in Coma

In recent years, several intensive care unit series tend to lump together "subtle" SE, ASE, CPSE, and EEG patterns suggestive of NCSE in comatose patients.[82,96,101,138] For example, Mayer et al. included seven patients with "nonconvulsive SE" in "comatose or obtunded patients"[111] and among the comatose patients studied by Towne et al.[172] 8% had "an EEG pattern suggestive of SE," a pattern whose validity has been challenged by Benbadis et al.[15] This conceptual extension appears to have been caused by some degree of misinterpretation in EEG findings. Prominent generalized paroxysmal activity in comatose patients is usually the expression of a severe encephalopathy of the hypoxic/anoxic type, rather than of NCSE.[117] As proposed by Kaplan,[87,88,89,90] the term *electrographic SE in coma* seems more appropriate, in its neutrality, to characterize generalized seizure activity in deeply obtunded patients with severe brain injury. Similarly, "subtle" SE,[173] the extreme end of an insufficiently treated generalized tonic–clonic SE must not be confused with ASE because context of occurrence, clinical features, prognosis, and treatment are dramatically different. Severe mental confusion in ASE may express itself as catatonia,[100,107] but this presentation is radically different from a comatose state.

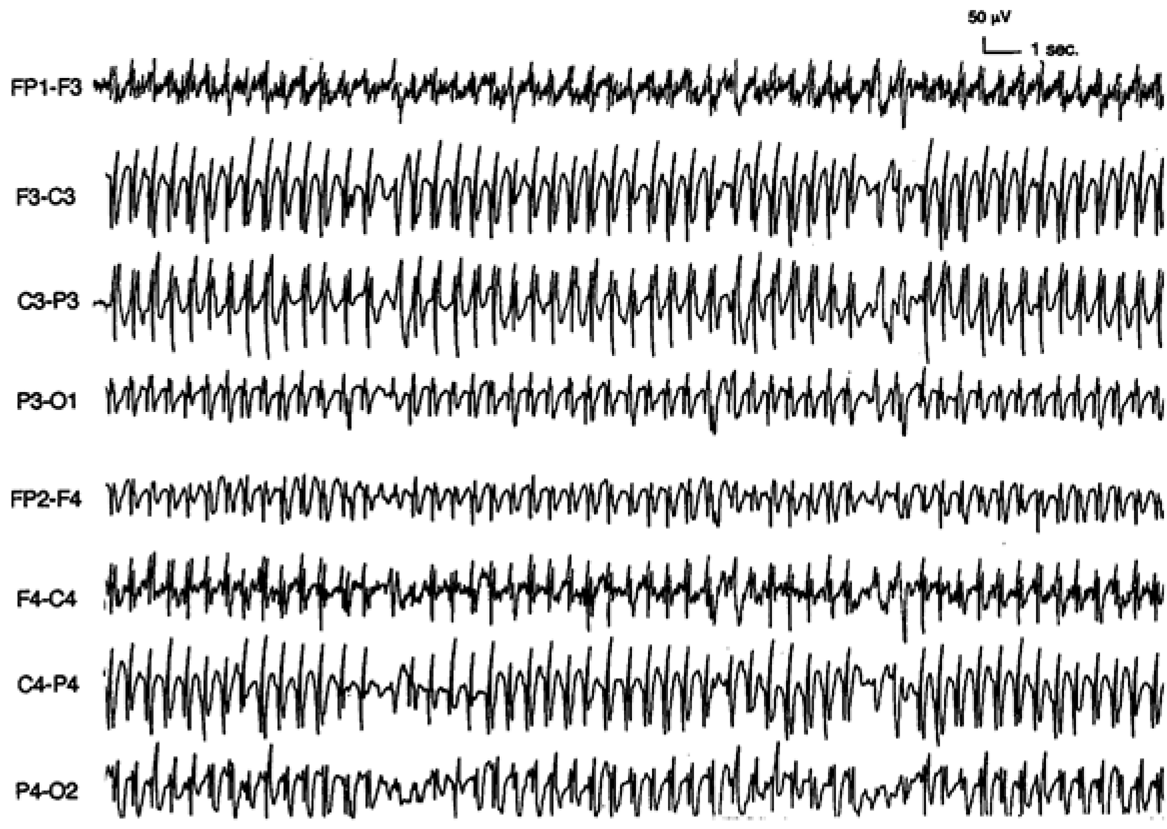

FIGURE 1. Typical absence status in a 13-year-old girl with juvenile absence epilepsy. ASE followed withdrawal of valproate and administration of carbamazepine. Patient had an isolated, permanent, mild-to-moderate confusional state. The EEG shows continuous, generalized 3-Hz spike-and-wave activity with little variation in amplitude and frequency.

Clinical Classification of Absence Status Epilepticus

We believe that four types of ASE may be recognized: typical ASE, atypical ASE, ASE with focal features, and "de novo" ASE of late onset. A number of cases appear to be transitional forms between these better defined clinical entities.

Typical ASE (Fig. 1) occurs as part of an IGE most often characterized by absences. Isolated impairment of consciousness, at times with subtle jerks of the eyelids, is the essential symptom. The EEG correlates with repetitive absence seizures and shows symmetric and bilaterally synchronous spike-and-wave or PSW complexes faster than 2.5 Hz, but this pattern is often not strictly maintained as the event continues. The immediate prognosis is excellent: An intravenous BZ injection stops the ASE.

Atypical ASE (Fig. 2) occurs in patients with symptomatic or cryptogenic generalized epilepsies and is characterized by a fluctuating confusional state with more prominent tonic, atonic, myoclonic, and/or lateralized ictal manifestations than occur in typical ASE. There is often no clear-cut onset and offset of the ictus. The EEG shows continuous or intermittent diffuse irregular slow spike-and-wave or PSW complexes. The immediate prognosis is guarded, as these episodes tend to recur and to be resistant to medication.

ASE with focal features (Fig. 3) occurs in subjects with a preexisting or newly developing localization-related epilepsy, most often of extratemporal origin. The EEG shows bilateral, but often asymmetric ictal discharges. Many of these cases may represent the natural evolution of CPSE of frontal lobe origin,

P.695

and the EEG may not conclusively distinguish these from ASE, especially late in the episode. The immediate prognosis is variable.

In middle-aged or elderly subjects with no previous history of attacks, “de novo” ASE of late onset (Fig. 4) is characterized by toxic or metabolic precipitating factors leading to seizures. Patients often have a history of psychiatric illness, with multiple psychotropic drug intake. The electroclinical characteristics and the immediate prognosis are variable. These episodes of ASE generally represent acute symptomatic seizures and may not recur if the triggering factors can be controlled or corrected. Long-term AEDs thus may not be needed.

Epidemiology

Lob et al.[104] found that of 148 patients with ASE collected by 1962, 93% had preexisting epilepsy, and 92% of these patients had a form of IGE. Nevertheless, 16% of these patients had only absence seizures, and 11 patients had no history of epilepsy. Porter and Penry[130] found that 85% of patients with ASE had preexisting epilepsy. Of the patients discussed by Rohr-Le Floch et al.[137] 78% had preexisting epilepsy, and all of these had IGE. Dalby[35] found that 6.2% of patients with IGE had had episodes of ASE. Patients with absences more often had ASE (9.3%), than those who did not (3.4%). In patients with childhood- and adolescence-onset absence epilepsy, the incidence of ASE has varied: 3% of patients according to Cascino and Hauser,[27,74] 5.8% for Loiseau and Cohadon,[105] 9.9% for Livingston and Brown,[103] 28.3% for Lorentz de Haas and Magnus,[106] and 37.7% for Oller-Daurella.[124] A reasonable estimation is to consider that almost 10% of adults who continue to have absence seizures that began in childhood will have an episode of ASE, and that its incidence appears to increase with the frequency of absence attacks. However, with a 100 per million prevalence of absence epilepsy and a 1% occurrence of ASE in these patients, Shorvon estimated the annual incidence of typical ASE to be very low, occurring in about 1 per million persons in the general population.[144]

ASE has been reported in epileptic encephalopathies, such as the Lennox-Gastaut syndrome, in 15% to 40% of patients.[41] Other studies[13,42] show that almost all these patients have periods of epileptic confusional states at one time or another. In a mentally handicapped population, the annual incidence of ASE can be estimated to be 100 to 200 cases per million.[144]

No reliable data are available to estimate the occurrence of “de novo” ASE of late onset. Studies from emergency wards of general hospitals in which immediate EEG is available, generally in cities of one million or more, describe two to five new cases per year.[137,140,170]

Clinical Features

The cardinal clinical sign of ASE is variable clouding of consciousness, ranging from subtle subjective impairment of thought processes to severe stupor with incontinence. Subtle motor signs are seen in half the patients. In 90% of cases, the confusional symptoms fluctuate. This is an important clue in favor of the ictal nature of the confusional state, this fluctuation being most marked when the level of consciousness is well preserved. However, impairment of consciousness in ASE

P.696

P.697

is never clearly organized in a cyclic and a discontinuous way, as may be observed in some patients with CPSE of presumed amygdalo-hippocampal origin.[173]

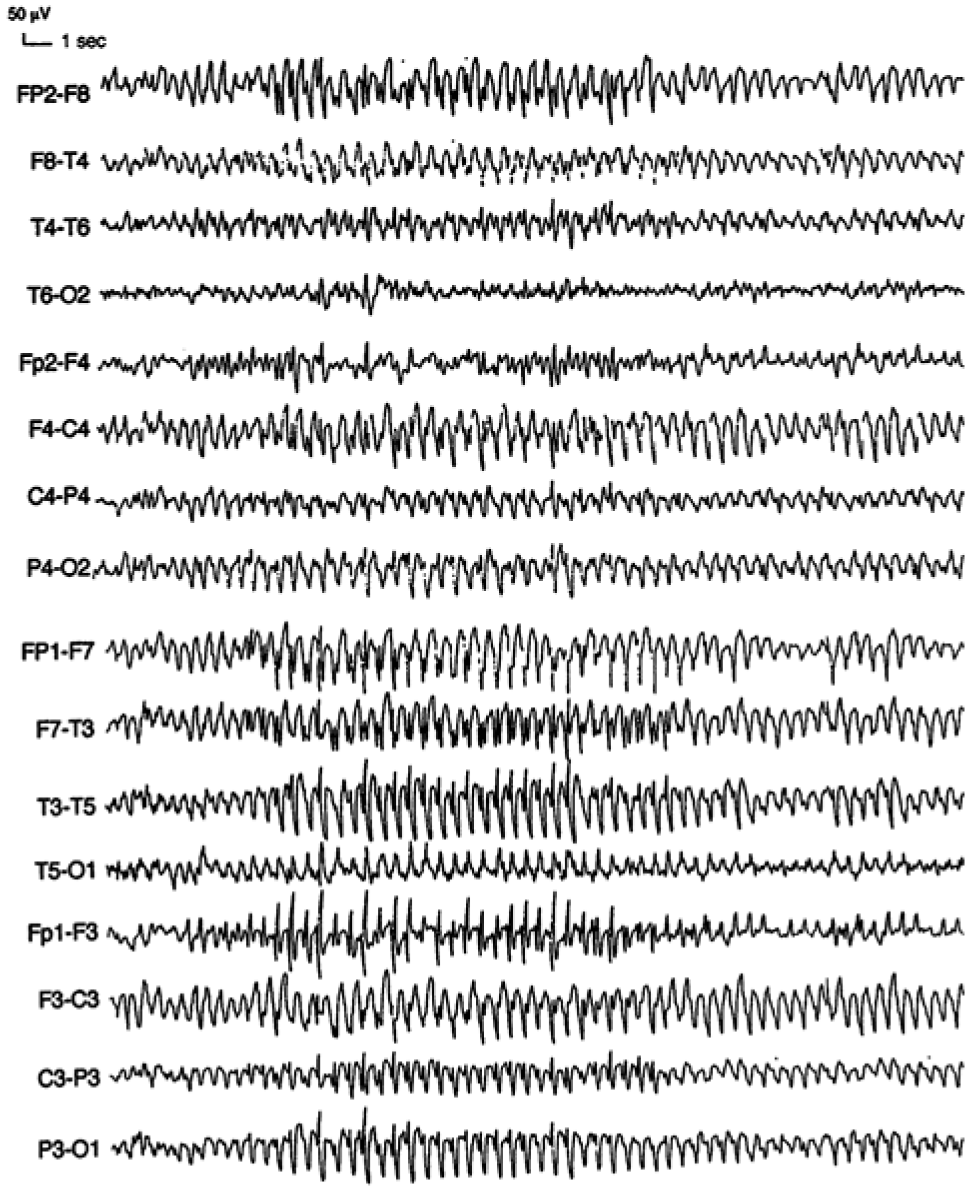

FIGURE 2. Atypical absence status in a 15-year-old boy with Lennox-Gastaut syndrome. His head and eyes were slightly turned to the right, and he was moderately confused, with periocular myoclonia and hypersalivation. The EEG shows almost continuous irregular bilateral 2-Hz spike-and-wave complexes with left centrotemporal predominance. Intravenous benzodiazepines were ineffective.

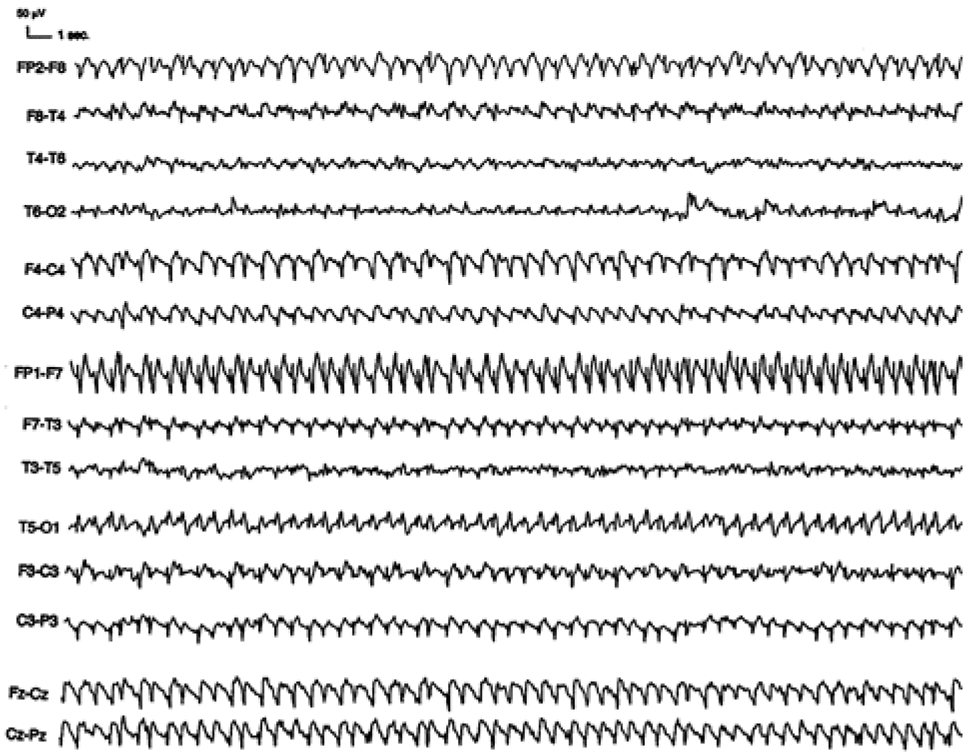

FIGURE 3. Absence status with focal characteristics in a 55-year-old woman with cryptogenic left frontocentral epilepsy. Patient was moderately confused, with some disinhibition, echolalia, and palilalia. The EEG shows bilateral 1.5-Hz slow spike-and-wave complexes with a clear left frontotemporal predominance.

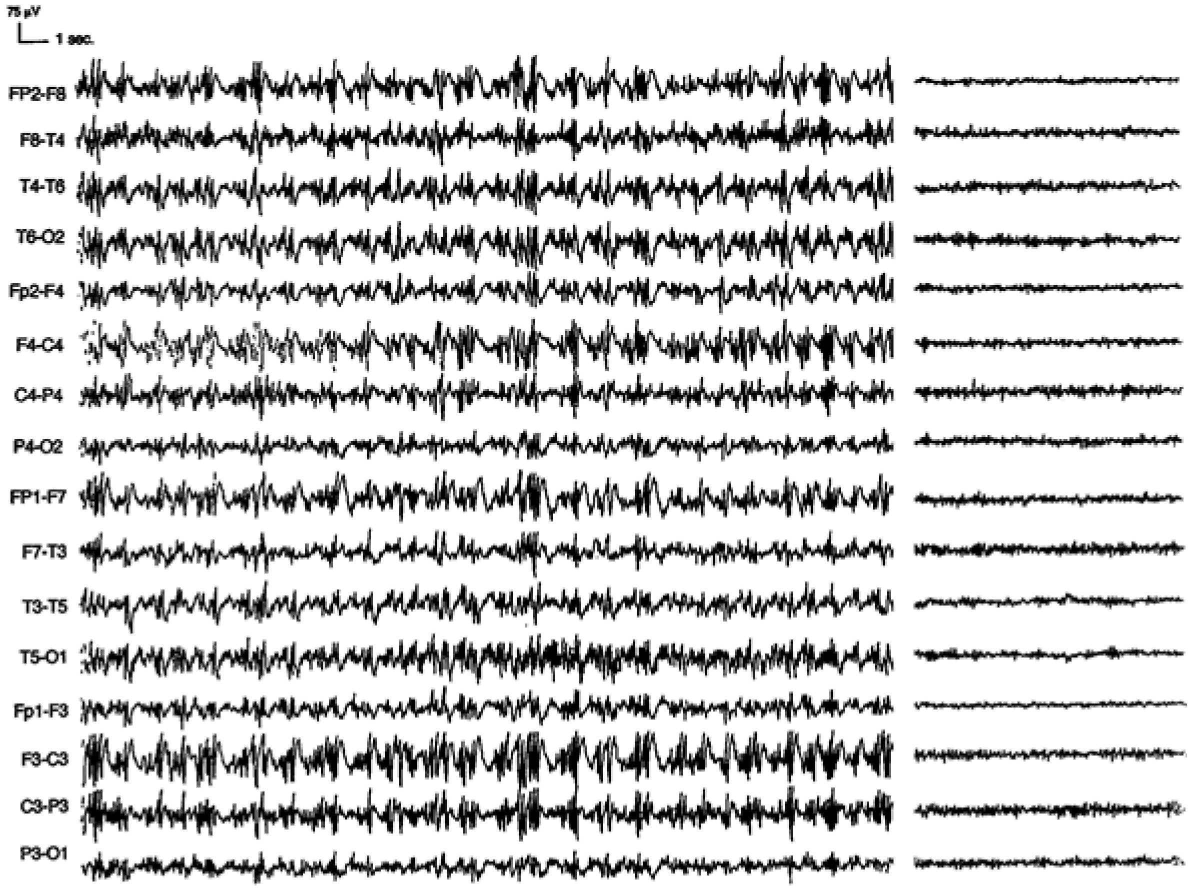

FIGURE 4. A positive diagnostic and therapeutic trial of intravenous benzodiazepines in an 82-year-old woman with "de novo" absence status of late onset, related to multiple psychotropic drugs intake and withdrawal. The EEG shows continuous irregular polyspike and slow wave activity, which stops 140 seconds after injection of 1 mg of clonazepam. Her level of consciousness returns to normal.

Clouding of Consciousness

Although the alteration of consciousness in ASE is best represented by a continuum,[6] recognition of four grades of severity in disturbance of consciousness[104,136] may be useful in clinical practice. This classification was based on the largest series of ASE, the 148 cases collected at the time of the 1962 Marseilles Colloquium.[60]

Slight clouding of consciousness is present in 19% of cases. This consists of simple slowing of thought processes and expression, often so subtle that only the patient himself can recognize it. There is often no true mental confusion.[7,129] Patients with recurrent ASE may learn to recognize these periods, which may be defined as "bad days" often described to "a lack of efficiency" or "the inability to perform at a normal level."[6] Patients with the mildest degree of disturbance have no apparent psychological disturbance and may be able to speak fluently. Although these patients are able to carry on with typical activities of daily living, they are unable to normally perform complex intellectual tasks involving choices, strategy, planning, or initiative. Formal neuropsychological testing, in one report including dichotic listening,[55] may be necessary to document mild degrees of altered consciousness in ASE.[118,184] Neuropsychological deficits may also suggest a more localized disturbance,[65] typically with sparing of language, unlike some cases of CPSE. Shorvon[144] noted the frequent and striking dissociation between these mild clinical manifestations and the impressive ictal EEG abnormalities.

Marked clouding of consciousness is most typical and is reported in 64% of cases. A frank confusional state occurs with disturbance of alertness, attention, memory, judgement, language, and with some agnosia and apraxia. The patients are severely disoriented. They are usually calm, immobile, indifferent, with little or no spontaneous language or motor activity. Simple commands are only obeyed after repeated requests, often correctly, but very slowly and after some delay. Patients usually are unable to follow more complex commands. Language is reduced to fragmented, hesitant, and at times irrelevant responses interrupted by long pauses. Echolalia and palilalia may be present. Motor tasks are performed clumsily and slowly, and sequential tasks are usually interrupted more because of attention difficulties than because of a true apraxia. Many have spontaneous or environmentally induced automatisms of variable complexity. Simple gestural automatisms are frequent. More elaborate motor patterns, which appear to represent a combination of complex automatisms and the behavioral disturbance caused by the clouding of consciousness, are associated with perseverative and compulsive features, a highly suggestive feature of ASE.

Profound clouding of consciousness is reported in 7% of cases. Even with vigorous stimulation, only very brief and limited motor or verbal responses can be elicited. The patients remain motionless, cannot move without help, and are unable to feed themselves.

Lethargic stupor is reported in 8% of cases. This resembles catatonic stupor, with apparent suspension of all psychic activity.[100] Patients are motionless, with eyes turned upwards,

and incontinent of urine and stool. They are completely dependent and react only to strong painful stimulation.

Associated Signs

Myoclonus is the most frequent and most suggestive associated sign, occurring in about half the cases.[137] It is an important diagnostic clue, because as it does not occur in CPSE.[137] ASE with myoclonic components could be associated with less impairment of consciousness.[57] It is characterized by bilateral jerks of the eyelids or face, most often subtle and intermittent, and more easily diagnosed with the patient's eyes closed.[109] Myoclonic jerks occasionally may involve the arms and hands. These may be asymmetric, falsely suggesting a localization-related SE.[136] Rarely, they may be so marked as to dominate the presentation, overlapping clinically with myoclonic SE.[163,176] A history of myoclonic episodes associated with confusion can suggest a retrospective diagnosis of ASE especially in patients with preexisting IGE.[78,92] Epileptic negative myoclonus may also be intermingled with the positive myoclonic jerks (Thomas, unpublished personal observation).

Complex automatisms occasionally may be responsible for prolonged fugue states, or *poriomania*. At times, some of these behaviors can cause legal problems (e.g., in the case of compulsive masturbation[81] or destructive behavior[6]). Psychiatric manifestations have been reported in atypical ASE. These include hallucinations, illusions, experiential phenomena, psychotic depression,[6,54,68] and acute pathologic neurologic laughter.[22] These symptoms are very unusual and, if present, never as marked as those which occur in CPSE.[137]

Natural History of Absence Status Epilepticus Episodes

The spontaneous duration of each episode of ASE is variable and ranges from about half an hour to several weeks.[63,84] Most episodes last from 6 to 72 hours, only exceptionally exceeding 1 week.[34] In most typical cases, spontaneous cessation of the ASE is sudden, with a striking clinical improvement. Some patients fall asleep and awaken normal. Typically, the episode most often ends in a tonic–clonic convulsion.

Electroencephalographic Findings

Emergency EEG with a therapeutic trial of BZs is the key to confirming the diagnosis of ASE.[91]

Electroencephalographic Characteristics of Absence Status Epilepticus

The essential EEG feature of ASE is a bilateral, synchronous, and symmetric epileptiform activity that is unreactive to sensory stimulation. The most characteristic tracings show continuous trains or frequently repeated bursts of polyspike and slow-wave complexes or slow spike-and-wave complexes that are diffuse, rhythmic, and nonreactive.[171] Nevertheless, the EEG manifestations may be so variable that Porter and Penry[130] noted that “virtually any generalized continuous or nearly continuous abnormality could be a substrate for this syndrome.” Roger et al.[136] found that half of cases of ASE in patients with IGE had continuous, usually rhythmic, bilaterally synchronous and symmetric SWDs or PSW discharges with a bifrontal predominance and a frequency between 1.5 and 3 Hz. Less commonly, the discharges were discontinuous and broken up into bursts separated by more or less normal background rhythms. Continuous spike-and-wave activity could also become discontinuous during the same EEG recording.

Only rarely does the spike-and-wave activity occur at precisely 3 Hz. In 80% of cases, it ranges from 1 to 2.5 Hz. Granner and Lee[69] reported 59 patients with ASE whose paroxysmal activity ranged in frequency from 1.0 to 3.5 Hz, with a mean of 2.2 ± 0.6 Hz. Only 7% had an ictal EEG pattern of typical absence. One quarter of the patients showed some focal predominance of their paroxysmal activity.

Occasionally, the spike-and-wave activity may be unusually rapid, from 4 to 6 Hz,[59] or unusually slow, slower than 1 Hz.[75] Other variants of the ictal epileptiform activity include irregular slow spike-and-wave activity,[16] slow waves with sporadic spike-and-wave complexes,[169] and rhythmic triphasic slow waves.[187] In these unusual EEG presentations, correct identification of ASE is a challenging problem, given the fact that "any rhythmic EEG rhythmic activity recorded during a confusional state does not inevitably correspond to ASE."[15]

No clear correlation exists between the degree of altered consciousness and the EEG. Stupor may however be more frequently associated with the pattern of continuous, rhythmic, 3-Hz spike-and-wave activity.[144]

Therapeutic Trial of Benzodiazepines

The intravenous injection of a BZ during the EEG recording is mandatory to confirm the ictal nature of the episode. Difficulties may indeed arise in distinguishing true ictal epileptiform EEG patterns from interictal or nonictal EEG discharges,[90] such as, for example, runs of triphasic sharp waves in hepatic encephalopathy. The injection must be given slowly, in successive boluses over 30 to 60 seconds each, and must produce rapidly progressive disappearance of the paroxysmal activity, leading to normalization of the EEG; SWDs or PSW discharges are typically replaced by low-amplitude diffuse β activity (see Fig. 4). The effective doses are usually relatively low, and typical ASE responds to diazepam 0.2 to 0.3 mg/kg, clonazepam 1 to 2 mg (0.5 mg in children), or lorazepam 0.07 mg/kg (0.1 mg/kg in children). An average of 3.8 mg of diazepam has been reported effective in adults.[69] Normalization of the EEG must also be associated with disappearance of the confusion, which may be dramatic when immediate or may take minutes or even hours in elderly patients. For a therapeutic trial to be considered successful, both EEG and clinical normalization must occur.[53] Recording must be continued for at least 60 minutes after EEG normalization to detect any early recurrence of ASE, and follow-up recording is needed if any later alteration of consciousness occurs, to diagnose any possible recurrence of ASE.

If intravenous access is not available, or if there is a high risk of respiratory depression in a disabled patient, a single oral dose of 1 mg/kg of clobazam, a rapidly absorbed BZ, has been proposed as an alternative.[64] With this regimen, clinical and EEG improvement is often noticeable after approximately 10 minutes, and complete cessation of the ASE usually occurs within 15 to 30 minutes. There are usually no noticeable effects on vigilance, and respiratory depression does not occur. Other AEDs may be used with similar results, including intravenous lorazepam,[84] parenteral valproate,[29,66,79,86] and, in ASE associated with the Lennox-Gastaut syndrome, propofol.[32] Intravenous valproate may avoid some of the morbidity of repeated doses of BZ or prolonged infusions of propofol: for children in ASE, a loading dose of 20 mg/kg has been suggested followed by maintenance infusion of 1 mg/kg/h in noninduced patients and 2 mg/kg/h in those on multiple drugs.[77] Although phenytoin[5] and phenobarbital[104] have been reported to be useful in the treatment of ASE, these drugs are not generally recommended because they are not only ineffective against absence seizures, but are known to exacerbate both clinical and

P.699

experimental absence.[156] The potential neurologic morbidity of ASE, which is most often a relatively benign event especially with typical ASE, must be weighed against the possible morbidity of intravenous AEDs, and overtreatment must be avoided.[88]

A paradoxical worsening of the electro-clinical picture has been reported in the atypical ASE of the Lennox-Gastaut syndrome after BZ injection.[102]

Diagnostic Considerations

EEG and BZ therapeutical trial prove the ictal nature of the confusion and settle issues of differential diagnosis. In most cases,[53,72,85,107,170,171] nonictal events are suspected initially (Table 2). Among ictal events, ASE may be completely indistinguishable from CPSE[108] or from a prolonged postictal encephalopathy.[19] The main practical problem is to think of the diagnosis and to obtain a rapid EEG: Kaplan notes that in most instances, "the diagnosis was all too evident in retrospect, and frequently missed or delayed initially."[84] In a single study,[78] remote risk factors for seizures, severely impaired mental state, and ocular movement abnormalities were the most sensitive indicators for an emergency EEG.

When a reliable clinical history can be obtained, and the beginning of the confusional state is reportedly sudden, its epileptic nature may be suspected.

Another diagnostic point is that the EEG at the time of the ictal event should represent a definitive change from the preictal state. Such a change is more clear-cut in typical ASE, in which the interictal EEG is not as replete with ongoing paroxysmal abnormalities as that seen in a patient with epileptic encephalopathy in whom there is a diagnostic question of atypical ASE. In these latter cases, it may be far from clear that the atypical ASE represents a change from their baseline condition either clinically or electrographically.

Primary or secondarily generalized tonic–clonic seizures may appear at the beginning[12,50] or, more classically, at the end of ASE.[6] When the seizures occur at the onset, the unusually long duration of the presumed postictal confusional period should raise a suspicion of the diagnosis, and an urgent EEG should therefore be obtained.

The delay in diagnosis is often long. Rohr-Le Floch et al.[137] found that the correct diagnosis was made at the time of initial clinical examination in only four of 60 cases (7%). In 18 of 60 cases (30%), the diagnosis was that of a prolonged postictal state. In recent series,[90,164] delays in diagnosis ranged from 8 hours to 4 days. As noted by Kaplan,[84] in adults, the altered mental status of ASE may be attributed to a metabolic disturbance or to excessive psychotropic drug use or withdrawal, each of which may also induce ASE. In these cases, impaired consciousness can result a combination of ASE and encephalopathy, and it may be impossible to assess the relative part played by these two factors.

Etiologic Factors in Absence Status Epilepticus

Endocrine factors appear important in women of childbearing age. The catamenial period,[114] pregnancy,[46] the immediate postpartum period,[14] and menopause[136] have all been implicated.

Drug-related factors are clearly important in many cases, particularly, but not exclusively in "de novo" ASE of late onset. Many authors[45,71,132,164,167,177] suggest an etiologic role for psychotropic medication either taken in excess, alone, or in association with other drugs, or during rapid drug withdrawal.[51] Many psychotropic drugs have been implicated, in order of frequency and probable causality: BZ, neuroleptics (especially butyrophenones), tricyclic antidepressants (especially amitriptyline), lithium, meprobamate, viloxazine, methaqualone, barbiturates, and monoamine oxidase inhibitors.

Many cases have also been reported to occur in relation to other drugs. Only some of these are known to lower the convulsive threshold: bemegride and metrazol,[104] theophylline,[180] cyclosporin,[37] ifosfamide,[145,187] baclofen,[191] metformin,[71] cimetidine,[177] cefepime,[131] and ceftazidine.[93]

A number of cases have been reported with the use or withdrawal of AEDs, including one during a valproate-related encephalopathy, which was partially reversed by flumazenil.[159] Therapeutic concentrations of carbamazepine and/or phenytoin may exacerbate IGE in the specific form of ASE.[125,158] Patients with absence seizures appear to have a heightened risk for this paradoxical response, underscoring the value of an adequate syndromic approach.[125] Tiagabine has been implicated in episodes of atypical ASE.[47,49,146] Although this has been challenged as a valid phenomenon,[142] the exacerbation of experimental absence seizures by all γ-aminobutyric acid (GABA)ergic agonists, be they direct $GABA_A$ receptor or $GABA_B$ receptor agonists or indirect GABA agonists (GABA transaminase inhibitors, such as vigabatrin) and GABA uptake inhibitors, such as tiagabine[76,153,156] is well established. As well, a clinical correlate exists for the exacerbation of absence seizures and potential triggering of ASE by GABAergic drugs other than tiagabine, such as baclofen[191] and vigabatrin.[127,190] However, in most cases, EEG data were not really convincing of the ictal nature of the disorder, and this issue remains controversial.[142] True syndromic aggravation related to tiagabine use also has been associated with typical ASE in IGE[94] and in ASE with focal features in lesional focal epilepsy.[182] Replacement of valproate with lamotrigine precipitated ASE in a

single patient.[174] Levetiracetam has also recently been implicated in two patients with symptomatic partial epilepsy.[8]

Metabolic disturbances, either isolated or associated with drugs are frequently reported to be associated with ASE: hyponatremia,[48,98] hypocalcemia,[181] hypoglycemia,[71] decompensated chronic renal or hepatic failure,[48] hyperthyroidism,[160] psychogenic polydipsia with metabolic imbalance,[48] electroconvulsive therapy,[70] and cobalamin deficiency.[2]

Metrizamide and other contrast-enhancing products deserve special mention. A number of ASE case-reports have been documented following the use of these agents during myelography.[4,120,121,134,183,184] One case occurred after carotid angiography.[180] Another single case was described after intrathecal fluorescein injection.[30]

Other nonspecific triggering factors have also been reported occasionally (these have been reviewed[165]), but the mechanism by which they lead to ASE is speculative: alcohol, hyperventilation, intermittent photic stimulation, stress, grief, fatigue, disturbances of the sleep–wake cycle. Cases have also been reported following surgery, mild head trauma, severe head trauma, fever, paraneoplastic syndrome,[43] and neurosyphilis.[133] Genetic factors may also be implicated.[24]

In contrast to the number and variety of possible etiologic factors, no focal lesions have been documented in

ASE on imaging studies. However, in elderly patients with frontal mild to moderate cortical-subcortical atrophy of vascular and/or degenerative origin, it has been suggested that various toxic and/or metabolic factors may express themselves more easily in brains structurally damaged by such nonspecific lesions.[59]

ASE has been associated with other neurologic syndromes: Inoue et al.[80] reported six cases of ring chromosome 20 (RC 20) and epilepsy with prolonged confusional states resistant to AEDs associated with bilateral high-voltage ictal slow waves occasionally beginning with focal frontal EEG activity. These authors proposed that this constitutes a new syndrome.[80,128] ASE was also described in a child with the congenital bilateral perisylvian syndrome,[161] in patients with the eyelid myoclonia with absences syndrome,[185] in the perioral myoclonias with absences syndrome,[1,18] and in another syndrome of idiopathic generalized epilepsy with phantom absences of undetermined onset.[126] An isolated case report of atypical ASE has been reported in the context of a syndrome of increased intracranial pressure and transient MRI abnormalities.[26] Another patient with new-onset ASE[164] had unilateral frontal hyperperfusion on ictal single photon emission computerized tomography (SPECT). SPECT images were similar to those found in patients with focal NCSE.[95,168]

Long-Term Treatment and Prognosis

ASE generally has no effect on the natural history of any preexisting epilepsy, although Wirrell et al. have suggested that it is a factor predicting that childhood absence epilepsy will not remit.[188] In IGE, the occurrence of ASE appears to have no appreciable effect on subsequent seizure frequency, and the patients' cognition and mentation remain normal, as reviewed by Drislane.[44]

The influence of atypical ASE on the cognitive prognosis in epileptic encephalopathies is not as clear. It probably relates more to the encephalopathy that gives rise to the epilepsy than to the atypical ASE itself: In most instances, ASE does not appear to have any significant effect.[136] However, Doose and Völzke believe that repetitive ASE may aggravate intellectual deterioration in children with myoclonic-astatic epilepsy,[41] and Manning and Rosenbloom reported 13 children with atypical ASE followed by a deterioration of their mental handicap.[110] In NCSE, some adult patients were reported to show a significant increase of neurospecific enolase, a marker of neuronal damage,[36,135] but a recent study showed normal values in ASE.[143]

ASE has an inconsistent tendency to recur. Most patients have a single ASE, some have a few episodes, while others have a marked tendency to recur despite AEDs: Andermann and Robb reported a man with IGE who had more than 500 episodes of ASE between ages 40 and 65 years.[6] When ASE occurs with a preexisting IGE, the drug of choice to prevent recurrence is valproate[17]: In a series of 18 patients with IGE, the rate of recurrent attacks during a 4.4-year period was reduced with valproate from 5.7 to 0.6 attacks per year. Trimethadione, ethosuximide, phenytoin, barbiturates, and carbamazepine also have been used with less favorable results.[6] In elderly patients, the identification and correction of probable triggering factors may be sufficient to prevent recurrence.[166]

Pathophysiology

The fundamental underlying mechanisms of absence seizures have been delineated as well as any mechanism of human epileptogenesis. GABA-mediated inhibition and low-voltage activated or T-type calcium current activity becomes phase locked with glutamate-mediated excitation within thalamocortical circuitry, with resultant abnormal oscillatory rhythms that characterize absence seizures.[33,39,58,112,113] However, it is unknown whether these same mechanisms are operative in ASE. Perhaps a more important question is: What is the mechanism by which absence seizures usually are self limited, lasting only seconds? In this regard, some evidence shows that the α_4 subunit of the $GABA_A$ receptor complex may be involved in the maintenance and termination of absence seizure activity in the γ-hydroxybutyric acid (GHB) animal model of absence seizures.[10] These data raise the possibility that, in some instances, perturbation of the α_4 subunit of the $GABA_A$ receptor might lead to generalized ASE in a brain predisposed to absence seizures.

Very few animal models are available that might help us to understand the pathogenesis of epileptogenesis in ASE. However, the few experimental preparations of ASE that have been reported all have in common the prolongation of GABA agonist–induced absence seizures.[150,151,152,153] For example, based on the low-dose pentylenetetrazole model of absence seizures,[155,156] Wong et al.[189] administered repetitive low doses of pentylenetetrazol to create a rodent model of ASE that showed no evidence of immediate pathologic damage.

Of interest is the fact that, in those experiments, Wong and colleagues were able to induce ASE only in adult animals, but not in developing rats. In addition, Snead[153] has shown that if one superimposes a $GABA_B$ receptor agonist, baclofen, on the GHB model of absence seizures,[154] ASE results.

In another series of experiments using the prodrug of GHB, γ-butyrolactone (GBL)[157] in conscious marmoset monkeys, Tenney et al.[162] confirmed earlier work showing GHB-induced absence seizures in monkey[148,149] and also demonstrated functional magnetic resonance imaging activation of both thalamus and sensori-motor cortices concomitant with the GHB-induced SWDs. In a recent positron emission tomography study,[20] [18F]fluoro-L-DOPA uptake was significantly decreased bilaterally in the putamen and caudate nucleus of 14 patients with ring chromosome 20 and epilepsy, suggesting that a reduction of striatal dopamine plays a key role in seizure interruption in some ASE patients. These clinical data comport with experimental data that implicate nigrostriatal and corticostriatal pathways in the pathogenesis of absence.[38,147,152]

Summary and Conclusions

ASE forms a major heterogeneous subgroup of NCSE. The clinical hallmark is an altered mental state with eyelid myoclonus

associated on emergency EEG with concomitant, bilaterally synchronous electrographic SWDs or PSW discharges. The literature indicates that four types of ASE may be recognized. Typical ASE occurs as part of an IGE most often characterized by typical absences, and immediate prognosis is excellent after BZ injection. The major defining feature of atypical ASE is that it occurs in the context of a preexisting neurologic abnormality, usually an epileptic encephalopathy. Therefore, atypical ASE is more difficult to treat and has a poorer prognosis than typical ASE in terms of long-term neurodevelopment and seizure control.

ASE with focal features occurs in patients with a localization-related epilepsy, most often of extratemporal origin. Ictal features tend to overlap with CPSE of frontal lobe origin. “De novo” ASE of late onset is a situation-related condition precipitated by toxic or metabolic factors in elderly subjects with no epileptic antecedents. ASE appears to be a rather benign condition: intellect, memory, behavior, and worsening of preexisting epilepsy do not appear to deteriorate from baseline even after recurrent attacks. Finally, the pathogenesis of ASE is virtually unknown, although some experimental data point to perturbation of GABA-mediated inhibition as playing a potential mechanistic role in this phenomenon.

Chapter 61

Simple Partial Status Epilepticus and Epilepsia Partialis Continua of Kozhevnikov

Heinz Gregor Wieser

Patrick Chauvel

Introduction

Literature reports of simple partial status epilepticus (SPSE) seem to be relatively rare in comparison with those of generalized convulsive SE, complex partial SE (CPSE), and absence SE. One reason may be that SPSE very often progresses to CPSE, so that many overlaps between SPSE and CPSE exist in the literature, and cases are finally categorized according to their full-blown semiology, that is, as CPSE, even though for a certain time they might fulfill the criteria of SPSE (for definitions, see later discussion). Moreover, some subjective forms of SPSE have been described under the recently rediscovered term "aura continua"[285] and nonconvulsive SE (NCSE),[121] although levels of alteration of consciousness in the latter are often difficult to assess.

Among the multiple potential subtypes of SPSE, certain manifestations (which are readily accessible to the patient's awareness or physician's observation) seem to predominate, such as SPSE with motor symptoms and with certain sensory symptoms. Numerous studies have dealt with the pathophysiology of epilepsia partialis continua (EPC), whereas few have been devoted to SPSE with the expression of emotional/affective and subtle vegetative-autonomic symptoms only. Apart from the problem of the so-called interictal personality and behavioral syndrome[271] and other described peculiarities of personality, there remains the question of the boundaries of SPSE being expressed through very localized, ongoing epileptic discharges in "relatively silent" brain regions (e.g., nondominant frontal lobe) that might not be associated with any overt symptom at all but might be detected only with subtle decreases in very sophisticated neuropsychological test performance.

In contrast to the history of epilepsy, SE was infrequently recorded until the dissertation of Louis Calmeil,[40] where the expression *état de mal* is first found, but still in reference to convulsive generalized SE only. The proceedings of the Xth Marseilles Colloquium of 1962 represent the first monograph (*Les états de mal épileptiques*)[94] on this subject. At the Marseilles Colloquia of 1962 and 1964, definitions and classifications of seizures and of SE were proposed with the obvious notion that there are *as many types of status as there are types of seizures*.

The modern conceptual basis of SE as having an "etymologic definition" and the notion that this term is to be used "whenever a seizure persists for a sufficient length of time [subsequently defined as at least 30 minutes] or is repeated frequently enough to produce a fixed or enduring epileptic condition" has been widely accepted and enshrined in the WHO *Dictionary of Epilepsy*[90] as well as in the *Handbook of Clinical Neurology*[210] and the *Handbook of Electroencephalography and Clinical Neurophysiology*.[95] The first international classification of seizure types[88,89] and its revision[58] divided partial seizures into "simple" and "complex" according to whether consciousness was retained or lost. The subsequent classification of epilepsies and epileptic syndromes[59] included a few syndromes that might conform to the widened definition of status (e.g., EPC, CSWS, Landau-Kleffner) but otherwise lacked a synoptic view. A major review of SE occurred at the Santa Monica, California, conference in 1980, which was published in 1983.[66]

In the new proposal,[74] *continuous seizure types* are divided into *generalized status epilepticus* (including generalized tonic–clonic SE, clonic SE, absence SE, tonic SE, and myoclonic SE) and *focal status epilepticus* (epilepsia partialis continua of Kozhevnikov,[284] aura continua,[285] limbic SE [psychomotor status[283]], and hemiconvulsive status with hemiparesis). The division of partial seizures into "simple" and "complex" is not retained. In addition, the terms "partial" and "localization-related" have met with criticism, and a task force proposed that these terms be replaced by the older term "focal."

Pathophysiologically, a clear distinction should be made between the terms *epilepsia partialis continua* (EPC), or so-called *Kozhevnikov syndrome*, and *Rasmussen encephalitis* (see section Pathophysiology). Clinically, Bancaud's EPC type 2 largely corresponds with Rasmussen encephalitis.

Epilepsia partialis continua was first described by Kozhevnikov in 1894 as a "peculiar form of cortical epilepsy" that consisted of localized continuous jerks intermingled from time to time with spreading jacksonian seizures.[129,130] In his 4 cases, the seizure disorder continued for 3.5 to 5 years in the same part of the body. Kozhevnikov postulated a localized inflammation of the brain involving the motor strip. Omorokow reviewed 42 cases of "Kozhevnikov syndrome" in the literature and described a further 52 cases from his Siberian clinic, recognizing that this form of epilepsy may be due to Russian spring-summer tick-borne encephalitis.[174,175] In 1958, Rasmussen et al.[206] described 3 cases of persisting focal epilepsy due to chronic focal encephalitis. By 1988, a total of 48 Rasmussen chronic encephalitis cases had been identified and described,[205] differing in many ways from those of Russian spring-summer tick-borne encephalitis.[7] Since the first descriptions of EPC, many localized cerebral disturbances have been found to give rise to similar patterns of ictal behavior,[219] and the definition and nomenclature of EPC has become a subject of controversy.[29] In 1966, Juul-Jensen and Denny-Brown[120] pointed out that in various papers, the definition of EPC was not the same. They asked for a differentiation between true EPC with "clonic muscular twitching repeated at fairly regular short intervals in one part of the body for a period of days or weeks" and "focal epilepsy with motor seizures with frequent recurrence and with 'Jackson march' or progression from tonic to clonic phase." Gastaut and Broughton[92]

P.706

commented that "certain authors now also include chronic localized myoclonus without intercurrent somatomotor seizures or, conversely, recurrent somatomotor seizures without local myoclonus. Other authors also include the subacute episodes of localized myoclonus observed during certain syndromes of diffuse hemispheric ischemia." Later authors characterized EPC as a "partial somatomotor SE for a minimum of 1 hour and recurring in intervals of no more than 10 seconds"[249] and as "spontaneous regular or irregular clonic twitching of cerebral cortical origin sometimes aggravated by action or sensory stimuli (reflex component) confined to one part of the body and continuing for a period of hours, days, or weeks."[171] In 1989 the International League Against Epilepsy (ILAE) Commission defined EPC (Kozhevnikov) syndrome as a specific form of partial somatomotor seizure disorders involving the rolandic area of the motor cortex.[59] Schomer used EPC and focal SE as synonymous terms.[219]

Definition

For the purpose of this chapter, we suggest the following operational definition: SPSE is an epileptic condition (defined by clinical and electroencephalographic signs and symptoms) of at least 30 minutes' duration with a large spectrum of clinical manifestations and encompassing subtle clinical signs, as well as at least some behavioral disturbances and psychosis-like states, in particular, elementary and complex (polymodal) hallucinations, without loss or severe alteration of consciousness (in other words, "with preserved consciousness" in the sense of an [operationally defined] adequate reactivity and response). Furthermore, we add the criterion that observed symptoms should fit with the known functional anatomy and, thus, with localization of the electroencephalographic (EEG) discharge, and, in the case of more diffuse and difficult-to-describe personality and behavioral changes, that there be a clear-cut relationship in time of the particular subtle signs and symptoms with epileptic EEG activity.

Epidemiology

Incidence

There exist no population-based studies on SPSE. Until very recently, computations of frequency were restricted to generalized tonic–clonic SE, but even here, only vague guesses could be given, at best. At a conservative and approximate estimate, status syndromes, including West syndrome, neonatal and childhood status syndromes, EPC, other SPSE, and absence status in the elderly, contribute to the annual incidence of status no more than 5 to 10 cases per one million persons in the general population. SPSE is, thus, very rare, but this statement might require revision if the boundary syndromes (mentioned earlier) are included.

Prevalence

Hauser[112] attempted to break down SE by seizure type into the categories *generalized* (23%–51%), *unilateral* (39%), *partial motor* (24%–72%), *partial, secondary generalized* (5%–62%), *other* (5%), and *nonconvulsive* (5%–33%), based on the studies of Aminoff and Simon,[5] Celesia,[42] Hauser,[111] Aicardi and Chevrie,[2] and Forster et al.[81] Unfortunately, no precise mention is made in these studies of the incidence and prevalence (or definite absence) of SPSE. Brett[35] reported 22 children with "minor epileptic status" and differentiated this from "petit mal status" by the presence of myoclonus and less frequently occurring spike-wave patterns in EEG.

There seems to be a consensus that SPSE with motor phenomena is at least as common as SPSE without motor phenomena, that is, SPSE with sensory and/or autonomic signs and symptoms and SPSE with disturbances of language and higher cortical functions.

Epilepsia partialis continua is a condition with a wide range of underlying pathologies. Articles about EPC include case reports or small series of patients. For this reason, no epidemiologic data exist. Based on their survey of all registered cases in the United Kingdom during 1993, Cockerell et al.[53] estimated the prevalence of EPC to be <1 per million.

Etiology

No specific etiology leading to SPSE is known, and a large spectrum of underlying causes has to be considered (See also section Differential Diagnosis).

Myoclonic seizures progressing into status ("myoclonic storm"), in general, may be due to a wide variety of etiologies (essential hereditary myoclonus epilepsy, lipidosis of the central nervous system, acute encephalitis, subacute sclerosing panencephalitis, acute cerebral anoxia, Creutzfeldt-Jakob disease, and renal insufficiency with uremia) and may occur in various epileptic conditions (common generalized epilepsy, Lennox-Gastaut syndrome, infantile spasms).[167] Benign idiopathic neonatal convulsions, described in the literature as "fifth day fits," present often as lateralized clonic seizures and may lead to a SE lasting about 20 hours (from 2 hours to 3 days).[199] Some subtypes of the early infantile epileptic syndromes with suppression-burst must be considered here also. They can be viewed as falling into two main categories: (a) the Aicardi syndrome,[1,3] which is, in essence, a complex malformation syndrome, and (b) an inborn metabolic disease, nonketotic hyperglycinemia.[63] The majority of these patients have an EEG showing suppression-burst, for example, 98 of 146 in the Aicardi syndrome.[50] Suppression-burst was also described in other metabolic or malformation syndromes, such as olivary dysplasia,[109,207] hemimegalencephaly,[177,250,267] Menkes disease,[56,194] D-glyceric acidemia,[100] methylmalonic acidaemia,[152] propionic acidaemia,[268] and sulfite oxidase deficiency.[17] In early myoclonic encephalopathy (neonatal myoclonic encephalopathy), segmental and erratic myoclonias are usually the earliest ictal events (accompanied later by one or more of the other seizure types, such as massive myoclonias, simple partial seizures, and infantile spasms of the tonic type) and can recur frequently, so that they present as a status.[1]

Cases of *epilepsia partialis continua* (EPC) or *Kozhevnikov syndrome* have been a posteriori attributed to Russian spring-summer encephalitis.[219] A Russian spring-summer tick-borne virus has been isolated from monkey brain after several months of incubation, supporting the hypothesis of a slow-viral disease.[304] Dereux,[67] reviewing a series of 102 cases of Kozhevnikov syndrome, found that >50% were caused by an "encephalitic process," as were 31% of 85 pathologically verified cases in the review published by Löhler and Peters in 1974.[141] In a study of 36 cases by Cockerell et al.,[53] 7 patients had Rasmussen encephalitis, 9 had vascular diseases, 4 had a "multisystem" disease, 4 had neoplastic diseases, 2 had perinatal injury, 1 had trauma, 1 had hyperglycemia, and 1 had Creutzfeldt-Jakob disease.

Rasmussen encephalitis roughly corresponds to Bancaud's type 2 epilepsia partialis continua.[19,20,21] In the statistics published by Oguni et al.,[172] EPC developed in only 56% of the cases of Rasmussen syndrome as they evolved. In a recent Indian study of 20 patients,[180] type 1 and type 2 EPC were found in respectively 55% and

45%; infectious etiologies were found in 60% (Rasmussen encephalitis in 25% of these, or 3 cases) and vascular etiologies in 25%, with the remaining 15% consisting of 1 mitochondrial disorder and 2 undetermined causes.

Creutzfeldt-Jakob disease (CJD) rarely presents with epilepsia partialis continua with subacute progression in which the EEG shows focal epileptiform activity and neuroimaging is negative.[183]

Patients with human immunodeficiency virus (HIV) infection may present new-onset EPC as an early manifestation of progressive multifocal leukoencephalopathy (PML).[25,79]

Cerebral tumors, such as astrocytomas, hemangiomas, lymphomas, and metastases, have been reported as causes of EPC. In fact, these tumors are associated with EPC because of their anatomic location near the central sulcus and probably not because of their neoplastic nature. The same relation may exist in cases of EPC in multiple sclerosis[115,240,244] and in the earlier American[120] and recent Indian cases[180] with infectious mass lesions, especially of tuberculosis.

The vascular etiologies reported were occlusive, embolic, or hemorrhagic stroke; arteriovenous malformations; cortical venous thrombosis; and vasculitis in lupus and in Sjögren syndrome.[23]

Traumatic lesions are present in many series.[22,53,141,249]

Cortical dysplasias, especially hemimegalencephaly, can present with EPC, as well as tuberous sclerosis, linear sebaceous nevus syndrome, and Sturge-Weber syn-drome.[83,84,68,133,150,151,165]

EPC may be associated with widespread gliomatosis cerebri[224] and paraneoplastic recurrent multifocal enceph-alitis[164] and was seen in cat scratch disease.[202] It can be observed in hemiconvulsion, hemiplegia, epilepsy (HHE) syn-drome.[45]

EPC and SPSE can occur as a complication in nonketotic hyperglycemia in children and adults, including elderly patients (>50 years).[176,214,234] Such a condition may show progressive development over days. Clinical symptoms associated at the beginning are polydipsia, loss of appetite, simple partial seizures with motor symptoms, and a mild-to-moderate psycho-organic syndrome. In a hyperosmolar nonketotic coma, glucose values are often very high, and osmolarity may be >320 mmol. Because phenytoin can reinforce hyperglycemia, it is contraindicated. Renal failure giving rise to *uremia* in older patients is particularly often associated with frequent myoclonic jerking. In renal insufficiency, the EEG becomes frequently abnormal and is characterized by excessive slowing. Not infrequently, EEG abnormalities are enhanced during and after hemodialysis.

EPC has been described in mitochondrial disorders such as Leigh syndrome,[72] mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes,[9,51] subacute measles encephalopathy in immunosuppressed children, and Alpers disease with, in the case of Bourgeois and Aicardi,[32] a deficiency of cytochrome c oxidase.

Iatrogenic partial motor SE has been reported after exposure to penicillin, azlocillin, or cephotaxime[301] and after diagnostic use of metrizamide.[229]

Somatomotor SPSE occurs about 50% of the time as a first manifestation in otherwise nonepileptics, is usually seen in the elderly, and often reflects an embolic but otherwise asymptomatic ischemia (sylvian or suprasylvian). The so-called *somatomotor SPSE* accompanying severe brain lesions in nonepileptics presents differently, with periodically repeated, about 1/sec localized myoclonus involving, as a rule, a proximal part of limbs or one side of the trunk or flank. It is nearly exclusively observed in elderly patients, most often representing infarction in watershed territories (so-called interterritorial infarction), or, less frequently, metastatic brain tumor or brain contusion.[44,166] The EEG most often shows corresponding periodic lateralized epileptiform discharges (PLEDs; Figs. 1 and 2). In vascular cases, Gastaut[91] referred to the “initial myoclonic phase of interterritorial infarction” in such a situation, to avoid the term *status*.

PLEDs may be an ictal EEG pattern in SPSE. Ictal PLEDs are often associated with corresponding jerks in the sense of EPC. In addition, PLEDs can be associated with recurrent and prolonged episodes of a confusional state associated with psychic and neurologic manifestations. Terzano et al.[248] reported seven elderly (>60 years of age) patients with PLEDs and prolonged confusional states. In these seven patients, the EEG became normal when the ictal episodes subsided, either spontaneously or following intravenous diazepam. More often, however, PLEDs are viewed as an “interictal” pattern that can last as long as 3 months to 2.5 years[274] and can occur in a variety of disorders. Snodgrass et al.,[238] for example, found PLEDs most often in acute unilateral lesions (vascular, 35%; mass lesion, 26%; infection, including herpes simplex encephalitis, 6%; anoxia, 2%), but also in other conditions (22%), such as alcohol withdrawal and toxic-metabolic disorders. They are also seen with chronic seizure disorders or with old static lesions when associated with recent seizures.

The determination of whether such a periodic EEG pattern, if not associated with obvious ictal signs and symptoms, reflects an interictal or ictal state (in the sense of an ongoing ["sub-clinical"] electrographic status) has important implications for antiepileptic therapy. Single photon emission computed tomography (SPECT) studies strongly suggest that PLEDs may be ictal in some patients. Whereas Treiman[253] feels that treatment is appropriate until all EEG discharges are gone, Lothman et al.[142] and Brenner and Schaul[34] suggested that a stable periodic pattern may represent underlying pathology with neuronal damage rather than seizure activity and does not demand antiepileptic treatment.

Pathophysiology

Why and how epileptic discharges can remain restricted to a given cortical (or corticothalamic sector) region without noteworthy propagation, over long periods of time to produce SPSE might be related to (a) certain pathologies, (b) the localization of the lesion, and (c) sufficiently preserved inhibition to limit the epileptic process in space.

In general, the pathophysiology of SPSE is poorly understood. Considerable knowledge, however, has been accumulated on EPC. Bancaud's classification of EPC into types 1 and 2 is clinically useful.[22] In type 1, the myoclonias correspond to a focal structural lesion in the contralateral rolandic cortex. This type does not show any age dependence, the continuous myoclonias are restricted, and the EEG usually also shows a sharply delineated spike focus. The clinical course and the prognosis are determined by the underlying pathology. The unaffected brain regions are often and remain, as a rule, more or less normal. Type 2, also called *Rasmussen syndrome*,[6,10,172,206] is a progressively evolving "chronic encephalitis" with a predominance in children and a peak around the sixth year of life.[101,205] (see Chapter 243.) In about two thirds of cases, there is a history of a preceding nonspecific infection. Often, the disease starts with a grand mal seizure or several simple partial motor seizures and eventually includes complex partial seizures. In about 50% to 60% of patients, EPC develops and is then the predominating seizure type.[172] Seizures are usually resistant to antiepileptic drugs, and extensive resective surgery was the only known effective treatment.

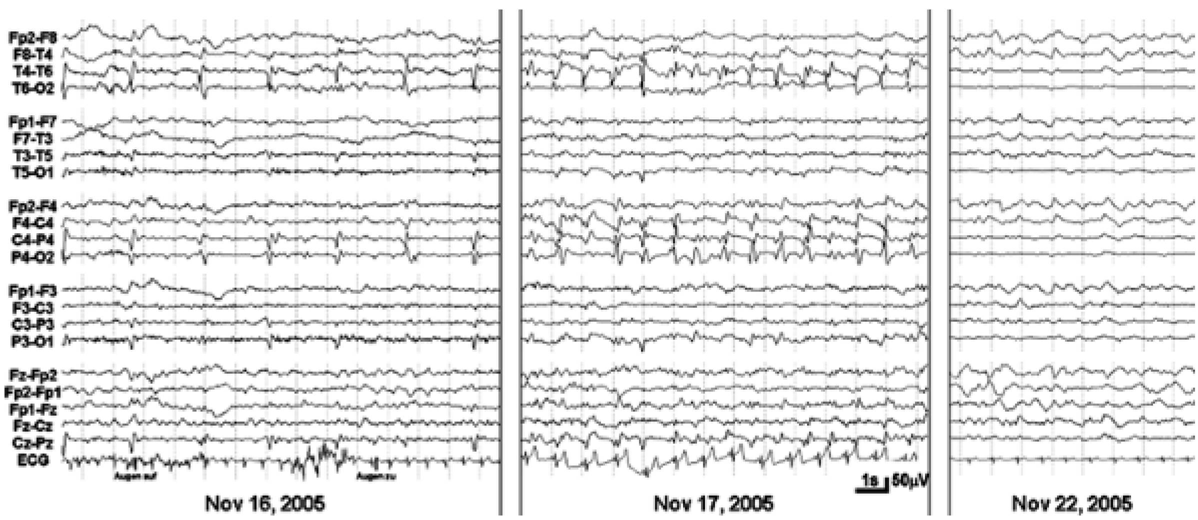

FIGURE 1. Illustration of periodic lateralized epileptiform discharges (PLEDs) followed for 1 week. On November 16, 2005 **(left),** there was a periodicity of sharp waves at T6 and P4 of about 0.4/s with an intermingled seizure discharge (see Fig. 2). Valproate was administered. One day later, the PLEDs showed a periodicity of 1/s, and there were now seizure discharges. Five days later, PLEDs were no longer present, but there was a flattening at T6 and P4. One day before admission (November 15, 2005), the patient experienced a left hemiplegia due to a new hyperintense magnetic resonance imaging lesion in the right crus cerebri. This

was diagnosed as new plaque within the diagnosed chronic-progressive multiple sclerosis (since 1985). The patient also suffered from schizophrenia-like psychosis and anorexia nervosa. She had had several seizure-like episodes (falls during the last year but without the clear diagnosis of epilepsy).

In relatively well-preserved brain areas, perivascular lymphocytic cuffs and glial nodules, and in later stages microcystic degeneration with marked neuronal fallout but without evidence of inflammatory elements, are typical histologic findings.[208] It is fair to say that the nature of this disease remains obscure, although in recent years an autoimmune process has been postulated, as prompted by various reports.[11,211,257] Autoantibodies in sera from patients with active Rasmussen

encephalitis and experimentally induced antibodies in rabbits seemed to act as agonists for glutamate receptors consisting of or containing GluR3 subunits. Agonist activity of autoantibodies on a glutamate receptor subunit suggested their role as pathogenetic factors, potentially as highly specific excitotoxins or neuromodulators. Our search, however, for the presence of anti-GluR3 antibodies in sera and cerebrospinal fluid of four patients with typical histologic findings of Rasmussen encephalitis yielded negative results.[252] In other patients with Rasmussen encephalitis, autoantibodies against the glutamate receptors (GluR3, GluRepsilon2) were detected,[131,211,246,247,257] suggesting an autoimmunologic etiology in a subgroup of this syndrome. Preliminary data with plasma exchange therapy in some patients with Rasmussen's encephalitis seem also to support this etiology.[221,291]

The definite proof for a cortical origin of EPC was provided by three studies using depth-electrode recordings (Fig. 3).[21,39,287] An experimental model of EPC was achieved by injections of aluminum hydroxide into monkey motor cortex.[46] Using this experimental model, Chauvel and associates proved the role of the long-loop reflexes for generation of the cortical myoclonus.[47] Thermocoagulation of the thalamic nucleus ventro-lateralis posterior (VPL) oralis disrupted the reflex loop and led, in the majority of cases, to a cessation of the myoclonus.[48] The participation of the (presumably) ventrolateral and intralaminar thalamic nuclei[119] in the epileptic process was illustrated on fluorodeoxyglucose (FDG)-positron emission tomography (PET) by a simultaneous metabolic increase in both the cortical and the ipsilateral thalamus in a patient with an EPC.[106]

On the other hand, absence of epileptogenic EEG abnormalities in some patients with EPC[189] and presence of subcortical brain lesions with preserved cortex[31,120] led to the hypothesis of a subcortical origin of the EPC in at least some patients. A recent report even implicates a cerebellar lesion as possible cause for EPC.[263]

In 1985, Hallett introduced three types of epileptic myo-clonus: (a) cortical reflex myoclonus as a fragment of partial epilepsy, which represents hyperactivity of a focal area of cerebral cortex; (b) reticular reflex myoclonus as a fragment of generalized epilepsy with hyperactivity of medullary brainstem reticular formation; and (c) primary generalized epileptic myo-clonus as a fragment of primary generalized epilepsy, which may represent a generalized hyperactive response of cortex to subcortical input.[107] (For further discussion of myoclonus, see Chapter 277.)

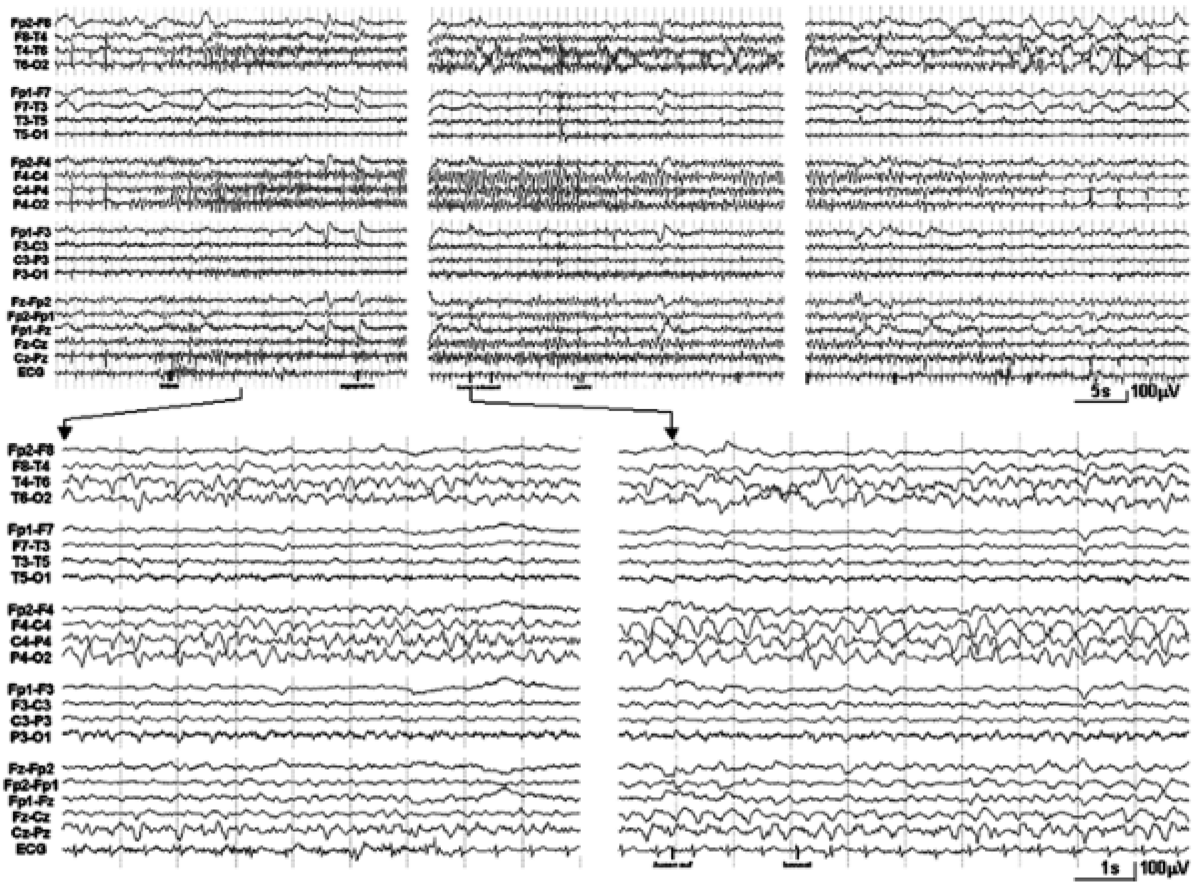

FIGURE 2. Same patient as in FIGURE 1. During the electroencephalogram (EEG) recorded on November 16, 2005, with periodic lateralized epileptiform discharges of a periodicity of sharp waves at T6 and P4 of about 0.4/s, the depicted seizure discharge occurred with evolving slow rhythmic activity at the right temporo-parieto-central region. **Upper rows:** Sections showing the beginning, height, and the end of the seizure. **Lower row:** Corresponding EEG sections (indicated) with better time resolution.

In cases with cortical reflex myoclonus, the epileptogenic focus is localized in the contralateral rolandic cortex, and the EEG may show spikes related to the myoclonic jerks. In cases without a clear-cut temporal relation between epileptic events and myoclonus in the EEG, the back-averaging technique identifies the spikes preceding the myoclonus.[227] Somatosensory-evoked potentials of the rolandic cortex are abnormally enlarged.[228] Tight relations between the afferent volley evoking abnormal evoked potentials in the primary motor cortex itself and triggering of focal myoclonus have been demonstrated by depth recordings in patients with EPC.[49]

Without such proof of the cortical origin of the myoclonus by neurophysiologic methods, a subcortical or even spinal origin of the myoclonus has to be considered. Cockerell et al. suggested that the diagnosis of EPC should be confined exclusively to cortical myoclonus.[53] They proposed the term "myoclonia continua" for myoclonus that arises extracortically.

In cases of EPC in which the jerks are associated with other seizures, the physiologic characteristics of the jerks are identical to those of cortical myoclonus.[230] In this sense, cortical myoclonus is cortical epilepsy, that is, a hypersynchronous discharge from a group of cortical cells. By employing different physiologic methods, such as back-averaging of EEG recordings in relation to the jerks, evoked potentials, and electromyographic recordings of the sequence of recruitment of muscle

P.709

groups in a myoclonic jerk, a distinction of myoclonus into cortical, brainstem, and spinal myoclonus is possible in most cases. Typically in cortical myoclonus, the EEG cortical generator potentials precede the jerks; sensory-evoked potentials are enlarged; and the myoclonus may be spontaneous and action or stimulus sensitive with a rostrocaudal pattern of muscle recruitment and antagonist and agonist cocontraction. In stimulus-sensitive myoclonus, the reflex timings are compatible with a cortical loop. Obeso et al.[171] reported patients showing a spectrum of spontaneous and stimulus-sensitive myoclonus, EPC, jacksonian seizures, and generalized seizures, all with similar physiology. In these cases, EPC is repetitive cortical myoclonus. In cases without seizures, however, jerks resemble EPC clinically but not neurophysiologically. In such cases the jerks might be of subcortical origin. Menini and Naquet[149] called this variant type C myoclonus with suggested origin in the brainstem. It is, however, fair to say that this variety is neither as common nor as well studied as the cortical myoclonus, and its exact nosologic position is not clear.

The neurophysiologic criterion for a cortical generator of myoclonus is the presence of a preceding potential in the central region contralateral to the jerk. However, many circumstances, related to the rate of occurrence of myoclonus or presence of a lesion modifying the geometry of the cortex or volume conduction, can impair the reliability of jerk-locked averaging. Applying methods that analyze EEG-electromyograph (EMG) and EMG-EMG relations in the frequency domain, several studies have demonstrated functional coupling between cortical and muscular activity during myoclonus even when back-averaging was negative.[37,38,146,154] Distinction between the pathologic corticomuscular coupling and the physiologic one might be only quantitative, and polygraphic EMG recordings remain essential for identifying pathologic drives to muscles.[104,261] In addition, an exaggerated coupling in the efferent pathway does not preclude the existence of putative generators upstream of the motor cortex.

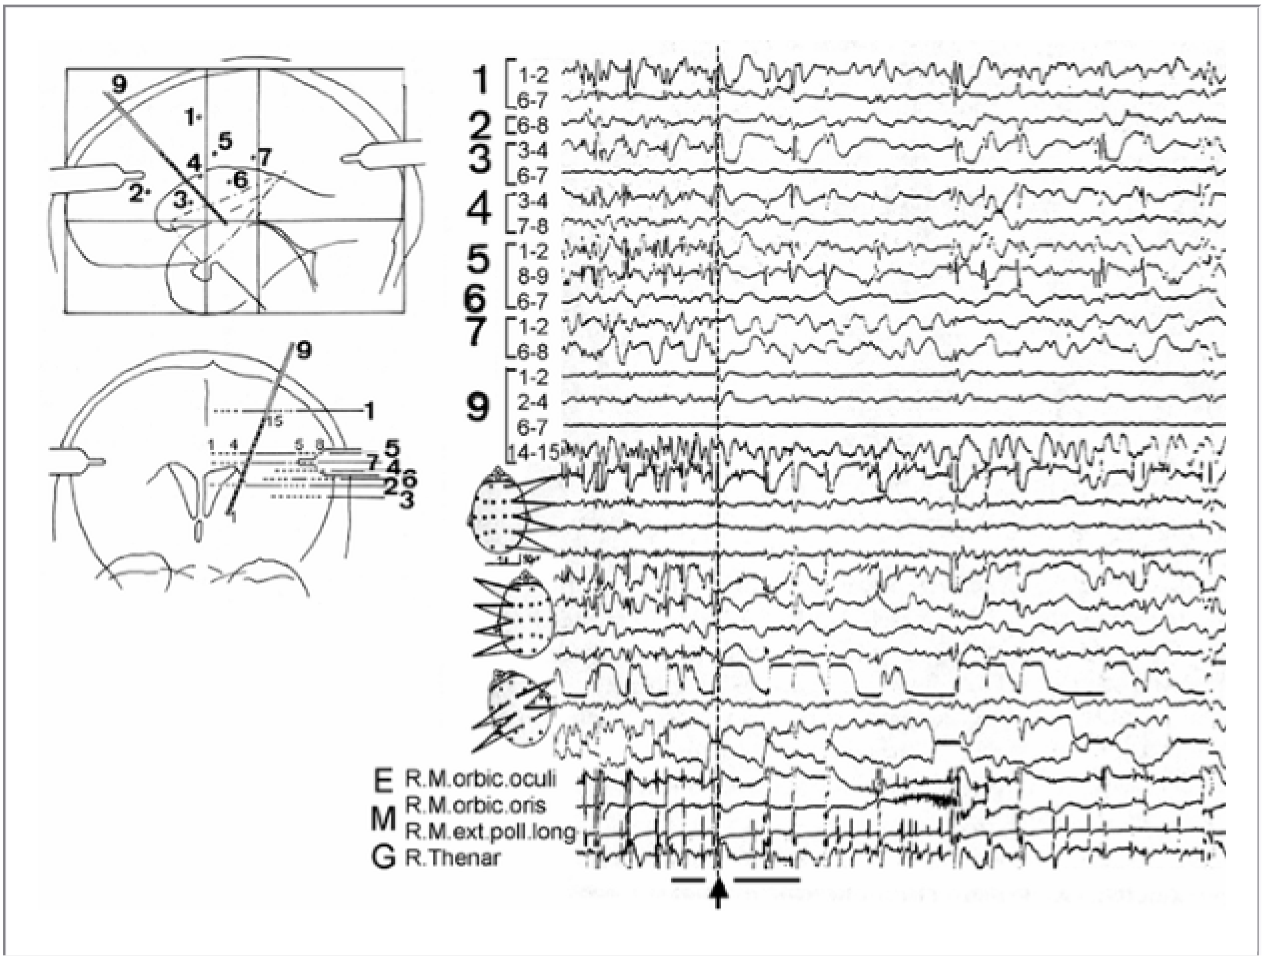

FIGURE 3. Stereo-electroencephalogram in a patient with epilepsia partialis continua recorded by eight left-hemispheric, 8-contact stereotactically inserted depth electrodes (of the "chronic" type) and by an additional rigid 15-contact electrode (#9) with its tip in the ventrolateral thalamus. Note the correspondence of left central spikes with the corresponding electromyographically (EMG) recorded muscle jerks and the different time scales (the paper speed was doubled at the time indicated by the vertical line). The patient underwent thermocoagulation of the ventrolateral thalamus with initially good, but in the long-time course moderate, therapeutic effect (follow-up >20 years; no definitive histologic diagnosis).

Clinical Features

Ictal Signs and Symptoms

SPSE can be described from a practical standpoint within the following categories[91]:

1. Somatomotor SPSE, which, according to Passouant et al.,[186] accounts for approximately two thirds of all cases of partial SE occurring in known epileptics. Somatomotor SPSE can be further divided into the following categories:

    a. One subtype that occurs during the course or at the onset of somatomotor partial epilepsy, that is, somatomotor SPSE stricto sensu.
    b. Epilepsia partialis continua (Kozhevnikov).
    c. So-called somatomotor SPSE accompanying severe brain lesions in nonepileptics ("initial myo-clonic phase of interterritorial infarction with PLEDs"[91]).
    d. Another special subtype, adversive SPSE, in particular, the oculoclonic form.
2. The less frequent sensory SPSE can be divided into the following subtypes:
    a. SPSE with dysesthesia
    b. SPSE with visual phenomena
    c. SPSE with acoustic phenomena
    d. SPSE with olfactory or gustatory phenomena
    e. SPSE with vertigo
3. SPSE with autonomic phenomena, with a special subtype in children—abdominal SPSE—might be classed separately.
4. Dysphasic or aphasic SPSE may be divided into intermittent versus continuous and into receptive ("fluent aphasia") versus expressive ("aphemia") types. The Landau-Kleffner syndrome and CSWS are sometimes listed in this context. Whether this is appropriate is a matter of controversy. Arguments against it are that the core symptoms do not immediately resolve after cessation of seizures and disappearance of spikes.
5. French authors also have used a category *erratic*. Other rare manifestations of SPSE and boundary conditions can be subsumed under this category.
6. Finally, we have SPSE with psychic and emotional phenomena.

Somatomotor SPSE is characterized by frequently repeated typical somatomotor seizures with or without jacksonian march and with more or less pronounced EEG discharges in the rolandic region. Consciousness is well preserved, and there are no marked vegetative signs. EPC is a particular subtype with localized segmental myoclonus.

Adversive SPSE is briefly reported by a few authors[43,209] but might be exceptional if we exclude cases with secondary generalization and tonic status with predominantly unilateral seizures and accompanied by head and eye turning. *Oculoclonic SPSE* with occipital discharges and *epileptic nystagmus*[87,93,236] and *palatal tremor*[168] are other rare manifestations of motoric phenomena of SPSE.

Epilepsia partialis continua is characterized by almost continuous, rhythmic muscular contractions affecting a limited part of the body for a period of hours, days, or even years. The myoclonic jerks have a frequency of about 1 to 2 per second and may persist during sleep.[22,193,287] About 60% of the

patients exhibit other types of seizures in addition to an EPC,[53] such as secondary generalized seizures and complex partial seizures. In addition to muscle twitching, patients may show varying degrees of muscle weakness, sensory loss, or stretch reflex changes.

The presentation of the disorder depends on the underlying cause (see section Etiology). Patients with localized neoplastic, vascular, or infectious brain lesions may have neurologic deficits and isolated seizures prior to the onset of the focal SE.[19] With metabolic causes, however, such as nonketotic hyperglycemic diabetes mellitus, or hypersensitive reactions to certain drugs such as penicillin or metrizamide, the onset of focal SE is sudden.[219]

In the Russian patients, the epilepsy usually developed 3 to 4 months after a febrile illness, associated with a hemiplegia or monoplegia in 30% of cases. In this condition, the jerks typically affect agonist and antagonist muscles with a rhythmic quality, in short bursts of 1 to 2 seconds' duration alternating with quiescent phases 2 to 4 seconds long, persisting in sleep and worsened by action or stress. Motor seizures with jacksonian march or generalized epileptic seizures are almost invariable accompaniments, although they have a strong tendency to improve over time. The jerking, often highly focal, continues relentlessly for years. Sensory symptoms occur in about one fifth of cases, and 80% have a persisting hemiparesis. EPC associated with Rasmussen encephalitis manifests itself in children in the majority of cases (mean age 6.8 years, with 85% being <10 years of age). All children present with epileptic seizures, often generalized tonic–clonic, although focal simple or complex partial seizures also occur as a first manifestation of the disease. In Rasmussen encephalitis, about one half of the patients exhibit episodes of EPC, usually within 3 years of onset with epilepsy. These episodes last hours to years and are often discontinuous. The condition is progressive, and after a highly variable period of 3 months to 10 years, fixed focal deficits develop, notably hemiplegia, hemianopia, and (depending on the hemisphere) aphasia, as well as progressive intellectual impairment. After an initial progressive course in which the focal motor seizure activity is often multifocal, the disease process appears to eventually burn itself out, at least in a substantial proportion of Rasmussen encephalitis patients.[162]

With regard to localization, EPC is a particular form of rolandic partial epilepsy that involves the motor strip of one hemisphere and usually has a clinically localized appearance. In Rasmussen encephalitis, the disease process seems to be more widespread, with diffuse patchy inflammatory changes in the cortex and white matter (microglial nodules, perivascular cuffs of small lymphocytes and monocytes, multifocal neuronal loss, and some spongy degeneration) depending on the features of the disease activity. (See also Robitaille,[208] who classified the Montreal specimens into four groups of disease activity.)

Current views are that the physiologic characteristics of the jerks in most cases of EPC are identical to those of cortical myoclonus (see section Pathophysiology). The myoclonic jerks in EPC can affect any muscle group. They may be confined to a single muscle or muscle group or they may be widespread. Face, upper limb, and trunk predominate. The distribution of jerks can vary over time. Agonists and antagonists are affected together, and distal muscles are affected more often than proximal ones. Isolated clonic twitching of the abdominal muscles due to a metastatic cortical lesion and considered as a rare manifestation of EPC has been described.[78] Jerks are unilateral. Bilateral cases have been included,[141,249] but it is questionable whether such cases should be described within the category called EPC. Takahashi et al.[245] studied EPC of childhood involving bilateral brain hemispheres; Ashkenazi et al.[16] described a bilateral focal motor status epilepticus with retained consciousness after stroke; and Lim et al.[140] described a generalized myoclonus evolving into EPC due to a cingulate gyrus venous angioma.

Familial alternating EPC with chronic encephalitis as another variant of Rasmussen syndrome has been described by Silver et al.[233]

Sensory SPSE was described by Scott and Masland[222] as a possible "continuous symptom" based on the notion that such an “aura continua” reflects the intrinsic epileptogenic properties of an epileptogenic focus that remains “well controlled” without further recruitment, that is, without increase of the number of epileptically involved neurons. A hippocampal epileptic focus causing electrographic focal SE may be limited to a volume of <1 cm in diameter.[77,288] Metaphorically speaking, one assumes that the “critical mass” necessary for the spread of the discharge is not reached in such a condition. A pure sensory aura continua, or SPSE, is rare. Not infrequently, in our experience, it is seen in relation to a marked increase in antiepileptic medication, in particular, with drugs preventing spread, or after surgical removal of parts of the primary epileptogenic area mediating seizure spread along preferential pathways. Although pure *localized* (*or hemi-*) dysesthesia as a cortical phenomenon of ongoing ictal discharges is likely to exist, convincing evidence—support by clear-cut EEG findings—is scanty. *Unilateral symptoms* point to the contralateral postcentral area and include tingling, numbness, sense of movement or desire to move, somatic pain, heat or cold, electric shock, agnosia for a body part, and phantom sensation.[138,189,191,212,259,260,303] Bilateral somatosensory symptoms often affecting fingertips, feet, lips, or tongue (perioral region) point to the second sensory area localization (termination of the motor strip of the frontal parietal operculum and superior bank of the frontoparietal sylvian fissure).[191]

Pain as an epileptic aura[275] and painful epileptic seizures are uncommon but have been described.[232,297,303] Direct evidence that long-lasting pain is a special form of SPSE is scanty, but this possibility should not be discarded. Indeed, Seshia and McLachlan[223] reported two patients with long-lasting aura continua and “pain” (patient no. 1: 21 years old, with nose pain for 2 years; left temporal seizure origin; symptom abolished after surgery; without pathology in the resected tissue; patient no. 3: 43 years old, with epigastric pain; right temporal seizure origin; symptom abolished after surgery; glioma). Certain forms of pain per se might be closely linked to epileptic basic phenomena,[82] and the positive therapeutic effect of antiepileptic drugs in such circumstances is well known. The so-called abdominal aura continua (abdominal epilepsy, recurring abdominal pain) has been described, particularly in children,[153,192,217] and has been found to be associated with amygdalar discharges.[76]

Hemicrania epileptica is a rare ictal phenomenon[116,292] (for a review, see Andermann and Lugaresi[8]), which may last >30 minutes and, therefore, can then be labeled as a form of SPSE.

Gastaut reported *simple partial status epilepticus with elementary visual phenomena only*,[91] and Sowa and Pituck described prolonged complex visual hallucinations.[239] FIGURE 4 gives an example of this type of SPSE. *Status epilepticus amauroticus* was described by Ayala[18] and Barry et al.[24] Hadjikoutis and Sawhney[105] described a case with occipital seizures presenting with bilateral visual loss. Ictal visual hallucinations with reversible postictal hemianopia with anosognosia have been reported by Barry et al.[24] and Spatt and Mamoli.[241] Sheth and Riggs[226] reported an unusual case of a clinically silent occipital electrographic SE persisting for >3 years in a 13-year old girl. Calcarine and pericalcarine occipital cortex are the principal localizations.[213,216]

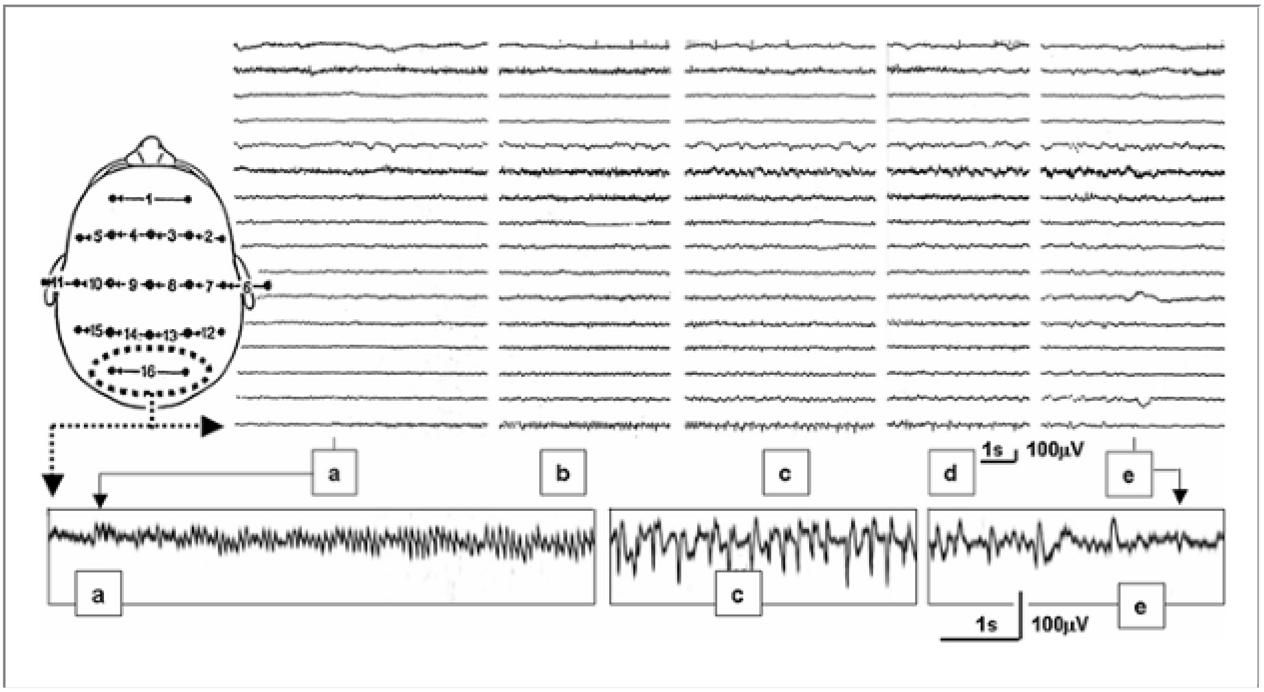

FIGURE 4. A very localized posterior simple partial seizure with elementary visual hallucinations (flickering lights) during simple partial status epilepticus (SPSE) with frequently recurring seizures of this type. This patient had a history of occipital venous thrombosis following a splenectomy at age 8 years (1963). After some initially generalized seizures, he developed severe drug-resistant partial epilepsy with frequently recurring psychomotor seizures. He underwent presurgical evaluation with stereo-electroencephalogram (SEEG) (with electrodes in the occipital and temporal lobes) in January 1980 and underwent selective amygdalohippocampectomy in March 1980 because his seizures originated at these structures. Postoperatively the patient was seizure free with the exception of two grand mal seizures during a safari in Africa. In the last months of 1994, during slight reduction of antiepileptic drug monotherapy, he experienced "funny flickering lights" similar to what he had had before operation as one of several aura symptoms. Although no headache was associated with the SPSE, he was believed to suffer from migraine and referred for a control with EEG, which showed the epileptic nature of his visual disturbances. He responded well to an increase of the dose of his carbamazepine treatment, without further disturbances of this type during more recent years.

Simple partial status epilepticus with auditory hallucinations only has been observed[277] but was published under the heading CPSE. This because the SPSE with stereo-EEG–documented discharges restricted to Heschl's gyrus and accompanied by musical hallucinations (the patient experienced a song well known and familiar to her) in "endless repetition"

finally spread to the ipsilateral mesiobasal limbic structures, resulting in alteration of consciousness. FIGURE 5 illustrates the onset of this electrical status activity that was accompanied at the beginning by musical hallucinations only. Schiffter and Straschill[218] reported on a case with aura continua musicalis. Most cases with simple auditory hallucinations described in the literature, however, do not fulfill the criteria of an aura continua.[123,190] Blanke et al.[30] described a patient with epilepsy (secondary to left parietotemporal brain damage) suffering from the paroxysmal unilateral experience of hearing a person in her near extrapersonal space associated with a deficit in spatial auditory perception and other paroxysmal disorders of somatognosia.

Simple partial status epilepticus with *olfactory symptoms* is rare but has been documented.[279] FIGURE 6 gives an example of long-lasting kakosmia associated with fronto-orbital discharges. Jackson and Beevor[117] and Jackson and Stewart[118] reported olfactory sensations with the mesial temporal lobe ("uncinate fits"). Projection areas for olfaction include the anterior perforate, prepiriform and lateral olfactory gyri, amygdala, periamygdalar and entorhinal cortices, and septal nuclei as well as hypothalamus

"*Gustatory aura continua*" was the leading symptom of case 4 of the 1985 paper of Wieser et al.,[288] with electrical left hippocampal status activity in the EEG. The parietal operculum near insula and the anterior insula have been classically implicated in taste.[113,189] In our case, the gustatory SPSE was also associated with subtle higher cognitive deficits detected with a tachistoscopically presented lexical decision task (Figs. 7 and 8). Seshia and McLachlan[223] reported one pati-ent with long-lasting metallic taste for 2 years (patient no. 6: 46 years old; left temporal seizure origin; symptom abolished after surgery; oligodendroglioma) and another with foul taste for 5 years (patient no. 2: 34 years old; right temporal seizure origin; symptom abolished after surgery; mesial temporal sclerosis).

Whereas complex or simple partial seizures *with autonomic symptoms* as the leading feature are well known,[295] evidence is less convincing for SPSE with autonomic signs and symptoms only. An exception might be *umbilical sensations in children*[262] and autonomic seizures and *autonomic SE in Panayiotopoulos syndrome*.[178] In this syndrome with good prognosis, which is now recognized in the new classification scheme of the ILAE, seizures start with autonomic symptoms, mainly emesis, while the child is fully conscious. Half of the seizures last >30 minutes, constituting autonomic SE.[179]

Long-lasting borborygmi and long-lasting episodes with widened pupils (or hippus pupillae), pilomotor phenomena, goose-flesh, periodic shivering, and so on were described,[36,102,243,276,280,281,294,296] but often they were accompanied by certain peculiarities of personality and behavior, and, therefore, they were often described in the context of "limbic dyscontrol syndrome."[97,293]

Under the category *nonconvulsive status epilepticus*, Rabending and Fischer[203] described ictal bradycardia and asystole. Zijlmans et al.[305] determined the prevalence of heart rate changes and electrocardiogram (ECG) abnormalities during epileptic seizures in 281 seizures in 81 patients. ECG abnormalities were found in 26% of seizures (44% of patients), and long seizure duration increased the occurrence of ECG abnormalities.

P.713

P.714

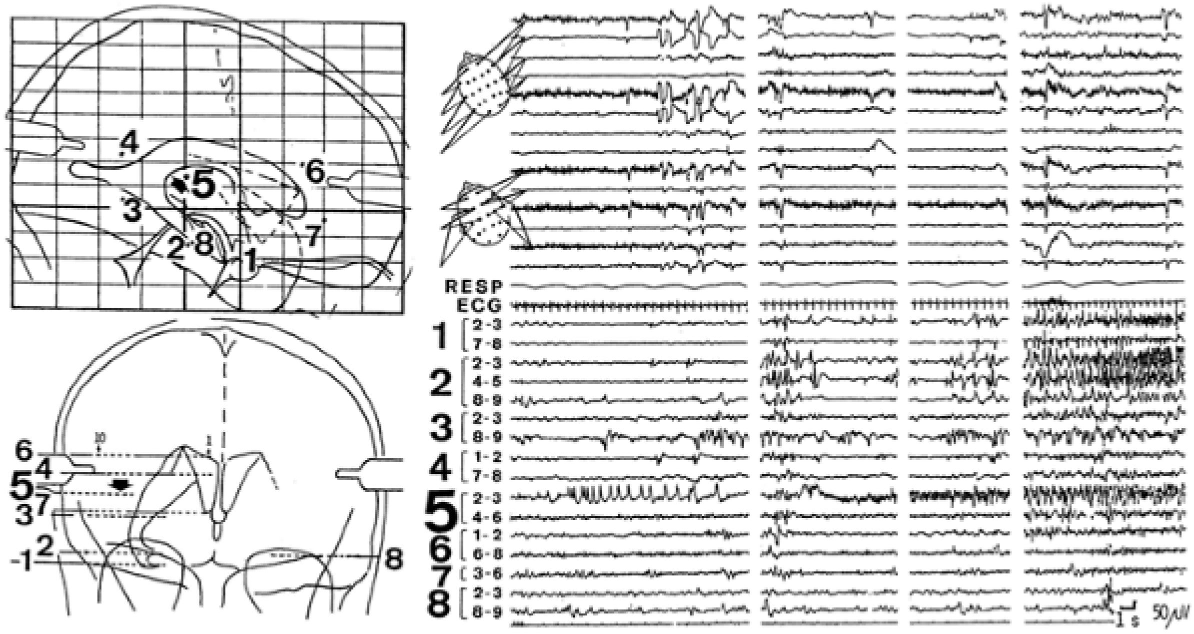

FIGURE 5. Onset of a partial status epilepticus with long-lasting discharges at the right gyrus of Heschl (5/2-3) and with subsequent spread to the right mesiobasal temporal lobe structures (hippocampal formation, 2/2-3; and amygdala, 1/2-3). At the onset of this electrical status activity this 22-year-old Portuguese woman experienced a hallucination of music (the Portuguese song “Santa Maria”) in “endless repetition.” Initially, she reported a “good quality of the record”; after 3 hours, the quality was reported to become worse and worse, with the voice of the singer ceasing and the drums becoming more prominent. Later, she entered a complex partial status epilepticus. (See detailed case report in Wieser.[277])

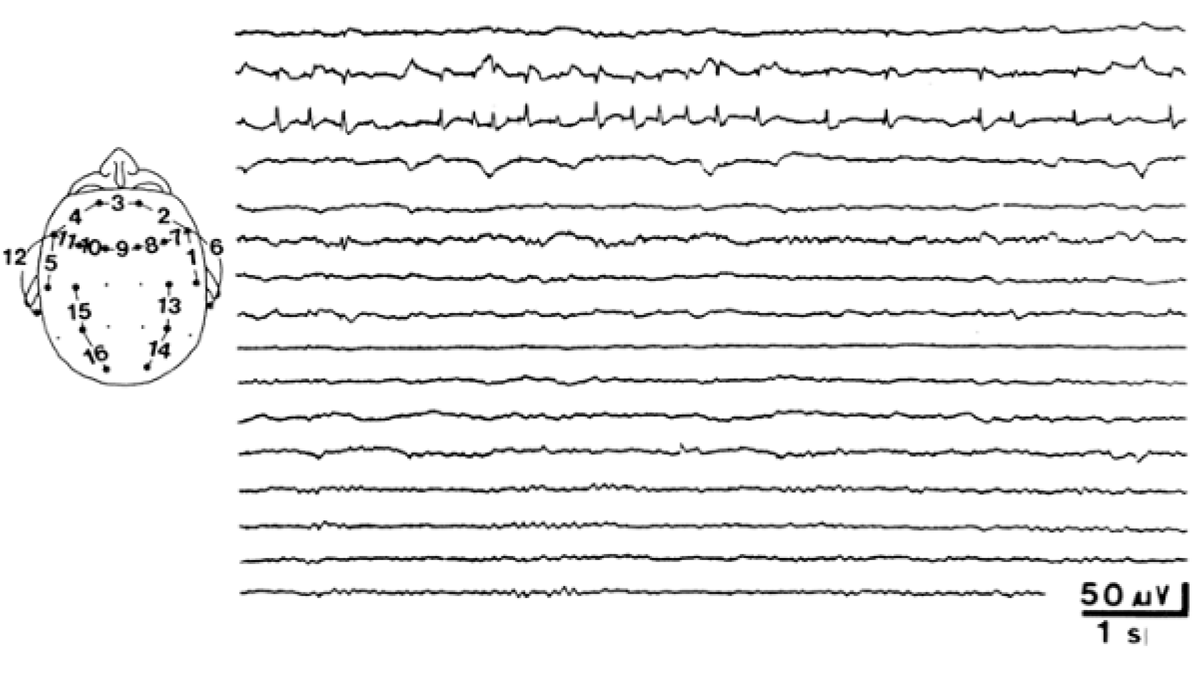

FIGURE 6. Surface electroencephalogram (EEG) in a 42-year-old man with a history of repeated simple partial status epilepticus with long-lasting kakosmia as the sole symptom. During such an episode, the EEG showed continuously repetitive spike discharges right frontal. Single photon emission computed tomography (Tc^{99m}-pertechnetate) revealed a hyperactivity right frontal. A tumor was suspected but could not be verified with computed tomography. There was good response to antiepileptic drug treatment. (For a more detailed case report, see Wieser,[279] pp. 79–80.)

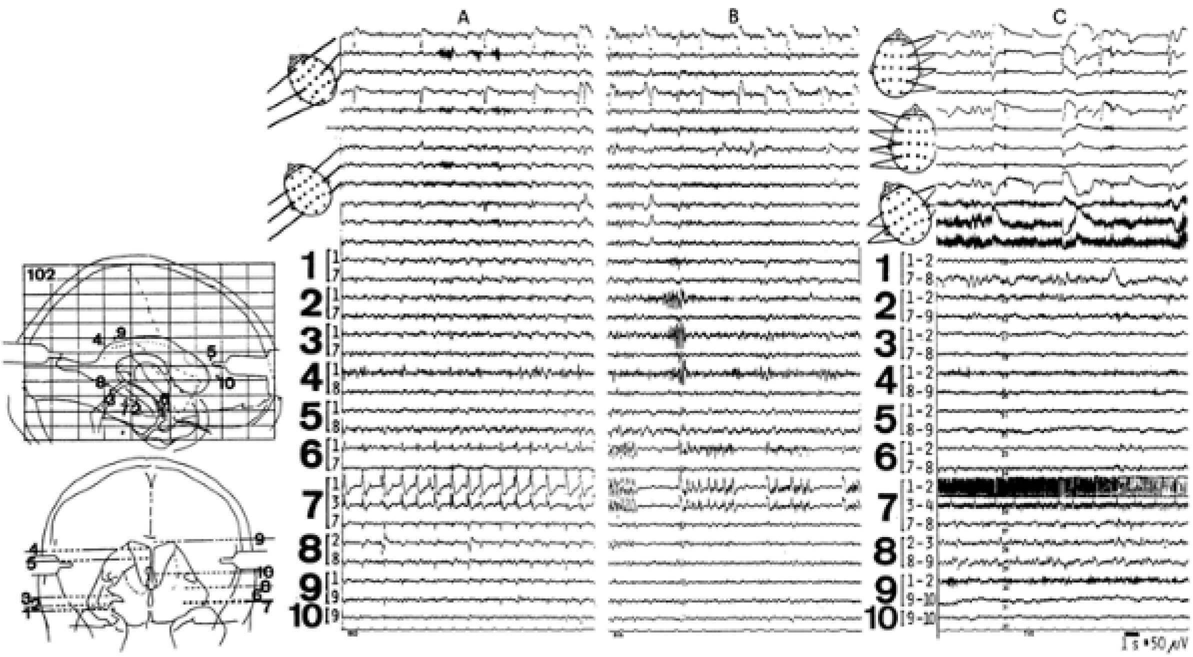

FIGURE 7. A left hippocampal electrical status activity (case no. 4 of Wieser et al.[288]). Combined surface and depth electroencephalogram (EEG) shows the epileptic discharge patterns of the left hippocampus (inner contacts of electrode 7) during the limbic status. **A, B:** Common average reference. Panel A shows a slow clonic and panel B shows a tonic–clonic discharge pattern. **C:** Bipolar surface and depth EEG recordings show tonic discharges in the left hippocampus. Note that the surface EEG does not pick up the hippocampal epileptiform activity. In panels A and B, there is moderate propagation to the homolateral amygdala (6/1-2), and this synchronized activity also affects the common intracerebral average reference, giving rise to some "erroneous" activity with opposite polarity in the scalp EEG, best seen in panel B (far left). (For a more detailed description, see Wieser et al.[288])

With regard to *SPSE with psychic and emotional phenomena*, we believe that autonomic phenomena usually are associated with overt or subtle behavioral changes, such as irritability, fear, panic, and sometimes existential emptiness or some other form of pathologic self-perception. Seshia and McLachlan's[223] aura continua patient (patient no. 5) suffered from epigastric fear for 8 years, which started after surgery (left temporal seizure origin; mesial temporal sclerosis).

Ictal depression and anxiety in temporal lobe disorders is frequent,[272] and *SPSE with fear as the outstanding clinical expression* was described by Henriksen[114] and McLachlan and Blume.[148] A large literature exists on this topic (for recent reviews see Smith et al.[235] and Trimble and Bolwig[255]). *Ictal aggression* seems to be rare.[65]

Limbic encephalitis may be associated with long-lasting, usually fluctuating signs and symptoms of disturbed self-perception, altered states of mood, emotion, and autonomous signs, and perturbations of higher cognitive functions,[124] not classed as SPSE. Pilomotor SE has been recently reported in a case with voltage-gated potassium channel antibody-positive, non-paraneoplastic limbic encephalitis.[296]

Dysphasic or aphasic SPSE is rare but well documented as the sole manifestation of focal status epilepticus.[52,69,70,103,108,110,127,163,185,201,204,256,258,266,273] A few cases were labeled as CPSE, although aphasia was reported as the sole manifestation.[70,127] In other described cases, persistent aphasia followed repeated partial seizures.[270] Dysphasic or aphasic SPSE is characterized by an episode of aphasia, sometimes associated with alexia and agraphia. Several subtypes have been identified, depending whether (a) receptive or expressive language is predominantly affected and (b) language recovers within short interictal intervals. If language recovers between the attacks, which recur every 2 to 3 minutes with aphasia of 10 to 20 seconds' duration, the true nature or even the disturbance itself might be missed. Most cases had left posterior temporal discharges[70] or seizure foci and presented with fluent (Wernicke type) aphasia,[127,237] but prolonged epileptic aphemia also has been described.[188] Kirshner et al.[126] described aphasia secondary to partial status epilepticus of the basal temporal language area. Single photon emission computed tomography revealed hyperperfusion in the left temporo-occipital[302] or left temporoparietal region.[139] It is fair to say, however, that in many of these cases the question remains open whether the persisting dysphasias were really ictal or were postictal.

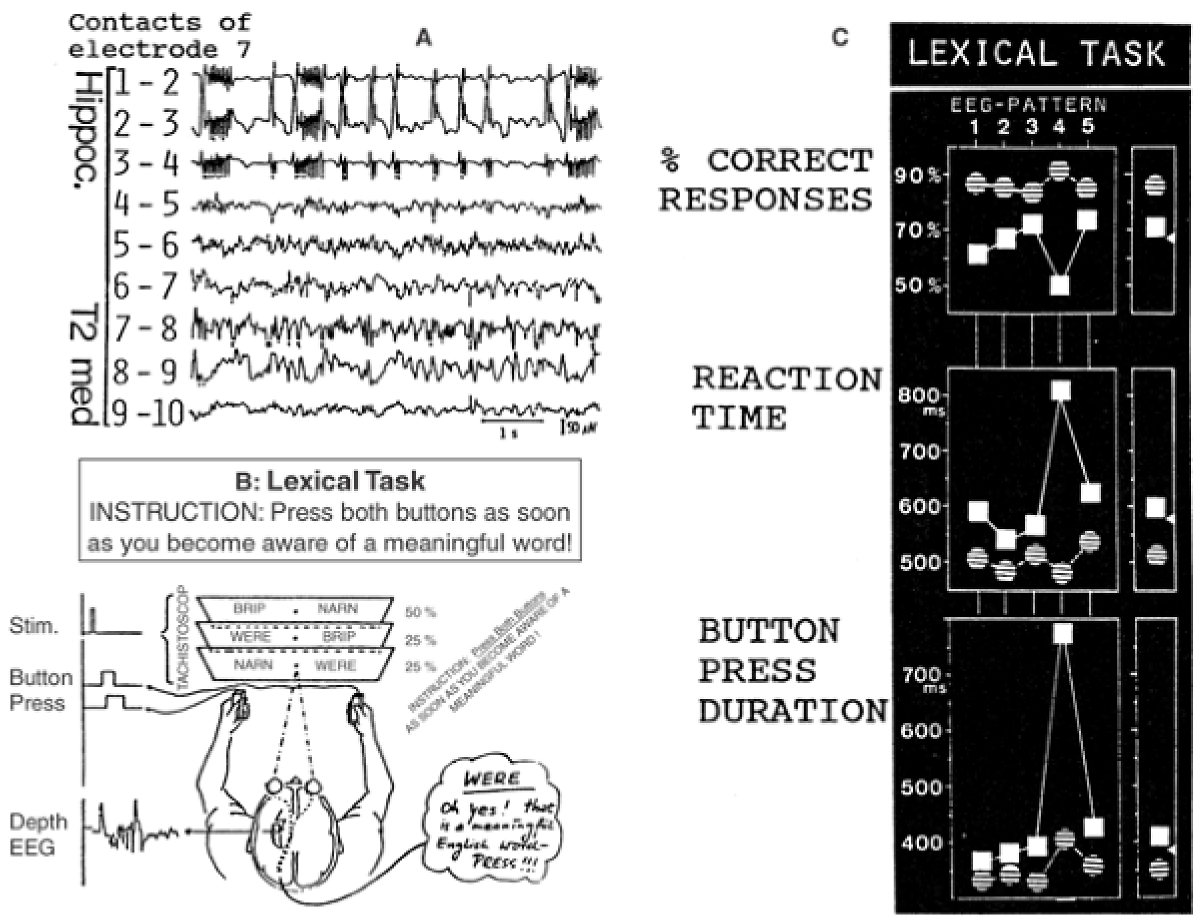

FIGURE 8. A: Bipolar derivations along the 10 contacts of electrode 7 (case no. 4 of Wieser et al.[288]) (see also FIGURE 7) of patient SEEG #102, showing that the epileptic discharge pattern is restricted to the left hippocampus (contacts 1–3) and illustrating the "tonic–clonic" electroencephalogram (EEG) pattern labeled 5 in FIGURE 7C. **B:** The test situation during the tachistoscopically presented lexical decision task. Fifty percent of the stimuli consist of two matched nonsense words (example: BRIP–NARN), and 50% of the stimuli pairs consist of a nonsense word and a matched meaningful high-frequency filler word, either in the left (25%) or in the right (25%) visual half-field (example: WERE). **C:** Results of lexical decision task of patient SEEG# 102 during left hippocampal status activity. Overall result (1–5, right) and breakdown according to the left hippocampal EEG pattern (1, normal and flat; 2, slow "clonic" sharp-waves <1/sec (see Fig. 7A); 3, fast "clonic" sharp-waves >1/sec; 4, high-frequency "tonic" spike discharge (as illustrated in Fig. 7C); 5, tonic–

clonic [as illustrated in Figs. 7B and 8A]). Note that the number of correct button presses during tonic discharges drops to chance level (50% correct responses) when stimuli addressed the left hemisphere with its hippocampus epileptically discharging (*white rectangle*, right visual half-field stimuli), whereas the percentage of correct responses to stimuli addressing the right hemisphere (*shaded circles*, left visual half-field) in general was high (87%) and even showed a kind of compensatory improvement during left hippocampal tonic discharges (EEG pattern 4). Measurement of reaction time and button press duration (mean of both hands) likewise resulted in a marked increase, but only for stimuli addressing the epileptically disturbed left hemisphere during tonic hippocampal discharges. The right column shows the mean of all stimuli. (For a more detailed analysis, see Wieser et al.[288])

According to the review of Beaumanoir,[27] overt SE of various types occurred in about 15% of children suffering from the syndrome of *acquired epileptic aphasia*.[135,300] In this disorder, aphasia develops in more or less tight correlation with usually left temporal focal high-voltage spike or spike-wave discharges,[181,231] with remarkable activation in slow-wave sleep, evolving then into continuous electrographic ("bioelectric") status. Overt epileptic seizures are manifest in only about 70% of cases and are usually mild. Although >200 cases have been reported,[230] the etiology, pathogenesis, and pathophysiology are unknown.[134] Family history is usually negative, and

P.715

children (male preponderance of about 2:1) have previously developed normally. Neuropathology findings consist of nonspecific gliosis (two lobectomy specimens[57]), encephalitis (one biopsy[144]), and isolated arteritis (four patients, angiographic findings[184]).

The similarities of the Landau-Kleffner syndrome with CSWS are obvious. Although in CSWS the EEG changes are essentially generalized, some authors have included cases in CSWS with relatively focal abnormalities. According to the review of Morikawa et al.,[161] CSWS is present in 0.5% (of 12,854) children with epilepsy, and about 20% to 30% have identifiable brain pathology (e.g., previous meningitis, birth asphyxia, cytomegalovirus infection), 3% have a family history of epilepsy, and 15% have a history of febrile seizures.

Diagnosis

Essential Clinical Features

The diagnosis of SPSE should be made only if clinical signs and symptoms that last for >30 minutes are accompanied by clear-cut localized epileptiform discharges in the corresponding brain region. In an operationally defined sense, consciousness must be retained. Symptoms and signs are manifold[64,73,96]

P.716

and can combine, although often they consist of localized somatomotor symptoms. Isolated sensory symptoms are less frequent.

Electroencephalography

Not infrequently, the conventional scalp EEG is uncharacteristic or even normal. If it is abnormal, the EEG in SPSE may exhibit localized high-frequency "tonic" discharges, but more often the epileptiform discharges consist of rhythmic clonic patterns with sharp-slow-wave complexes of about 0.3 to 3/sec with a peak about 1/sec. Waxing-waning, as well as paroxysmal pattern changes ("paroxysmale Umschaltungen"[196,282]), can occur. Waxing-waning may be seen not only in terms of time (i.e., appearance and disappearance, or at least amplitude reduction, of epileptiform patterns), but also in terms of enlargement and diminution of the epileptogenic area (i.e., the volume). Both phenomena might be interrelated and most probably are a function of the specific properties of the neuronal population pathologically recruited into the epileptiform discharges. Specific seizure-suppressing maneuvers might exert a recognizable effect on the formal aspects of the EEG discharges.[277,286]

Prolactin, Luteinizing Hormone, and Creatine Phosphokinase in Blood

These were reported to show a good correlation with seizure frequency,[26,137] and it has been suggested that an increase in prolactin would be helpful for the diagnosis of epileptic seizures and SE. Further studies, however, have shown that the absence of elevated prolactin levels does not exclude SE—not even grand mal status, and certainly not SPSE, CPSE, or absence status.[80,251] Therefore, prolactin, luteinizing hormone, and creatine phosphokinase do not contribute much to the diagnosis of SPSE.

Diagnostic Workup of Simple Partial Status Epilepticus and Epilepsia Partialis Continua

Every case with SPSE and EPC requires a general medical and neurologic evaluation to search for a metabolic or hereditary disorder and a structural imaging with magnetic resonance imaging (MRI), which often reveals a brain lesion. Functional neuroimaging with SPECT, PET, or functional MRI (fMRI) may be helpful (Fig. 9).[306] The EEG may show focal spikes and slowing, but there are no characteristic EEG patterns that aid in diagnosis. In EPC cases without a conclusive EEG, the back-averaging technique may help to identify the spikes preceding the myoclonus. In Rasmussen encephalitis, the documentation of a progressive atrophy of usually one hemisphere is important. A moderately to severely abnormal EEG with progressive slowing and spiking is the rule. It is important to note that in Rasmussen encephalitis, cerebrospinal fluid (CSF) may be abnormal with elevation of protein and lymphocytes, but a normal CSF does not rule out the presence of Rasmussen encephalitis.

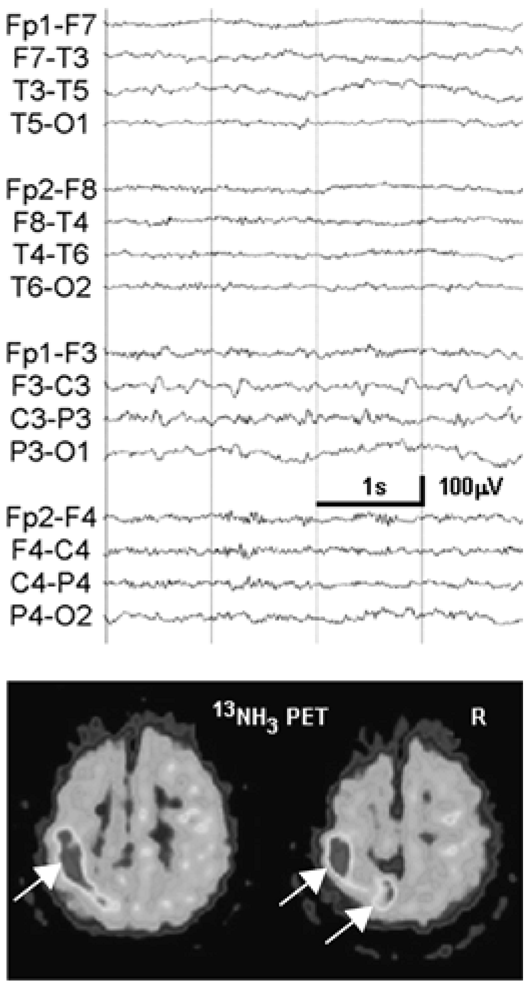

FIGURE 9. $^{13}NH_3$ positron emission tomography (PET) and conventional electroencephalogram (EEG) (performed within 4 hours of each other) in a 25-year-old woman with a 2-year history of epilepsia partialis continua (EPC) due to histologically proven Rasmussen encephalitis with mild right spastic hemiparesis with rhythmic jerks of about 2/s. Note the periodic sharp wave complexes at C3 and the corresponding PET focus (*arrows*). A focal cortical resection of the left sensorimotor hand area, which showed continuous ictal discharges at intraoperative electrocorticography, was performed, which

aborted EPC but not isolated focal seizures. (For details, see Zumsteg et al.[306])

Kim et al.[125] studied seven children with Rasmussen syndrome in a prospective longitudinal MRI study with three to eight MRIs per patient performed between 12 months before and 9 months after the onset of EPC; the most common region of initial MRI signal change was the frontocentral region (six patients). From their findings of three patterns of neuroimaging abnormalities, they concluded that the differences in these neuroimaging patterns might reflect inherent differences in the pathogenesis of Rasmussen syndrome. MR spectroscopy in patients with EPC revealed increased ratio of lactate to creatine and reduced ratio of *N*-acetyl-aspartate to creatine in the affected hemispheres.[182]

Differential Diagnosis

Differential diagnosis of SPSE might be difficult, even in *somatomotor SPSE*, if the surface EEG does not show corresponding epileptiform abnormalities. A variety of disorders, such as endocrine (hypoglycemia, porphyria), cardiac, cardiovascular, and gastrointestinal disorders and carcinoid, pheochromocytoma, limbic encephalitis, panic attacks, and paroxysmal autonomic dysfunction, have to be considered.

As has been repeatedly reported, very circumscribed epileptogenic generator zones in the depth of the rolandic fissure might escape detection in the routine scalp EEG, despite a clear-cut cortical origin of epileptiform spikes that correlate well with the myoclonic jerks when intracranial (i.e., subdural or intracerebral depth-electrode recordings) and special back-averaging techniques are employed.[287] In other cases with a more favorably located generator zone, the temporal relationship between cortical frontorolandic spikes and the

myoclonic jerk can be extremely intimate and convincing.[278] A corresponding slow-wave focus might be demonstrated with mapping techniques.[289]

Subcortical as well as *spinal myoclonus* and certain tremor forms must be excluded by special neurophysiologic examinations. As already mentioned, in *EPC*, the two types 1and 2 should be differentiated. Careful examinations are necessary in type 1 EPC with a view toward the detection of a lesion amenable to successful curative surgery. EPC of the abdominal muscles may pose diagnostic difficulties.[78]

In EPC, the differential diagnosis depends on its definition. If the diagnosis of EPC is based on the presence of cortical myoclonus, the diagnosis requires electrophysiologic verification. If the diagnosis of EPC is based on the clinical appearance alone, a differentiation between cortical and subcortical origin is not possible. Rasmussen encephalitis is usually considered a distinct syndrome from Kozhevnikov EPC. Fifty percent of Rasmussen encephalitis patients exhibit EPC.

A major step in the diagnosis of EPC is to differentiate between type 1 and type 2.[20] These two clinical forms differ by their clinical signs, EEG patterns, and mode of evolution. Type 1 may start at any age, and its clinical and EEG characteristics are more focal and unilateral. Background EEG is generally unaltered. Myoclonus is limited to a group of muscles, but it may spread to neighboring muscles and even initiate a simple and then a complex partial or a secondary generalized seizure. Type 2 is much more variable; myoclonus is often multifocal and bilateral, and multiple seizure types may be seen. Background EEG is slow; its characteristics evolve rapidly with time, with extensive paroxysmal activities and frequent subclinical ictal discharges. The delay between the first seizure and the onset of myoclonic jerking is shorter in type 2 than in type 1. Seizure frequency is higher in type 2 than in type 1. Progressive neurologic deficit (at least hemiparesis) and neuropsychological impairment with evolution occur in type 2; deficit, if any, is stable and depends on etiology in type 1. Type 1 corresponds to a local and nonprogressive lesion in or near the central cortex. Type 2 is part of the clinical manifestations of a progressive inflammatory lesion of the central nervous system (CNS), typically in Rasmussen encephalitis.

It is generally accepted that EPC may be associated with focal, multifocal, and diffuse brain lesions and may include numerous syndromes (see section Etiology). For the differential diagnosis of EPC, the age of the patient should be considered and whether EPC occurs as the first clinical manifestation. In *children*, besides Rasmussen encephalitis, the other main causes for an EPC are as follows: (a) infections, such as subacute measles encephalitis, viral encephalitis or meningoencephalitis, or infective granuloma[15]; (b) developmental malformations, such as cortical dysplasia (see Chapter 259); (c) genetic causes, such as mitochondrial cytopathies, in particular mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episode (MELAS),[9,12,41,156,265] or mitochondrial encephalopathy with ragged red fibers and MELAS plus syndrome[195] (see Chapter 262); (d) metabolic causes, such as nonketotic hyperglycemia and diabetic ketoacidosis (see Chapter 267); and (e) gliomatosis cerebri (see Chapter 264).[224]

In *adults*, EPC is most frequently related to cerebrovascular diseases (embolic or thrombotic ischemic stroke, cerebral venous thrombosis, cerebral hemorrhage, arteriovenous malformations) and tumors (metastatic tumors, gliomas). Less frequent causes are metabolic disturbances, such as diabetic ketoacidosis, nonketotic hyperglycemia,[55] particularly nonketotic hyperglycemia associated with hyponatremia,[234] renal and hepatic encephalopathy,[160] and cortical dysplasia.[62,68,150,165,169] EPC has also been observed with multiple sclerosis.

EPC as the first clinical manifestation has been described in progressive cerebral degeneration of childhood with liver disease (Alpers Huttenlocher disease),[298,299] with cytochrome oxidase deficiency,[299] as well as in a patient with a missense mutation in the mitochondrial DNA CO I gene encoding the cytochrome c oxidase subunit I[264] and in association with a homoplasmic mitochondrial tRNA [Ser(UCN)] mutation.[220] EPC also has been observed as a new manifestation of anti-Hu–associated paraneoplastic encephalomyelitis,[200,225] in Creutzfeldt-Jakob disease,[136,183] and following bone marrow transplants.[14] It was observed as an atypical presentation of cat scratch disease,[170,202] in association with type 1 diabetes mellitus and elevated anti-GAD65 antibodies,[173] in ketotic and nonketotic hyperglycemia,[198,215] and in HIV-infected patients.[25,79] Kufs disease has also presented as late-onset EPC.[85] EPC has also been found in progressive multifocal leukoencephalopathy as a motor cortex isolation syndrome[28] and in benign epilepsy of childhood with centrotemporal spikes. Metrizamide, penicillin, and azlocillin-cefotaxime may also induce this disorder.[219]

Due to its typical course, the *diagnosis of Rasmussen encephalitis* is usually not too difficult in latter stages but might be difficult at the beginning.

Somatomotor SPSE in nonepileptics often accompanies severe brain lesions and very often represents, at least in the elderly, the "initial myoclonic phase of interterritorial infarction,"[91] usually associated with PLEDs in the EEG.[86] Restless leg syndrome and other periodic movements during sleep might require video monitoring and polygraphic night sleep recordings.[157]

The *dys-/aphasic SPSE* is more difficult to diagnose if it presents in the intermittent form with recovery of speech between seizures. The *Landau-Kleffner syndrome* has similarities with CSWS and other syndromes of "bioelectric status."

Sensory and autonomic SPSE expressing itself with strange and unusual phenomena might be difficult to diagnose in the absence of clear-cut EEG findings. As discussed and illustrated in previous sections, convincing ictal discharges are frequently not seen without intracranial recordings, and such invasive techniques, of course, are justified only in the context of epilepsy surgery. Particular problems are represented by long-lasting autonomic phenomena and peculiarities of behavior and personality in which the mesial temporal lobe and insular cortex are candidate areas for suspected discharges. Discharges at such a location are difficult to detect in routine scalp EEG. Whereas humoral changes—in particular, prolactin—are not very helpful in such conditions for differentiating SPSE of these types from psychiatric disorders or from other nonepileptic neurologic disorders, PET and SPECT might significantly contribute to the correct diagnosis; for example, SPECT can be extremely helpful in separating the focal status from nonepileptic conditions.

CPSE and prolonged postictal confusional states are by definition easily differentiated from SPSE because of altered consciousness. Nevertheless, there exist convincing SEEG-documented cases, including our observations, with prolonged focal "afterdischarges" in some brain regions following well-elaborated seizures in whom "postictal" confusional status or only "minor symptoms" persist because of ongoing focal electrical status activity.[280]

Epileptic behavioral disturbances and psychosis-like states might sometimes be due to prolonged seizure discharges.[293] Usually, epileptic psychosis is classed into ictal, postictal, and interictal categories, each with distinctive features.[255] Whereas the postictal psychosis is, as a rule, associated with delirium, altered consciousness, and amnesia, the interictal psychosis is characterized by clear consciousness, retained memory, and less severe behavioral disturbances. The ictal psychosis with fluctuating or frequently recurring focal electrographic epileptic discharges arising in temporal or extratemporal regions pres-ents most often as a confusional state with variable productive (i.e., “positive”) signs and symptoms. Extratemporal—in par-ticular, frontal—focal status has less cycling symptomatology,

and confusion is less pronounced in comparison with limbic (psychomotor) SE.[123] Fronto-orbital polar status epilepticus may be particularly “poor” in clinical symptoms.[290]

Response to Treatment

In general, response to high-dose antiepileptic drug (AED) treatment can be used in the differential diagnosis, but there are well-documented cases in which classic AEDs of first choice, such as diazepam, did not completely suppress the localized discharges associated with SPSE.[277] In addition, there is the problem that diazepam can also arrest nonepileptic signs and symptoms, particularly psychiatric ones. EPC and somatomotor SPSE associated with PLEDs and severe vascular brain damage are known to respond only moderately, if at all, to AEDs. If hyperglycemia is the reason for EPC, it can be stopped by insulin.[132] Rasmussen encephalitis associated with EPC almost never can be controlled by available AEDs, but was reported to respond to plasma exchange (see earlier discussion) and to immunoglobulin therapy.

Focal SE, according to the literature,[230] is controlled by *diazepam* in 88% of 67 patients. Lorazepam and midazolam, an imidazobenzodiazepine, are considered AEDs of first choice. Midazolam is short acting and, therefore, can be well titrated on prolonged infusion. The recommended regimen is for one or two bolus injections of 0.1 to 0.3 mg/kg followed by an infusion of 0.05 to 0.4 mg/kg per hour. Mild bradycardia and a slight fall of arterial blood pressure may occur at conventional doses. Apnea has not been reported in SE, but this is clearly a potential risk because in anesthetic practice with higher doses for the induction of anesthesia, apnea occurred in 10% to 77% of patients (71).

Treatment of Epilepsia Partialis Continua

Treatment of EPC should concentrate on the underlying cause when possible. The management of iatrogenic and metabolic disturbances is apparent.[132] The major antimyoclonic drugs are piracetam, valproate, ethosuximide, and benzodiazepines (clonazepam). AEDs such as sulthiame and carbamazepine may be effective in treating EPC associated with benign childhood epilepsies and centrotemporal spikes. Other causes of Bancaud type 1 EPC tend to be refractory to AEDs. In single case reports, therapeutic success was achieved by nimodipine, a calcium-channel blocker,[33] and clonazepam.[219] In addition to conventional AED therapy, steroid administration may be indicated in EPC. In Cockerell's study of 36 patients, EPC resolved in 4 patients and persisted in the remaining 32. In cases with Bancaud type 1 EPC and a lesion, the appropriate therapy is surgical excision of the structural lesion. When the epileptogenic region involves the primary motor cortex, multiple subpial transection may be an option. Multiple subpial transection can eliminate seizures without inducing severe additional neurologic deficit.[155,159,187,242] Repetitive transcranial magnetic stimulation has been tried in an attempt to dampen hyperactive cortical regions in EPC.[98,151,158]

In Rasmussen encephalitis, many authors consider functional hemispherectomy as the only effective treatment (hemispherotomy[269]). Usually, however, it is only performed at a relatively late stage, that is, not before a hemiparesis already exists. Lozsadi et al.[144] used botulinum toxin A to improve involuntary limb movements in Rasmussen syndrome. Based on the assumption that the cause of Rasmussen encephalitis is either infective, probably viral, or the result of an autoimmune process, ganciclovir, zidovudine, high-dose interferon, high-dose steroids and immunoglobulins, and plasmapheresis have been tried. A beneficial influence of plasmapheresis observed in two studies[11,211] led us to introduce a combined treatment with plasmapheresis and CSF filtration in two patients with some initial but no long-lasting effect.[291]

Antozzi et al.[13] reported that long-term selective immunoglobulin G immunoabsorption improves Rasmussen encephalitis; Dabbagh et al.[61] were able to stop seizures by intraventricular interferon-alpha in one case of Rasmussen encephalitis. In the case of Olson et al.,[173] with the diagnosis of type 1 diabetes and anti–glutamic acid decarboxylase 65 antibodies in serum and cerebrospinal fluid, antiepileptic agents did not improve seizures, but high-dose steroids, plasmapheresis, and intravenous immunoglobulin resulted in decreased anti–glutamic acid decarboxylase 65 antibody levels and resolution of seizures.

When the diagnosis of Rasmussen encephalitis is being considered, it is important to rapidly exclude other causes of EPC. Although there are no good data from randomized trials of different immune-related therapies, treatment with immunoglobulin G (IgG), steroids, or plasmapheresis is advocated as first-line therapy. It is not unreasonable to institute at least two treatment options (e.g., IgG followed by plasmapheresis) if response to the first treatment is poor.[60,99]

Prognosis and Complications of Epilepsia Partialis Continua

The long-term prognosis of EPC depends on the underlying disorder. When it appears early in the course of a metabolic disturbance, the condition may be benign. Iatrogenic EPC induced by certain antibiotics and metrizamide disappears with removal of the offending agent. EPC associated with benign childhood epilepsy syndromes with rolandic foci usually responds to treatment with AEDs. EPC due to Rasmussen encephalitis has an almost invariably poor outcome with respect to the function of the affected hemisphere. There seems to be a progressive phase (mean of 5.3 years in one series of 48 patients), and the condition then becomes static.[172] Death is exceptional because eventually the condition stabilizes, although with severe disability. In many cases with EPC due to Rasmussen encephalitis, a functional hemispherectomy is the only effective treatment option. In a few exceptional patients, the EPC disappeared after some months to years, suggesting that the disease can "burn out." These few observations are in opposition to the opinion that in very rare cases Rasmussen encephalitis may also affect the opposite hemisphere (see Chapter 243).

Other forms of EPC, although not progressive, also usually respond poorly to AED medication but may disappear with time or resolve with surgical excision of a focal lesion. There may be associated weakness in muscle groups involved in the clonic activity, which can persist when the EPC abates. It is unclear to what extent this is due to the persistent epileptic discharges and to what extent the residual neurologic deficit is due to the underlying lesion. In the retrospective series of Thomas et al.[249] of 26 patients with EPC of various causes, 11 patients were alive and 15 had died after a follow-up of 1 to 18 years. Outcome was largely determined by the underlying cause, and seizures were more likely to remit in patients with stroke or other acute insults than in encephalitis cases.[249]

In contrast to convulsive generalized SE and various other age-dependent syndromes of SE in neonates and in childhood, morbidity and mortality are low in nonmotor SPSE of the adult. In *nonmotor SPSE*, there is no mortality, and there is no convincing evidence that this condition results in secondary brain damage. This contrasts with psychomotor status, in which the situation is less clear. Although most reported cases with psychomotor status have returned to baseline

P.719

neurologic function,[54,147] several well-described patients have had prolonged memory deficits.[75,254] Patients with electrographic SE in the setting of serious medical illness have a poor prognosis, but this is due most often to the underlying serious cerebrovascular or other medical illnesses.[4,121] In SPSE with EPC type 2 (Rasmussen encephalitis) and the initial myoclonic phase in severe brain damage and in the elderly, associated with PLEDs, the prognosis is usually poor. Long-term follow-up of 1 to 18 years in EPC revealed that 58% of patients had died, and the survivors had severe neurologic deficits: 96% had severe unilateral weakness, 49% had homonymous field defect, 29% had cortical sensory loss, 23% had dysarthria, and 18% had dysphasia. In addition, 85% showed mild to severe mental retardation.[230]

Factors identified as influencing outcome in general are (a) underlying etiology, (b) duration of status, (c) complications (cardiorespiratory failure, autonomic disturbance, hyperthermia, hypoxia, and medical and systemic complications not infrequently due to therapy), and (d) age of the patient (strongly interrelated with the first factor, i.e., underlying etiology). (See also Maegaki et al.[145])

Summary and Conclusions

Simple partial status epilepticus is relatively rare if borderline or boundary conditions (such as continuous spike-wave discharges during sleep, the Landau-Kleffner syndrome, neonatal convulsions, early infantile syndromes with suppression burst, and early myoclonic encephalopathies) are excluded. Whereas the separate classification of these borderline and boundary conditions can be well justified and actually was accepted for the purpose of this book, a discussion of SPSE without considering these boundary conditions with malformations and metabolic as well as special etiologic syndromes remains unsatisfactory because it does not take into account the growing evidence that status epilepticus is a condition (or a group of conditions) with distinctive pathophysiologic features and not just an iterative version of ordinary epilepsy. Consequently, the borderline and boundary conditions, including PLEDs, have been briefly discussed in this chapter.

Simple partial status epilepticus, in a narrow sense, is divided into somatomotor and sensory SPSE with the additional special categories of autonomic-vegetative SPSE and dysphasic/aphasic SPSE. Whereas considerable knowledge has accumulated on epilepsia partialis continua, and completely new pathophysiologic insights have appeared on the horizon suggesting that Rasmussen encephalitis is an autoimmune disease, the characterization of several other types of SPSE remains limited to anecdotal case reports. This is particularly true for SPSE with autonomic signs and symptoms. Some evidence has been provided for the intriguing possibility that some abnormal mental states, including peculiar personality and behavioral changes (commonly described under the category of "limbic dyscontrol syndrome"), are due to prolonged seizure activity in certain limbic or paralimbic areas. It is unknown, however, to what extent the generality of "interictal behavioral peculiarities" might be associated with such "subclinical status" in deep structures.

Chapter 62

Myoclonic Status Epilepticus

Shunsuke Ohtahara

Yoko Ohtsuka

Introduction

There are as many types of status epilepticus as there are types of epileptic seizures. Myoclonic status epilepticus is defined as a condition in which generalized myoclonic jerks are repeated continuously or occur in clusters lasting for a sufficiently long period, usually >30 minutes.

Myoclonic status is divided into two types—pure and symptomatic.[12,31] The former is observed in epileptic patients. The latter is associated with degenerative encephalopathies, that is, the dyssynergia cerebellaris myoclonica of Ramsay-Hunt, progressive myoclonus epilepsy, and, especially, Lafora disease; with various lipidoses or metabolic (hepatic and renal) encephalopathies; with toxic encephalopathies; and with severe anoxic encephalopathies. However, Treiman[42] argued that symptomatic myoclonic status epilepticus should be considered a subtle presentation of generalized convulsive status and that the term "myoclonic status epilepticus" should be used only for pure myoclonic status. Therefore, this chapter discusses only pure myoclonic status epilepticus.

Definition and Classification

Pure myoclonic status epilepticus is seen in patients with generalized epilepsy, especially in types that exhibit myoclonic seizures. Pure myoclonic status is further subclassified into primary and secondary forms.[12]

Primary myoclonic status epilepticus is regarded as the prototype of myoclonic status epilepticus and is observed in patients with one of the primary (idiopathic) generalized epilepsies, such as juvenile myoclonic epilepsy.[3]

Secondary myoclonic status epilepticus occurs in children with one of the secondary (symptomatic) generalized epilepsies,[12] such as myoclonic-astatic epilepsy, Lennox-Gastaut syndrome, and epilepsy with myoclonic absences. This secondary form has also been reported as minor epileptic status[5,6,36] and has been observed in myoclonic epilepsy ("myoclonic status") in nonprogressive encephalopathies,[8] and in association with obtundation status in severe myoclonic epilepsy in infancy.[10] Status epilepticus associated with negative myoclonus is also classified as a type of secondary myoclonic status epilepticus and is seen in epilepsy with continuous spike-waves during slow-wave sleep (CSWS)[40] and its related epilepsies.[22,26,29] The Commission on Classification and Terminology of the International League Against Epilepsy classifies severe myoclonic epilepsy in infancy and epilepsy with CSWS into "epilepsies and syndromes undetermined whether focal or generalized."[7]

Epidemiology

Although the incidence and prevalence of the primary and the secondary types of myoclonic status epilepticus have not been precisely delineated, the primary type is regarded as relatively rare.[11,12] In contrast, the secondary type of myoclonic status is far more frequent.[12]

Etiology (Mechanism)

There are various etiologies of pure myoclonic status epilepticus, and the underlying pathophysiology of myoclonic status epilepticus is unclear.

Recently, seizure aggravation by antiepileptic drugs (AEDs), especially a worsening of seizures resulting from an inappropriate choice of an AED, has been attracting much attention.[13,30] Although in this case AEDs may provoke aggravation by a purely pharmacodynamic mechanism, the precise biological mechanisms involved are unclear. Aggravation by AEDs is probably more common in children than in adults.[13,30] Potential AEDs include carbamazepine, phenytoin, phenobarbital, vigabatrin, lamotrigine, gabapentin, and tiagabine.[13,30] Generalized seizures such as myoclonic seizures and absences are aggravated,[30,35,37] sometimes evolving into nonconvulsive status epilepticus such as myoclonic status.[13] Although such aggravation usually occurs in generalized epilepsies, it is also observed in severe myoclonic epilepsy in infancy,[10] in epilepsy with CSWS and its related epilepsies,[22,26,29] and even in localization-related epilepsies.[28,35,37]

Clinical and electroencephalogram (EEG) findings suggest that perhaps the secondary type of myoclonic status epilepticus should be considered a modified form of atypical absence status.[12] In some cases diagnosed as absence status, however, myoclonus constitutes the main symptom rather than a consciousness disturbance.[41,43] Differentiation between myoclonic status epilepticus with absence features and absence status epilepticus with myoclonic features remains a problem in the classification of status epilepticus.

Pathophysiology

Several investigators have attempted to classify myoclonus based on its pathophysiology.[17,18,23] Electrophysiologic examinations of myoclonus, such as jerk-locked averaging, somatosensory-evoked potentials (SEPs), enhanced long-latency reflexes (C reflexes), magnetoencephalography, and transcranial magnetic stimulation, have been performed to investigate the pathophysiology of myoclonus.[33,34]

Shibasaki et al.[33,34] classified myoclonus into three types (cortical, subcortical, and spinal myoclonus) based on the presumed physiologic mechanism underlying its generation. They emphasized the existence of cortical reflex myoclonus in which

a myoclonus-related cortical spike was detected by jerk-locked averaging, and a giant SEP accompanied by an enhanced C reflex was observed. They speculated that the sensory and motor cortices mediated the occurrence of cortical reflex myoclonus. However, the pathophysiology of myoclonic seizures in epilepsy has not been fully elucidated.

In cortical myoclonus, the EEG usually shows multifocal or generalized spike-wave or multiple spike-wave discharges with or without associated myoclonus. On the conventional polygraph, however, the temporal and spatial relationships between myoclonus and its EEG correlate are often difficult to determine quantitatively.

Simultaneous EEG and electromyogram (EMG) polygraphic recording demonstrates that muscular inhibition, namely, negative myoclonus, can arise from the central nervous system in addition to positive myoclonus, which refers to sudden, brief, shock-like involuntary movements caused by muscular contractions. Negative myoclonus of cortical origin also can be associated with an EEG spike or spike-wave complex. Again, however, it is difficult to determine precisely the temporal and spatial relationships between the EMG silent period and the associated EEG spike on the conventional polygraph. Furthermore, because the silent period tends to be preceded or followed by an abrupt EMG discharge (positive myoclonus),[46] it is often difficult to judge whether the detected EEG spike is directly related to the positive component or the negative component of the EMG discharge. Myoclonic status epilepticus characterized by negative myoclonus has also been described.[22,26,28,29]

Clinical Features

In the primary type of myoclonic status epilepticus, consciousness is basically preserved in spite of long-lasting seizures. A polygraphic recording of the myoclonic jerks[31] shows brief muscular contractions of 100- to 200-msec duration repeated at a rate of 3 to 6 per second. These contractions are diffuse, predominating over the proximal muscles of the extremities, and they are bilaterally synchronous in homologous regions.

The secondary type of myoclonic status epilepticus is characterized by myoclonic jerks, which, although bilateral, are often asymmetric, asynchronous, and of small amplitude. A variable extent of impairment of consciousness is characteristic in this condition and can dominate the clinical picture.[12]

As outlined, several epileptic conditions and syndromes can develop the primary and secondary types of myoclonic status epilepticus, and each shows characteristic electroclinical findings. They are described as follows.

Myoclonic Status Epilepticus in Juvenile Myoclonic Epilepsy

Juvenile myoclonic epilepsy (JME) is an idiopathic generalized epilepsy characterized by myoclonic seizures. Often, generalized tonic-clonic seizures occur, and less often, infrequent absences. Myoclonic seizures can occur as myoclonic status. Although Asconapé and Penry[3] reported that 5 of 12 JME patients experienced at least one episode of myoclonic status, it is believed that myoclonic status is rare in JME.[11,12] Myoclonic status epilepticus in JME can last for a few hours, when the myoclonic jerks recur every few seconds, either isolated or in clusters of three to five jerks.[3] Consciousness is maintained,[3] or change in mental status, such as confusion, can be associated.[11,32,41,43] Sleep deprivation or other precipitants are usually present. Recently it has been reported that AEDs, especially carbamazepine, have aggravating effects on patients with JME. Aggravation is mostly in the form of increased myoclonic jerks, including myoclonic status.[14]

Nonconvulsive Status Epilepticus in Eyelid Myoclonia With Absence

Eyelid myoclonia with and without absences are the characteristic seizure types of this epileptic syndrome, which is one of idiopathic generalized epilepsies starting in childhood and persisting into adulthood. These seizures can be very frequent: Sometimes hundreds occur every day. Seizures are readily precipitated by eye closure in an illuminated room. All patients are highly photosensitive.

It was reported that some patients with eyelid myoclonia with absence experience status epilepticus, especially nonconvulsive status epilepticus.[1,45] During status epilepticus, some of these patients were confused, resulting in limitations in their daily activities. In others, however, absences were extremely brief and mild, in spite of severely persistent eyelid myoclonia. A patient reportedly could continue riding a bicycle safely for 20 minutes during status epilepticus.[1] We also experienced a patient who told her mother after walking down a stairway that she had continued to have eyelid myoclonia for >10 minutes without an impairment of consciousness.

During status epilepticus, EEG shows generalized poly-spikes or polyspike-waves concomitant with eyelid myoclonia.

Minor Epileptic Status

Minor epileptic status was proposed by Brett in 1966.[5,6,36] Many of his reported cases would now be categorized as Lennox-Gastaut syndrome; the remainder fit into other syndromes. This condition may last for hours, days, or even weeks. The patients are obtunded and drool, and speech is absent or slurred. They cannot understand or obey commands (pseudodementia). Symmetric and asymmetric jerks are seen in the limbs, the trunk, and the face to variable degrees. Sudden atonia may occur, resulting in head nodding, flexion of the trunk, or falls. The gait is lurching and unsteady (pseudoataxia).

The EEG shows multifocal continuous spikes or sharp waves or even continuous irregular slow waves without spikes. Minor epileptic status is a heterogeneous condition that includes atypical absence status and myoclonic status.

Myoclonic Epilepsy ("Myoclonic Status") in Nonprogressive Encephalopathies

Dalla Bernardina et al.[8] reported a peculiar type of symptomatic myoclonic epilepsy characterized essentially by the recurrence of atypical status combined with an impairment of attention and continuous jerks in infants suffering from a nonprogressive encephalopathy, and they considered that it constitutes a peculiar syndromic entity.

The electroclinical manifestations during myoclonic status are characterized by brief bursts of diffuse slow spike-waves accompanied by myoclonic jerks and mixed with other continuous and polymorphous abnormal movements. Sometimes the myoclonic jerks are rhythmic, bilateral, continuous, and strictly related to EEG discharges. Frequently, in the same patients, however, they are continuous but asynchronous in the different muscles without the definite one-to-one relationship between the jerks and paroxysmal EEG discharges. Besides paroxysmal discharges, the EEG often displays continuous theta activity (4–6 c/s), which is relatively monomorphous but varying in amplitude. During the status, positive and negative myoclonus is nearly continuously observed. In some cases, negative myoclonus is predominant, continuously fragmenting the voluntary movements and inhibiting the maintenance of any fixed antigravitary posturing.

Dalla Bernardina et al.'s series[8] included 18 cases of Angelman syndrome, 2 cases of 4p- syndrome, and 1 each of Rett syndrome and Prader-Willi syndrome. Other researchers[24,27,38,44] also reported the frequent occurrence of a peculiar epileptic status in Angelman syndrome. In our 11 cases of this syndrome, 10 presented with nonconvulsive status epilepticus[27] characterized by reduced alertness associated with brief atonias and erratic myoclonus.

Obtundation Status in Severe Myoclonic Epilepsy in Infancy

Obtundation status was reported in severe myoclonic epilepsy in infancy.[10] It consisted of an impairment of consciousness that was variable in intensity; the presence of fragmentary and segmental, erratic myoclonus of low amplitude, involving the limbs and the face; and sometimes a slight increase of muscular tone. It persisted for several hours or even several days.

The EEG is characterized by diffuse dysrhythmia of slow waves intermixed with focal and diffuse spikes, sharp waves, and spike-waves, of higher voltage in the anterior regions and the vertex without correspondence between the spikes and the myoclonic jerks except during the epileptic myoclonic seizures.

A clouding of consciousness characterizes the obtundation status, but its degree is variable. In some cases, myoclonus may dominate the clinical picture. Dravet et al.[10] classified this peculiar status among atypical absence status.

AEDs such as lamotrigine sometimes induce a worsening of seizures and can cause myoclonic status, namely, obtundation status.[10]

Myoclonic Status in Myoclonic-Astatic Epilepsy and Lennox-Gastaut Syndrome

The status of myoclonic astatic seizures accompanying absences is especially characteristic of myoclonic-astatic epilepsy.[9] The condition is characterized by apathy or even stupor. Careful observation reveals irregular twitching of the facial muscles and the extremities. Astatic seizures and head nodding can appear serially. The status epilepticus may last for hours or even days, but the status of pure myoclonic seizures seems to be extremely rare.

During the status of myoclonic astatic seizures, the EEG shows 2- to 3-c/s spike-waves and, especially, in younger children, very irregular polymorphous hypersynchronous activity, sometimes resembling hypsarrhythmia. In very rare cases with myoclonic status, the EEG is dominated by polyspike-waves.

The status in myoclonic astatic epilepsy can rapidly lead to dementia. The younger the children when the status epilepticus appears, the higher is the risk of dementia.[9]

Status epilepticus is not rare in Lennox-Gastaut syndrome.[4,19] It is composed of tonic status epilepticus and atypical absence status (including so-called minor epileptic status).[25] Myoclonic status in a strict sense has rarely been reported in typical Lennox-Gastaut syndrome.[21] However, myoclonic status may appear in the myoclonic variant of Lennox-Gastaut syndrome. Myoclonic status following high-dose lamotrigine therapy was reported in a patient with Lennox-Gastaut syndrome.[15]

Epilepsy With Myoclonic Absences

Status epilepticus has rarely been reported in epilepsy with myoclonic absences. According to Tassinari et al.,[39] 1 of their 36 cases presented a status with diffuse spike-waves and rhythmic myoclonic jerks interrupted after 20 minutes by an intravenous injection of diazepam. Two other cases had myoclonic absences repeated at close intervals. In myoclonic absence, myoclonic seizures constitute the constant characteristic feature, and a tonic component is often associated. An impairment of consciousness is of variable degree.

Status Epilepticus Associated With Negative Myoclonus

Epilepsy with continuous spike-waves during slow sleep (CSWS)[40] and its related conditions sometimes exhibit status with frequent myoclonic seizures and/or negative myoclonus. Nonconvulsive status epilepticus with epileptic negative myoclonus (NSENM),[26] which we originally named “a peculiar type of nonconvulsive status epilepticus,”[22,29] and atypical benign partial epilepsy (ABPE)[2] both have partial or generalized motor seizures as clinical seizure types. The former is also characterized by frequent “brief atonic episodes” and the latter by frequent “atonic fits” and myoclonic seizures. In NSENM, transient “paresis” is sometimes observed in the upper limb, where frequent “brief atonic episodes” occur. Neuropsychologic abnormalities and even mental deterioration are observed transiently during the status episode and can persist in long-term follow-up as in epilepsy with CSWS.[22,26,29] In contrast, ABPE is associated with neither neuropsychologic abnormalities nor mental deterioration.[2] Guerrini et al.[16] also reported five patients with partial epilepsy of diverse etiology who presented with very frequent epileptic negative myoclonus in one or more somatic segments. Three of them displayed a higher-order brain dysfunction that closely resembled motor neglect. This consisted of a reduction in spontaneous movements of affected segments of the body that could not be attributed to deficits in strength or sensation, a phenomenon similar to “paresis” observed in NSENM.

On the waking EEG, multifocal spikes, especially rolandic spikes, are seen in NSENM,[22,26,29] and rolandic spikes in ABPE.[2] In both, diffuse spike-waves are also seen. The sleep EEG demonstrates continuous focal spike-waves with a tendency to generalization, and diffuse spike-waves appear as in epilepsy with CSWS, but the spike-wave index is not usually as high as in typical epilepsy with CSWS.[22] Polygraphic recordings reveal that “brief atonic episodes” and “atonic fits” are both negative myoclonus. This occurs simultaneously with spike-waves on the EEG. On the other hand, spike-waves on the EEG do not always accompany negative myoclonus clinically. In all patients with frequent epileptic negative myoclonus reported by Guerrini et al.,[16] sleep activated continuous epileptiform EEG activity—central in three and diffuse in two.

Diagnosis

Essential Clinical Features

Essential clinical features are myoclonic jerks that are repeated continuously or that occur in clusters lasting for a sufficiently long period—30 minutes or more. Myoclonic jerks are mainly generalized bilateral synchronous in the primary type of myoclonic status, but asymmetric or asynchronous myoclonic jerks are often observed in the secondary type of myoclonic status.

Electroencephalography

In the primary type of myoclonic status epilepticus, simultaneous EEG recordings show multiple spikes closely related to, and usually preceding, the myoclonic jerks; these spikes are generalized with predominance over the anterior region of

P.728

the head.[31] Background activity is normal during the interictal period.

In contrast, the EEG of the secondary type of myoclonic status epilepticus does not always show generalized and synchronous multiple spike-waves, but rather arrhythmically repeated spike-waves interspersed with high-amplitude delta activity mixed with bursts of theta waves and epileptic recruiting rhythms.[12] Background activity usually shows slow-wave dysrhythmia.

Differential Diagnosis

Pure myoclonic status should be differentiated from symptomatic myoclonic status associated with acute or subacute brain disorders in nonepileptics. These disorders include various types of degenerative, toxic, and severe anoxic encephalopathies. The patients with symptomatic myoclonic status have the characteristic clinical and laboratory findings of each disorder. The EEG is useful in the differential diagnosis. The EEG of symptomatic myoclonic status can manifest the specific findings of each disorder. Because myoclonus in symptomatic myoclonic status is usually nonepileptic, it is not accompanied with spikes on the ictal EEG. However, epileptic myoclonic seizures are sometimes observed in such cases along with nonepileptic myoclonus.

With regard to pure myoclonic status epilepticus, differentiation from absence status epilepticus is important. As mentioned earlier, the secondary type of myoclonic status is sometimes difficult to differentiate from absence status. The secondary type of myoclonic status often shows a slight disturbance of consciousness along with myoclonus. In such cases, however, myoclonus constitutes the main symptom, but in absence status, an impairment of consciousness dominates the clinical picture. The fundamental EEG finding of absence status is bilateral synchronous generalized spike-wave discharges at about 3 c/s, appearing more or less continuously, but that of myoclonic status epilepticus is generalized multiple spike-waves. However, there are a significant number of cases without the typical EEG findings in both absence status and myoclonic status. The differential diagnosis of myoclonic status from absence status should be made by the overall clinical and electroencephalographic picture.

Response to treatment

Intravenous injections of benzodiazepines, especially diazepam and clonazepam, may be effective at stopping myoclonic status epilepticus. Intravenous valproic acid was reportedly effective for myoclonic status in JME.[32] However, the secondary type of myoclonic status epilepticus is often refractory. Even if it is once suppressed, relapse is common. Adrenocorticotropic hormone (ACTH) may sometimes control the secondary type of myoclonic status.[6,9] An oral administration of valproate and ethosuximide can also be effective.[8,20]

Consequences

Prognosis depends on the type of myoclonic status epilepticus. Basically, the primary type enjoys a favorable prognosis, but the secondary type shows poor mental prognosis. Furthermore, prognosis in the secondary type is closely related to the type of epilepsy and also to the length and frequency of the myoclonic status.

Summary and conclusions

Myoclonic status epilepticus consists of pure myoclonic status epilepticus and symptomatic myoclonic status epilepticus. This chapter described only pure myoclonic status epilepticus, which mainly appears in patients with generalized epilepsy. Pure myoclonic status epilepticus is further divided into the primary type and the secondary type. The former is relatively rare and is seen in patients with primary generalized epilepsy, namely idiopathic generalized epilepsy. The latter is much more frequent, especially among children, and is mainly observed in patients with symptomatic or cryptogenic generalized epilepsy who have myoclonic seizures. Because the secondary type of myoclonic status epilepticus is usually associated with various degrees of disturbance of consciousness, the differential diagnosis from absence status is difficult. The position of this type of myoclonic status epilepticus in the classification of status epilepticus is a future problem.

Chapter 63

Febrile Status Epilepticus

Darrell V. Lewis

Shlomo Shinnar

Introduction

Febrile seizures (FS) are acute symptomatic seizures that occur in 2% to 5% of children, making them the most common form of childhood seizures. About 5% of FS can be classified as febrile status epilepticus (FSE). Due to the long-debated relationship between prolonged FS, mesial temporal sclerosis (MTS), and temporal lobe epilepsy (TLE), there is currently a great deal of interest in the causes, effects, and long-term prognosis of FSE.

Definitions

The International League Against Epilepsy defines a FS as a seizure in association with a febrile illness in the absence of a central nervous system (CNS) infection or acute electrolyte imbalance in children older than 1 month of age without prior afebrile seizures.[20,21] FSE is defined as a FS of 30 minutes' duration or greater, or a series of FS lasting more than 30 minutes, between which the infant does not return to normal level of alertness.[20,73] FS, and by extension FSE, are also divided into those without prior neonatal seizures and those with prior neonatal seizures. No upper age limit is specified; however, FS, and also FSE, are most common between 6 months and 3 years of age, with peak incidence at about 18 months of age.

Epidemiology

Although the majority of FS are simple, approximately 5% are of sufficient duration to be classified as FSE. In a study of 428 children with a first febrile seizure, 14% had duration of longer than 10 minutes, 9% of longer than 15 minutes, and 5% of longer than 30 minutes or FSE.[8] Although only 5% of FS are FSE, these seizures nevertheless account for approximately 25% of all childhood status epilepticus (SE)[23,74] and more than two-thirds of cases of SE in the second year of life. FSE can also be classified as partial (focal) or generalized, depending on the presence or absence of focal features in the ictus. The age distribution of FSE is identical to that of simple FS, with 74% of episodes occurring younger than 2 years and 96% at ages younger than 5 years.[73]

Anatomic Pathways and Pathophysiology

Anatomic Pathways

The site of origin and pathways of propagation of electrical seizure activity underlying FS and FSE are unknown. Generalized delta waves, spikes, and polyspikes have been seen in simple FS recorded fortuitously in human infants (Morimoto et al 1991; Maehara 1988). The electroencephalographic (EEG) sources and propagation patterns during FS will very likely depend on the type of seizure (e.g., focal vs. generalized) and on the genetic susceptibility factors in each case. There are a few anecdotal case reports of EEGs recorded during FSE, one showing ictal activity over a temporal lobe and several showing diffuse bilateral but asymmetric ictal activity during FSE.[57,77] Interestingly, in these few cases, MTS was ultimately documented by follow-up magnetic resonance imaging (MRI) in the temporal lobe ipsilateral to the predominant ictal EEG activity.

More information is available on the EEG correlates of hyperthermia-induced seizures in rats used to model FS in human infants. Hyperthermia to approximately 42°C core temperature reliably induced 20-minutes' duration seizures in 10- to 11-day-old rats with electrodes placed on the cortex, and in the hippocampus and amygdala. The clinical seizure activity suggested limbic origin, and the EEGs documented onset in the amygdala or, less often, in the hippocampus.[6] Others have also found evidence of limbic origin of hyperthermia-induced seizures in infant rats.[67] The paucity of information on anatomic pathways associated with FSE prevents any firm conclusions, however.

Pathophysiology

The pathophysiology of FS has been studied only to a limited extent in animals, and even less is written on models of FSE. To model FS, investigators have induced hyperthermia in rats using radiant heat, hot air, or hot water immersion. A consistent finding has been that hyperthermic seizures in infant rats result in lowered seizure thresholds when the affected rats are adults.[25,39] The most intensely studied model exposes 10-day-old rat pups to heated air, consistently evoking hyperthermic seizures of about 20 minute duration, apparently arising in the hippocampus or amygdala.[6] Within about 24 hours and up to about 2 weeks following these seizures, silver staining revealed argyrophilic neurons in the central nucleus of the amygdala and in CA3 and CA1 sectors of the hippocampi in these rats.[76] Ultimately, the argyrophilia resolves, and no cell loss is noted when cell counts are done at later age.[7] Nevertheless, hippocampal excitability is permanently altered, and the threshold for chemically induced seizures is permanently decreased.[25] This persistent decrease in seizure threshold after infantile hyperthermic seizures has been noted by prior investigators also.[25,39] Although the limbic seizure threshold is reduced, there is a paradoxical increase of perisomatic γ-aminobutyric acid $(GABA)_A$ inhibition due to increased pre-synaptic GABA release.[19] In addition, a permanent alteration occurs in the properties of the hyperpolarization-activated cation current (I_h) in hippocampal CA1 and CA3 pyramidal cells.[18] I_h is a depolarizing current carried by sodium (Na) and potassium (K) that is normally activated by hyperpolarization of the cell and tends therefore to counteract hyperpolarization and to return the cell to a more depolarized level following

P.732

hyperpolarization. After rat pups have experienced hyperthermic seizures, hippocampal I_h is activated at more depolarized levels, resulting in mild resting depolarization of pyramidal cells and an enhanced posthyperpolarization rebound with depolarizing overshoot and a resultant burst of spikes. Therefore, when a brief tetanic train of stimuli is applied to the pyramidal neurons, the enhanced $GABA_A$ inhibition produces a hyperpolarization that is followed by a depolarization and burst of spikes due to the enhanced I_h. This tendency for bursting may underlie the reduced seizure threshold. The altered I_h properties result from a change in relative expression of isoforms of these channels that persists into adulthood.[12]

The only structural alteration so far noted in these animals is mildly increased mossy fiber density in the granule cell and molecular layer of the dentate gyrus.[7] It is very interesting that many of these rats develop spontaneous limbic seizures in adulthood even though the prolonged hyperthermic seizures they suffered as infants did not produce hippocampal sclerosis.[26] Thus, this model raises the possibility that a single prolonged febrile seizure in a human infant could permanently alter hippocampal seizure threshold and even predispose to TLE in the absence of obvious structural alteration.

Many investigators have proposed that both prolonged FS and the epilepsy that occasionally develops after these seizures may be a result of preexisting brain pathology. A few animal studies have combined induced brain anomalies with hyperthermic seizures to test this concept. Rat pups exposed to methylaxozymethanol (MAM) during gestation display extensive cortical and hippocampal dysgenesis and a heightened vulnerability to hyperthermia-induced seizures.[37] Hyperthermia induced cortical electrographic seizures in both the MAM-treated and the control pups. However, the MAM-exposed pups had a higher incidence of behavioral (clinical) seizures, probably due to increased spread of seizure activity. Significant pyramidal cell loss, independent of seizure activity and presumably due to hyperthermia alone, was documented in the CA1 and CA3/4 hippocampal subfields of MAM rats 4 weeks after exposure to hyperthermia. It was concluded that extensive dysgenesis lowers the threshold for hyperthermia-induced behavioral seizures and irreversible neuronal injury. In a different model, more restricted neocortical freeze lesions causing a focal microgyrus have also been shown to predispose infant rats to more severe hyperthermia-induced seizures.[66] These lesions reduced the latency to hyperthermia-induced generalized convulsions, and the convulsions themselves were followed by prolonged electrographic seizure activity compared with hyperthermic seizures induced in controls. Finally, video-EEG recordings from the same rats as adults revealed a high incidence of spontaneous limbic seizures in the rats with both lesions and hyperthermic seizures but not in lesion-only or hyperthermic seizure–only rats.[66] As was the case in the pure hyperthermia model,[6] the spontaneous limbic seizures occurred without any obvious evidence of hippocampal sclerosis induced by the hyperthermic seizures experienced in infancy. These animal studies support the hypothesis that preexisting brain abnormalities could predispose to prolonged FS and subsequent epilepsy in human infants.

Contribution of Magnetic Resonance Imaging to Understanding Pathophysiology of Febrile Status Epilepticus

FSE is an uncommon and unpredictable event and generally does not recur. Therefore, studies of pathophysiology of FSE are quite limited and consist of tests such as EEGs and MRIs that can be done during or shortly after the acute and emergent presentation of the affected infants.

Animal Models

A brief review of MRI changes observed with animal models of SE will help put the human data in perspective. MRI analyses of SE in rats usually employ limbic SE evoked by kainic acid (KA) or pilocarpine, and hence the anatomic distribution of abnormalities reflects the regional specificity of these agents, with changes being seen most commonly in the amygdala, piriform cortex, and hippocampus as well as in extralimbic areas of the neocortex and thalamus. Six to 24 hours following lithium-pilocarpine–induced SE in adult rats, the apparent diffusion coefficient for water (ADC) is usually reduced in the amygdala and piriform cortex, and thalamus and cortex if affected.[31,34] Along with ADC changes, T2 signal intensity is increased in amygdala, piriform cortex, hippocampus, and often in thalamus and cingulate cortex. The areas of increased T2 signal intensity have, in general, correlated with areas of neuronal injury, neuronal loss, and tissue edema on histologic analysis.[31,62] Acute ADC changes in the hippocampus in these models have been inconsistent. Some have seen an increase in ADC initially using pilocarpine,[31,34] and in others no significant change using KA.[52,60,75] When the hippocampal MRI changes have been followed beyond the acute phase for 2 or more weeks, increased ADC and increasing T2 signal have been seen along with atrophy and cell loss.[59,63,75] Acutely increased piriform and entorhinal cortex T2 intensity and T2 relaxation times were predictive of ultimate development of spontaneous seizures and increased hippocampal T2 signal in a study of pilocarpine SE in 21-day-old adolescent rats.[63] Thus, in adult and adolescent rats, MRI changes following status reflect tissue damage and may be surrogate markers for the development later of MTS and limbic epilepsy.

The significance of MRI abnormalities is less clear in hyperthermic seizures of shorter duration studied in infant rats. There is only one MRI analysis of prolonged hyperthermic seizures in infant rats using P10 rat pups exposed to heated air and suffering approximately 20-minute-long seizures. These are relatively brief seizures, compared to the 2- to 4-hour-long SE typical of the kainate or pilocarpine models. Nevertheless, transiently increased T2 signal was noted in the dorsal hippocampus, amygdala and piriform cortex at 24 hours in six of eight rat pups and at 8 days in seven of eight with the hippocampal changes lagging behind the other areas. However, Fluoro-Jade staining failed to reveal evidence of dying neurons in these areas at 1, 2, 4, and 7 days after the hyperthermic seizures.[27] Recently, the same group has shown that their model of P10 prolonged hyperthermic seizures results in about a third of the rats developing spontaneous limbic seizures by 3 months or more of age.[26] Therefore, in these 10-day-old infant rats, transient acute postictal T2 hyperintensity did not correlate with cell death or persistent MRI abnormality.

Human Magnetic Resonance Imaging Studies

There are only a few MRI studies of human infants performed soon after an episode of FSE, and these have emphasized abnormalities in the hippocampus. Vanlandingham et al.[77] described 27 infants with FSE, the majority of whom were imaged within 4 days of the episode of FSE. Of 15 with lateralized seizures, six had definite hippocampal MRI abnormalities. Presumed chronic hippocampal injury with atrophy and increased T2 signal bilaterally were seen in two subjects with histories of perinatal asphyxia and evidence of periventricular leukomalacia. In the other four, presumed acute abnormalities of increased T2 signal and increased volume were seen on the side of presumed seizure origin. Of note in the lateralized group was the longer average seizure duration of 99 minutes in subjects with swollen, bright hippocampi versus 41 minutes in those without these findings.

There were 12 infants with generalized FSE, and only one had subtle bilateral increase of hippocampal signal and size. The authors concluded that both chronic and acute hippocampal abnormalities could be seen following FSE, and that focal and prolonged FSE was more likely to be associated with these abnormalities. Follow-up MRIs have demonstrated that hippocampi with definite increased size and T2 signal on acute imaging developed atrophy with persistently increased T2 signal months to years later, a picture consistent with MTS.[45]

A more recent study of this type[68] carefully analyzed hippocampal T2 signal relaxation times and volumes in 21 infants with presumed generalized FSE. Visual assessment of the MRIs was normal in 16, three appeared to have hippocampal asymmetry (of which two were confirmed by volumetry), one had a left temporoparietal arachnoid cyst, and one had poor gray-white differentiation in the left midtemporal gyrus. Unlike the Vanlandingham study,[77] there were no hippocampi with grossly increased T2 signal intensity on visual inspection. However, the group mean calculated T2 relaxation time was increased compared with controls in those imaged within 2 days of the event but not in those imaged later at 3 to 5 days after FSE. In addition, the mean hippocampal volumes of the FSE group were increased compared with an age-matched control group. Follow-up imaging of 14 of these infants from 4 to 8 months later[69] showed that there was no longer any difference between mean T2 relaxation time or mean hippocampal volume when compared with the controls. However, the hippocampal volumes of the subjects had decreased from the initial studies, and the hippocampal asymmetry had increased and was outside the 95% of control limits in five of the 14. In one of these five, the asymmetry was visually apparent. The conclusion was that FSE could produce transient hippocampal edema and in some cases perhaps neuronal loss.

Grunewald et al.[38] looking at MRI findings in 10 infants imaged within 2 weeks of FSE found abnormal hippocampal volume ratios in nine when compared with volume ratios of controls. Because no abnormalities of hippocampal T2 signal or T2 relaxation time constants were found, the authors concluded that the abnormal right to left volume ratios could not be ascribed to edema. No follow-up scans were reported. However, based on the findings of Scott et al.[68] that increased T2 signal tended to reverse by several days after FSE, the MRIs done an average of 11 days after FSE in the Grunewald study might have been too late to detect increased T2 relaxation times.

Very few data are available on hippocampal ADC changes in FSE in human infants. The ADC data in theory could help determine if the structural changes seen soon after FSE were acute or chronic. ADC maps of chronic hippocampal injury—MTS—have consistently shown increased ADC.[5,65] As discussed previously, acute reductions of ADC have been reported in the animal models of limbic status in amygdala and piriform cortex during the phase of cellular swelling and death, although hippocampal changes have not been uniform. In humans, acute changes in ADC are rarely reported and certainly have not been studied in an organized prospective fashion in large samples of infants with FSE. A report of five infants imaged following SE is the largest series thus far.[33] Although four of the five had low-grade fevers during the status, it is not clear that these were straightforward episodes of FSE, because the initial status was quickly followed by recurrent seizures of uncertain nature in four subjects. Four subjects imaged within 2 to 3 days of status had hippocampal increased T2 signal and size on the affected side and 5% to 20% reductions of ADC in the affected hippocampus compared with the unaffected side. Follow-up MRIs months later in four cases showed increased ADC in the abnormal side along with hippocampal atrophy. Two other case reports noted similar findings acutely after SE[29] and single temporal lobe seizures in established TLE.[41] A tenuous suggestion exists, therefore, that in human limbic status epilepticus, acute reduction of hippocampal ADC might be found immediately postictally followed later by increased ADC if the initial injury results in MTS. More animal and human data will be needed before the changes in ADC can be used to gauge the age and nature of hippocampal abnormalities following FSE.

Differing conclusions about the type and significance of hippocampal abnormalities associated with FSE very likely reflect both differences in subject groups and pathogenesis. Detection of FSE-induced T2 abnormalities may require prompt postictal imaging. Scott et al.[68] documented that subtle increases in T2 signal returned to normal after 2 to 3 days following FSE, and some animal data demonstrates that T2 may transiently return to normal 2 to 4 days following FSE.[60,63] Generalized FSE may have a lower incidence of acute MRI abnormalities than does focal FSE.[77] Finally, extremely prolonged and focal FSE lasting 90 minutes or more may be required to produce striking hippocampal abnormality such as that reported by Vanlandingham et al.[77]

These initial MRI studies raise more questions that remain to be answered regarding the relationship of FSE to hippocampal injury.[45] How often and under what circumstances does hippocampal injury occur during FSE?

What determines whether the initial injury is reversible or evolves instead to MTS? What are the clinical parameters and MRI findings in FSE that are predictors of MTS? Do infants with obvious acute hippocampal abnormalities and subsequent MTS develop TLE? Do infants with subtle hippocampal MRI abnormalities, even those below visual threshold, ultimately develop TLE? Can acute injury be differentiated from preexisting hippocampal abnormality using diffusion weighted imaging (DWI), subsequent hippocampal growth curves, or other techniques? Assuming that hippocampal injury can occur in FSE, what are the mechanisms of neuronal injury and subsequent epileptogenesis? What other brain abnormalities detectable on MRI can be found in children with FSE? Can pharmacologic intervention to prevent neuronal death and epileptogenesis reduce subsequent TLE?

Clinical Features

No distinguishing ictal or postictal features of FSE differentiate these seizures from other acute symptomatic or cryptogenic prolonged seizures except for the association with febrile illness. Given that this is an acute symptomatic seizure type triggered by febrile illness, there are no persisting distinguishing interictal features either.

By definition, the duration of these seizures is 30 minutes or more; however, detailed studies of FSE have shown that many are much longer. Of 180 cases of FSE, Shinnar et al.[73] found 58% lasting from 30 to 59 minutes, 24% from 60 to 119 minutes, 15% from 120 to 239 minutes, and 3% over 240 minutes. If the FSE was focal, as it was in 64 subjects (35%), the distribution of seizure durations was similar, with about half lasting 30 to 59 minutes and the other half more than 60 minutes. This breakdown was similar whether the bout of FSE presented as the first febrile seizure event or after an initial shorter FS. Comparing the FSE group to a group of complex FS not including FSE, the proportion of focal seizures to generalized was similar. However, focal features were more common in the FSE group than in a comparison group of 244 unselected, prospectively identified children with FS.

As an interesting corollary to the animal studies linking brain lesions with severe hyperthermic seizures, preexisting neurodevelopmental abnormalities were more common in subjects with FSE than in the comparison group. Twenty-one percent of the FSE group had previously documented neurologic abnormalities compared with 5% of the comparison group.

The question of whether an episode of FSE makes subsequent FSE more likely or not has clear clinical implications

when deciding on future management. One episode of FSE does not seem to increase the risk of recurrence of a FS in general.[10] However, if the initial FS is prolonged, a recurrent FS is also more likely to be prolonged.[8]

Response to Treatment

No studies have specifically addressed the response to treatment of FSE as opposed to other causes of SE. However, as with SE of any etiology, prompt and aggressive treatment is clearly indicated.[24]

After the FSE episode, the question of preventative therapy arises. The indications and choice of subsequent preventative therapy following FSE are not clearly determined and may be controversial. Physicians may be more inclined to place an infant on prophylactic medication following an episode of FSE than following an initial complex FS of lesser duration or following a simple FS. However, in this situation, when the major concern is recurrent prolonged FS, the therapy can be designed not to prevent FS but to limit their duration, as in the use of rectal diazepam.[43] Rectal diazepam has been demonstrated to be effective in terminating FS,[58,70] and it is widely used in Europe, Canada, Japan, and United States. Children at high risk for prolonged or multiple FS and those who live far from medical care would be candidates for this approach.[56] Intranasal midazolam has also been used in treating acute childhood seizures, including prolonged FS, with some success.[4,11,35] However, it should be noted that to date there is no true intranasal preparation, and the data come from using the intravenous preparation intranasally.

Long-Term Consequences

Relationship to Epilepsy

Retrospective studies from epilepsy surgery centers demonstrate that adults with intractable TLE commonly have a history of prolonged or atypical FS in childhood.[1,16,17,22,32,40,47,48,49,64] The animal studies discussed earlier also indicate that prolonged FS may be associated with long-term changes in hippocampal excitability,[25,76] and that induced cerebral dysgenesis predisposes to hyperthermic seizures that are more severe than those seen in animals with normal brains.[37,67] Despite these observations, population-based studies have failed to find a consistent causal link between FS and brain injury or TLE.[13,14,44,53,54,61,78] Camfield et al.,[13] with access to data encompassing the entire population of Nova Scotia, concluded that the sequence of prolonged FS to MTS to TLE was highly unusual and might occur only once in 75,000 children. Lee et al., in Denmark, also concluded that TLE was not a consequence of FS.[44] On the other hand, Rocca et al.[61] looked at the population of subjects with complex partial seizures (with two case controls for each subject) drawn from the population of Rochester, Minnesota, and concluded that FS was more common in the histories of the subjects (20%) than in controls (2%). Complex FS was also more common in the subjects with complex partial seizures. Again, however, it was not clear whether FS increased the risk of complex partial seizures or whether both were due to common preceding risk factors. It is a common dilemma that, if an association of partial seizures and prolonged or complex FS is found, one cannot determine whether this is a causal relationship or an association based on some common underlying predisposition. In addition, the partial seizures are usually not further characterized, thus preventing any determination of an association with TLE specifically.

However, when considering FSE specifically, the evidence for a link to later partial epilepsy does become more convincing. In the longest follow-up study available[3], the relative risk for epilepsy following FS was assessed in a group of 687 subjects who had FS, but with no prior apparent neurodevelopmental abnormalities identified from the medical records linkage of the Rochester Epidemiology Project. These were followed for a first afebrile, unprovoked seizure for an overall average follow-up duration was 18 years. The overall relative risk for unprovoked seizures was only about fivefold that of a control cohort, or an individual cumulative risk of 0.024 for an unprovoked seizure by age 25 years. However, focal seizures, prolonged seizures, and multiple seizures within 24 hours markedly increased risk. For seizures that were focal, the risk was 0.081; for seizures of 30 minutes or more in duration, the risk was 0.065; and for repeated seizures in 24 hours, the risk was 0.064. Multiple risk factors characterizing the same seizure markedly increased the risk. Focality and a duration 30 minutes or more combined carried a risk of 0.215 and, if these seizures were also repetitive, the risk increased to 0.49 or a 50% chance of later unprovoked seizures by age 25 years. The unprovoked seizures that occurred in this focal prolonged group were classified as partial seizures; however, the lobe of origin was not determined. In the study of Berg and Shinnar,[9] each complex feature of duration, focality, and multiple occurrences was also predictive of unprovoked seizures, but the presence of multiple complex features in a subject did not increase the risk. The predictive value of focality and prolonged duration for later epilepsy, and the observation that focality and long duration are correlated in complex FS,[8] may indicate that in these children, the complex FS are a manifestation of an underlying brain abnormality predisposing to both focal FS and partial epilepsy. Alternatively, the recent MRI studies (discussed earlier) suggesting acute hippocampal abnormalities following FSE argues that the FSE itself, whatever its cause, may contribute injury that adds to the later tendency for epilepsy. Other prospective studies have confirmed that, of children suffering FS, those experiencing focal and/or prolonged seizures are much more likely to develop epilepsy than are those without these features.[47,68,78,81] Unfortunately, the detailed analysis needed to determine if the epilepsy that develops following FSE is indeed TLE is missing from the large prospective studies.

Given the multiple and careful studies just discussed, we are still unable to clearly define the relationship between FSE, severe and prolonged FS, and TLE. This remaining ambiguity reflects the inherent difficulties of demonstrating the relationship between FSE and subsequent epilepsy. First, only 5% of FS meet criteria of FSE and, of these, somewhere between only 14%[51] and 42%[73] are over 60 minutes' duration. Based on what little evidence we have in infants,[77] FSE may need to be of greater than 60 minutes' duration to be associated with clear MRI evidence of hippocampal injury. Not only are such long FS rare, but hippocampal injury is probably exceptional even given adequate duration. Second, hippocampal injury and MTS are clinically silent and therefore detection of FSE-induced brain injury requires MRI imaging, a method not readily applicable to large cohort studies. Finally, the latent period between initial insult, in this case FSE, and subsequent TLE is often over a decade, requiring long follow-up of subjects. Also, once unprovoked seizures are detected in a subject, these must be clinically and electroencephalographically characterized and assigned to a specific epilepsy syndrome using published criteria.[20] The requisite study would therefore require a very large number of subjects with FSE, available MRI facilities for initial and follow-up imaging, and very long follow-up with detailed seizure characterization. The population studies of FS available thus far have not been designed to meet these criteria, and therefore they cannot answer definitively the question of a relationship between FSE and TLE. An ongoing prospective multicenter study of FSE that is attempting to address this question has to date recruited over 100 children and is finding a high rate of acute MRI hippocampal abnormalities.[46,71]

Neurodevelopmental Outcome

Relatively few studies have addressed the long-term neurodevelopmental outcome of FSE. Early publications described higher rates of neurologic and intellectual morbidity following SE and FSE in infants[2,15,36] than do more recent studies. Reasons for the higher morbidity have been given such as lack of modern emergency transportation and care, retrospective studies of hospitalized subjects more likely to select severe cases, and less effective drug treatment. Recent studies of FSE in childhood are more optimistic.[50,73] Of 180 infants with FSE recruited prospectively, none were left with new neurodevelopmental defects following FSE, based on neurologic examinations, mental status exams, and parental reports.[73] Ellenberg and Nelson[30] examined 431 sibling pairs, one of each with a history of FS, using Wechsler Intelligence Scales for Children and Wide Range Achievement Tests. This sample included 27 children whose FS lasted longer than 30 minutes. There were no differences in cognitive function at 7 years of age between affected and siblings. Specifically, there were no differences considering the group with status alone or considering a group of 14 whose status was greater than 1 hour in duration. This is in agreement with other studies reflecting low morbidity and mortality.[23,28,80] In the British Cohort Study, there were no differences between 5-year-olds with or without FS, even when the analysis was limited to complex FS.[79,80] Verity et al.[80] reported outcomes in 19 subjects with FSE whose seizures lasted longer than 1 hour in most cases. Using British ability scales, standardized mathematics, and reading tests, 12 were tested at 10 years of age and were normal, three were tested at 5 years of age and were normal. One whose seizure was 4 hours long was abnormal, and two were documented to have been abnormal prior to the FSE. One was not tested.

In adults with MTS and TLE, memory impairment has been well documented.[42,55] If hippocampal injury were significant in FSE, one would expect memory dysfunction to be detectable in a sufficiently large sample of children following FSE. Presently, detailed memory testing data are not available in children who experienced prolonged FS.

Summary and Conclusions

FSE is a common cause of SE in infants. FSE is, in general, a one-time event; hence, studies of the pathophysiology of FSE in humans have not been done. The pathophysiology of FSE as studied in animal models of hyperthermia-induced seizures suggest that hyperthermia-induced seizures in infant rats originate in limbic brain areas, and that preexisting brain abnormalities are associated with prolonged hyperthermic seizures. It is demonstrated that prolonged hyperthermic seizures in rats can cause lifelong reduced limbic seizure threshold and, in a fraction of affected animals, the development of spontaneous limbic epilepsy. This occurs in the absence of the classical pathologic picture of MTS.

The relationship of FSE to hippocampal injury, MTS, and TLE is gradually being addressed in human studies but answers remain elusive. MRI-based studies of human infants are also demonstrating hippocampal abnormalities following FSE. These abnormalities vary from subtle and visually unapparent to gross signal and size abnormalities that often evolve in a manner suggesting that the injury was acute and due to the FSE. The ultimate significance of these MRI findings remains to be determined.

Although it remains a serious and common medical emergency in infancy, FSE appears to have a low morbidity and mortality, in large part due to rapid and aggressive medical management, and serious brain injury is probably an infrequent occurrence. Prospective studies in progress may provide more data on the relationship between FSE and TLE.

Chapter 64

Acute Physiologic Changes, Morbidity, and Mortality of Status Epilepticus

Simon D. Shorvon

John M. Pellock

Robert J. DeLorenzo

Introduction

Status epilepticus is a relatively infrequent but serious manifestation of epilepsy. In population-based studies, annual incidence rates have been shown to vary between 9.9 and 41 per 100,000.[18,25,26,27,28,29,30,31,32,44,49,51,56,85,88,99,106] The highest annual incidence rate (41 of 100,000) was found in the prospective population-based study carried out by De Lorenzo et al. in Richmond, Virginia (Fig. 1). The age distribution of the frequency of total status epilepticus events per year and the incidence of status epilepticus are presented in FIGURE 2. Extrapolating these data, 102,000 to 152,000 individuals would be affected each year in the United States (with 126,000 to 195,000 status epilepticus episodes), and over 22,000 to 42,000 deaths per year occurred in patients with status epilepticus. From hospital studies, Hauser[44,45] estimated that status epilepticus occurs in 50,000 to 60,000 individuals in the United States annually: One third of these patients present with status epilepticus (SE) as a first unprovoked seizure; one third present with established epilepsy; and one third present with no previous history of epilepsy. Recent cost studies from the Richmond group have developed estimates of the cost of SE in an urban hospital.[76] The estimate from this data indicated that the cost for care of SE in the United States per year is approximately $3 billion to $4 billion. Projecting the population of the United States to the world would suggest that SE would cost more than $70 billion to $93 billion per year on an international basis.

The differences in these incidences may reflect the different methods of data collection and the ability to correctly identify cases of SE from the medical record. Analysis from the Richmond study indicates that it is very difficult to identify cases of SE from International Classification of Diseases (ICD)-9 codes, discharge summaries, and retrospective chart reviews.[26,27] The higher incidence in the Richmond study may in part be due to the prospective nature of this study and the ability of this study to detect nonconvulsive SE cases. Nonconvulsive SE is often not detected unless aggressive electroencephalographic (EEG) monitoring is conducted on all comatose patients. Nonconvulsive SE was found in 8% of comatose patients in the Richmond study.[98] In addition, environmental, genetic, racial, and other differences may contribute to the ranges in incidences for SE in these studies. Race is a significant contributing factor in determining the incidence of SE.[26,27] Studies from Richmond had an incidence of SE of 41 per 100,000.[28] This incidence was about one to four times that of SE in the predominantly white (Caucasian) populations of other studies.[18,44,45,49,51,56,85,88,99,106] The incidence of the white population in Richmond was 19 per 100,000,[28] which compared well to several other predominantly white populations.[44,45,51,56,88,106] However, the nonwhite, African American population in Richmond had a much higher incidence of SE, 57 per 100,000.[28] Since Richmond is over 50% African American, the higher incidence in this group accounted for the higher incidence in the overall Richmond population. Correcting the Richmond data for the higher percentage of African Americans in the population gives an incidence very close to the Rochester[44,45] and Hessen[51] studies. Further investigations are needed to more fully evaluate the effects of genetic factors and race on the incidence of SE. It is essential to further evaluate these ethnic disparities in the incidence and mortality of SE around the world.

Status epilepticus can cause cerebral damage in various ways.[30] The damage caused by physiologic changes that are a direct consequence of seizure activity ("excitotoxic" damage) is usually considered the most important mechanism of damage, although status epilepticus can cause other physiologic changes that also may result in cerebral damage. The drug therapy of status epilepticus also carries risks. The situation is complex and these variables are often interrelated, and skillful medical management is essential to minimize the physiologic changes, morbidity, and mortality. Most studies have been carried out in tonic–clonic status epilepticus, and it is clear that the risk of morbidity and mortality is highest in this form. In this chapter, only this form of status epilepticus will be considered.

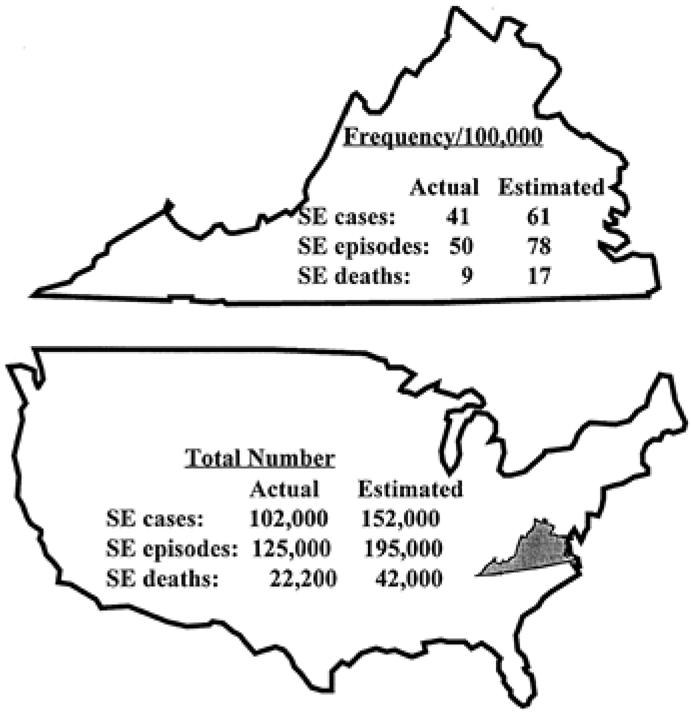

FIGURE 1. Schematic representation of the frequency and total number of status epilepticus (SE) episodes and status epilepticus deaths in Richmond, Virginia **(top),** and the United States **(bottom).** "SE cases" represents the number of patients presenting with one episode of status epilepticus in a year. "SE episodes" represents the number of occurrences of status epilepticus per year. "SE deaths" represents the number of deaths associated with status epilepticus per year. The data represent the actual and estimated values based on the validation of the case ascertainment studies in Richmond (see Materials and Methods). The estimates projected for the United States assume that Richmond, Virginia, is a representative population for the country. Further corrections for the distribution of factors such as age, race, and etiologic variations between Richmond and the United States are necessary to make more accurate projections. Studies are in progress at the VCU/MCV Comprehensive Epilepsy Institute to obtain more accurate estimates of the rates of occurrence and mortality for status epilepticus in the country and the world. (Reprinted with permission from Towne AR, Pellock JM, Ko D, et al. Determinants of mortality in status epilepticus: a retrospective study of 292 adult patients. *Epilepsia.* 1994;35:27–34.)

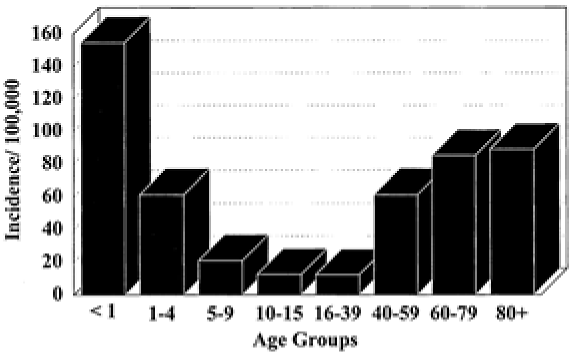

FIGURE 2. Age-specific distribution of the incidence of status epilepticus per year per 100,000 population in Richmond, Virginia. Incidence of status epilepticus represents the number of patients who developed a first episode of status epilepticus in Richmond per year per 100,000 population in each age group. These data do not include recurrent episodes of status epilepticus. The population for each age group was obtained from the 1990 U.S. Census Bureau for Richmond, Virginia. (Reprinted with permission from Towne AR, Pellock JM, Ko D, et al. Determinants of mortality in status epilepticus: a retrospective study of 292 adult patients. *Epilepsia.* 1994;35:27–34.)

Systemic Physiologic Changes in Status Epilepticus

These have been reviewed in detail elsewhere.[10,22,30,64,85] The majority of information comes from tonic–clonic SE, but some data exist from other types of SE. Below we list the changes that can influence outcome in tonic–clonic status epilepticus. Monitoring and skillful management of these changes are vital.

Blood Pressure and Heart Rate

Generalized seizures in animals and humans result in elevated systemic arterial pressures. Similar changes occur in the early phases of convulsive status epilepticus and levels occasionally reach those encountered in hypertensive encephalopathy. In the 21 patients of White et al.,[103] whose blood pressures were recorded during pentylenetetrazol-induced seizures, the mean elevation in systolic pressure was 85 mm Hg and in diastolic pressure 42 mm Hg (maximum changes over baseline were 120 mm Hg for systolic and 100 mm Hg for diastolic, with the minimum changes being 25 and 10 mm Hg, respectively). The time course of seizure-induced hypertension has been studied more thoroughly in animals.[65,90] In the setting of bicuculline-induced status epilepticus in sheep, systemic pressure, heart

P.738

rate, and plasma epinephrine/norepinephrine concentrations each peaked within the first minute of seizure activity (Fig. 3). Systemic pressure elevations of approximately 150% then returned gradually to baseline over the first 60 minutes of status epilepticus, whereas epinephrine and norepinephrine concentrations as well as heart rate showed only modest attenuation. Benowitz et al.[8] speculated that the mechanism responsible for the decline in blood pressure despite persistent sympathetic activation during status epilepticus was desensitization of vascular adrenergic receptors or hypovolemia induced by vasoconstriction with the resultant movement of blood volume into extracellular spaces. Plasma catecholamine levels after spontaneous single seizures[89] in humans are presented in FIGURE 4. With single seizures or a flurry of seizures, systemic hypertension occurs as well. Again, the peak pressures occur within the first minute, and the maximum level reached is not different between one seizure, a flurry of seizures, or status epilepticus[7] (Fig. 5).

With prolonged status epilepticus, blood pressure decreases to levels below baseline.[8,63] The risk of cerebral hypoperfusion then arises due to the inhibition of cerebral autoregulation during seizures due to a decrease in cerebral vascular resistance.[78] In experimental primates, boundary zone lesions occurred in the cortex and cerebellum when blood pressure was <75 mm Hg during the final 30 minutes of status epilepticus.[65] Drug therapy can also greatly lower blood pressure, and this is a common clinical problem, for instance, with the use of bolus doses or prolonged infusion of anesthetic agents, barbiturates, phenytoin, and benzodiazepines. Pressor agents are often required during anesthesia in status epilepticus, and blood pressure must be carefully monitored.

Cardiac Effects

Status epilepticus can have significant effects on cardiac function. The Richmond study has provided direct evidence in humans of the effects of SE on cardiovascular function.[11,12] These studies indicate that during or immediately after control of SE, patients exhibit a high frequency of electrocardiographic (ECG) abnormalities when compared with expected rates of abnormalities in control populations. Several ECG abnormalities, including ischemia, conduction defects, prolongations of the QTc interval, the presence of latent potentials on sinoatrial ECGs, and the absence of the expected sinus tachycardia during SE, correlated significantly with mortality.[12] Monitoring patients after SE and up to the time of death with cardiac monitoring, it was found that at the time of death after SE, two distinct cardiovascular patterns of mean arterial pressure (MAP) and heart rate (HR) were observed.[11] One group of patients manifested a gradual decline in MAP and/or HR (GDP), and the other group showed sudden death with an acute cardiac decompensation pattern (ADP). These studies represent the only large comprehensive, prospective, population-based data to evaluate central nervous system (CNS) and cardiac factors in the mortality of generalized tonic–clonic, partial complex, and nonconvulsive SE in humans.

Acidosis

A severe lactic acidosis is a prominent accompaniment of status epilepticus in humans and animals[5,64,72] (Fig. 6). Arterial pH measurements in 70 spontaneously ventilating patients with status epilepticus ranged from 6.28 to 7.5; the pH was <7.35 in 59 patients and <7.0 in 23 patients.[5] A respiratory component to the acidosis was found in 30 patients, of whom 13 had a recorded PCO_2 over 60 mm Hg. The decrease in blood pH

P.739

P.740

P.741

is rapid (from 7.33 to 6.83 within 4 minutes in rats),[91] reaching minimal levels within 15 to 20 minutes of status epilepticus in baboons (6.47 to 6.86).[65] The rapid rate of decrease of pH is also demonstrable by the similar pH values found after a single seizure: 6.86 to 7.36.[72] A respiratory component to the acidosis in a single seizure also was seen (PCO_2 range 31 to 65 mm Hg). The pH then normalizes over 60 minutes as the causative agent, lactic acid, is metabolized. Other potential causes of acidosis include an acceleration of glycolysis, tissue hypoxia, and catecholamine release. Seizure-induced acidosis is markedly attenuated by treatment with neuromuscular paralysis,[67,91] showing that anaerobic metabolism in muscle is the major source of lactate accumulation. In well-ventilated and paralyzed patients, acidosis is not usually a major clinical problem, and although the administration of bicarbonate can be helpful, this is not usually required and should not be given routinely.[85]

FIGURE 3. A: Responses of systemic arterial blood pressure and heart rate to status epilepticus induced by bicuculline injection (time 0). Seizure activity persisted for the duration of the experiment in paralyzed sheep. Data points represent mean (± standard error of the mean [SEM]) of five animals, except for heart rate at 120 and 180 minutes, which represent data collected from two animals. Asterisks indicate a significant difference from pressurized value (p <0.05). **B:** Plasma norepinephrine and epinephrine response to status epilepticus (mean ± SEM). Asterisks indicate a significant difference from pressurized value (p <0.05). (From Aminoff MJ, Simon RP. Status epilepticus. Causes, clinical features and consequences in 98 patients. *Am J Med.* 1980;69:657–666.)

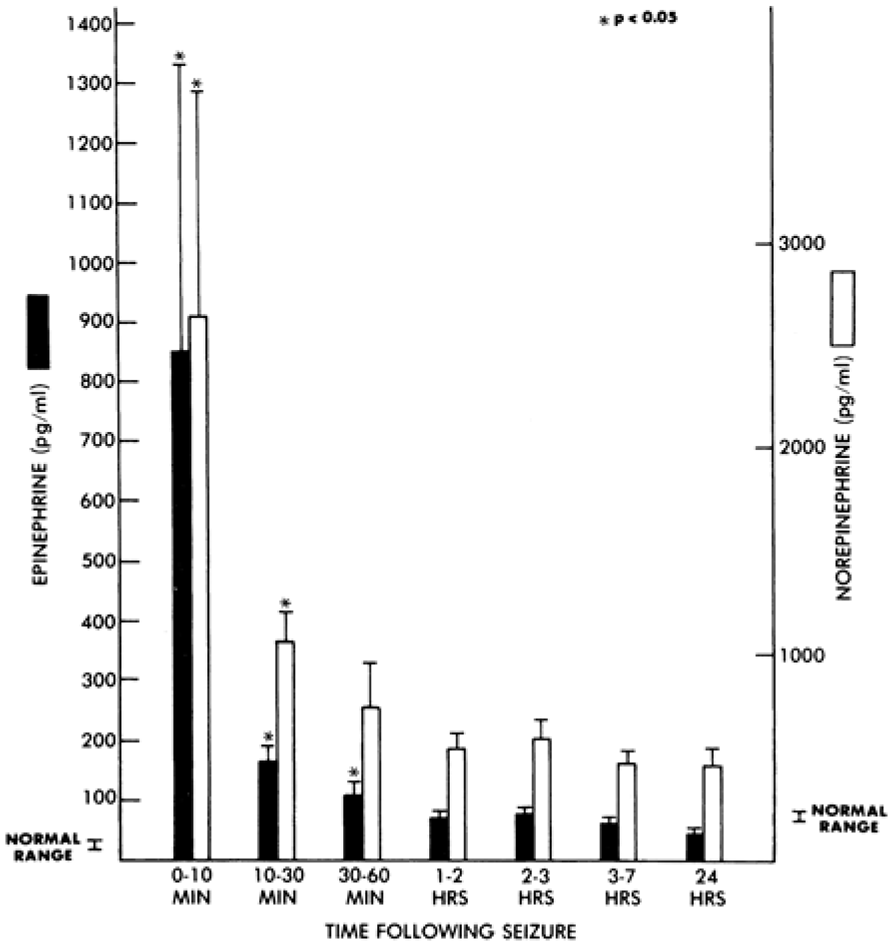

FIGURE 4. Plasma epinephrine and norepinephrine concentrations after a single generalized tonic–clonic convulsion. Data expressed as geometric means (± status epilepticus). (Reprinted with permission from Simon RP, Aminoff MJ, Benowitz NL. Changes in catecholamines after tonic clonic seizures. *Neurology.* 1984;34:255–257.)

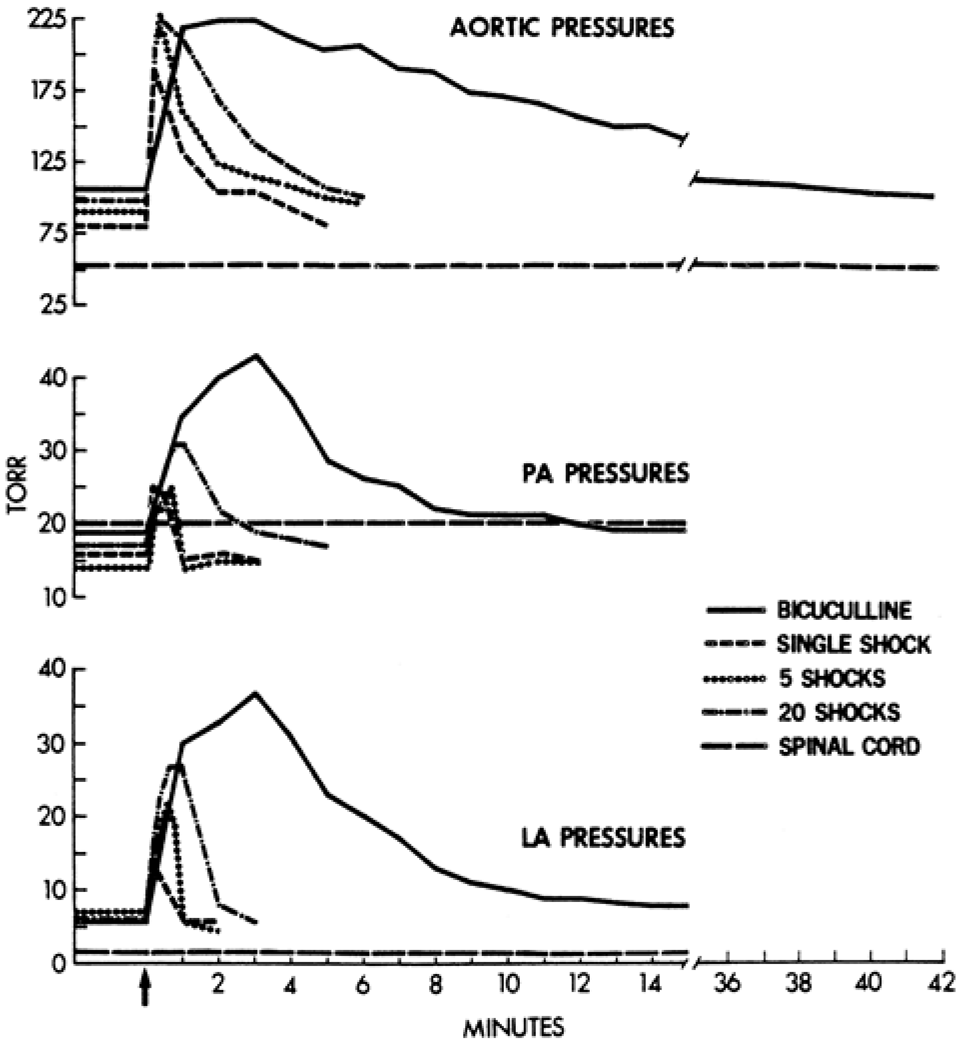

FIGURE 5. Vascular pressure elevations during seizures in sheep; mean values, plotted at 10-second intervals. "Spinal cord" refers to animals with cervical spinal cord transection before seizures. "Single shock," "5 shocks," and "20 shocks" refer to numbers of electroconvulsive seizures induced. "Bicuculline" refers to bicuculline-induced status epilepticus. PA, pulmonary arterial; LA, left atrial. (Reprinted with permission from Bayne LL, Simon RP. Systemic and pulmonary vascular pressures during generalized seizures in sheep. *Ann Neurol.* 1981;10:566–569.)

The induced acidosis is not thought to be generally correlated with the degree of neuronal injury in status epilepticus. In the classic studies of Meldrum and Brierley,[64] the mean arterial pH during the last 30 minutes of status epilepticus was 6.92, 7.08, and 7.14 in animals with no, moderate, or severe CNS damage, respectively. Using heat shock protein immunocytochemistry as a marker of neuronal injury in experimental status epilepticus, acidotic animals (paralyzed and ventilated with 10% CO_2) had less neuronal injury than did animals with normal pH. However, the apparent protective effect was due to attenuation of seizure duration in the acidotic animals.[79] It is also worth noting that acidosis has a strong anticonvulsant effect (a fact underpinning the use of the ketogenic diet in epilepsy, for instance).[104]

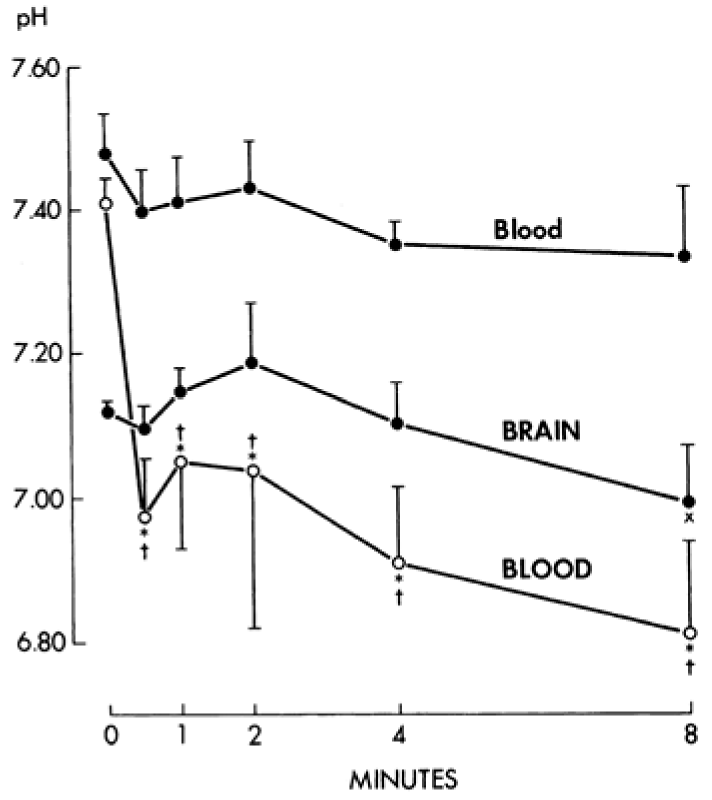

FIGURE 6. Blood and brain pH during status epilepticus. •, paralyzed–ventilated animals; ○, nonparalyzed (freely convulsing) animals (brain pH not determined in freely convulsing animals). Status begins at time 0. Data plotted as means ± standard deviation. **p* <0.001 control value (time 0) versus each time point for blood pH in freely convulsing seizures. *p* <0.001 blood pH paralyzed versus nonparalyzed animals at each time point. ×*p* <0.005 brain pH, time 0 versus all time points. (Reprinted with permission from Simon RP, Aminoff MJ, Benowitz NL. Changes in catecholamines after tonic clonic seizures. *Neurology.* 1984;34:255–257.)

Hypoxia

Arterial oxygen tension decreases modestly in status epilepticus.[64,65,80] The mean arterial PO_2 values were 58 to 68 mm Hg in experimental primates that showed no moderate or severe neuropathic change.[64] Results of human and experimental studies support the concept that hypoxia alone does not induce brain damage, at least in the early stages of status epilepticus.[13,42] In fact, there is some evidence that hypoxia may be neuroprotective during seizures. Blennow et al.[10] demonstrated that a reduction of arterial PO_2 to 50 mm Hg during the 2 hours of experimental status epilepticus protected animals from neuropathic damage in the cortex hippocampus and striatum; prominent ischemic cell change occurred in animals with induced status epilepticus without hypoxia. Blennow suggested that its protection was due to an attenuation of seizure intensity as measured electroencephalographically. Amano et al.[4] also noted the ameliorative effect of hypoxia (8.5% oxygen with balanced nitrogen) upon seizure induction and excitotoxic injury resulting from intravenous kainic acid. On the other hand, maximal oxygenation (ventilation with 100% oxygen) does not exacerbate neuropathic change in experimental status epilepticus.[94] As status epilepticus proceeds, however, it is likely that prolonged hypoxia does carry a risk of serious damage via many potential mechanisms including free radical release, rupture of lysosomes, and the induction of intracellular acidosis and apoptotic cascades. The increased demands for oxygen are not confined to cerebral tissue, and there are impressive metabolic demands from convulsing muscles. The protection of respiratory function and administration of oxygen is an important element of the emergency management of convulsive status epilepticus.

Pulmonary Edema

Status epilepticus affects not only inspiratory and expiratory effort, but also the passage of fluid across the pulmonary capillary bed. The barrier to this movement is at the pulmonary capillary. The major clinical problem is the occurrence of pulmonary edema. This was found in 15 of 41 patients who died during status epilepticus[71] and in eight patients with the diagnosis of epileptic sudden death.[95] Repetitive seizures or status epilepticus are more likely to be followed by pulmonary edema than by a single seizure.[20] The best experimental studies have been carried out in sheep, and status epilepticus resulted in increases in pulmonary arterial pressure of up to 685% of that in resting states.[7] The greater the number or the longer the duration of seizures, the higher are the increases in intravascular pressures (Fig. 6), and the fall in pulmonary arterial pressure after seizures lags behind that of the systemic arterial pressure. These pulmonary arterial pressures are well in excess of the osmotic pressure of blood, and the lung capillaries also suffer from stretch injury. These marked increases in intravascular pressure in the pulmonary capillaries cause a doubling of pulmonary lymphatic drainage, an increase in transcapillary albumin conductance, and an alteration in pulmonary capillary permeability[90] (Fig. 7).

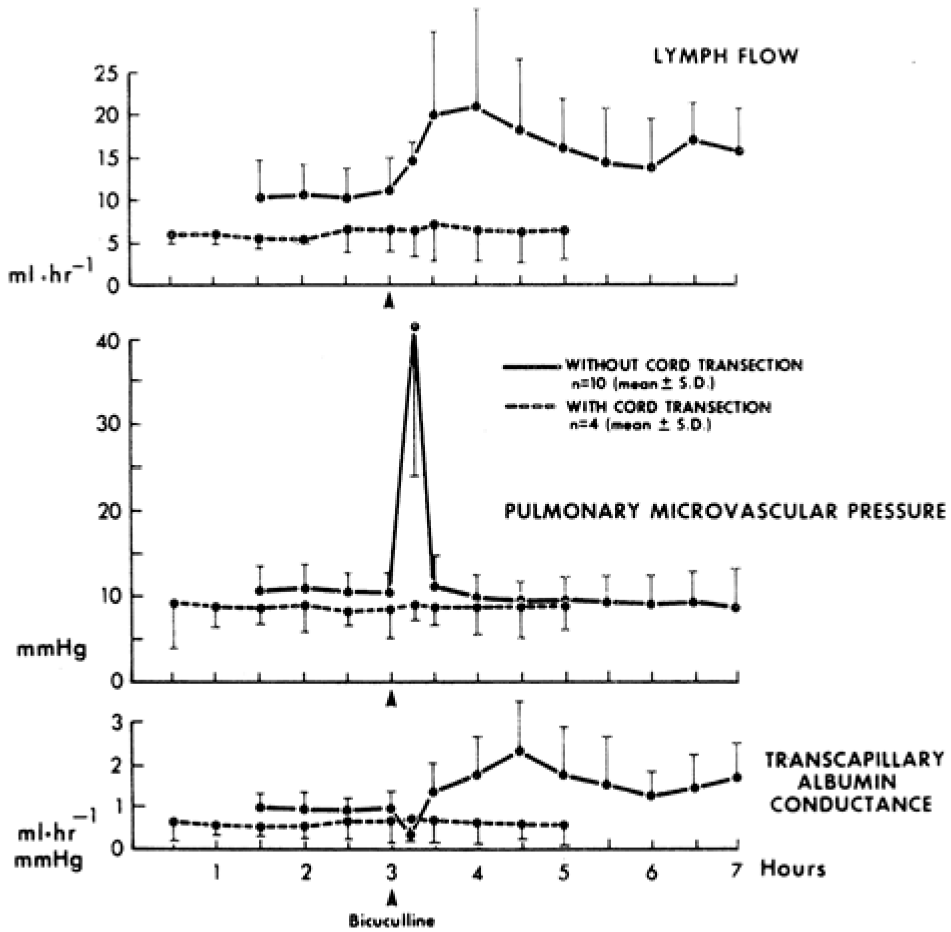

FIGURE 7. Pulmonary lymph flow, calculated pulmonary microvascular pressure, and calculated pulmonary transcapillary albumin conductance before and during bicuculline-induced status epilepticus in ten paralyzed, halothane-anesthetized sheep (*solid line*) and four sheep with cervical spinal cord transection (*broken line*). Values are presented as means ± standard deviation. *Arrowheads* indicate administration of bicuculline. (Reprinted with permission from Simon RP, Bayne LL, Tranbaugh RF, et al. Elevated pulmonary lymph flow and protein content during status epilepticus in sheep. *J Appl Physiol.* 1982;52:91–95.)

Status epilepticus. Causes, clinical features and consequences in 98 patients. *Am J Med.* 1980;69:657–666.)

Body Temperature

Hyperthermia is a very common accompaniment of major motor status epilepticus. The convulsing muscles and the sympathetic overactivity due to the heat produce the rise in temperature. The importance of the latter is shown by the increase in body temperature in paralyzed animals.[100] In baboons paralyzed at the onset of status epilepticus, a mean temperature

P.742

increase was 2.05°C (range 1.0 to 2.7) over a 7-hour period of observation. In freely convulsing experimental primates, a core temperature of >40°C, persisting for more than 3 hours, was associated with neuronal damage, greater than that predicted from the seizure duration alone.[64,100] The neuronal damage was most prominent in the cerebellum. In these animals, the temperature elevation of 40°C was reached within 60 to 90 minutes of status epilepticus onset.[100]

In 90 patients in status epilepticus, hyperthermia was found in 75, with core temperatures reaching 107°F (42°C) (Fig. 8). The highest temperatures were found in patients with prolonged status epilepticus (more than 9 hours) and were

P.743

associated with brain injury.[5] The duration of hyperthermia persisting after status epilepticus cessation can be estimated from reports of temperature elevation after single seizures. Most patients remained febrile at 12 hours, but only 3 of 27 were febrile at 48 hours.

Leukocytosis

An elevation in the peripheral white blood cell count in status epilepticus is common, possibly due to the rapid elevation in plasma catecholamine concentrations. Such demarginated leukocytes resulted in white blood cell counts of 12,700 to 28,800 cells/mm^3 in 50 of 80 patients in status epilepticus in whom there was no evidence of infection.[5] A polymorphonuclear predominance was found in 17 of these patients, a lymphocytic predominance in 11, and a differential cell count with a normal distribution in 15.

Rhabdomyolysis and Renal Failure

Prolonged or violent convulsive movements during generalized tonic–clonic status epilepticus can cause muscle necrosis and acute rhabdomyolysis.[105] Anoxia due to decreased muscular vascular supply in decubitus comatose status epilepticus patients can contribute to severe muscle damage and rhabdomyolysis. Although severe rhabdomyolysis is uncommon in status epilepticus, it can be a serious complication because myoglobinuria can result in renal failure from acute tubular necrosis.[43,93] Renal damage due to tubular necrosis from myoglobinuria or dehydration can lead to fulminant renal failure in extreme cases. Use of artificial ventilation and muscle paralysis in the intensive care unit can minimize the extent of rhabdomyolysis.

Cerebrospinal Fluid Changes in Status Epilepticus

A rise in cell count in the spinal fluid in the absence of an infectious process is rare after single seizures but is common in status epilepticus. Such a phenomenon was found in 12 of 65 cases (18%) reported by Aminoff and Simon.[5] The cell counts were often maximal the day after the status epilepticus. The rise in cells is usually modest, and in the series of Aminoff and Simon[5] was above 70 cells/mm^3 in only 2 out of 70 cases (3%). Personal cases have occasionally been encountered with cell counts of up to 100 cells/mm^3. Cell counts normalize over a few days, with polymorphonuclear predominance yielding to mononuclear cells as the pleocytosis resolved. Modest elevations in protein content can be seen as well (maximum 62 mg/100 mL). Cerebrospinal fluid (CSF) glucose concentrations in the series of Aminoff and Simon[5] were modestly elevated (range 52 to 204), reflecting the elevation in plasma glucose levels. Similar observations have been made subsequently by others.[6,82]

Other Physiologic Changes

A wide range of other physiologic changes and systemic complications can occur in status epilepticus,[83] and the incidence and risk rises the longer the status persists. Changes include disseminated intravascular coagulation (DIC) and multiorgan failure. Various mechanisms may predispose to this including rhabdomyolysis, hypoxia, acidosis, thromboplastin release, hyperpyrexia, and drug renal or hepatic failure.[21,37] The use of valproate or lamotrigine may also increase the risk.[80] Electrolyte disturbances (of many types) and renal failure can occur in status epilepticus due to dehydration, systemic hypoxia, hyperpyrexia, drug therapy, or rhabdomyolysis. Hepatic failure seems, at an anecdotal level, to be more common and again may be induced by drug therapy (particularly valproate) or the underlying cause of the status epilepticus—a particular issue in Alpers syndrome or other mitochondrial diseases. Vomiting; acute pancreatitis[70]; excessive sweating, salivation, and tracheobronchial secretions; inhalation and asphyxia; trophic and skin changes; bed sores; limb fractures[75]; infection; thrombophlebitis; and peripheral ischemia are other complications of status epilepticus that interfere with management and can worsen outcome.

Central Nervous System Physiologic Changes in Status Epilepticus

Oxygen and Glucose Utilization in Status Epilepticus

Cerebral oxygen and glucose utilization is probably greater in epileptic seizures than in any other cerebral activity. In the early stages of status epilepticus, the cerebral cellular metabolic rate and the demand for oxygen and glucose are profoundly increased. This has been clearly demonstrated in human studies with positron emission tomography and metabolic analysis.[38,39,62,87] It has been recognized that the capacity of cerebral tissue to cope with these metabolic demands deteriorates over time. Initially, the increased demands are compensated for by greatly increased cerebral blood flow. This initial physiologic state is referred to as stage I of status epilepticus (stage of compensation).[14,100,101] During this time, because the demand for oxygen and glucose is matched by supply (from the markedly increased cerebral blood flow), no damage occurs.

As status epilepticus continues, the supply of oxygen and glucose begins to fail, and stage II (the stage of decompensation) develops. Cerebral cellular hypermetabolism recedes, and indeed, in late status epilepticus, hypometabolism and ischemia are common. The time taken for stage I to evolve into stage II depends on factors such as etiology, duration and severity of seizure activity, the site of seizure activity, and the treatments used. One factor probably key to this process is the fall in cerebral blood flow. This falls over time as systemic blood pressure falls, and the failure in cerebral perfusion is probably critical in the transition from stage I to stage II, although evidence is contradictory. Siesjo's group[87] showed that in stage II, cerebral blood flow was no longer increased to meet the increased demand of the elevated cerebral metabolism, thus resulting in neurologic injury. In contrast, however, Meldrum[62] found that during stage II of status epilepticus, cerebral blood flow did not decrease, and suggested that a mismatch between metabolism and blood flow was not critical for brain damage. He suggested that a toxic chemical or chemicals are released during status epilepticus and that these compounds are responsible for brain injury. In addition, decreased glucose levels and oxygenation can be observed in very late stages of status epilepticus if patients are not properly ventilated, further contributing to cerebral hypoxia and anoxia. More human and animal studies are necessary to fully understand the relationship of blood flow

and oxygen and glucose utilization during the very late stages of status epilepticus.

Excitotoxic Cellular Damage

Meldrum,[62] based on his classic experimental studies of status epilepticus, suggested that excessive accumulation of intracellular calcium ions in neurons during status epilepticus precipitates a cascade that leads to cell damage. This *excitotoxic* cellular damage is thought now to contribute most to cellular damage in tonic–clonic status epilepticus, and it is because of this risk that urgent intravenous therapy is required.[30] The cerebral cortex, hippocampus, and cerebellum are the cerebral areas most affected by excitotoxic damage. Both apoptosis and necrosis occur and the resultant histologic changes include neuronal loss, atrophy, and gliosis.

Intracranial Pressure Changes and Cerebral Edema

Intracranial pressure during spontaneous seizures in children has been shown to increase by 30 to 40 mm Hg, and this elevation has been shown to persist for up to 20 minutes after seizure cessation.[68] Intracranial pressure during status epilepticus increases in a linear relationship with arterial pressure.[66] During pentylenetetrazol-induced seizures in humans, the mean intracranial pressure elevation was 549 cm H_2O (42 mm Hg), with a range of 270 to 800 cm H_2O or 21 to 61 mm Hg.[68] Electroshock-induced seizures in dogs[46] produced intracranial pressures of approximately 80 mm Hg over baseline. In this study, the elevation in blood pressure (150 mm Hg) was greater, however, resulting in cerebral perfusion pressure that remained above baseline values. In human status epilepticus, the intracranial pressure is often elevated, especially in the early stages. As systemic blood pressure falls, the intracranial pressure can also fall. Cerebral edema is a common occurrence in tonic–clonic status, especially in children, and is often the result of changes in intracranial pressure, low cerebral perfusion, and systemic hypoxia. However, localized cerebral edema in the seizure focus is commonly shown on imaging[47] and so edema can be produced presumably by local membrane changes related to seizure activity as well as any general rise in intracranial pressure. In generalized tonic–clonic status epilepticus, intracranial pressure monitoring is often indicated, especially in children, to anticipate and prevent cerebral edema and ischemia. Raised intracranial pressure is associated with a poor outcome, and this has been well studied particularly in status epilepticus due to infection (Japanese B encephalitis or malaria).[19,69]

Blood–brain Barrier Changes

Cerebral blood vessels are lined with endothelial cells that allow less molecular transfer across the wall of the blood vessels than elsewhere in the body. This blood–brain barrier prevents the entry of certain blood compounds into the brain tissue. Only small molecules or ions with specific transfer systems or highly lipid-soluble molecules can normally easily enter the brain.[89] During severe status epilepticus, the blood–brain barrier is compromised[41] and more compounds gain entrance to the brain. This exposes brain tissue to risk of injury and damage and adds potentially to the morbidity and mortality of status epilepticus. The extent to which blood–brain barrier injury does contribute to morbidity in human status epilepticus is unknown. The increased local permeability of the brain in epileptic foci may in fact aid the distribution of therapeutic agents (e.g., phenobarbital) to these foci.[92]

Cerebral Vascular Changes

Cerebral arterial hemorrhage and infarction, cortical venous thrombosis, and other vascular catastrophes are well recorded in status epilepticus and are a reflection of poorly controlled metabolic and physiologic changes. Vascular changes have also been implicated in cerebral edema, and infarction due to coning can occur.

Electrophysiology Changes

There are several important EEG[32,48] and evoked potential (EP)[89] electrophysiologic changes that have been shown to occur following SE. These changes have been shown to be predictive of both morbidity and mortality in SE.[32,48,89] Abnormal EP changes following SE indicate neuronal injury and were observed in both cortical and subcortical structures following both tonic–clonic SE and partial SE.[89] DeLorenzo et al. have shown that 1 hour after the successful treatment of convulsive SE, 67% of SE cases were still in coma either due to medication effects or underlying medical problems. Continuous EEG monitoring of patients in coma for more than 2 hours after the successful treatment of clinical convulsive SE demonstrated that 14% of the comatose patients were still in nonconvulsive SE[32,48] and an additional 40% manifested persistent after SE ictal discharges.[32] These results demonstrate the pronounced effects of both tonic–clonic and partial SE on the central nervous system.

Acute Morbidity of Status Epilepticus

The morbidity of human status epilepticus has been surprisingly poorly studied. The main sequelae among survivors of tonic–clonic status epilepticus are intellectual dysfunction, permanent neurologic deficits, and continuing recurrent seizures.[1,16,59,86] Neuropathologic studies in animals by Meldrum and others have demonstrated conclusively that prolonged epileptic activity, even if blood sugar and oxygen are maintained at normal levels, can result in irreversible neuronal damage.[63,64,67] These were the first studies to show that the duration of the seizure activity is a crucial factor in determining outcome, and this finding has been confirmed repeatedly both in experimental and human studies. They showed that seizures lasting <1 hour may produce neuronal changes that are reversible, but longer-lasting seizures produce permanent neuronal injury.[63] Similarly, in human status epilepticus, many studies have shown that the longer the seizure duration, the worse the outcome in terms of both mortality and morbidity.[25,26,27,31,86,96] Several other clinical parameters also have been associated with morbidity and mortality. Studies have suggested that prognosis depends on the interval of time allowed to elapse between the onset of status epilepticus and the start of effective treatment.[3] Almost all clinical studies have shown also that the underlying etiology is an important determinant of morbidity and mortality.

Most studies have been of children and concentrated on neurologic deficits. There are few studies of psychometric changes after status epilepticus, in spite of the common clinical experience of cognitive and particularly memory deficits in the aftermath of status epilepticus, albeit often transitory.[33,34,35] Furthermore, it has proved extremely difficult to disentangle the effects of status epilepticus per se from the effects of the

precipitating cause (e.g., encephalitis, vascular insult, etc.). This issue has bedeviled studies in this field. The longer-term morbidity in terms of mental impairment and neurologic deficit are discussed in Chapter 65.

The main acute deficit caused by status epilepticus in children has been termed the HH and HHE syndromes (initials referring to the permanent hemiplegia or hemiparesis, mental retardation, and chronic epilepsy [in about three quarters]). This is usually the result of a prolonged asymmetric or unilateral febrile convulsion in a child under 4 years of age (usually under 2 years).[1] Many of these children have some neurologic dysfunction before the SE, and the SE may be of greater severity than usual, reflecting this. The damage is probably due to a mixture of vascular and excitotoxic mechanisms. It used to be a relatively common sequela to febrile SE,[1,2,3] and indeed was present in 25 of 79 children with status lasting 1 hour or longer in a Japanese series published in 1979.[40] Nowadays, however, with rapid and effective early therapy, HH and HHE are rare occurrences in developed countries, although they are still frequent and preventable in the developing world. This improvement is very likely to be the consequence of more rapid and urgent control of convulsive and febrile SE.

There is equally little information available on the rate of morbidity associated with status epilepticus in adults. There are a number of old studies from a period when drug treatment was more limited and when therapy was not administered with the same degree of urgency as is current practice. Rowan and Scott[80] examined 42 patients with tonic–clonic status epilepticus and indicated that 26% had neurologic sequelae but did not provide details. Their study indicated that greater deterioration related to longer periods of status epilepticus. The first modern study of outcome among 86 patients was carried out by Oxbury and Whitty.[73,74] They demonstrated that 2% of the patients without a specific neurologic etiology deteriorated with adverse personality and intellectual changes after status epilepticus. Aminoff and Simon[5] evaluated 98 patients with histories of tonic–clonic status epilepticus in a retrospective study and demonstrated that approximately 8% of the patients had diffuse encephalopathy and intellectual impairment after status epilepticus. Their study also indicated that longer episodes of status epilepticus were associated with a greater degree of impairment. The risk of epilepsy following status is discussed in Chapter 65.

Acute Mortality of Tonic-Clonic Status Epilepticus

Status epilepticus results in significant mor-tality.[16,17,22,23,24,25,26,27,28,29,30,31,32,36,52,54,55,56,57,59,60,73,74] Case fatality rates as high as 50% have been reported, but the more recent studies have reported rates between 8% and 32%.[16,22,23,24,25,26,27,28,29,30,31,32,56,57,59,73,74] The rates reported in large hospital series have varied considerably, depending on the type of population evaluated, whether all types of SE were included, and the referral base of individual hospitals.[16,22,23,24,25,26,27,28,29,30,31,32,56,57,59,73,74] The variability in mortality rate also relates to the distribution of underlying etiologies within each series, as well as to the duration of follow-up of patients in the acute versus late stage of mortality after status epilepticus. The mortality rate for status epilepticus has decreased over the past 60 years, probably being related to more rapid and aggressive treatment of this condition. The mortality rates in more recent population-based studies have been reviewed[57] and have reported case fatality rates of between 7.6% and 39%. Much of the variation is due to the inclusion or exclusion of patients with myoclonus due to acute anoxic encephalopathy within the rubric of status epilepticus. Series in which such cases are excluded[18,51] show a low mortality, whereas studies in which they are included have much higher rates.[28,29,30,31,32,56,57] Rates have also been found to be higher in white Americans compared to black Americans (31% vs. 17%) in one study.[28] A largely consistent finding has been the higher mortality in status epilepticus due to acute brain disorders. In the Rochester study, for instance, 90% of all deaths were in the acute symptomatic group and no deaths occurred in the idiopathic group,[56,57] and this reiterates the similar findings of studies over the previous decades (see 85 for a review). The importance of the underlying cause is shown in the meta-analysis of series up to 1989[85] in which the overall mortality rate of 1,686 cases was 18%, of which only 2% were attributable to the status epilepticus itself.[85] A large study from Waterhouse et al. has evaluated the interaction between SE and the underlying etiology or symptomatic conditions associated with SE.[102] In this study it was shown that there was a synergistic interaction between the underlying etiology, cerebral vascular event, and SE in causing mortality. The mortality of SE alone or the cerebral vascular event was much less than the mortality due to a combination of SE and stroke. This study controlled for the size and severity of the cerebral vascular event. These results indicate that the combination of SE and an underlying etiology have a complex effect on mortality, and this important area needs further investigation.

Classic studies by Aicardi and Chevrie[2] reported in 1970 indicated that the mortality rate in children approached 11%, and in half of these cases, death was due to status itself. Many of these children had febrile status epilepticus. These studies stressed, for the first time, the importance of early therapy and were very influential. The more urgent approach to therapy greatly improved mortality rates, and a subsequent study by Maytal et al.[61] described 193 children of whom only seven died after status epilepticus. Similarly, in 1989, Philips and Shanahan[77] reported their study, designed to revisit those of Aicardie and Chevrie, of 218 episodes of childhood status epilepticus in patients admitted to a pediatric intensive care unit over a 5-year period, among whom there was an overall mortality rate of only 6%. The importance of early therapy continues to need to be stressed, as the outcome of status in children remains poor in developing countries, where access to early therapy may not be available.

The mortality rate in adults is consistently reported to be higher than that in children. Nineteenth-century studies, conducted before effective therapy (other than bromide) was available, estimated that 30% to 50% of adults with status epilepticus died.[9,15,58] A series of studies between 1970 and 1990 reported mortality rates in adults between 14% and 35%.[85] In more recent studies, Towne et al.[96] in a series of 256 patients demonstrated an overall mortality rate in adults of 22%. De Lorenzo et al.[23,24,25,26,27,28,96,97,98] studied mortality in a population-based prospective study from Richmond, Virginia. This is the largest and most comprehensive clinical investigation of status epilepticus carried out and has provided very important data (Figs. 9,10,11,12). The overall mortality rate associated with status epilepticus in the entire population was 22%. The mortality rate of status epilepticus at different ages is shown in Figures 9 and 10. Mortality rates increase with age, and the highest rates were seen in the elderly (38%). The rate in children was 3% and among young adults 13%. The Richmond studies also compared mortality rates in generalized and partial status epilepticus[31,96] and no significant differences were found. Seventy-three percent of patients had generalized status epilepticus and 27% had partial status epilepticus (Fig. 11A). Of those patients with partial status epilepticus, the mortality rate was 30.4%. Patients with generalized tonic–clonic seizures had a mortality rate of 20.7% (Fig. 11B). The lack of difference probably reflects the importance of the underlying etiology in

determining mortality, and those presenting with focal neurologic lesions, such as stroke or infection, in this study are classified as partial status epilepticus.

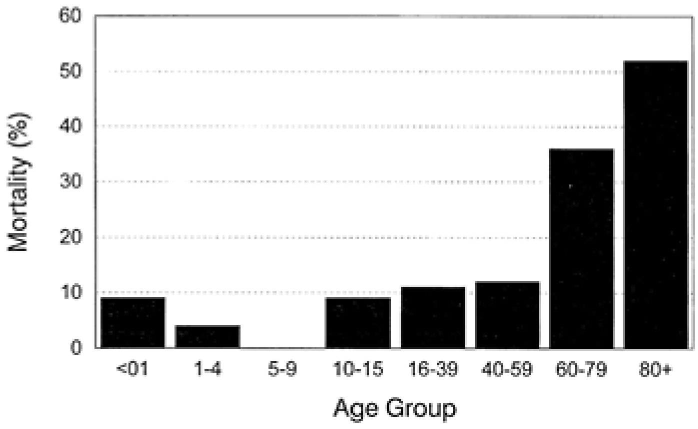

FIGURE 9. Mortality of each age group in the Medical College of Virginia population. Data represent the mortality for each age group. (Reprinted with permission DeLorenzo RJ. Clinical and epidemiologic of status epilepticus in the elderly. In: Rowan AJ, ed. *Seizures and Epilepsy in the Elderly.* Newton, MA: Butterworth-Heinemann; 1996:191–205.)

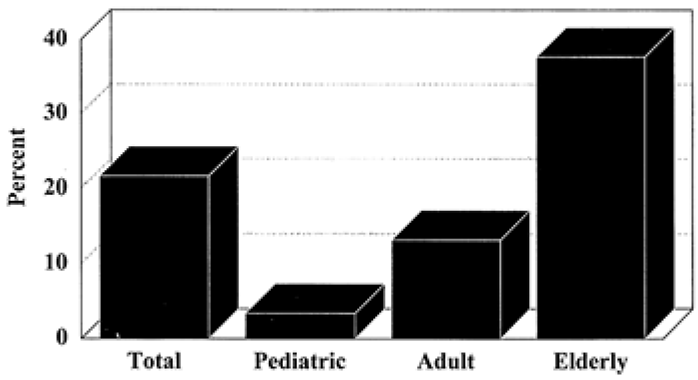

FIGURE 10. Mortality of status epilepticus in Richmond for the total, pediatric, adult, and elderly populations. Data represent the percentage mortality for each age group in the population. Mortality is expressed as the number of status epilepticus–associated deaths in each age group and as a percentage of the number of patients that died in each age group. (Reprinted with permission from Towne AR, Pellock JM, Ko D, et al. Determinants of mortality in status epilepticus: a retrospective study of 292 adult patients. *Epilepsia.* 1994;35:27–34.)

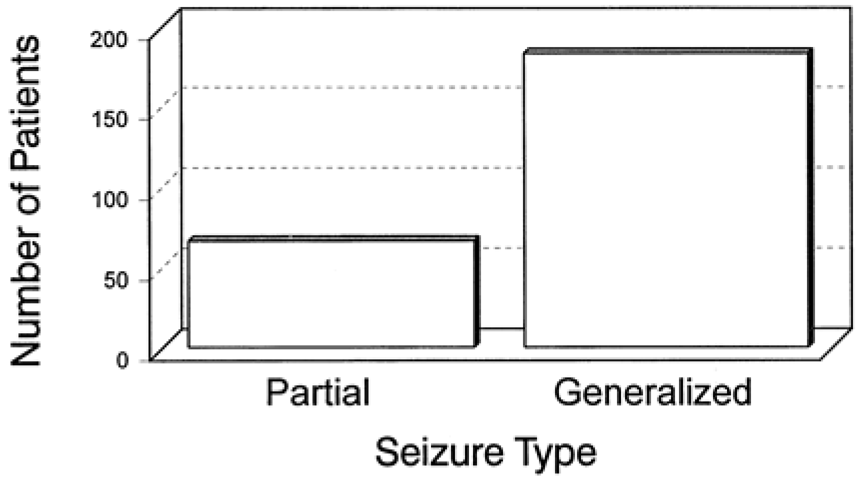

FIGURE 11. Seizure type and mortality. **A:** Seizure type as a function of the number of patients. Most patients had generalized seizures. **B:** Patient mortality rate for partial and generalized seizures. (Reprinted with permission from Towne AR, Pellock JM, Ko D, et al. group. (Reprinted with permission from Towne AR, Pellock JM, Ko D, et al. Determinants of mortality in status epilepticus. *Epilepsia.* 1994;5:27–36.)

The etiology of status epilepticus has an overriding influence on mortality, and indeed in modern practice, the fatality rates of status itself are under 5%.[5,26,27,28,44,45,53,56,57,81,85,96,97] The etiologies of status epilepticus in pediatric and adult patients in the Richmond Study are shown in Table 1. The major cause of status epilepticus in children was systemic, non-CNS infections, which accounted for more than 51% of status epilepticus cases in children. This was the only cause resulting in death. In the adult population, major etiologies included lowered antiepileptic drugs (34%), stroke (22%), alcohol-related disorders (13%), metabolic disorders (15%), and anoxia/hypoxia (18%). The mortality rates in children and adults are shown in Table 1. Rates are higher in adults and are highest in cases due to acute anoxia and hypoxia (71% and 53%, respectively) and are significant for cerebrovascular disease (33%), tumor (30%), and metabolic (30%) etiologies. Lowered antiepileptic drugs (4%) and alcohol-related disorders (20%) had lower mortality rates.

Table 1 Etiology and Mortality Rates for Pediatric and Adult Cases of Status Epilepticus (SE)

	Pediatric		Adult	
Etiology	**% of SE cases**	**Mortality**	**% of SE cases**	**Mortality**
Anoxia	0	0	5	71
Hypoxia	5	0	13	53
CVA	10	0	22	33
Hemorrhage	0	0	1	0
Tumor	0	0	7	30
Infection	52	5	7	10

Trauma	0	0	3	25
Remote	38	0	25	14

CNS, central nervous system; CVA, cerebrovascular accident; LAED, lowered antiepileptic drugs; OD, overdose.

Summary and Conclusions

Status epilepticus is a major medical and neurologic emergency that is associated with acute physiologic changes that can be severe enough to cause significant morbidity and mortality. SE has significant effects on blood pressure and heart rate and also can cause marked acidosis. Hypoxia and impairment of respiratory function are also associated with SE. Hyperthermia and leukocytosis are prominent features seen in association with SE. Violent convulsive movements during SE can lead to rhabdomyolysis and renal failure. Increased intracranial pressure and CSF pleocytosis also have been described in this condition. Breakdown of the blood–brain barrier and changes in oxygen and glucose utilization and supply may also contribute to the morbidity and mortality associated with this condition. Morbidity associated with SE has been difficult to study, but the condition has been clearly associated with significant morbidity in adults and some, but reduced, morbidity in children. Further research on the acute and chronic morbidity associated with SE is necessary to fully establish the effect of SE on brain function. SE has been associated with significant rates of mortality in adults, ranging from 20% to 25%. The mortality rate in children is much less significant and in well-treated cases is <5%. Seizure duration, age, and etiology have been shown to influence morbidity in SE. Recent studies demonstrate that another 102,000 to 152,000 individuals are affected with SE in the United States every year. Approximately 22,000 to 42,000 deaths per year are associated with SE in the United States. Thus, SE represents a significant public health problem. Partial and generalized SE is associated with approximately the same mortality rate. The mortality rate is much higher in the elderly. The pronounced physiologic effects of SE on the CNS and the body contribute to the significant morbidity and mortality associated with this condition.

Chapter 65

Long-Term Sequelae of Status Epilepticus

Shlomo Shinnar

Thomas L. Babb

Solomon L. Moshé

Claude G. Wasterlain

Introduction

Status epilepticus (SE) is a common neurologic emergency that can result in significant morbidity and mortality. Convulsive status epilepticus is the most common and potentially detrimental form of status, but long-term sequelae have been reported even following nonconvulsive status. Three major population-based prospective studies investigated the epidemiology of SE. The annual incidence of SE around Richmond, Virginia, was 41/100,000 individuals.[37] It was 27/100,000 for young adults and 86/100,000 for the elderly. The mortality rate was also higher in the elderly: 14% for young adults and 38% for the elderly, but only 3% in children. The annual incidence from two prospective studies in Europe was 17.1/100,000 in Germany[76] and 10.3/100,000 in the French-speaking part of Switzerland.[31] These findings are close to the incidence of 18.1/100,000 found in an early retrospective study of SE from 1965 to 1984 in Rochester, Minnesota.[72]

It is estimated that, in the United States alone, status epilepticus affects 100,000 to 150,000 individuals each year, approximately half of whom are children. In >50% of the cases, there is no prior history of seizures.[40,67] Status epilepticus can occur either as part of an established seizure disorder or in the context of an acute illness. Approximately 10% of children and adults who have epilepsy initially present with status epilepticus.[15,40,67,142]

In the past, status epilepticus was associated with a high morbidity and mortality. This has changed dramatically, especially in children. Recent clinical data (see Chapter 126) indicate that with proper treatment, the acute morbidity and the mortality of status per se is quite low, particularly in children. The adult data still show a significant morbidity and mortality, much of which is related to the underlying etiology.[3,36,40,45,46,64,92,166,171] This chapter reviews the potential long-term sequelae of status epilepticus with an emphasis on the issue of whether status epilepticus results in a chronic seizure disorder. The old definition of status epilepticus was a condition in which epileptic seizures are sufficiently prolonged or repeated at sufficiently brief intervals to produce "an unvarying and enduring epileptic condition."[60,126] More recent data suggest that if this occurs in humans, it is not very common. In this context we also review the association between status epilepticus, particularly in early life, and mesial temporal sclerosis.

Cognitive Deficits Following Status Epilepticus

In animal models, status epilepticus has been associated with neuronal changes, particularly in the adult animals.[32,95,96,97,126,127,131,132,157,158] In humans, chronic intractable seizure disorders have been associated with cognitive deficits and in some cases even intellectual decline.[38,54,125] Isolated case reports of cognitive impairment following status epilepticus, whether convulsive or complex partial or even absence, are frequent,[41,135] but none gives a sense of how commonly this occurs. In an entity associated with a significant morbidity and mortality, one would expect that cognitive impairment might occur. However, much of the morbidity and mortality of status epilepticus is associated with the precipitating acute neurologic insult.[3,36,39,40,45,46,64,66,92,116,166,171] The morbidity and mortality have dramatically declined over the last 50 years, especially in children, and other sequelae may have decreased as well.[2,3,4,7,36,40,45,46,64,92,127,166,171] Therefore, the high rate of adverse sequelae reported in the older series are probably not representative of the current reality.[39,40,64] In this section we address the issue of whether status epilepticus per se results in long term-cognitive impairment.

To answer this question, we need to identify the appropriate group of patients. This turns out to be a very difficult task. Status epilepticus is often seen in the context of an acute brain insult such as trauma, stroke, or encephalitis.[3,39,40,92] In this setting, it is difficult if not impossible to differentiate cognitive impairment due to prolonged status epilepticus from that caused by the acute brain injury itself. Status epilepticus also occurs in the context of chronic intractable epilepsy. In this setting it may be difficult to separate the effect of status epilepticus from the cumulative effects of many briefer seizures. Ideally, one would look at patients who had an isolated episode of status epilepticus near the onset of their epilepsy. This is a not an infrequent occurrence. Approximately 10% of patients who present with a first unprovoked seizure or with newly diagnosed epilepsy present with status epilepticus.[11,16,64,67,68,69,70,91,139] However, very few of these patients have had neuropsychological testing before their episode of status. Thus, when a subtle deficit is found, it is difficult to know whether it was a result of status or preexisted. These considerations apply to both adults and children. In children, there is the additional difficulty that status epilepticus most often occurs in very young children, with half the cases under age 15 years occurring under age 3 years.[92] At this young an age it is very difficult to get an accurate estimate of premorbid intellectual function unless the child was very severely impaired.

The data regarding cognitive impairment following status epilepticus were reviewed by Dodrill and Wilensky.[39] They excluded case reports and reviewed 14 studies of status.[3,7,29,38,42,46,47,48,58,59,66,81,92,117,127] They noted that most studies are of children, and few studies of children or adults used any formal psychological testing. In addition, many studies were retrospective. Of the 14 studies reviewed, the more recent and prospective ones were the ones that reported the lowest morbidity, including cognitive outcomes. This may be attributable to less skewed patient samples in prospective

P.752

studies, an improved ability to identify etiologies (e.g., some older studies included cases of meningitis in the category of febrile status epilepticus), and perhaps improved treatment in the modern era.

There are some excellent prospective data on adults. Dodrill and Wilensky performed complete neuropsychological testing on 143 adults on two occasions 5 years apart.[39] Of these, 9 had a definite episode of status epilepticus in the 5-year period, including cases of both generalized tonic–clonic status and complex partial status. These were compared to matched controls that had not experienced an episode of status in the 5-year period. The group with status epilepticus had lower IQ scores and performed worse on a variety of cognitive measures. However, some of these differences were present at the baseline testing prior to the episode of status. This is consistent with the epidemiologic data that status epilepticus is more common among those who are neurologically abnormal.[40,66,67,68,92] The authors concluded that most investigators described at least a few adverse changes attributable to SE rather than to underlying neurologic disease. However, in general, status epilepticus has only a modest adverse effect on cognitive abilities and in many individuals no effects are discernible.[39]

The data on children are even more difficult to tease out. However, data from the National Collaborative Perinatal Project (NCPP) suggest that status epilepticus per se has few if any adverse effects on the young child. Ellenberg and Nelson examined 27 children with febrile convulsions lasting >30 minutes and found no differences in cognitive function at 7 years of age between them and their siblings.[47] They also found no evidence of decline in cognitive function in children with onset of epilepsy between ages 4 and 7 years who had cognitive testing as part of the NCPP at ages 4 and 7 years.[48] The group included 8 children who experienced status. Dunn[46] and Maytal et al.[92] also found few long-term sequelae following status epilepticus in children unless it was associated with an acute or progressive central nervous system (CNS) insult. Animal data also suggest that the immature CNS, while more susceptible to developing status epilepticus, is more resistant to adverse sequelae.[6,21,27,33,65,73,74,75,83,102,103,105,112,116,150,151,152,167,168]

In summary, there are case reports that document the occurrence of cognitive deficits following status epilepticus in both children and adults. These deficits may occur not only following convulsive status, but also following complex partial status and perhaps absence status. However, in large studies the morbidity of status epilepticus is primarily a function of the underlying etiology. Patients with status epilepticus are more likely to have had prior cognitive deficits. The incidence of demonstrable cognitive deficits following an episode of status appears to be low. More studies are needed to address this issue.

Hemiconvulsion-Hemiplegia-Hemiparesis Syndrome

A particular neurologic syndrome frequently found in the older series of convulsive status in children was an acquired hemiplegia, the so-called hemiconvulsion-hemiplegia-epilepsy syndrome (HHE).[3,59,61] In one series, the syndrome was present in 25 of 79 children with convulsive SE lasting >1 hour.[59] The association is well established in the older literature.[3,5,28,59,61,126] These cases of acquired hemiplegia were also almost invariably associated with subsequent intractable seizures.

However, more recent studies report not only a much lower acute morbidity and mortality of status epilepticus,[36,40,45,46,64,67,92,166,171] but also a lower rate of adverse sequelae. The syndrome of HHE is notably absent from studies of status epilepticus over the last two decades.[36,40,45,46,64,67,92,166,171] Whether this is a result of improved therapy or of other factors remains a matter of speculation. However, it does coincide with the decrease in mortality and other acute and long-term adverse sequelae of status epilepticus.

Status Epilepticus and the Development of Future Seizures

The textbook definition of status epilepticus as “a seizure of such duration as to create a fixed epileptic condition”[60,126] might lead one to assume that all cases of status epilepticus are inevitably associated with a subsequent chronic seizure disorder. Indeed, if “seizures beget seizures” as has been argued by some authors,[49,62,122,123] then one would expect that the occurrence of a prolonged seizure such as status epilepticus would inevitably result in subsequent seizures. However, the epidemiologic data do not support this conclusion.[15,17a,67,69,70,106,130,137,139] This section reviews the data regarding the development of a subsequent seizure disorder following an episode of status epilepticus.

Experimental Data

Status epilepticus–induced epileptogenesis is a widespread phenomenon that reproducibly occurs in the vast majority of animals after many types of experimental status epilepticus. The majority of subjects develop spontaneous recurrent seizures after status epilepticus induced by kainate, pilocarpine with or without lithium, tetanus toxin, stimulation of excitatory pathways such as the perforant path, or stimulation of limbic structures such as amygdala[111] or ventral hippocampus in a number of animal species.[20,22,79,82,129,133,160] Acutely, neuronal loss in the dentate hilus and CA1 and increases in diffusion-weighted and T2-weighted imaging (by magnetic resonance imaging [MRI]) are seen in hippocampus.[50,124] Chronically, an increased T2 signal reveals hippocampal cell loss coupled to gliosis, a combination that is reminiscent of human medial temporal sclerosis.[124] The respective role in epileptogenesis of loss of GABAergic interneurons[115,147] and of sprouting of excitatory fibers[154,155,169] is debated. In immature animals, SE can lead to spontaneous recurrent seizures and chronic epilepsy, although the immature brain is more resistant than the adult brain.[71a,71b,132,133] However, this epileptogenicity is highly model dependent: Whereas the lithium-lipocarpine model is highly epileptogenic,[133,153] the perforant path model of status epilepticus generates spontaneous recurrent seizures in only about 15% of subjects.[134,169]

Domoic acid (a close analog of kainic acid) ingested from mussels induced status epilepticus in a man who later developed chronic epilepsy, and this case may offer the closest human approximation to the animal models.[26]

Status Epilepticus as a First Unprovoked Seizure

Approximately 10% of patients who come to medical attention with a first unprovoked seizure present with SE.[11,16,40,64,67,68,69,70,91,139] The majority of these have a cryptogenic or idiopathic etiology. In both children and adults, the risk of seizure recurrence following a cryptogenic/idiopathic first unprovoked seizure is not influenced by the duration of the initial seizure.[11,15,69,70,139,142,143,143a] This is true whether one

P.753

examines seizure duration as a continuous variable or compares those with status epilepticus as their first unprovoked seizures with those who presented with a brief first seizure. These studies, which include follow-up periods of >15 years, support the view that status epilepticus per se does not create a permanent seizure disorder.[70,142,143,143a]

In both children and adults who present with status epilepticus as their first unprovoked remote symptomatic seizure, the risk of recurrence is increased.[16,69,70,139] As discussed later, these patients are at increased risk not just for recurrent seizures, but also for recurrent status epilepticus.[15,43,140,143a] However, it should be noted that status epilepticus as the initial seizure is relatively uncommon in this group. In one study of childhood status epilepticus, 29 (63%) of 46 children with idiopathic status epilepticus had no prior history of seizures, whereas 34 (75%) of 45 children with remote symptomatic status had a prior history of seizures.[92] The fact that status epilepticus is a risk factor for subsequent seizures in remote symptomatic cases but not in idiopathic ones suggests that either it is a marker for epilepsy in those cases or that the already compromised brain is more susceptible to injury as a result of status. More research is needed on this point, and animal models are being developed to address this issue (see Chapter 36).

When one looks at long-term outcomes following an initial episode of status epilepticus, the epidemiologic data in children also do not show long-term adverse effects of an isolated episode of status epilepticus. The occurrence of status epilepticus does not influence long-term remission rates in children who present with status epilepticus as their first unprovoked cryptogenic seizure.[141a,142] In a case–control study of predictors of intractability in children with newly diagnosed epilepsy, the occurrence of status epilepticus was found to be a marker for future intractability.[18] The best predictor, however, was the presence of an underlying neurologic abnormality. Furthermore, of the four children believed to have cryptogenic epilepsy whose presentation included an episode of status epilepticus, one was later diagnosed as having a brain tumor, one had retardation, and one had a progressive neurologic disorder. Thus, status in this population seems to be a marker for an abnormal brain, which is known to be a predictor of future intractability.[18] Similarly, in Sillanpaa's study, the occurrence of status epilepticus was more common in remote symptomatic cases, which are also more prone to recurrent status. However, it had an only modest effect on long-term outcome once one controls for etiology.[145,146] Few data are available on this question in adult-onset epilepsy.

Epilepsy Following Febrile Status Epilepticus

The literature regarding this issue is confusing. Retrospective studies from tertiary epilepsy centers reported that many adults with intractable temporal lobe epilepsy had a history of prolonged or atypical febrile seizures in childhood.[1,19,24,25,52,53,58,84,86,87,88,89] However, population-based studies failed to find this association, nor did prospective studies of febrile seizures.[8,10,48,90,108,163,164] In this section we review some of the data as they relate to the association of prolonged febrile seizures and subsequent epilepsy.

One must be careful to distinguish between very prolonged febrile convulsions, which are the extreme end of the complex febrile seizure spectrum,[107] and status epilepticus associated with fever. The latter term often includes cases of encephalitis, meningitis, and other forms of acute brain injury as well as children with already established epilepsy who decompensate in the context of an acute febrile illness. These are discussed in the section on acute symptomatic status epilepticus. This section focuses on the data on the consequences of prolonged febrile seizures (for a more detailed discussion see Chapter 63).

Studies that limit themselves to children with prolonged febrile seizures uniformly report a low morbidity and mortality.[8,10,36,40,45,46,48,64,67,89,90,108,163,164,166,171] As with all forms of complex febrile seizures, there is a somewhat higher risk of epilepsy compared to children with a simple febrile convulsion.[8,10,17,40,48,51,89,90,108,163,164] In a study of a British cohort of 16,004 children born during a single week in April 1970, the proportion of those who developed afebrile seizures was 3.4% after febrile convulsions lasting <30 minutes but 21% after febrile convulsions lasting >30 minutes.[164] This increased risk may express itself many years later.[8,10,164] At highest risk are those whose febrile seizures are both prolonged and focal[10] and those who are already neurologically abnormal prior to the febrile seizure.[10,16,90] In children who were previously neurologically abnormal, even the short-term risks of developing epilepsy are substantial.[90]

The difficulty in interpreting the data centers on whether the febrile seizures are markers for subsequent epilepsy or a cause of the epilepsy. Those who argue that there is a causal relationship point to the retrospective studies of temporal lobectomy patients, autopsy studies,[1,19,24,25,32,51,52,53,58,84,89,172] and adult animal data on the sequelae of status epilepticus.[83,95,96,97,148] On the other hand, there are those who would argue that febrile seizures are simply an age-specific marker for subsequent epilepsy.[141] Namely, those patients with a predisposition to epilepsy based on a genetic predisposition or based on underlying structural abnormalities will, at the age-specific developmental window, also be more likely to experience febrile seizures, possibly even prolonged ones. The data in favor of this view include the fact that the risk of subsequent epilepsy is highest in those with focal seizures or prior neurologic abnormality.[8,10,17a,90,108,139a,163,164] The risk of epilepsy is also high in those with four or more febrile seizures even if they are brief.[10] This population tends to have a high incidence of generalized spike-and-wave abnormalities on the electroencephalogram (EEG) when older, pointing again to probable genetic causes.[42,139a,161] Finally, in the study of Annegers et al.,[10] which provided the longest follow-up, those with generalized status developed a generalized seizure disorder, whereas those with focal status developed a focal disorder, which is what one would expect if the prolonged febrile seizure were a marker for subsequent epilepsy.[10] By contrast, if one proposed a causal relationship between status per se and later epilepsy, then one would expect a high rate of focal seizure disorders regardless of whether the initial episode of status was generalized or focal.

In reviewing the data from retrospective series of epilepsy surgery candidates,[1,19,23,24,25,32,52,53,58,84,86,87,88,89] one must keep in mind that these are highly selected patient groups. Many of these patients had complex febrile seizures or at least seizures associated with fever, but few actually had status epilepticus. It is often very unclear whether they truly had febrile seizures or if seizures were associated with fever in patients who may have had an acute brain insult such as encephalitis or in patients with a preexisting epilepsy. Atypical febrile seizures of the latter type have been associated with a worse prognosis for remission[18,138,141] but should not be confused with febrile seizures. If febrile seizures are simply a marker for seizure susceptibility, then quite possibly those most susceptible will experience more frequent and/or more prolonged febrile seizures.[139a] Note that complex febrile seizures in general and very prolonged febrile seizures in particular are much more common in children who are already neurologically abnormal and are most likely to be focal, suggesting prior focal pathology.[10,28,47,108,163,164] Current prospective studies on the long-term outcomes of febrile SE with an emphasis on the development of mesial temporal sclerosis and epilepsy will provide the answer to these questions, but given the long latency, it will be some time before the precise relationships between

febrile SE and subsequent epilepsy are defined (see Chapter 63).

Epilepsy Following Acute Symptomatic Status Epilepticus

A proportion of patients with acute symptomatic status epilepticus develop a seizure disorder at some time in the future. This proportion varies and is a function of the severity of the underlying insult. In most cases it is on the order of 15% to 30%. However, the seizure disorder may not develop for several years.[9,68,71,156] There are few data that support prophylactic antiepileptic drug (AED) treatment to prevent the subsequent development of epilepsy in acute symptomatic seizures.[56,104,137,156] There is some evidence that acute symptomatic seizures, including status epilepticus, are associated with an increased risk of subsequent epilepsy in patients with acute CNS injury. However, it is unclear whether patients with acute symptomatic status epilepticus have a higher risk than other patients with briefer acute symptomatic seizures.[66,67,70,71] The majority of patients with acute symptomatic or febrile status epilepticus do not have unprovoked seizures later, even with long follow-up periods.[8,10,56,66,67,68,90,108,156,163,164]

Recurrent Status Epilepticus

Although not clearly a sequela of status epilepticus, the issue of recurrent status is best dealt with in this chapter because it is closely related to the issue of status epilepticus and subsequent seizures. Most of the available data in this regard are in pediatric series, which are discussed first. Pediatric studies report that 11% to 25% of children with status epilepticus experience at least two episodes.[3,43,46,92,140] These studies included both prospective and retrospective cases. Shinnar et al.[140] followed 95 children from the time of their first episode of status. Sixteen children (17%) experienced recurrent status, including 5 with three or more episodes. All but 2 of the 16 had prior neurologic abnormalities. The risk of recurrent status epilepticus in the remote symptomatic and progressive encephalopathy group was almost 50%, compared with only 3% in children who were otherwise neurologically normal. The neurologically abnormal group constituted 32 (34%) of the 95 children, but they accounted for 14 of 16 (88%) of children with recurrent status epilepticus and all 5 children with three or more episodes of status epilepticus.

It is of interest that the increased risk of recurrent status epilepticus for neurologically abnormal children was present not only in the remote symptomatic and progressive encephalopathy group, but also in the febrile[92,140] and acute symptomatic group. Driscoll et al.[43] reported similar findings in a retrospective review. Thus, it would appear that the risk of recurrent status epilepticus is primarily in children with preexisting neurologic abnormalities. This is also the population that is at higher risk for developing seizures[14,68,71,109] and status epilepticus in the first place.[3,36,40,45,46,64,67,92,166,171] These data support the notion that status epilepticus is primarily a marker for an abnormal or injured brain destined to be epileptic rather than the cause of an injury sufficient to produce an epileptic condition. In adults there is one study with similar conclusions.[13]

More recently, there is an accumulation of data that suggest that there is a subgroup of children with a predisposition to prolonged seizures.[17,18a,18b,31a,139,143,143a,146a] These children are not necessarily at risk for frequent or intractable seizures, but are at increased risk for prolonged seizures. The evidence comes from several studies. In children with febrile seizures, an initial prolonged febrile seizure is not associated with an increased risk of recurrent febrile seizures. However, if another febrile seizure does occur, it is likely to be prolonged.[17] Similarly, in children with a first unprovoked seizure who are neurologically normal, a prolonged first seizure including status does not increase the risk of recurrence, but if a recurrence does occur, it is likely to be prolonged.[139,143,143a] In the Finnish childhood onset epilepsy cohort, the majority of cases of status occurred early in the disorder. If status did occur, there was a high likelihood of recurrent status. However, if there was no episode of status in the first few years of the disorder, then status did not occur even if there was a continuing active seizure disorder for many years.[146a] In the Connecticut study, the majority of cases of status also occurred early, but there were more late cases.[18a,18b] Finally, genetic studies of twins have shown that, if one twin has status, there is an increased risk of not just seizures, but also status in identical but not fraternal twins.[31a]

Status Epilepticus and Mesial Temporal Sclerosis

The pathological entity of mesial temporal sclerosis is described in detail in Chapter 13. In this section we review the data regarding whether MTS is a sequela of status epilepticus, particularly in early childhood (see also Chapter 65).

Falconer et al. described the pathologic findings in temporal lobes obtained from 100 patients with intractable temporal lobe epilepsy.[53] Forty-seven percent had mesial temporal sclerosis, varying from loss of cells in Sommer (H1) sector of the hippocampus to more widespread involvement of the temporal lobe. Of those with MTS, 40% had a history of prolonged convulsions in infancy. The major controversy regarding mesial temporal sclerosis is whether it is a sequela of status epilepticus, particularly of prolonged febrile seizures in early life or due to some other cause.[128] We review the data for and against the hypothesis that MTS is a sequela of status.

In favor of this hypothesis are the elegant experiments in adult animals that have produced MTS with a variety of models of status including kainic acid, pilocarpine, and fluorothyl.[21,83,95,96,97,102,103,105,150,151,152] Meldrum et al. showed that in the adult monkey, even if one paralyzes the animal and adequately ventilates and oxygenates it, neuronal changes occur as a sequela of status.[95,96,97] Such changes are readily produced in the adult rat as well.[21,83,102,103,105,150,151,152]

In patients with refractory complex partial seizures who undergo epilepsy surgery and are found to have mesial temporal sclerosis, a substantial number have a history of complex febrile seizures in early life, although, as discussed previously, not necessarily of status epilepticus.[1,19,24,25,32,51,52,53,58,84,89,172]

A number of imaging studies found cerebral edema acutely, and atrophy chronically, after convulsive or nonconvulsive status epilepticus,[30,77,78] but others did not.[129] One 5-year-old patient had a normal brain MRI before and atrophy after nonconvulsive status epilepticus,[119] and neuronal loss was found at autopsy in areas that became atrophic after his bout of status epilepticus.[113] Focal atrophy has been reported to develop in areas of intense seizure activity,[57,100,101] supporting a mechanistic explanation. However, the problem with these studies is that although they establish that sequelae can occur, they do not give any sense of how common the event is.[136]

Although this view of a causal relationship between prolonged seizures in early childhood and subsequent MTS has become entrenched in the literature, there is a large body of data that do not support this view. The animal and clinical data simply do not match in this regard. The clinical

data from adults evaluated for epilepsy surgery suggest that MTS is associated with an insult or seizure onset in early childhood but not in adult life.[1,12,24,25,58,85,86,87,88,89] The animal data indicate that although the immature CNS is more susceptible to seizures in general and status epilepticus in particular, it is far more resistant to its sequelae.[6,21,27,33,65,73,74,75,83,102,103,105,112,116,150,151,152,167,168] In many, although not all, animal models of status, rat pups who experience an episode of status do not develop MTS. This is true in a variety of models, including kainic acid, pilocarpine, flurothyl, and kindling.[102,103,104,105,150,151,152] Reversible hippocampal injury has been shown in the infant rat using the kainic acid model.[27] Based on the use of Timm staining, aberrant reinnervation has been demonstrated following status in the adult rat, but it only occurs in some models in the rat pup.[133,134,150,151,152] Rat pups that experience kainate status and are allowed to reach adulthood have the same seizure threshold as control adult animals using the kindling model,[116] but in other models, after status epilepticus at P15, a majority of animals show spontaneous recurrent seizures.[153]

The pathologic data show that MTS is often associated with developmental abnormalities such as migration defects, suggesting that there is preexisting pathology.[12,80,86,87,93] The association of MTS with brain tumors of the adjacent temporal lobe, particularly when these tumors are adjacent to the hippocampus, also points to preexisting pathology as a frequent correlate of MTS.[12,89] Using autopsy material of patients who died following an episode of status epilepticus is problematic because these are extreme cases, which do not necessarily represent the effects of status per se, which has a low mortality, but rather probably represent the results of acute brain injuries associated with status epilepticus.[55,94,149,172]

The clinical data are also problematic. MTS is most common in cases with childhood onset. However, MTS is not diagnosed in childhood but many years later. In fact, documentation of MTS under age 6 years is uncommon.[44,110] Whether this is because MTS occurs later in the course of the epilepsy or is simply due to lack of early diagnosis is unclear. Recent data indicate that mesial temporal sclerosis, similar to that found in adults, can be seen in children with intractable mesial temporal lobe epilepsy.[88]

Radiologic evidence of hippocampal damage is reported primarily in adults. An example is a paper in which five adults with status had magnetic resonance imaging with fast spin echo techniques demonstrating reversible abnormal hyperintensity and swelling of the hippocampus and amygdala.[159] Two of these patients subsequently had evidence of hippocampal atrophy. In children, the data are sparse. One case report of a very young child with status epilepticus followed by MTS has been reported.[114] The child was neurologically abnormal previously, had focal status suggesting focal pathology, and had almost no latent period between the status and the intractable seizures. Although this case is interesting in demonstrating that MTS can occur early in life, it is hardly a demonstration of the proposed paradigm of a prolonged seizure followed by a silent interval and then complex partial seizures. In fact, most childhood intractable epilepsy is extratemporal.[44,104,110] Although temporal lobe epilepsy does occur in children and can be associated with MTS, other etiologies such as cortical dysplasia and developmental tumors are more common.[44,63,170] Status epilepticus is actually much more common in frontal lobe epilepsy and in Lennox-Gastaut syndrome, neither of which is associated with MTS. The clinical data regarding the association of prolonged febrile seizures and subsequent MTS or temporal lobe epilepsy were discussed previously.

More recently a number of case reports and series have shown that febrile SE can cause increased T2 signal in the hippocampus, which in some cases is associated with subsequent hippocampal volume loss.[80a,80b,101,144,162] Some of those radiologic findings were confirmed at autopsy.[113] Recent animal data from rats with hyperthermic seizures have also indicated increased T2 signal,[43a] although in that model it was not associated with cell death. Thus, it is now clear that febrile status epilepticus can lead to hippocampal atrophy, although the frequency with which this occurs and the required seizure duration are unclear.[135a,136] For a detailed review of this important topic see Chapter 63.

Mathern et al. have tried to document the relationship between mesial temporal sclerosis and various preceding insults.[84,85,86,87,88,89] They found that an injury prior to age 5 years, whether or not associated with a seizure, was most likely to be associated with MTS. Those with MTS were most likely to have initial precipitating injuries, including trauma and encephalitis. In addition, severe hippocampal neuronal losses (hippocampal sclerosis) were often associated with mesial temporal lesions or masses adjacent to the body of the hippocampus.[89] Longer durations of temporal lobe epilepsy were associated with some secondary neuron losses. The data "support the hypothesis that the etiology of hippocampal sclerosis is an acquired injury to the hippocampus and that the pathogenesis is a combination of acute, subacute, and progressive changes following the initial injury."[86] Note that the initial injury need not necessarily be a seizure.

The entire field is being rewritten as newer studies with better imaging techniques are leading to a better understanding of the relationship of very prolonged febrile seizures and subsequent MTS. For a better discussion, see Chapter 63.

Other Pathologic Sequelae of Status Epilepticus

In postmortem examinations of five children who died after status epilepticus associated with a febrile illness, Fowler described neuronal necrosis in the cerebral cortex, basal ganglia, and cerebellum.[55] The exact etiology of these seizures, which lasted from 1 to 6 hours, is unclear, although the children were febrile. Similar findings were described in several other reports.[94,149] Of particular interest is the case of a 20-year-old who died following prolonged focal status epilepticus associated with fever and had unilateral pathology.[149] It is unclear whether the pathologic changes were due to hypoxia as suggested by Fowler, to the underlying brain insult, or to the status epilepticus. Cell loss in the cerebellum has also been described in patients with long-standing seizure disorders even without a history of status epilepticus.[12] Brain damage is often seen in children or adults who died from SE,[32] although the complexity of clinical situations usually makes it very difficult to tell whether damage resulted from the seizures themselves or from medical complications such as hypoxia or hypotension. DeGiorgio et al.[34] found decreased hippocampal neuronal densities in five patients who died after complex partial status epilepticus. Given the overall low morbidity and mortality of SE per se, it is difficult to extrapolate from these postmortem findings to those who survive an episode of SE, particularly when it is not associated with an acute neurologic insult.

What Further Studies are Needed

Further studies are needed in several areas. Prospective long-term follow-up studies after episodes of status epilepticus are needed to determine whether status epilepticus is associated with subsequent mesial temporal sclerosis and, if so, how often

P.756

this occurs. These studies should take into account differences in etiology and age that may affect outcome. Given the recent association of mesial temporal sclerosis with migration defects, studies are needed on whether preexisting brain abnormality or injury makes the brain more susceptible not only to developing status epilepticus, but also to sustaining damage as a result. Modern imaging techniques should also allow for better studies of pathologic changes associated with status epilepticus in humans as well as in animal models. Animal and human studies are also needed on ways to not just stop the seizures, but also to prevent the damage. The role of *N*-methyl-D-aspartate antagonists and other agents that may prevent secondary neuronal damage following brain injury is being evaluated in animals but not yet in humans.

Summary and Conclusions

The morbidity and mortality of status epilepticus have declined significantly in the last two decades. In the absence of an acute or progressive CNS insult, the morbidity and mortality of status epilepticus are low, particularly in children. Long-term sequelae are also difficult to document in the absence of an acute associated neurologic insult. Motor and cognitive sequelae, although they may occur, are rare. The epidemiologic data do not support the idea that status epilepticus is necessarily associated with a subsequent chronic seizure disorder. Status epilepticus is most common in young children. However, although the immature brain is more prone to develop status epilepticus, both human and animal data suggest that it is more resistant to its adverse sequelae.

Textbook definitions of status epilepticus that imply that it is always associated with subsequent chronic epilepsy need to be revised. The relationship between status epilepticus and mesial temporal sclerosis also needs further study. Defining the precise role of status epilepticus in human epileptogenesis requires further research.

Introduction to the Epilepsies

Anne T. Berg

Introduction

> This alleged divine character is only a shelter for ignorance and fraudulent practice…. Epilepsy is not more divine than other diseases are. Like all diseases, it is hereditary; its cause lies in the brain, a brain over-flowing with the superfluity of phlegm. When the phlegm rushes into the blood vessels of the body it causes all the symptoms of the attack. (Hippocrates, ~400 BCE[51])

More than 2000 years ago, epilepsy was recognized as a physical disease arising in the brain. Despite the enlightened approach reflected by the Hippocratic authors, the prevailing views about epilepsy were that it was due to supernatural forces—demonic possession or divine retribution. Some held that epilepsy was contagious. These attitudes largely account for the tremendous stigma associated with epilepsy, a stigma that still lingers to a greater or lesser extent.

The establishment in the mid- to late 1800s of specialized centers for the care and treatment of "epileptics" represented a shift from the highly stigmatized views of epilepsy as due to evil, supernatural forces to one in which epilepsy was regarded as a medical disorder. With the concentration of people with epilepsy in these specialized centers, early neurologists began to describe epilepsy from the medical perspective. This led to the characterization and long-held belief that epilepsy was a uniformly progressive, nonremitting disorder. Sir William Gowers wrote one of the most famous and influential dissertations on epilepsy, in which he said, "The tendency of the disease is toward self-perpetuation; each attack facilitates the occurrence of another by increasing the instability of the nerve elements…. The spontaneous cessation of the disease is an event too rare to be reasonably anticipated."[28] Since then, our understanding of how to study the natural history of a disorder and of epilepsy in particular has developed. This has been in large part due to conceptual and methodological contributions from two very different areas—epidemiology and "syndromology."

Epidemiology

The first development to be described here was greatly facilitated by the advent of modern epidemiologic and statistical principles and techniques and their application to the study of epilepsy in the overall population. This helped to lead to the recognition that findings based on the most severely affected patients seen in tertiary referral centers were of limited value in treating and counseling the vast majority of patients in the population, whose epilepsy was often mild enough not to require treatment at such centers. In other words, the earlier observations suffered from multiple and severe forms of bias.[49] The early epidemiologic efforts were largely due to Mayo Clinic investigators led by Leonard Kurland and later by W. Allen Hauser and J. Fred Annegers.[30,31,39] The epidemiologic approach cast a broad net and provided invaluable information about the frequency, risk factors, and overall outcomes in the population at large.[1,2,3,6,7]

The early epidemiologic studies yielded valuable information about the prognosis of epilepsy. They provided an overview by providing an understanding at the population level of the frequency of epilepsy, the distribution by age at onset and gender, and an assessment of the various factors that cause it. In general, however, epilepsy itself was treated as relatively undifferentiated disorder. Although the epidemiologic studies identified some broad categories with important prognostic significance (e.g., presence of an underlying symptomatic factor likely responsible for the epilepsy, the age at onset, and whether the seizures were of generalized or focal onset), these were viewed as factors that modified a single disorder much as height and weight can vary among members of a single species.

Syndromology

The other major development that occurred was the recognition that epilepsy, much like cancer, was not a single disorder but a term used for a wide range of disorders. The endeavors in this area have been and still are at the heart of efforts to identify and investigate individual forms of epilepsy, often called syndromes. This movement has largely come from the European schools of pediatric neurology. Among these the French investigators have been the most prolific and productive, with many notable and important contributions coming from German, Italian, and Japanese investigators as well. Efforts to apply this approach to adult-onset epilepsy are hindered perhaps by the relative lack of distinctive diversity within these forms of epilepsy.

The concept of an epilepsy syndrome was defined in 1985 as "an epileptic disorder characterized by a cluster of signs or symptoms customarily occurring together. The signs and symptoms may be clinical or findings detected by ancillary studies. In contradistinction to a disease, a syndrome does not necessarily have a common etiology or prognosis. Some epileptic syndromes are, however, of great prognostic importance."[18] An updated definition was provided recently: "A complex of signs and symptoms that define a unique epileptic condition."[25]

Contrary to the epidemiologic approach, individual forms of epilepsy, from this vantage point, represent complete, integrated disorders. Epilepsy is not a single disorder with a variation in prognosis statistically defined based on circumstances and risk. Traditionally, the epidemiologic approach would require an individual to have had at least two unprovoked seizures on separate days for the condition to qualify for the label of epilepsy.[20] From the syndromic perspective, it is not clear why it is necessary to withhold the diagnosis of the epileptic disorder in someone who, for example, has had a

P.762

single unprovoked seizure and whose underlying disorder can be clearly identified or in a child who presents with febrile status epilepticus and is shown to have a functional SCN1A gene mutation. In fact, to the extent that early identification of the nature of the disorder influences choice of treatment and management options, and to the extent that the correct choice may lead to better outcomes, it seems it would be irresponsible to insist on waiting for two unprovoked seizures to diagnosis and treat the underlying epileptic disorder.

With a syndromic approach, a disorder such as febrile seizures, which, for good practical reasons, has been distinguished from epilepsy proper,[6,21,41,42,43] might reasonably be reintegrated into the spectrum of epilepsy. The same might be said of benign nonfamilial neonatal seizures. In doing this, however, the older notion of epilepsy as a uniformly nonremitting, progressive disorder must be abandoned and the very broad spectrum of manifestations, duration, outcomes, and consequences of the wide variety of epilepsies acknowledged. In particular, without denying or forgetting the severe end of the epilepsy spectrum, we need a widespread recognition that, at least from the perspective of seizure control, many forms of epilepsy are actually quite mild, easily treated, often resolve on their own, and are associated with minimal consequences.

Concepts in classifying seizures and epilepsies

In the 1989 proposal for the classification of the epilepsies, two key axes were identified, one for generalized versus localization-related conditions and another for etiology (idiopathic, symptomatic, and cryptogenic).[19] Currently, these are well-accepted terms for organizing syndromes and epilepsies.

Generalized Versus Localization-Related Conditions

These concepts are used in relation to both seizures and types and syndromes of epilepsy. In relation to seizures, "generalized" has traditionally meant that both cerebral hemispheres are involved simultaneously and symmetrically during the actual seizures. By contrast, "localization related" (sometimes "partial" or "focal") indicates that the activity arises from a more discrete, lateralized region, usually in the cortex, regardless of later spread (see Chapter 43).

As applied to syndromes, these terms have been used in essentially the same manner, with the syndrome type being classified based on its predominant seizure types. Although this dichotomy is convenient, it obscures important gradations between the two extremes—generalized and partial.

The prototype for a generalized syndrome is childhood absence epilepsy. The syndrome is characterized by a typical age of onset of between 4 and 10 years, peaking around 5 to 6 years, with a preponderance of girls relative to boys. The hallmark absence seizure is accompanied by a highly recognizable bilaterally symmetric, 3-Hz spike and wave discharge with symmetric bilateral onset and offset. This is the description according to leading reference books.[46,48] In fact, our current understanding of generalized absence seizures is that they involve thalamocortical networks with projections predominantly involving the frontal lobes. Thus, the term "generalized" does not preclude the involvement of regional or even of relatively discrete, "focal" mechanisms or structures, including subcortical structures, such as the reticular nucleus of the thalamus. In fact, although the ideal is still that recognizable onset be bilateral and symmetric, there is likely a considerable variation in the extent to which this bilateral symmetry is expressed, and discernible asymmetric onset on the electroencephalogram (EEG) is not at all uncommon.[46]

The term "generalized" is also used in reference to a group of often difficult forms of epilepsy largely restricted to onset during infancy and early childhood. Disorders such as West and Lennox-Gastaut syndromes are among the better known. Although these disorders are characterized by "generalized" seizures, they can be associated with focal and multifocal pathology. Multifocality seen in the EEG tracing is not uncommon, and partial or focal onset seizures may occur. The application of the concept "generalized" to these syndromes is quite different from that to the idiopathic generalized epilepsies. It might ultimately be more useful to think of these in terms of diffuse or multifocal disorders and abandon a label that linguistically implies a similarity or relationship to the idiopathic generalized epilepsies.

Crossing over to the more focal side of the spectrum, there are syndromes such as benign rolandic epilepsy (BRE) and autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE), which involve more discrete and predictable areas of the cortex. For a given patient, at least in BRE, the activity observed on the EEG might alternate between left and right sides.[46] For such syndromes the term "localization related" seems particularly apt because the epileptic disturbance is functionally linked to a location or region. This is in contrast to epilepsies linked to a discrete structural lesion. In these latter instances, the term "focal" might be more precise.

Even within the nonidiopathic focal epilepsies, however, there is probably little that the condition is strictly focal. Mesial temporal lobe epilepsy, the most common form of epilepsy treated with surgical resection, might be considered the ideal focal epilepsy. Yet, our best understanding is that complex and extensive limbic networks are involved in this form of epilepsy.

The 1989 classification of the epilepsies includes a category for "undetermined." This contains two distinct subcategories. The first is for syndromes in which both focal and generalized features occur. Some of the better-known disorders in this category are Landau-Kleffner syndrome and Dravet syndrome.[48] As the generalized versus partial dichotomy is relaxed, it may ultimately be more reasonable to incorporate these syndromes within that spectrum rather than keep them apart. For example, the characteristic generalized EEG features, myoclonic seizures, and the generalized tonic–clonic seizures seen in Dravet syndrome might suggest that it fits in well with the concept of generalized/diffuse epilepsies. The focal features associated with this syndrome (e.g., focal febrile status epilepticus) would not preclude such a designation. The localization-related nature of Landau-Kleffner syndrome and apparent similarities between it and benign rolandic epilepsy invite speculation and, more important, investigation into commonalities between these nonlesional functional forms of epilepsies.

Use of the second subcategory under the label of "undetermined" reflects a diagnosis of ignorance, and by and large is intended for unclassified forms of epilepsy. It is important, however, to distinguish between someone who has been appropriately and competently evaluated and for whom it is unclear whether the seizures and underlying epilepsy represent a generalized versus a more localized process and the case in which information is simply missing. For example, someone who has one or more generalized tonic–clonic seizures without evidence of partial onset (seizures were reasonably well witnessed, post-ictal state is well described, etc.) and had a normal or uninformative EEG and a normal magnetic resonance imaging (MRI) study can reasonably be diagnosed as having an undetermined form of epilepsy without clear generalized or focal signs. By contrast, the patient who never had so much as an EEG and whose seizure description is obtained from a notation by a general practitioner in the medical records has been inadequately

P.763

evaluated for the purposes of accurate diagnosis of his or her type of epilepsy.

Etiology: Idiopathic, Symptomatic, and Cryptogenic

The early epidemiologic studies defined the term "remote symptomatic" to be used in reference to epilepsy that occurred in the presence of a preceding but remote (not acute) insult or condition, the occurrence of which had been demonstrated to be associated with an increased risk of epilepsy.[31] In fact, Gowers's writing reflects an awareness of these distinctions.[28] The list of potential conditions and insults is always subject to modification as knowledge changes. Some of the more salient factors include stroke, head trauma, intracranial infections, and what at the time were termed "congenital disorders." This group contains individuals with cerebral palsy and mental retardation but in whom no specific causative agent has been identified. An updated list was provided in 2001.[25]

The early epidemiologic studies also used the term idiopathic to mean "not remote symptomatic." The classification of the epilepsies, however, identified and reserved this term to be used specifically for well-characterized forms of epilepsy, primarily occurring in childhood and adolescence, and believed—although often not demonstrated—to have a genetic basis.[19] This distinction was later adopted by the International League Against Epilepsy (ILAE) Commission on Epidemiological Standards in Epilepsy.[20] The term "idiopathic" comes from the Greek and means sui generis, and refers to a disorder arising from itself in the sense that the seizures represent the direct and primary manifestations of the disorder. "Idiopathic" has often been inappropriately equated with the concept of benign, perhaps because, relative to epilepsy secondary to a remote symptomatic cause, seizures are typically well controlled and other outcomes are relatively good.

Finally, the term "cryptogenic" has had a contentious history. The Commission on Classification and Terminology in 1989 used it to mean "probably symptomatic."[19] The basis for the "probably" was not elaborated on and left the supposition up to individual variability in interpretation. When it adopted the Classification and Terminology Commission's definition of "idiopathic," the 1993 Commission for Guidelines for Epidemiological Studies defined cryptogenic neutrally as meaning "nature or cause unknown."[20] It was used in cases in which the epilepsy did not clearly fit the criteria of a defined idiopathic condition and there was no evidence (by exam or history) of a remote symptomatic cause. The use of the term reflects an absence of knowledge and relative uncertainty regarding the nature of the epilepsy. This is important to bear in mind because there have recently been several "idiopathic" syndromes identified from among epilepsies that were previously called "cryptogenic." These include Panayiotopoulos syndrome and autosomal-dominant nocturnal frontal lobe epilepsy. Whether the term cryptogenic is used or a separate term is coined, a label is needed to identify those individuals for which the nature of the underlying cause of their epilepsy is truly unknown. It may be symptomatic or it may be idiopathic.

Updated Understandings of Etiology

The terms symptomatic, idiopathic, and cryptogenic have been particularly meaningful and useful for both research and clinical purposes; however, the distinctions they represent are increasingly more complex. At this juncture, there is debate over whether the words should be retained but with modified meanings or whether new terminology, free from the baggage of the old, should be introduced. Several issues need to be considered, as follows.

Idiopathic Versus Symptomatic

The distinction between idiopathic and symptomatic is increasingly difficult to justify. In reality, all epilepsy is symptomatic of something, and idiopathic epilepsies have causes and consequences too. Mounting evidence demonstrates that idiopathic epilepsies as well as epilepsies that are considered cryptogenic are associated with a number of other neurologic disorders and that these other disorders precede the onset of seizures. Factors associated with new-onset epilepsy include behavioral disorders,[9,45] school problems,[13] attention deficit disorder,[33] and psychiatric disorders.[34,35,37] These findings suggest that whatever are the underlying mechanisms involved in idiopathic and cryptogenic epilepsies, they are not limited just to causing seizures. Thus the original meaning of the term idiopathic as "sui generis" really does not seem to be strictly applicable to any form of epilepsy. As we relax the association between idiopathic and benign, it seems reasonable to consider that some rather severe forms of epilepsy such as Dravet syndrome might best be thought of in terms of "idiopathic." In fact, Doose syndrome, as it was initially conceived, was considered a form of idiopathic generalized epilepsy. The 1989 classification moved it to the group of cryptogenic or symptomatic generalized syndromes. Now it is again being associated with the idiopathic generalized syndromes. Ultimately, as knowledge develops, epilepsies may be identified according to their fundamental mechanisms and not surface impressions or increasingly outmoded concepts.

Diversity Within Remote Symptomatic Causes

The initial distinction between remote symptomatic (predisposing abnormality clearly present prior to the onset of seizures) and idiopathic/cryptogenic is of tremendous significance, convenience, and value for clinical research purposes as well as for clinical decision making, especially early in the course of the disorder. It invites a certain degree of complacency especially in epidemiologic (both population-based and clinical) studies, however, in that it groups together forms of epilepsy that likely have very different underlying mechanisms. As with the "idiopathic" epilepsies, a future classification may better reflect fundamental mechanisms rather then convenient but broad categories.

Risk Factor Versus Cause

The link between a risk factor (a potential symptomatic cause) and epilepsy is almost always based on statistical knowledge of the association and not necessarily a demonstration of cause and effect through specific mechanisms in any specific instance. There is always the possibility that someone would have developed epilepsy even had he or she not had a particular predisposing condition or insult. When the risk is greatly increased in the presence of the risk factor, we generally accept a causal interpretation. For example, the relative risk of epilepsy associated with cerebral palsy is on the order of 30.[8] From that, we can calculate that the attributable risk (the increase in risk above background) is about 97%. This would mean that, of 100 individuals with cerebral palsy and epilepsy, about 3 of them would have had epilepsy regardless of the cerebral palsy and 97 have epilepsy secondary to the factors that caused the cerebral palsy in the first place. When the association between a risk factor and epilepsy is much weaker, it is less clear how to handle assessment of etiology. For example, mild head trauma is associated with a relative risk of epilepsy of 3.1 within the first year after the injury.[3] This indicates that about 32% of individuals who developed epilepsy within a year of experiencing a mild head trauma would have developed epilepsy regardless of the head trauma and about 68% developed it in (presumed causal) association with the head trauma. We cannot necessarily

P.764

distinguish cases attributable to the trauma from those not attributable to it. This information is valuable on a population level, it can sometimes be useful for public health purposes, and it identifies groups appropriate for intervention studies. It does not provide precise information at the individual level because in assigning mild head trauma as the cause of epilepsy, one would be wrong about one in three times.

Competing Causes

Causes do not have to be mutually exclusive. It is not unheard of for a child with mild retardation or who has a neurocutaneous syndrome (both considered symptomatic risk factors for epilepsy) to have a form of idiopathic generalized epilepsy. Whether the symptomatic cause further contributes to the expression of seizures (e.g., lowers the threshold for expression of the trait) or whether it might in any way modify the presentation or course of the disorder is generally not known. In fact, it may be the cause of a second and relatively independent form of epilepsy in a single individual. Exclusion of such complicated or ambiguous cases is common so as to keep the phenotype pool as clean as possible. However, adherence to rigorous definitions necessary for research may discourage certain interesting questions from being addressed.

Epileptic Encephalopathies

The concept of epileptic encephalopathies is intuitively appealing and seems to encompass a difficult group of epilepsies largely occurring in infancy and early childhood. Epileptic encephalopathies are forms of epilepsy in which it is believed that, as a result of interactions between the seizures, perhaps their underlying causes, and the ontogenetic backdrop of the developing brain, irrevocable alternations in brain development and brain function occur.[24] Children with these disorders usually develop signs of diffuse and severe neurologic compromise such as autism and mental retardation. A direct demonstration of the mechanisms by which epileptic encephalopathies realize their effects on the brain has yet to be made. Our ability to determine whether an infant is truly neurologically intact before the onset of seizures is impaired by the infant's limited behavioral repertoire relevant to assessing the integrity of later higher cortical and particularly intellectual functioning. Thus, we simply do not know whether the roots of the resulting mental retardation, autism, and other behavioral disorders observed later predated the onset of seizures or were the result of them or factors related to the seizures. Nonetheless, the label of epileptic encephalopathy meaningfully identifies and seems to describe an inherent aspect of disorders such as West, Lennox-Gastaut, Landau-Kleffner, and Dravet syndromes among others. Of note, many children with these disorders do not have a remote symptomatic cause. Dravet syndrome has been closely linked to mutations in several genes but particularly the gene coding for the SCN1A subunit of the sodium channel, thus raising the possibility that it might be reasonably construed as representing the dark end of the idiopathic spectrum.[26,38]

Landau-Kleffner syndrome typically has no identifiable symptomatic cause. Again, the similarities it can occasionally seem to share with benign rolandic epilepsy raise questions about whether it too may represent the more severe end of an idiopathic localization-related spectrum.[22] At this point, it would be more satisfying and useful to classify with greater precision the underlying causes and mechanisms rather than rely on broad and increasingly less meaningful category names such as “idiopathic."

Practical Gray Areas in Classifying Etiology

How does one classify the etiology in a patient who does not have a clear remote symptomatic cause when nonetheless one just “knows” the epilepsy is “symptomatic.” From the perspective of scientific research, definitions must be respected, and a clear a priori approach to such situations is needed. On the other hand, rigid adherence to the notion that the etiology is cryptogenic if a hard symptomatic cause or sign is not demonstrated can diminish the value and the credibility of the research. Neither of these last two statements should be taken as a justification to do whatever seems convenient, but rather they should be used together to balance the need for rigorous research standards with common sense. From the clinical perspective, not all of medical practice is based on scientific evidence. Where that evidence is missing or inadequate, experience and intuition must take over. It is such areas that are fertile grounds for future research.

Classification: Technology, natural history, and selection

Identification and classification of any of these aspects of seizures or epilepsy depend on adequate information and knowledge. In the ideal world, an individual would be thoroughly and accurately diagnosed right from onset. In reality, this is not always feasible for a number of reasons, some having to do with availability of technology, some having to do with the natural history of the disorder, and, related to that, some reflecting appropriateness in using medical care and procedures.

Technology

The concept of unknown cause depends on the adequacy of the evaluation and our understanding of causes. Early epidemiologic studies included patients who were evaluated before the advent of the computed tomography (CT) scan, let alone MRI. Video EEG technology was not available, nor were functional imaging techniques. Today, studies are done in developing countries in which routine access to such evaluations is not possible. Patients evaluated in such settings and who otherwise appear normal on exam and have no history of a remote symptomatic cause might be considered to have epilepsy of unknown (cryptogenic) nature or cause. In fact, some, perhaps many, of such individuals, had they been adequately evaluated, would have been shown to have demonstrable brain lesions likely contributing to their predisposition to seizures. The adequacy of evaluation is a moving target, however. In 10 to 20 years, current technology will be outmoded, and similar caveats will be leveled at studies done today.

Natural History and Related Factors

Clear, precise observations from the patient or other observer are key to accurate diagnosis, particularly for determining the seizure semiology. Such information may not always be readily available at initial presentation. For example, in one community-based cohort study of children, 11.6% of patients were considered unclassified at initial diagnosis (typically they had normal EEGs and only partially observed tonic–clonic seizure). Two years later, about one third of those whose form of epilepsy was initially unclassified received more precise diagnoses, largely because of new information from subsequent EEGs and more detailed descriptions of subsequent seizures.[12] Some of the newly appearing EEG abnormalities may reflect developmental changes in expression of the underlying epileptic traits, variation in quality and thoroughness of the EEGs, or variation in sampling the EEG tracing.

Certain forms of epilepsy may be particularly difficult to identify at the outset. This appears to be the case with mesial temporal lobe epilepsy (MTLE). In adult surgical groups, the majority of cases have onset during childhood and adolescence. Mesial temporal sclerosis (MTS) is rarely seen in either newly diagnosed children[15,23] or adults[29,50] but appears to develop over time. Although typically considered a form of symptomatic epilepsy, it is unclear how the initial epilepsy can be symptomatic of a lesion that has yet to develop, at least as best as can be visually determined. Whether a vicious (progressive) cycle ensues is unknown. As with idiopathic epilepsies, MTLE with MTS is certainly symptomatic of something, but the best characterization of exactly what remains elusive. For example, the APOE-4 allele is well established as a factor increasing the susceptibility to Alzheimer disease.[27] It also modifies the progression of mild cognitive impairment to Alzheimer disease[47] and modifies the risk and age of onset of Parkinson disease.[40] A full listing of the association with APOE-4 is beyond the scope of this chapter. A recent report, however, linked the presence of the APOE-4 allele to younger age at presentation of MTLE.[16] Overall, these observations invite speculation that more basic host mechanisms not specific to epilepsy proper might play an important role in the natural history of this and possibly other disorders.

Selection Factors

We often know far more about those who do poorly than about those who do well. For those who have multiple seizures, seizure descriptions are more detailed and likely more accurate. Witnesses learn what to look for and how to report that information. For the patient who has only a few seizures, the information is, by comparison, rather thin and can often be of doubtful accuracy. The initial (and maybe only) seizures also create an emotionally charged situation for the witness and may affect accuracy of reporting. Medical evaluations are also not uniformly performed on all patients. Although a several-day in-hospital video monitoring EEG might seem ideal for diagnosing everyone right from initial presentation, it is not feasible for two primary reasons. First, it is prohibitively expensive and simply not justified at the initial presentation. Second, the differential yield over a standard EEG is likely to be minimal. Many newly diagnosed patients may have no detectable EEG abnormalities, and most would probably not have a seizure during monitoring. This unevenness in the quality and extent of information can severely limit our ability to study the natural history of different forms of epilepsy. If certain forms of epilepsy can only be identified when they become intractable (e.g., MTLE), then only intractable forms of that epilepsy are ever recognized and that epilepsy then becomes known as a uniformly intractable disorder. Identifying only those instances of the disorder that become intractable might place serious constraints on studying and ultimately understanding the mechanisms behind intractability.

Purpose and Use of a Classification of the Epilepsies

The quality and value of the syndromic work are evident in the worldwide acceptance and use of this approach. Syndromic diagnoses are incorporated into clinical practice, they serve as the basis for many research endeavors, and they have vastly facilitated effective and rapid communication among investigators and clinicians worldwide. The syndromic approach to epilepsy, especially in children and adolescents, is of tremendous utility for clinical purposes. Its application in large-scale clinical and population-based studies further demonstrates it practicality and utility.[14,17,36,52] Although some argue that it is of limited value because not all forms of epilepsy fall into well-defined syndromic groups,[44] this is simply not a valid argument. For one, identifying, studying, and treating separately those well-defined forms of epilepsy from currently "nonsyndromic" forms allows both clinicians and researchers to be more precise and tailored in their evaluations, recommendations, and investigations. It is hard to imagine arguing that one should use a multivariate equation to determine the risks and consequences of epilepsy based on age at onset and seizure type when one can clearly identify syndromes such as childhood absence and West syndrome (both occurring in childhood and both characterized by generalized seizures). Second and related to that, by separating forms of epilepsy that meet clear criteria for specific syndromes, we can then focus efforts on forms of epilepsy that are not readily classified and that are clearly an important next horizon for future research.

Scientific classifications and other approaches to classifying epilepsy

Despite the enormous success of the syndromic approach, in fact because of its success, a paradigmatic shift is needed in how we classify epilepsy. The classification of the epilepsies largely has been based on descriptive work and expert opinion. With increasing efforts to identify the genomic and other mechanistic bases of the epilepsies and the need for more precise characterization of the epilepsies that have not conveniently conformed to the current approach for syndromic diagnoses, the importance of biologically relevant phenotypes is paramount.[10,11] Whereas useful broad or distinctive patterns can be and have been discerned, it is time that the field of epilepsy adopted a more structured and scientifically rigorous approach to recognizing epilepsy syndromes. A previous comparison of classification to evolutionary biology and phylogenetic systematics pointed out that, in the classification of species, and really for any scientific classification, one must have three components: (1) a rigorous conceptual and operational definition of the end node to be classified (species or syndrome)—one that is biologically relevant; (2) methods for collecting, analyzing, and interpreting data; and (3) a process or processes guiding the analysis and interpretation. This is the next set of logical steps needed to provide a structure and direction to facilitate future efforts to determine the root causes (especially genetic) of the diverse disorders called epilepsy. This in turn has the potential to open avenues to more effective treatment and perhaps, one day, prevention.

Summary and Conclusions

Epilepsy is an umbrella term used to refer to a complex set of disorders with different causes, manifestations, consequences, and outcomes. Both epidemiologic and syndromic approaches have contributed to general knowledge, treatment, and management of epilepsy. Both have also made important and extensive contributions to standardizing language and establishing concepts that have formed a basis for and facilitated communication internationally. The epidemiologic work has provided the broad view of the forest and thus a critical initial framework for approaching the incidence of epilepsy in the population. The syndromic approach has given us a very detailed understanding of the individual forms of epilepsy (the trees), something of tremendous clinical relevance to individual patients, as well as being an initial framework for a more precise and mechanistic approach to investigating and treating epilepsies.

P.766

Concepts developed and accepted over the last 30 to 50 years are now proving to be more complex than previously appreciated. Simple "generalized" versus "focal" and "idiopathic" versus "symptomatic" dichotomies, distinctions that are well engrained within epileptology, are increasingly less meaningful, or at least less apt. Whereas a common language facilitates communication, it can also constrain thought.[53] Consequently, some changes may be appropriate in the future. In addition, the syndromic approach has rested on description and expert opinion. Another challenge, in conjunction with carefully considered modification of terminology, will be to ensure that phenotypic characterizations of epilepsies are as biologically relevant as possible so as to facilitate investigation into their underlying causes.

Chapter 67

Classification of the Epilepsies

Jerome Engel Jr.

Natalio Fejerman

Anne T. Berg

Peter Wolf

Introduction

Although epilepsy is an ancient disease, described in writings of ancient Mesopotamia and India,[12] recognition that there are many forms of epilepsy is a fairly recent development. Petit mal and focal seizures were distinguished from grand mal seizures by nineteenth century neurologists,[3,9] and Hughlings Jackson noted that there could be many causes of epilepsy[16]; however, there was no universally accepted classification of epilepsy syndromes until the late twentieth century. Even in 1970, when the International League Against Epilepsy (ILAE) proposed the first international classification of epileptic seizures, the accompanying classification of the epilepsies merely divided them broadly into partial and generalized types (Table 1).[14] This classification further distinguished between primary generalized epilepsies, which were associated with epilepsy alone, and secondary generalized epilepsies, in which the seizures were symptoms of an identifiable cerebral disorder that itself could produce other signs and symptoms as well. At the time, it was thought that all partial seizures were symptomatic.

With the increasing description of reasonably well defined epilepsy syndromes, the ILAE made its first attempt to organize them into a coherent classification in 1985.[4] The 1985 classification retained the partial/generalized dichotomy but deleted the term "partial" because it seemed an inappropriate term for diseases and created misunderstandings when secondarily generalized tonic–clonic seizures were the only seizure type. The possible term "focal" was not chosen because the idiopathic epilepsies of childhood with focal seizures do not present stable foci but may have seizures coming from alternate sites and sides. "Localization related" was proposed instead as the preferred term. The primary/secondary dichotomy was retained, but these two groups were now referred to as idiopathic and symptomatic because "secondary generalized epilepsies" had become confused with "secondarily generalized seizures." The term "idiopathic," from the Greek word "*idios*," meaning self, referred to epilepsy as the disorder itself, or epilepsy sui generis. This classification recognized the fact that some localization-related epilepsies are idiopathic and, for the first time, listed specific syndromes within each of the categories. For generalized epilepsies, a category of "idiopathic and/or symptomatic" was included, as was a category of "epilepsies and syndromes undetermined as to whether they are focal or generalized," together with a category of special syndromes. The International Classification of Epilepsies and Epileptic Syndromes was again revised in 1989, and this is the classification in current use[5] (Table 2).

The 1989 Classification of Epilepsies, Epileptic Syndromes, and Related Seizure Disorders

The 1989 classification retained the localization-related/generalized and idiopathic/symptomatic dichotomies but introduced the term "cryptogenic" to define conditions in which the cause of the disorder is "hidden or occult."[5] The term "cryptogenic epilepsies" was intended to be used for conditions presumed to be symptomatic but without definitive evidence for the etiology. The use of this term became ambiguous, however, as a result of a 1993 report of the ILAE Commission on Epidemiology and Prognosis in which it was recommended that the term "cryptogenic epilepsies" be used to define "patients who do not conform to the criteria for the symptomatic or idiopathic categories."[6] As a result, there is considerable confusion regarding the use of the term "cryptogenic," and a more recent report of the ILAE Task Force on Classification and Terminology recommended that this term be discarded and replaced by "probably symptomatic" when this is the intent, or "unknown as to whether idiopathic or symptomatic" when this is the intent.[7] It should also be noted that, whereas the ILAE classification is a taxonomic classification,[18] the problem addressed by the term "cryptogenic" is more relevant to a diagnostic scheme intended to describe individual patients. The task force also made several other recommendations. Because the term "localization related" is cumbersome and not used by everybody, it was recommended that it be replaced with the commonly used term "focal," with the understanding that focal epilepsies do not usually result from a small, discrete cluster of epileptogenic neurons. The term "focal," however, is particularly inappropriate in this respect for the idiopathic localization-related epilepsies, which are distributed disorders. The words "convulsion" and "convulsive" were also felt to be imprecise, and it was recommended that they not be used to define specific syndromes.

Much of the 1989 classification of the epilepsies is derived from initial work done in children and adolescents, that is, age groups in which highly distinct and diverse forms of epilepsy occur. The use of epilepsy syndromes in children and adolescents has had tremendous utility for clinical as well as research purposes. Large-scale community-based and specialized centers–based studies have demonstrated that, within this young age group, 50% to 60% of children can be assigned a specific syndromic diagnosis.[2,11,17] Remaining cases carry

diagnoses of less well-defined and less specific entities, namely symptomatic or cryptogenic focal epilepsy and undetermined (essentially unclassified) epilepsy. The focal epilepsies are generally defined based on localization from semiology, electroencephalogram (EEG), or neuroimaging and by the presence or absence of an identified underlying cause. Many entities identified within the focal epilepsies do not conform to current concepts of what is meant by the term syndrome in the same way that, for example, childhood absence epilepsy or West syndrome do. The vast majority of adults have these latter forms of focal epilepsy and only about 10% or 15% meet the diagnostic criteria for other highly specific epilepsy syndromes.[11] This had led some to criticize the 1989 classification for attempting to include all epilepsies in a rigid classification structure. An alternative proposal maintains that it is sufficient to define individual patients by describing their ictal phenomenology in detail.[13] This is again relevant to diagnostic schemes or manuals and not to taxonomy, which only makes sense when it includes all recognized conditions, be they rare or frequent. Taxonomic classifications, however, need to be accompanied by diagnostic manuals.

Table 1 The 1970 ILAE Classification of the Epilepsies

I. Generalized
   A. Primary
   B. Secondary
   C. Undetermined
II. Partial (focal, local)
III. Unclassified

These were defined by clinical and electroencephalographic criteria but were not listed as syndromes.
Source: From Merlis JK. Proposal for an international classification of the epilepsies. *Epilepsia.* 1970;11:114–119; with permission.

An alternative or supplementary approach taken by the ILAE Task Force is to create a list of epileptic seizure types as diagnostic entities that, by themselves, have etiologic, therapeutic, and prognostic implications.[8,19] These seizure types, based on pathophysiologic mechanisms and anatomic substrates, information that was inadequately available to be used in the 1981 ILAE Classification of Epileptic Seizures, can be used to determine the diagnostic evaluation, treatment, and prognosis in patients for whom a syndrome diagnosis is not possible.

Although the 1989 classification represented an expert consensus based on thorough and discriminatory literature reviews,[15] another criticism is that it does not clearly enough distinguish between syndromes that are well-accepted and those that are controversial or lack sufficient data for verification. The ILAE Task Force is currently using methods of accepted biologic classification that use measurable objective criteria for recognizing natural classes that can be reproducibly distinguished from all other natural classes.[1] Each epilepsy syndrome should be a unique diagnostic entity, similar to a natural class in biologic classification. The Task Force has defined an epilepsy syndrome as

> a complex of signs and symptoms that define a unique epilepsy condition. This must involve more than just the seizure type: thus frontal lobe seizures per se, for instance, do not constitute a syndrome. An epilepsy syndrome must be distinguished from an epilepsy disease, defined as: a pathologic condition with a single specific well-defined etiology. Thus, Progressive myoclonus epilepsy is a syndrome, but Unverricht-Lundborg is a disease.[7]

(It is important to point out that syndromes can be used for diagnostic manuals that are applied to individual patients as well as constitute taxonomic classes. Most syndromes are both, but some are not. Progressive myoclonus epilepsy is useful for diagnosis of individual patients but not for taxonomic purposes.) Criteria used to identify specific syndromes as unique diagnostic entities include their seizure type, age of onset, progressive nature, interictal EEG findings, associated interictal signs and symptoms, pathophysiologic mechanisms, anatomic substrates, etiologic categories, and genetic bases.[8,10] A tentative list of syndromes that meet these criteria is shown in Table 3. These syndromes should be considered testable working hypotheses subject to verification, falsification, and revision. Evidence-based methodology will be developed to evaluate syndrome hypotheses on an ongoing basis, making syndrome classification a dynamic process.

The next step will be to arrange these syndromes into a logical format that is useful for a variety of purposes, including clinical discussion, teaching, epidemiologic studies, drug trials, and basic research. In the process of organizing diagnostic entities as natural classes into coherent groupings, a benign epilepsy syndrome has been clarified as “a syndrome characterized by epileptic seizures that are easily treated, or require no treatment, and remit without sequelae."[7] The specification “without sequelae” makes this definition different from other fields of medicine, for example, brain tumors, in which “benign” is a relative term comparing conditions that are still potentially serious and not always remediable with similar ones that take a much more deleterious course. In addition, a category of “epileptic encephalopathy” is now defined as “a condition in which the epileptic processes themselves are believed to contribute to the disturbance in cerebral function."[7] A “reflex epilepsy syndrome” is defined as

> a syndrome in which all epileptic seizures are precipitated by sensory stimuli. Reflex seizures that occur in focal and generalized epilepsy syndromes that also are associated with spontaneous seizures are listed as seizure types [but would in fact require the introduction of a new category of “traits” because the seizure semiology is not different from spontaneously occurring seizures]. Isolated reflex seizures also can occur in situations that do not necessarily require a diagnosis of epilepsy. Seizures precipitated by other, special circumstances, such as fever or alcohol withdrawal, are not reflex seizures.[7]

Table 2 International Classification of Epilepsies and Epileptic Syndromes

1. Localization-related (focal, local, partial)
   - 1.1 Idiopathic (with age-related onset)
     At present, the following syndromes are established, but more may be identified in the future:
     - Benign childhood epilepsy with centrotemporal spikes
     - Childhood epilepsy with occipital paroxysms
     - Primary reading epilepsy
   - 1.2 Symptomatic
     - Chronic progressive epilepsia partialis continua of childhood
   - 1.3 Cryptogenic (presumed to be symptomatic but with unknown etiology)
     The symptomatic and cryptogenic categories comprise syndromes of great individual variability that are based mainly on:
     - Seizure types (according to the International Classification of Epileptic Seizures)
     - Anatomic localization
       - Temporal lobe epilepsies
       - Frontal lobe epilepsies
       - Parietal lobe epilepsies
       - Occipital lobe epilepsies
       - Bi- and multilobar epilepsies
     - Etiology (in symptomatic epilepsies)
     - Specific modes of precipitation
2. Generalized
   - 2.1 Idiopathic (with age-related onset, in order of age)
     - Benign neonatal familial convulsions
     - Benign neonatal convulsions
     - Benign myoclonic epilepsy in infancy
     - Childhood absence epilepsy (pyknolepsy)
     - Juvenile absence epilepsy
     - Juvenile myoclonic epilepsy (impulsive petit mal)
     - Epilepsy with grand mal (GTC) seizures on awaking
     - Other idiopathic generalized epilepsies not defined above
     - Epilepsies with seizures precipitated by specific modes of activation
   - 2.2 Cryptogenic or symptomatic (in order of age)
     - West syndrome (infantile spasms, Blitz-Nick-Salaam-Krämpfe)
     - Lennox-Gastaut syndrome
     - Epilepsy with myoclonic-astatic seizures
     - Epilepsy with myoclonic absences
   - 2.3 Symptomatic
     - 2.3.1 Nonspecific etiology
       - Early myoclonic encephalopathy
       - Early infantile epileptic encephalopathy with suppression-burst
       - Other symptomatic generalized epilepsies not defined above
     - 2.3.2 Specific syndromes (see Table 3)
3. Epilepsies and syndromes undetermined as to whether focal or generalized
   - 3.1 With both generalized and focal seizures
     - Neonatal seizures
     - Severe myoclonic epilepsy in infancy
     - Epilepsy with continuous spike-waves during sleep

- Acquired epileptic aphasia (Landau-Kleffner syndrome)
- Other undetermined epilepsies not defined above

  - 3.2 Without unequivocal generalized or focal features (e.g., many cases of sleep-grand mal)

4. Special syndromes
   - 4.1 Situation-related seizures (Gelegenheitsanfälle)
     - Febrile convulsions
     - Isolated seizures or isolated status epilepticus
     - Seizures due to acute metabolic or toxic factors such as alcohol, drugs, eclampsia, nonketotic hyperglycemia, and so on

---

Table 3 List of Syndromes

Epilepsy syndromes and related conditions

Neonatal period

- *Benign familial neonatal seizures (BFNS)*: This may be a disease and not a syndrome.
- *Early myoclonic encephalopathy (EME)*: Although this may be different from Ohtahara syndrome, the clinical distinction can be difficult.
- *Ohtahara syndrome*: See above.

Infancy

- *Migrating partial seizures of infancy*: This has been sufficiently described by several independent investigators to merit recognition as a syndrome.
- *West syndrome*: This is a clearly defined syndrome based on specific clinical features and age of onset.
- *Myoclonic epilepsy in infancy (MEI)*: Because this is not benign in some infants, the word "benign" was removed from the name. It was initially introduced to distinguish it from Severe myoclonic epilepsy in infancy (SMEI), which is now called Dravet syndrome. Seizures may occasionally be reflex (i.e., touch).
- *Benign infantile seizures*: Whereas BFNS and Benign (nonfamilial) neonatal seizures clearly represent two distinct syndromes because of differences in seizure type and age of onset, the familial and nonfamilial forms of Benign infantile seizures are identical except for the family history. Consequently, the sporadic form cannot be considered a separate syndrome, and both should be combined into a single syndrome, unless subsequent information indicates otherwise.
- *Dravet syndrome*: Because many of these children do not have myoclonic components to their characteristic seizures in infancy, it cannot be called SMEI, and we should retain the eponym.

- *Myoclonic encephalopathy in nonprogressive disorders*: There is sufficient evidence to support this as a syndrome. It is important as a form of epileptic encephalopathy.

Childhood

- *Early onset benign childhood occipital epilepsy (Panayiotopoulos type)*: The consistency of localization remains controversial in this syndrome.
- *Epilepsy with myoclonic astatic seizures*: This syndrome is now well defined but the course is variable. Many are epileptic encephalopathies.
- *Benign childhood epilepsy with centrotemporal spikes (BCECTS)*: This condition also is not always benign, although nonbenign forms occur in only a small percentage of patients, and may represent related conditions.
- *Late onset childhood occipital epilepsy (Gastaut type)*: There was concern because this condition is rare and there has been a paucity of recent confirmatory reports. More data are needed.
- *Epilepsy with myoclonic absences*: This syndrome needs further study in the context of the work to be done on myoclonic seizures.
- *Lennox-Gastaut syndrome (LGS)*: This syndrome is clearly defined by clinical and EEG features and by age of onset.
- *Epileptic encephalopathy with continuous spike-and-wave during sleep (CSWS) including Landau-Kleffner syndrome (LKS)*: It was decided that there is insufficient evidence for mechanistic differences between LKS and CSWS to warrant considering them separate syndromes. It is unknown whether these conditions are idiopathic, symptomatic, or both.
- *Childhood absence epilepsy (CAE)*: Further deliberation and research will be needed to clarify the distinction between this syndrome and JAE, and to define the relationship of this syndrome to the other idiopathic generalized epilepsies such as JME.

Adolescence

- *Juvenile absence epilepsy (JAE)*: See above.
- *Juvenile myoclonic epilepsy (JME)*: See above.
- *Progressive myoclonus epilepsies (PME)*: This group is different from the others in that it consists entirely of specific diseases, and might be considered under diseases with epilepsy rather than epilepsy syndromes. However, because it is a very helpful concept for diagnostic purposes when it is not possible to reach a more specific diagnosis, it is still included in this list.

Less specific age relationship

- *Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE)*: All affected family members have nocturnal frontal lobe seizures. In some families, mutations in neuronal nicotinic acetylcholine receptor genes are found, but in many families the genetic etiology is unknown.
- *Familial temporal lobe epilepsies*: There are a number of forms that are being defined. Division into lateral and mesial temporal types based on the predominant seizure semiology is useful. The lateral temporal type (also known as Autosomal-dominant partial epilepsy with auditory features) is associated with mutations in the LGI1 gene in about half the families. The mesial group is heterogenous within and between families in terms of epilepsy severity, association with febrile seizures and presence of hippocampal sclerosis.

- *Mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE with HS)*: This condition probably consists of more than one syndrome, and it is not certain whether features of patients with HS clearly differentiate them from those with other mesial temporal lesions.

- *Rasmussen syndrome*: There continues to be a question as to whether this is best characterized as a syndrome or a disease; that is, whether there may be multiple etiologies for this inflammatory process.
- *Gelastic seizures with hypothalamic hamartoma*: This may be a disease and not a syndrome.

Special Epilepsy conditions

- *Symptomatic focal epilepsies not otherwise specified*: Disorders due to epileptogenic lesions that are localized, diffuse but limited to one hemisphere, or multifocal do not constitute syndromes per se, but can be defined according to the seizure type, the underlying pathophysiologic disturbance, if known, and the location of the lesion(s), if they do not fit into a described syndrome.
- *Epilepsy with generalized tonic-clonic seizures only* is not a syndrome, and the Core Group was unable to agree on any syndrome with this feature: The consistent diurnal pattern of seizures in some patients needs further investigation. Whether epilepsy with generalized tonic–clonic seizures on awakening exists as a distinct entity is unclear.
- *Reflex epilepsies*: Although Idiopathic photosensitive occipital lobe epilepsy, Primary reading epilepsy and Hot water epilepsy in infants are syndromes, it is unclear whether other reflex epilepsies constitute unique syndromes.
- *Febrile seizures plus (FS+)*: This is a condition that is part of the familial syndrome known as GEFS+. The latter is broader than a single generalized syndrome and may be a useful category for future classifications.
- *Familial focal epilepsy with variable foci*: This syndrome cannot be diagnosed in a single individual. Recognition depends on the occurrence within a family of individuals with different seizure patterns (commonly temporal or nocturnal frontal); each individual has a single seizure pattern.

Conditions with epileptic seizures that do not require a diagnosis of epilepsy

- The reasons for not considering some syndromes to be epilepsy seem to be more political than scientific. Two syndromes exist in this group.
- *Benign neonatal seizures (BNS)*: These are self-limited events without sequelae.
- *Febrile seizures (FS)*: Classically, the seizures that constitute this condition consist of two forms: simple and complex; however, many different types undoubtedly exist. This condition may eventually be understood to encompass many different entities.

Source: Adapted Engel J Jr. Report of the ILAE Classification Core Group. *Epilepsia*. 2006;47:1558–1568, with permission.

Future Directions

The work of the ILAE Task Force will be continued by a new commission, charged with preparing new flexible and dynamic systems of taxonomic classification and diagnostic manuals for epilepsy syndromes. A revised or new classification will need to take a critical look at the two basic dichotomies. For instance, even as the terms idiopathic and symptomatic seem to be straightforward, epileptogenesis is often complex, and there is no clear demarcation between idiopathic and symptomatic epilepsies, whatever this means for a taxonomic classification. It also is not likely that any form of epilepsy is truly generalized, and perhaps few, if any, are truly focal. However, because these terms have important implications in clinical practice and there is no simple way to replace them, they will be retained where useful, as in the description of certain idiopathic generalized epilepsies and certain idiopathic and symptomatic focal epilepsies. The border between "generalized" and "focal" idiopathic epilepsies seems to be dissolving in view of newer findings with some common reflex epileptic traits[19] and with functional imaging of both groups. These may eventually be considered variants of functional system disorders of the brain in the same sense as system disorders in neurology in which preexistent subsystems of the central and peripheral nervous system are involved in the pathologic process. What is now a major dichotomy would then become a distinction between subgroups of nosologically related disorders.

A variety of other logical groupings for categorizing epilepsy syndromes include autosomal-dominant epilepsies and the generalized and focal conditions related to generalized epilepsy with febrile seizures (GEFS+), which could constitute a group of syndromes sharing specific susceptibility genes, perhaps even including mesial temporal lobe epilepsy. Ultimately, a multivariate approach could be used to construct an organization of syndromes in diagnostic schemes and taxonomic classifications for variable purposes, allowing some syndromes to be represented in more than one grouping and others to be represented in none. Mechanisms will be provided to repeatedly reevaluate the contributions of new developments in clinical research, genetics, molecular neurobiology, and pathophysiology to the organization of the classification system(s), as well as the functional utility of the classification, so that it can be updated on an ongoing basis.

Summary and Conclusions

The ILAE has critically reviewed the 1989 Classification of the Epilepsies, but has not yet made recommendations for its replacement. The distinction between a taxonomic classification, which considers the entire field of epilepsy, and diagnostic manuals, which provide schemes for describing individual patients, is important for understanding the work that needs to be done to improve the current efforts to improve the 1989 classification. A proposal for a diagnostic scheme that includes epileptic seizure types as diagnostic entities as well as syndromes was proposed by the ILAE in 2001, but this does not constitute a new classification. A more recent report describes an evidence-based approach to identifying epilepsy syndromes as unique diagnostic entities, different from all other diagnostic entities, in the same manner that biologic classifications identify natural classes. Criteria for identifying discrete epilepsy syndromes have been established, and a list of syndromes that superficially appear to meet these criteria has been published. It is now necessary to apply evidence-based methodology to confirm these syndromes and to construct one or more new taxonomic classifications and diagnostic schemes for variable purposes. It is envisioned that these will be dynamic and flexible constructs, subject to verification, falsification, and revision as new research data become available and as practical experience is obtained from their use.

Chapter 68

Differential Diagnosis

Lawrence J. Hirsch

Frederick Andermann

Timothy A. Pedley

Introduction

Patients presenting with transient alteration of neurologic function offer neurologists the opportunity to do what they do best: Solve a medical mystery and make a diagnosis. In general, the history will provide the essential clues, with ancillary testing providing only a modicum of additional assistance.

A careful history in the setting of a possible first seizure will frequently disclose prior spells that provide important diagnostic clues. Often, however, patients will not have recognized the relevance of these previous symptoms, and the neurologist must ask about them specifically. In fact, many typical epileptic phenomena such as déjà vu and morning myoclonus ("I'm just clumsy when I first get up") may be considered normal by the person experiencing them or, alternatively, not neurologic in origin (e.g., "panic attacks"). A history that clearly indicates alteration of awareness is very helpful, but many patients—perhaps most—do not recognize brief changes in the degree of awareness.

Relatively few patients with epilepsy are able to recall all of their seizures, and a substantial number cannot remember any of them. Blum et al.[6] prospectively determined seizure awareness in 31 patients admitted to an epilepsy monitoring unit. Twenty-three had epileptic seizures, but only 26% of these were aware of all of their seizures (regardless of seizure type), and 30% were not aware of any. Thus, obtaining additional information from observers is crucial. For recurrent spells, video-electroencephalogram (EEG) recording in an epilepsy monitoring unit is the best way—and sometimes the only way—to make a definitive diagnosis. Health professionals who have spent substantial time in one of these units know that findings can be surprising, and can include unexpected psychogenic spells, subclinical seizures, or substantial impairment of awareness during "auras," to name a few.

Any highly stereotyped, recurrent, brief alteration of neurologic function without an obvious alternative explanation can be of epileptic origin. Table 1 lists some of the disorders that can mimic epilepsy in adults along with the clinical features that are most useful diagnostically. Table 2 provides similar information for children and adolescents. The most important condition to consider and recognize promptly is syncope, especially cardiac syncope due to a life-threatening arrhythmia that may be fatal in a subsequent spell.[31] Table 3 compares the clinical characteristics of syncope and seizures to assist in distinguishing the two.

Table 1 Common seizure mimics and useful clinical features for diagnosis

Diagnosis	Clinical features suggestive of diagnosis
Syncope	Trigger usually identifiable, with autonomic

	symptoms/pallor; no aura or unilateral symptoms; loss of consciousness <20 s with rapid return to normal; jerking/posturing, if present, is brief and occurs after the loss of consciousness; see also Table 3
Transient ischemic attack	Variable presentation depending on area involved; with any neurologic deficit, consider focal seizures if symptoms are recurrent and stereotyped with no signs of infarct on brain imaging
Migraine (especially basilar)	Slow march of neurologic symptoms over >5 min and prolonged duration (usually 20–60 min); posterior circulation symptoms; scintillating scotomata; subsequent headache (may be absent)
Transient global amnesia	Prolonged spell (hours) with normal behavior except for amnesia; personal identity always intact (if not, suspect psychogenic etiology)
Psychogenic nonepileptic seizures	Psychiatric history, especially somatization; history of physical or sexual abuse; eyes closed and normal vital signs during spell; recurrent spells not responding to treatment; precipitation by hyperventilation or other suggestive techniques
Panic attack, hyperventilation	Often with environmental trigger; severe fear; hyperventilation with perioral cyanosis, bilateral hand paresthesias, carpopedal spasm; loss of consciousness not complete; dyspnea; palpitations; >5 min in duration (seizures are shorter); associated depression and phobias (95%), especially agoraphobia; onset in young adulthood
Cataplexy	No loss of consciousness; triggered by emotion, especially laughter; other features of narcolepsy usually present (daytime somnolence, hypnagogic hallucinations, sleep paralysis)
Sleep disorders (somnambulism, night terrors, confusional arousals, enuresis, REM behavior disorder, hypnagogic hallucinations, periodic limb movements, paroxysmal nocturnal dystonia)	Sometimes difficult to distinguish from seizures without video-electroencephalographic monitoring, polysomnography, or both, especially if no reliable witness; paroxysmal nocturnal dystonia is a manifestation of epilepsy in most if not all cases; slow-wave-sleep parasomnias are usually in the first one third of the night; see Table 2
Staring/behavioral spells in patients with static encephalopathy or	Difficult to distinguish from seizures without video-encephalographic monitoring

dementia	
Hypoglycemia	Long prodrome; on treatment for diabetes (or insulinoma, rare)
"Drop attacks"	Can be due to cataplexy, cervical spine disease, basilar ischemia, vertigo attack (Ménières), seizures (myoclonic, tonic, atonic; rarely complex partial), or syncope (especially cardiac)

Misdiagnosis

An incorrect diagnosis of epilepsy creates a significant problem with serious consequences.[23] About one fourth of patients with a diagnosis of epilepsy have been misdiagnosed[29,30]; the rate of misdiagnosis is higher in children.[37] One should always remain open to the possibility that the initial diagnosis was incorrect, especially when antiepileptic drug treatment is ineffective, and take full advantage of future spells to help confirm or modify the diagnosis. The majority of patients misdiagnosed as having epilepsy are eventually found to have either psychogenic nonepileptic seizures (PNES) or syncope.[11,25,29,30,40] Misinterpretation of EEG findings or overreliance on the EEG frequently contributes to misdiagnosis.[11,30] The presence or absence of interictal epileptiform discharges on EEG is not definitive and may be misleading.[5,19] Interictal epileptiform discharges (IEDs) occur in about 0.5% of healthy adults and in 1.9% to 3.5% of normal children.[26] Multifocal IEDs and IEDs occurring over the frontal and anterior temporal regions are highly correlated with clinical seizures,[10,18] but only about 40% of children with central-midtemporal spikes and 50% with occipital spikes had seizures in one study.[18] When EEGs are interpreted by physicians without special training, a number of benign or normal patterns are commonly misinterpreted as epileptiform. These include benign epileptiform transients of sleep (also termed small, sharp spikes), wicket spikes, hyperventilation-induced high-voltage paroxysmal slow waves, various artifacts (such as overfiltered muscle potentials), repetitive vertex waves, especially in children, and the 6/sec "phantom" spike-wave phenomenon.[38] One study reported that 54% of patients referred to an epilepsy center with a previous diagnosis of epilepsy and wicket rhythms on EEG did not have epilepsy on further evaluation.[19] Benbadis et al. reported 15 patients who were eventually diagnosed with PNES but had previously carried a diagnosis of epilepsy based on EEGs misinterpreted as epileptiform.[5] Of the 15 records reviewed, the patterns that were incorrectly considered epileptiform were wicket spikes (n = 1), hypnagogic hypersynchrony (n = 1), and hyperventilation-induced slowing (n = 1). In the other 12 records, simple fluctuations of sharply contoured baseline background activity and fragmented alpha activity, not identifiable specific variants, were misinterpreted as epileptiform. Repeating the EEG or having it reinterpreted at a tertiary epilepsy center by a certified electroencephalographer can be helpful in problematic cases. It is also important to remember that EEGs can never rule out epilepsy. Even with repeated EEGs or prolonged monitoring, a significant number of patients with epilepsy (10% to 19%) will have no interictal epileptiform discharges[26]; even ictal recordings may not have an identifiable scalp correlate in many frontal lobe seizures, as well as in simple partial seizures from any location.

Zaidi et al.[40] investigated the utility of noninvasive cardiovascular tests (including head-up tilt test and carotid sinus massage during continuous electrocardiography, EEG, and blood pressure monitoring) in 74 patients with apparent treatment-resistant epilepsy. An alternative diagnosis was found in 31 (41.9%) patients, including 13 (36.1%) of 36 patients taking an antiepileptic drug (AED). The most common alternative diagnosis was vasovagal syncope (25.7% of patients), followed by carotid sinus hypersensitivity (9.5%). At follow-up at about

10 months, all patients in whom an alternative diagnosis was made had subjective improvement, and 61.3% were symptom free. Of the 13 patients who were taking AEDs and for whom an alternative diagnosis was identified, 11 had successfully stopped their medications. These findings underscore the importance of cardiovascular testing early in the evaluation of a patient with "blackouts." This is especially true in patients with cardiac risk factors, in whom it is essential to exclude cardiac arrhythmias.

The most challenging and most common alternative diagnosis in epilepsy monitoring units is PNES. Approximately 20% to 40% of patients admitted to such units have PNES,[3,4,13] including a substantial portion of those referred for epilepsy surgery. If seizures do not respond to trials of two AEDs, the patient should be referred for video-EEG monitoring, both for definitive diagnosis and, if epilepsy is confirmed, initial surgical evaluation. The chance of complete seizure control after failing two AEDs is <10%.[22]

The following sections discuss differential diagnosis based on clinical presentation. Because PNES can manifest with any of these presentations, they are addressed separately at the end and more extensively in Chapters 207 and 282.

Table 2 Common Seizure Mimics in Infants and Children

	Relative incidence with age			
Symptoms/signs	**0–2 yr**	**2–8 yr**	**8–18 yr**	**Description**
Unusual movements				
Infantile masturbation	•••			Can be confused with seizure activity, especially in young infants; can almost always be aborted by distracting stimulus
Shuddering	•••	•	•	No risk of developing epilepsy later in life, normal EEG; may have family history of essential tremor
Benign sleep myoclonus	•••	•	•	Most common seizure mimic in neonates; not stimulus sensitive; normal EEG; no association with a higher incidence of epilepsy/abnormal neurologic development in later life
Startle disorder/hyperekplexia	••	••	•	Rare familial disorder; infant becomes rigid when handled; forceful repetitive jerks on falling asleep; spells can lead to hypoxia
Spasmodic torticollis	•	••		May be due to labyrinthine imbalance or

				neuroleptic drugs; sometimes manifestation of focal dystonia; normal EEG
Self-stimulating behaviors	••	•••	••	Hand-shaking, head-rolling, head-banging, body-rocking; more common in children with mental retardation or autism
Tics		•	•••	Can be confused with myoclonus; unlike myoclonus, they almost always disappear in sleep; preferentially involve face; premonitory urge and transiently suppressible
Chorea/choreoathetosis		•	••	At times may be indistinguishable from multifocal myoclonic jerks
PNES		•	••	May present in a variety of ways; for more details see section in text on PNES
Unusual eye movements	•••	••	•	For example, spasmus nutans (triad of nystagmus, head-nodding, and head tilt)
Overflow movements (synkinesis)	••	••		Defined as “extra” motor activity seen during performance of a complex motor task due to underdevelopment of inhibitory neural circuitry; seen in children with ADHD, and persists into late childhood/adolescence
Sandifer syndrome	•••	••	•	Association of torsional dystonia (mainly neck and upper extremities) with esophageal reflux or hiatal hernia; spasms/posturing seen shortly after feeding
Loss of tone or consciousness				
Syncope		••	•••	See text and Table 3
Drop attacks		•	•	See text and Tables 1 and 5
Cataplexy		•	•	Usually with other symptoms of narcolepsy; see text and Table 1

		Disorders of respiration		
Apneic attacks	•••			May occur alone or as part of triad (apnea, staring, and flailing), often with gastroesophageal reflux
Breathholding	•••	•		Attacks of respiratory arrest following fright or minor injury; may be pallid or cyanotic; cyanotic spells feature vigorous crying, LOC (<1 min) and return to normal activity; pallid spells are longer (LOC >1 min), child rarely cries, may rarely result in a postanoxic seizure
Hyperventilation		•	•	Associated with anxiety/panic; may have perioral and bimanual paresthesias, carpopedal spasm
Deliberate syncope		•	••	Also known as the "fainting lark"; hyperventilation + straining + sudden standing = fainting (usually self-induced by children as dare or entertainment or for avoiding an undesirable task)
		Behavioral disorders		
Head-banging	••	•		Mainly in infants, usually resolves by age 10; if persists longer, it is usually associated with mental retardation or autism; occurs as child falls asleep; no association with emotional disturbances; normal EEG
Night terrors	•	•••	•	May be confused with CPS, especially of frontal lobe origin; occur during first 3 h of sleep, in stage 3 and 4 (slow-wave) sleep; child screams and sits up, often with increased sympathetic activity; typically has no recollection of the event; normal EEG
Nightmares		••	••	Occur primarily during REM sleep, usually later in night; child is restless during dream but usually does not scream; often recalls nightmare and develops a fear of sleeping alone; normal EEG

Sleepwalking	•••	••	May be confused with automatisms of CPS; trance-like episodes of walking from and back to bed; eyes open, rarely violent; child may mumble; has no recollection of event; usually in slow-wave sleep or associated with incomplete arousal
Rage	•••	••	Associated with other conduct/personality disorders, directed to source; behavior can be modified during episode; differentiate from ictal rage (rare, seen in frontal/temporal lobe epilepsy; unprovoked and not focused on a particular object/individual)
Fear	•	•••	Occurs as feature of chronic anxiety disorder or in depressed or schizophrenic patients; distinguish from "ictal fear" (often followed by CPS)
Daydreaming/attention deficit	•••	•••	Brief (30–60 sec) loss of contact with environment; generally responds to touch; daydreamers never interrupt their own speaking to stare ahead and lose track of time; a child who stops speaking in mid-sentence with staring almost always has a seizure disorder
	Migraine		
	•	•••	See text and Table 1 ; 3%–7% of children with migraine may have coexisting epilepsy
• Basilar			• Initial symptoms of brainstem/occipital lobe dysfunction (especially vertigo/bilateral visual loss) or less often LOC; one third have occipital spike-and-wave complexes between episodes on EEG
• Confusional			• Confusion, with or without delirium, is seen in confusional migraine, more common in adolescents; often no headache, may have past history of more typical migraines or family history

	of migraines
• Migraine equivalents	• Episodic nausea and vomiting can be from seizures (almost always with complex partial seizure, usually nondominant temporal onset) or can be a migraine equivalent, especially in younger children; brief, stereotyped, recurrent paroxysmal epigastric discomfort can be epileptic auras, most commonly temporal lobe

ADHD, attention deficit hyperactivity disorder; CPS, complex partial seizures; EEG, electroencephalogram; LOC, loss of consciousness; PNES, psychogenic nonepileptic seizures; REM, rapid eye movement. *Source*: Adapted and expanded from Prensky AL. An approach to the child with paroxysmal phenomena with emphasis on nonepileptic disorders. In: Pellock JM, Dodson WE, Bourgeois BFD, eds. *Pediatric Epilepsy: Diagnosis and Therapy*, 2nd ed. New York: Demos; 2001:97–116.

Table 3 Syncope Versus Seizure: Useful Distinguishing Features

	Syncope	Seizure
Before spell		
Trigger (position, emotion, Valsalva)	Common	Rare
Sweating and nausea	Common	Rare
Aura (e.g., smell, déjà vu)	Rare	Common
Unilateral symptoms	Rare	Common
During spell (from eyewitness)		
Pallor	Common	Rare
Cyanosis	Rare	Common

Duration of loss of consciousness	<20 sec	>60 sec
Movements	A few clonic or myoclonic jerks; brief tonic posturing (few seconds); duration <15 sec; always begin after loss of consciousness	Prolonged tonic phase (~30 sec), then prolonged rhythmic clonic movements (~30–60 sec); duration >1 min; may begin at onset of loss of consciousness or before; unilateral jerking (partial seizure)
Automatisms	Occasional	Common (in complex partial and secondarily generalized seizures)
Tongue biting, lateral	Rare	Occasional
Frothing/hypersalivation	Rare	Common
EEG (during event)	Nonspecific slowing	Ictal EEG pattern
	After spell	
Confusion/disorientation	Rare; <30 sec	Common; several minutes or longer
Diffuse myalgias	Rare, brief, usually upper body	Common, hours to days
CK elevation	Rare	Common (especially after 12–24 h)
EEG (between events)	Normal	Epileptiform discharges common
Features that are not helpful for differentiating	Incontinence, prolactin level, dizziness, fear, injury other than lateral tongue biting, eye movements (rolling back), brief automatisms, vocalizations, visual or auditory hallucinations	

CK, creatine kinase; EEG, electroencephalogram.

Table 4 Differential diagnosis of transient alteration of consciousness or awareness

Presentation	Possible etiologies
Blackout/faint	Seizures (multiple types)
	Syncope
	Sleep attack
	Vertebrobasilar transient ischemic attack
	Hypoglycemia
Confusional or fugue states	Nonconvulsive status epilepticus (absence or complex partial)
	Postictal state
	Acute toxic/metabolic encephalopathy
	Acute porphyria
	Hypersomnia (sleep drunkenness)
	Parasomnias
	Intermittent psychosis
	Transient global amnesia
	Psychogenic fugue
	Basilar artery migraine
	Flumazenil-responsive recurring stupor
	Stroke
Amnesia	Seizures, especially temporal lobe
	Transient global amnesia

	Daydreaming
	Sleep attack
	Alcoholic blackout
	Drugs
Hallucinations	Seizures, occipital (simple visual) or temporooccipital (formed visual)
	Drugs/hallucinogens
	Delirium tremens
	Toxic encephalopathies
	Peduncular hallucinosis
	Hypnagogic hallucinations
	Schizophrenia and other psychoses
Anxiety/rage	Seizures, especially temporal lobe
	Panic attacks
	Hyperventilation/anxiety attacks
	Intermittent explosive disorder (episodic dyscontrol)

Note: Psychogenic seizures can present under any category. *Source*: Partly adadpted from So NK, Andermann F. Differential diagnosis. In: Engel J, Pedley TA, eds. *Epilepsy:* A Comprehensive Textbook. Philadelphia: Lippincott-Raven; 1997:791–797; and NICE guidelines: the epilepsies: clinical practice guideline, October 2004, available: http://www.nice.org.uk/page.aspx?o=229389.

Transient Alteration of Consciousness, Awareness, or Mental State

Table 4 lists some of the possible causes for transient alteration of awareness; only the more common causes are discussed in detail here. As already mentioned, the most common differential diagnosis involves distinguishing seizure from syncope (Table 3; see also Chapter 271). *Syncope* ("fainting" or "blackout") is defined as transient alteration of consciousness and loss of muscle tone from an acute, reversible global reduction in cerebral blood flow.[16] The two most important types of syncope are neurally mediated reflex syncope ("neurocardiogenic" syncope) and cardiac syncope. Neurocardiogenic syncope includes vasovagal syncope, situation-related forms of syncope such as micturition and cough syncope, and carotid sinus

P.774

P.775

P.776

hypersensitivity. All of these types of syncope tend to have an identifiable trigger, occur most often while standing, and usually have a prodrome consisting of lightheadedness and dimming or "closing in" of vision (often described as tunnel vision). Patients appear pale and usually have profuse sweating (which is rare with seizures). The period of unconsciousness is usually only a few seconds unless the patient is held upright. It is not unusual to have brief tonic posturing, and it is even more common to have a few clonic or myoclonic jerks, referred to as "convulsive syncope." In a study of normal young adults with videotaped self-induced syncope, 90% had myoclonic jerks following the loss of consciousness.[24] In seizures, jerks may either precede or follow loss of consciousness. With syncope, consciousness returns rapidly, in marked contrast to generalized tonic–clonic seizures. Cardiac syncope is similar, but it may not have a prodromal phase or trigger, and the duration of loss of consciousness can be variable depending on the duration of the arrhythmia. A cardiac cause of syncope is especially important

P.777

to consider because 5-year mortality in this group can exceed 50% and is often preventable.[31] For patients with infrequent but recurrent syncope or possible syncope, subcutaneous implanted loop electrocardiogram recorders can be used to make a definitive cardiac diagnosis; these can be left in place for >1 year when necessary. Other features that suggest a generalized tonic–clonic seizure rather than syncope are lateral tongue biting, frothing, cyanosis, and subsequent headache and diffuse myalgias (Table 3). An aura other than dizziness or lightheadedness is helpful if present. It is important to note that incontinence and elevated prolactin level are not rare with syncope and, as a result, are not helpful in distinguishing syncope from seizure.[7,17]

Transient ischemic attacks (TIAs) can occasionally be confused with seizures. Vertebrobasilar TIAs occasionally present as drop attacks, but these are almost always associated with additional brainstem, cerebellar, or occipital lobe symptoms. Seizures manifesting with isolated aphasia are usually misdiagnosed as hemispheric TIAs until spells become recurrent and stereotyped with no evidence of ischemia or infarct. Global or atypical aphasia without hemiparesis or visual field deficit and negative magnetic resonance imaging with diffusion-weighted imaging should favor the likelihood of seizure, even with the first attack. We have referred to these spells as "transient global aphasia." Limb-shaking TIAs are rare, and are characterized by nonrhythmic, coarse, 3- to 12-Hz shaking of the arm (with or without leg involvement) contralateral to severe carotid stenosis.[1,32] These patients may experience symptoms on standing due to hemodynamic insufficiency in the distal carotid field (see also Chapter 275).

An *acute confusional state* can occur due to a number of causes, many of which are treatable (Table 4). It is important to rule out nonconvulsive status epilepticus, a condition that can occur in patients with or without a history of seizures. Delay in diagnosis of nonconvulsive status epilepticus is associated with lower likelihood of response to treatment and worse neurologic outcome, independent of etiology.[39] Intermittent episodes of confusion or altered behavior can be very difficult to diagnose definitively without video-EEG monitoring, particularly in patients with dementia or a static encephalopathy. On rare occasions, an intermittent or episodic nature is not noticed at all, and patients present with dementia. This situation has been termed "*epileptic pseudodementia.*"[33] When fluctuations in the confusional state are present, nonconvulsive seizures are a more obvious consideration. Treating the seizures improves cognition and may restore a normal mental state.

Table 5 Differential diagnosis of abnormal paroxysmal movements

Presentation	Possible etiologies

Bilateral motor activity	Epilepsy: primary or secondarily generalized, or supplementary motor
	Convulsive syncope
	Startle disorders (hyperekplexia)
	Myoclonus
	Paroxysmal dyskinesias
	Other movement disorders
	Decorticate and decerebrate rigidity/posturing
	REM behavior disorder
	Other parasomnias
	Rabies
	Tetanus
	Strychnine and camphor poisoning
Unilateral/focal motor activity:	Focal motor seizures
• Twitching	Myoclonus
• Jerking	Tics
• Shaking	PLMS
• Posturing	Tonic spasms of multiple sclerosis
	Limb-shaking TIAs
	Esophageal reflux (Sandifer syndrome) in children

Facial muscle and eye movements	Partial seizures
	Hemifacial spasm
	Oculogyric crisis
	Dystonia
	Tics
	Other movement disorders
Episodic phenomena during sleep	Normal physiologic movements
	Epilepsy, especial frontal lobe
	Paroxysmal nocturnal dystonia (may be seizures)
	Pathologic fragmentary myoclonus
	Restless leg syndrome/PLMS
	Parasomnias
	Sleep apnea
Paralysis	TIAs
	Hemiplegic migraine
	Alternating hemiplegia of childhood
Drop attacks	Seizures: atonic, tonic, myoclonic or astatic
	Syncope
	Vertebrobasilar TIA
	Metabolic disorders

Cataplexy

Note: Psychogenic seizures can present under any category PLMS, periodic limb movements of sleep; REM, rapid eye movement; TIA, transient ischemic attack. *Source*: Partly adapted from So NK, Andermann F. Differential diagnosis. In: Engel J, Pedley TA, ed. *Epilepsy:* A Comprehensive Textbook. Philadelphia: Lippincott-Raven; 1997:791–797; and NICE guidelines: the epilepsies: clinical practice guideline, October 2004, available: http://www.nice.org.uk/page.aspx?o=229389.

Basilar migraine (see Chapter 274) occasionally causes alteration of consciousness, but associated symptoms and its

slow evolution usually allow it to be readily distinguished from a seizure. *Transient global amnesia* (TGA) produces abrupt memory loss but does not involve alteration in consciousness or awareness. Episodes of TGA last several hours but almost always <1 day. Patients appear bewildered and anxious, ask repeated questions as a result of their memory loss, but are otherwise normally alert and interactive. Seizures only rarely cause transient amnesia in isolation ("epileptic amnesia"); usually there are other indications of complex partial seizures, although these can be quite subtle.

Panic attacks can be confused with partial seizures, with errors occurring in both directions. Panic attacks have several features not usually associated with seizures. They tend to be triggered by known stressors, last >5 minutes, and are associated with dyspnea, palpitations, trembling, and intense fear. There may be some sense of detachment, but there is no loss of consciousness or responsiveness. Some patients hyperventilate, which can lead to oral and bimanual paresthesias, carpopedal spasm, and dizziness. Almost all patients with panic attacks (95%) have associated anxiety disorders, phobias, or depression. Features suggesting seizures are absence of a consistent trigger, short duration (<5 minutes), amnesia for parts or all of the spell, an observed period of unresponsiveness, and prominent oral or hand automatisms. Differentiating the two conditions is sometimes difficult and may require video-EEG monitoring for definitive resolution.

Table 6 Differential diagnosis of paroxysmal sensory disturbances

Presentation	Possible etiologies
Somatosensory attacks/parasthesias	Seizures: parietal onset
	Transient ischemic attack
	Multiple sclerosis
	Peripheral neuropathy
	Restless leg syndrome
	Hyperventilation/anxiety attack

	Hypnagogic hallucinations
	Schizophrenia
Visual symptoms	Seizures: occipital or temporooccipital
	Migraine with aura
	Transient ischemic attack
	Ocular disorders
	Disorders of optic pathway (phosphenes/photopsias)
	Hypnagogic hallucinations
	Schizophrenia
	Drugs
Auditory symptoms	Seizures: posterior temporal neocortical
	Ear disorders (including Ménière disease)
	Cranial bruits
	Palatal myoclonus
	Drugs
Vertigo	Seizures: temporoparietal
	Vestibular disorders (including Ménière disease)
	Basilar artery migraine
	Brainstem disorders
Abdominal sensation	Seizures: variable onset, most commonly limbic

	Migraine
	Drugs: side effects
	Gastrointestinal disorders
Autonomic disturbances:	Seizures: most commonly limbic onset
• Flushing	Panic attacks
• Pallor	Presyncope
• Sweating	Hypoglycemia
• Palpitations	Pheochromocytoma
	Carcinoid syndrome
	Mastocytosis

Note: Psychogenic seizures can present under any category. *Source*: Partly adapted from So NK, Andermann F. Differential diagnosis. In: Engel J, Pedley TA, eds. *Epilepsy:* A Comprehensive Textbook. Philadelphia: Lippincott-Raven; 1997:791–797; and NICE guidelines: the Epilepsies: clinical practice Guideline, October 2004, available: http://www.nice.org.uk/page.aspx?o=229389.

The symptoms of *hypoglycemia* can also mimic epilepsy, usually in individuals being treated for diabetes mellitus. On rare occasions the hypoglycemia may be due to an insulinoma.[2] Insulinomas present with an insidious onset of transient neurologic (usually motor) deficits, confusion, lethargy, personality change, and autonomic disturbances. Diagnosis is

often delayed because other neuropsychiatric diagnoses tend to be considered first.[15] *Idiopathic recurrent stupor*[36] is a controversial syndrome thought to be due to excessive endogenous benzodiazepine levels causing recurrent episodes of prolonged stupor and prominent rhythmic beta activity on EEG (identical to what is seen in patients taking benzodiazepine drugs). Symptoms respond to flumazenil, a benzodiazepine antagonist. Some investigators have suggested that this syndrome is due to unrecognized exogenous benzodiazepine use.[14]

Paroxysmal Abnormal Movements

Convulsive syncope and limb-shaking TIAs were discussed in a previous section. *Myoclonus* (see Chapter 277) can be epileptic or nonepileptic (Table 5). When it is epileptic, jerks are associated with generalized spike-wave or polyspike-wave discharges on EEG; other seizure types are usually present but can be absent. Myoclonic seizures in idiopathic generalized epilepsy are

usually part of the syndrome of juvenile myoclonic epilepsy. They tend to be most frequent in the morning shortly after awakening and present during adolescence or in early adulthood and are exacerbated by recent alcohol intake or sleep deprivation. Nonepileptic myoclonus is not associated with other seizure types or epileptiform discharges in the EEG. Patients with multiple sclerosis can have "*tonic spasms*" that appear similar to epileptic tonic seizures, and these often respond to antiepileptic drugs.

Paroxysmal movements in sleep usually require video/EEG/polysomnographic monitoring for definitive diagnosis. Even with such testing, the nature of *paroxysmal nocturnal dystonia* is often unclear. Some authorities have argued that it is a movement disorder, whereas others have shown that, in many cases, it is a manifestation of localization-related epilepsy.[35,41] We believe that it is usually or always epilepsy. Regardless, it is quite responsive to AEDs such as carbamaze-pine.

Sometimes seizures present with purely "negative" symptoms such as weakness or numbness, thereby mimicking a TIA. The brief, recurrent, stereotyped and reversible nature of these events or their eventual spread to areas that result in positive phenomena usually leads to the correct diagnosis. On occasion, the negative ictal phenomenon is followed by postictal migraine (especially common in occipital epilepsy, but not rare in any epilepsy syndrome), mimicking migraine with aura, hemiplegic migraine, or other complicated migraine attack. The reverse—a seizure triggered by a migraine aura, possibly due to cortical spreading depression—can also occur, although this is much less common. To make matters more confusing, there are rare families with both seizures and familial hemiplegic migraine. In fact, mutations in the same calcium-channel gene on chromosome 19 can cause familial hemiplegic migraine, epilepsy, episodic ataxia, chronic ataxia (SCA-6), or some combination of these.[21,27,34]

Drop attacks are sudden falls with or without momentary loss of consciousness. They can occur due to syncope (discussed previously), cataplexy, Ménière disease, vertebrobasilar TIAs, or seizures. Seizures that cause sudden falls can be myo-clonic, tonic, atonic, or combinations of these. These seizures are usually part of an epileptic syndrome with multiple seizures types in neurologically abnormal children, most commonly with Lennox-Gastaut syndrome. On rare occasions, temporal lobe seizures can cause drop attacks, but virtually always late in the course of chronic temporal lobe epilepsy.[12] Focal seizures (temporal and frontal, more often left hemisphere) can also lead to asystole with cardiac syncope, fortunately a relatively rare occurrence.[8,28]

Cataplexy is usually triggered by strong emotions, especially laughter, and is eventually associated with other symptoms of narcolepsy such as sleep attacks, hypnopompic or hypnagogic hallucinations, and sleep paralysis in the majority of cases. In vestibular drop attacks associated with *Ménière disease*, there is almost always a history of previous attacks of more typical vertigo (without sudden drops), usually accompanied by tinnitus, ear fullness, and hearing loss. Patients often describe a sensation of being pushed suddenly to the ground. Historically, consciousness is not lost with these falls, although momentary loss of consciousness may not be recognized or recalled by patients with drop attacks from any cause. Vertebrobasilar TIAs have already been discussed; they are rare causes of isolated drop attacks. In some elderly patients, a firm diagnosis is elusive. As with syncope, cardiac arrhythmia is the most important entity to diagnose quickly because life-threatening ventricular arrhythmias (particularly a prolonged pause or asystole) can present as drop attacks.

Paroxysmal Sensory Disturbances

Paroxysmal sensory disturbances are listed in Table 6, and several have already been discussed. Paroxysmal visual disturbances are likely encountered most often and are clinically the most important. Simple visual hallucinations are common in both migraine with aura and occipital lobe seizures (see Chapters 237, 238, and 274). The most reliable differentiating feature is the time course: Migraine auras almost always last >5 minutes, typically 20 to 30 minutes, whereas seizures are almost always <5 minutes and typically <2 minutes in duration. Occipital seizures are often followed by a typical migraine headache. Thus, a migraine with a visual aura that lasts <5 minutes is likely to be caused by, or associated with, a seizure. Migraine auras tend to be black and white or glittery, have straight lines with sharp angles, and march across a visual field quite slowly (over several minutes). Occipital seizures include colors and circles or dots and march across a field quickly (seconds).

Psychogenic Nonepileptic Seizures

Psychogenic nonepileptic seizures are found in 20% to 40% of patients referred to epilepsy centers[3,4,13] (see also Chapters 207 and 282). Episodes of PNES are variable in presentation, and strong emotional or psychological elements are common precipitants. A history of physical or sexual abuse or a personal or family history of psychiatric disease is often obtained in patients with PNES, but a definite diagnosis on the basis of history alone is usually not possible. Repeatedly normal interictal EEGs in the presence of medically refractory seizures also raise the possibility of PNES. Incontinence and injuries are unusual but can occur.

Violent flailing or thrashing of arms and legs, side-to-side head movements, and pelvic thrusting are common in patients with PNES, although similar phenomena can be observed in partial seizures of frontal lobe origin. Preserved consciousness with sustained bilateral motor activity of the limbs is rare in epilepsy but occurs in some patients with frontal lobe seizures, especially those involving the supplementary motor area. Other features suggestive of PNES include variability from spell to spell, lack of spells occurring during sleep, spells in the physician's office, prolonged spells, starting and stopping of symptoms or movements, motionless state with eyes closed, lack of tachycardia, and a slow-motion, neurasthenic state with hypophonia during recovery. Even the most experienced observers cannot always distinguish epileptic from psychogenic spells. A definite diagnosis of PNES can be made only with video-EEG recording. A negative ictal EEG alone does not prove a nonepileptic etiology because a significant proportion of simple partial seizures and a small number of complex partial seizures (predominantly those of extratemporal origin) do not have identifiable scalp EEG correlates. In these cases, clinical semiology, stereotypy, and spells arising from EEG-documented sleep allow proper diagnosis.

To complicate matters further, PNES and epileptic seizures may coexist in the same patient.[3,9,20] Therefore, recording nonepileptic attacks in a patient with uncontrolled seizures does not prove that all the patient's seizures are psychogenic. Before reaching a final conclusion, one must verify with the patient and family that the recorded events are typical of the habitual spells experienced at home.

The AAN Therapeutics and Technology Assessment Subcommittee recently reported on the use of serum prolactin in differentiating epileptic seizures from nonepileptic seizures.[7]

Data from one Class I study and seven Class II studies supported the use of serum prolactin levels measured at 10 to 20 minutes following the event as an adjunct test for differentiating generalized tonic–clonic or complex partial seizures from PNES in adults and older children. These levels should then be compared with interictal baseline prolactin levels drawn on a different day at the same time. With epileptic generalized tonic–clonic seizures, prolactin levels are elevated to at least three times baseline. An epileptic etiology is also more likely if there is a prominent but transient metabolic acidosis and elevated creatine kinase after 12 to 24 hours.

Summary and Conclusions

Almost any condition manifesting with recurrent, stereotyped, and episodic symptoms can represent epileptic seizures. The extent to which other conditions are considered in the differential diagnosis of epilepsy depends on the nature of the symptoms and the age of the patient. A detailed history is the cornerstone of diagnosis because few patients have seizures in the office or clinic. It is important to bear in mind that many patients are unaware of some or all of their seizures or do not realize that they are associated with impaired awareness. Although ancillary tests are necessary and usually helpful, they can also be misleading. Incidental findings on brain imaging or misinterpretation of benign EEG patterns or artifacts can result in misdiagnosis. Dual diagnoses are not unusual, and having a nonepileptic condition does not preclude the possibility of coexisting epilepsy. Some of the most common coexisting illnesses with paroxysmal features are migraine and psychogenic nonepileptic seizures.

Cardiac syncope is the most important alternative diagnosis to consider in a patient with transient loss of consciousness because lack of appropriate and timely treatment can be

fatal. A few myoclonic jerks and transient posturing occur in a significant number of patients with syncope. Neurally mediated reflex syncope, the most common type, is characterized by an identifiable stimulus or set of circumstances, a characteristic prodrome, pallor, diaphoresis, and rapid return to normal. In contrast, a seizure is suggested if the loss of consciousness is followed by postictal symptoms that clear gradually, lateral tongue biting, myalgias, and, on the following day, elevated creatine kinase. Incontinence and elevated prolactin levels can be seen in both conditions and are therefore not helpful in differentiating between them.

Panic attacks are often confused with partial seizures, but they are usually longer and associated with psychological stress and do not involve complete loss of awareness. Paroxysmal movements in sleep usually require EEG-video monitoring or polysomnography for definitive diagnosis. EEG-video monitoring is also required to make a firm diagnosis of PNES. Serum prolactin levels drawn 10 to 20 minutes after a spell and compared to baseline levels drawn at the same time on a different day can be helpful in differentiating between generalized tonic–clonic or complex partial seizures (elevated prolactin level in many but not all cases) and PNES (no change in prolactin).

Anyone whose spells persist despite reasonable treatment or remain of uncertain etiology should be referred to an epilepsy monitoring unit. With the widespread availability of EEG-video monitoring systems, polysomnography, autonomic function laboratories, and other diagnostic tests, it should be possible to make a definitive diagnosis in nearly all patients with recurrent spells.

Acknowledgment

We thank Dr. Hiba Arif for assistance in preparation of this chapter.

Chapter 69

Overview: Diagnostic Evaluation

Solomon L. Moshé

Timothy A. Pedley

Introduction

Because epilepsy is a group of conditions and not a single homogeneous disorder, and because seizures may be symptoms of both diverse brain disorders and an otherwise normal nervous system, it is neither possible nor desirable to develop inflexible guidelines for what constitutes a "standard" or "minimal" set of diagnostic tests. Furthermore, it is not always clear from the history that the patient has even had a seizure or has epilepsy. Thus, the role of the physician is threefold: (a) to determine whether epilepsy or seizures exist and not some alternative diagnosis; (b) to define, if possible, an underlying cause; and (c) to optimize treatment.

The Clinical Data

Epilepsy is primarily a historical diagnosis, and the initial assessment and approach to management are based, in large part, on the clinical history, especially on an accurate description of the event in question. Information should be obtained from the patient when possible, as well as from other individuals (especially family members) who have observed typical attacks. Memory is always highly selective, however, and the abrupt and unexpected nature of seizures—especially the first—may render witnessed accounts unreliable. The patient's recollection may also be limited by alteration of consciousness and postictal amnesia. Important focal features may be overlooked, and estimates of seizure duration are almost invariably exaggerated. Auras are often particularly difficult to characterize from the patient's description because the subjective experiences are only vaguely recalled ("a feeling in my head") or conveyed using terms that different individuals use to mean quite different things (e.g., dizzy, shaking, chill, numbness, spacey). Finally, there are important age-related differences in seizure semiology that physicians must take into account. Even with these limitations, physicians must train themselves to take a systematic history that does not overlook important features (Table 1). Family members of patients who have recurrent episodes may succeed in capturing one or more of them on videotape, and this can provide invaluable information not otherwise available. As Aicardi and Taylor conclude (Chapter 70), "Clinical diagnosis is an intellectual process whereby all available sources of information, from the purely clinical to the highly technical, are integrated with a view to arrive at a meaningful conclusion."

Laboratory Tests

The clinical data from the history and physical examination should allow a reasonable determination of probable diagnosis, seizure and epilepsy classification, and the likelihood of an underlying pathologic condition of the brain. Based on these considerations, diagnostic testing should be undertaken selectively. Thus, a normal child with brief lapses of attention whose symptoms can be reproduced in the office by hyperventilation is a very different patient than is a middle-aged man who has developed partial seizures and seems to be getting progressively worse. It must be remembered, too, that diagnostic testing is never a substitute for clinical judgment and observation through follow-up and reexamination.

A great number of both routine and highly specialized diagnostic tests are available to aid physicians in the evaluation of patients with known or suspected seizures. Routine blood tests are rarely diagnostically useful in healthy children and adults but are necessary in newborns and in older patients with acute or chronic systemic disease to detect abnormal electrolyte, glucose, calcium, and magnesium values and impaired liver or kidney function.

Monitoring antiepileptic drug (AED) levels depends on the clinical situation. Leppik (Chapter 71) suggests that levels be determined at steady state after good seizure control has been attained to establish a useful benchmark. This can be repeated at annual follow-up as needed, for example, at the time of renewal of a driver's license, to ensure that adequate levels are being maintained. Other times when AED levels may be indicated are when a patient has breakthrough seizures, experiences toxicity, or is being treated with other drugs known to influence AED metabolism (especially when such comedication is altered).

The electroencephalogram (EEG) remains the most useful diagnostic test when a seizure disorder is considered (Chapters 73,74,75). An EEG should generally be obtained in every case as an aid to diagnosis or to assist in classifying the type of seizure or epilepsy syndrome. In some instances, EEG findings will aid in prognosis and in determining the need for treatment. Buzáki and Traub (Chapter 72) provide an excellent discussion of the physiologic basis of EEG activity and introduce new concepts concerning EEG oscillatory patterns. They suggest that the term *desynchronization* is misleading and that synchronous EEG activities should be characterized in terms of slow and fast oscillatory patterns. The same oscillatory patterns may be responsible for generating both interictal (Chapter 73) and ictal (Chapter 74) discharges. Bleck et al. (Chapter 75) discuss the greatly expanded use of EEG in intensive care unit (ICU) settings, which has led to major improvements in ICU care. Tassinari and Rubboli (Chapter 77) advocate the use of polygraphic recordings in selected patients to help differentiate sleep-related phenomena from epileptic seizures. Visual qualitative analysis of seizure-related EEG discharges has relied mainly on the experience and expertise of the electroencephalographer. Wong and Lopes da Silva (Chapter 76) describe and advocate the use of quantitative methods to characterize electrical and electromagnetic signals responsible for interictal and ictal discharges. The magnetoencephalogram

(MEG) (discussed in Chapter 78) can provide additional information concerning the spatial features of the epileptogenic brain region, although it is unlikely that MEG will ever be routinely available. These and other quantitative analyses are complementing traditional visual assessment of EEG and other physiologic data and providing additional information that is clinically useful in selected situations. Long-term monitoring (Chapters 92 and 93) with simultaneous collection of EEG data and videotaped behavior has allowed improved characterization of seizure semiology and definitive separation of epileptic from nonepileptic behaviors. It has also opened the possibility of surgical intervention to far greater numbers of patients. LeVan and Gottman (Chapter 95) summarize the essential role played by computers in data reduction and analysis of physiologic data obtained during both routine EEG and long-term monitoring.

Table 1 important historical features of epileptic seizures

First event in the seizure (aura, initial movement, or sensation)
Subsequent evolution of the seizure
Postictal manifestation [focal (e.g., Todd paresis) vs. diffuse nonspecific]
Is there more than one seizure type?
Has there been a change in the seizure pattern?
Date and circumstances of first attack
Subsequent precipitating or triggering factors (alcohol, sleep deprivation, hormonal)

Age of onset, average frequency of attacks, and longest seizure-free interval

Response to previous medication (doses, blood levels, cominations)

Family history (parents, offspring, siblings)

Is there a history of neonatal seizure or febrile seizures?

Is there a history of previous brain injury?

Is there personal or family history of other neurologic, mental, or systemic disease?

The modern era of structural brain imaging—first with computed tomography (CT), then with magnetic resonance (MR)—has revolutionized our ability to identify epileptogenic brain lesions (see Chapter 79). With high-resolution MR scans, a wide variety of pathologic lesions can now be diagnosed routinely and noninvasively. These include mesial temporal sclerosis, well-differentiated gliomas, gangliogliomas, cavernous malformations, neuronal migration defects, and dysembryoplastic neuroepithelial tumors. Fewer seizure disorders are now justifiably classified as "idiopathic" or even "cryptogenic." The identification of lesions that are potentially surgically resectable has added a new dimension to treatment and given hope to many patients with medically intractable epilepsy. Functional brain imaging, such as positron emission tomography (PET) (Chapter 80), single photon emission computed tomography (SPECT) (Chapter 81), and magnetic resonance spectroscopy (Chapter 82), is providing additional and often critical information about the extent of metabolic changes and alterations in regional cerebral blood flow associated with seizures, and graphically illustrates how widespread can be the disruptive effects of an epileptogenic brain region. Indeed, surgical decisions in infants with seizures may actually rely more on functional characterization of the epileptogenic "focus" than on delineating structural pathology. Chapter 83 describes the current and future uses of functional MRI, and Chapter 84 addresses the use of computational anatomic studies to characterize structural abnormalities in patients with epilepsy.

Chapters 92 and 93 describe how to organize an effective monitoring unit that meets both technical requirements and patients' needs for a pleasant environment that can be tolerated for relatively long inpatient stays. Due to quality-of-life and fiscal restraints, it is important to maximize the yield of meaningful data obtained within a reasonable time frame. Drug withdrawal and activation techniques (Chapter 94) increase the yield of epileptiform EEG abnormalities and facilitate recording clinical events in compressed time intervals. Neuropsychological testing (Chapters 90 and 91) provides measurements of a patient's intellectual capacity as well as insights into the effects that epilepsy is having on an individual's cognitive functioning and psychosocial adjustment. In addition, neuropsychological assessment is an essential part of the pre- and postsurgical evaluations. The particular tools used, as well as data interpretation, are highly age dependent.

Even with all of these diagnostic aids, there are many patients in whom the epileptogenic mechanisms, including even where in the brain seizures originate, are poorly understood. In the previous edition of this book, we identified MR spectroscopy and functional MRI as exciting new directions. Both these methods are now used routinely. In this second edition, new directions that we have chosen include the remarkable possibility of seizure prediction (Chapter 85); optical imaging (Chapter 86), which may provide physiologic data that can be compared to the biochemical data obtained with in vivo microdialysis (Chapter 87); transcranial magnetic stimulation (Chapter 88); and cellular and molecular imaging (Chapter 89).

Summary and Conclusions

Many of the newest diagnostic methods are most readily applicable to older children and adults. Because of various social, ethical, and practical constraints, the newest ancillary tests are not routinely used in infants and very young children, and the role of these technologies in the youngest age groups remains to be determined. Nonetheless, it is readily apparent that the ability of physicians to diagnose, classify, and intervene rationally in epileptic disorders has improved dramatically, to the overall benefit of their patients. Comprehensive epilepsy centers, with their multidisciplinary teams, are probably best positioned to make optimal (including cost-effective) use of the various clinical and investigative diagnostic tools available in the management of patients with complex or intractable seizure disorders.

Chapter 70

History and Physical Examination

Jean Aicardi

David C. Taylor

Introduction

Careful and detailed history taking remains the cornerstone of accurate diagnosis of epilepsy,[13] the prototype of diseases for which the diagnosis rests entirely on clinical grounds and especially on historyâ€"the diagnosis is as good as the history.[16] Therefore, history taking and physical examination should be performed in a comprehensive and methodic manner, although flexibility in their practical modalities is an absolute requirement in the examination of children, especially younger ones. The investigation of any disorder should be scaled in proportion to the severity of the problem. Epilepsy has a tremendous impact on patients' lives, both physically, because it is a threatening and dangerous condition, and psychosocially, because of its chronicity, the fears it generates, and the still-present prejudice against affected persons. Therefore, patients with a suspected diagnosis of epilepsy should be investigated using all means necessary for making a definitive diagnosis, establishing a prognosis, and planning the proper treatment. The necessary investigations vary with the clinical presentation and need not include much in the way of laboratory or other ancillary examinations. However, the process often requires considerable time and is best completed from onset. A succession of fragmentary assessments that may initially seem to save time often results in delaying the diagnosis, sometimes with disastrous consequences, and usually turns out to represent a considerable waste of time.

Taking a history of a paroxysmal disorder demands a proper technique of medical interrogation and a good knowledge of the protean manifestations of the disorder. The aim is to determine as precisely and reliably as possible the objective characteristics and course of a sudden, brief, and unexpected event that has occurred in a highly emotional context and is only partially recalled, often in a biased manner, by both the patient and witnesses. The objective of physical examination is to look for any evidence of an underlying cause, whether limited to the brain or involving other systems as well, as is the case with neurocutaneous disorders, chromosomal abnormalities, and some systemic illnesses.

History Taking

Background

History taking cannot follow strict rules and has to be adapted to each individual case and person. It is often wiser to take advantage of opportunities that may arise during conversation with the person relating the history than to try to maintain a chronologic and logically constructed questioning.

As previously indicated, history should be scaled in detail in proportion to the seriousness of the illness; therefore, it should be meticulously detailed for epilepsy. In some cases, apparently casual details are of tremendous importance.

Although the basic aims of history taking are fundamentally the same, there may be some variation depending on the position of the person taking the history, and the emphasis may not be the same for primary physicians and those in secondary or tertiary care. More importance may variably be given to clearing previous diagnostic confusion, to assessing overall life situation, or to reviewing treatment. History taking is also the first act of the doctorâ€"patient relationship, with long-lasting consequences for the subsequent development of this relationship.

Some physical conditions of the room in which the history is taken are important. Information cannot be properly exchanged in impossible situations. Seating and lighting arrangements should be meant to favor communication, and disturbing factors, such as telephone calls or the repeated entrance of a secretary or colleagues, should not interfere with the exchange. It is essential that patients have the feeling that their personal history is being listened to and given the importance it deserves. This is one of the reasons that sufficient time should be allowed, even for relatively simple cases, and even if the doctor feels that questioning has been thorough. Time is also essential to gather information about fine details, which may constitute valuable cues. It may take a very long time to disentangle the threads of a history and reweave them into a true likeness to the event.[16] Indeed, more than one session is often necessary. An additional advantage is that both patient and doctor can think again about the case and possibly come up with new questions or newly remembered details.

With children, the history is usually obtained mainly from parents or guardians, and such third-party questioning poses special problems. The child's account, if any can be given, should be particularly facilitated. Older children and adolescents can contribute information on subjective phenomena that are unobtainable from any other source; such information may prove crucial for the diagnosis and be important to the young patients in coming to terms with their illness. One of the difficulties of third-party questioning is the increasing risk for biased and overrehearsed accounts, with the description of the attacks conforming more and more to a preconceived, once-and-forever established idea of what they are like, without the possibility of rectification on the basis of phenomena personally felt by the patient.

Another risk is to give credence to only one parent's account, usually the mother's, and ignore the other's. Listening to both parents, however, might result in contradictory statements. A decision of which account is more credible must be made, which may be in part arbitrary. For these reasons, a fresh history and not a simple repetition of previously given accounts should be obtained at each new consultation. Accepting previous accounts uncritically is a major source of diagnostic errors. Jeavons[10] emphasized the trap represented by a previous

P.786

diagnosis of known epilepsy often based on a history that may not have been properly obtained. Such a diagnosis may nonetheless remain accepted for years, thus delaying the true diagnosis. Doctors' and nurses' accounts are potentially of great value. In some cases, however, they can also be misleading because professionals often have a tendency to describe attacks as they should theoretically be rather than as they are. Whoever the witnesses, critical scrutiny of their accounts is essential. A distinction should be drawn between first-hand versus second-hand witnesses and between witnesses who have been able to observe the whole of a seizure and those who saw only a part of it. An assessment of the degree of reliability of the witnesses has to be done. It should not be based only on how articulate they are; attempts at checking the veracity of their accounts (e.g., by gathering details that indicate whether they were really in a position to observe some reported phenomena) are important.

The style of history taking depends on individual patients and physicians. With some patients it may be best to listen first to their own account with minimal interference and later ask precise questions about specific points. With others, more directed questioning may be necessary to avoid garrulous, irrelevant, and interpretative accounts. In such cases, it is useful to formulate direct questions about uninterpreted events that are to be answered as yes or no. The meaning of terms has to be made clear and medical terms avoided as much as possible. It is often helpful to offer patients several simple words that are synonymous with medical terms, among which they can choose. Stephenson gave a useful list of such words.[16] Questioning several witnesses may permit some cross-checking of data, and going back to the history to gain more and finer details can clarify some issues.

Obtaining a description of the paroxysmal events is the most important part of history taking, and it requires a high degree of attention and considerable time. The history, however, is not limited to this description. Such events occur in individual persons who react in their own way and in a given setting. Thus, there are two approaches to history takingâ€"obtaining a history of the complaint and obtaining a history of the person.

History of the Complaint

It is often very useful and always recommended to ask for a description of specific attacks. This should especially include *the last attack actually witnessed* because it is better remembered. The physician should not forget that there may be two or several types of seizures. In such cases, efforts should be made to obtain a description of the most recent seizures of every type.

A description of the *first* seizure is also of great interest because it not infrequently differs from subsequent attacks. For example, it may have been a febrile convulsion followed by complex partial seizures. In addition, the impact it had on the patient's life and the way the patient reacted to the first epileptic event can tell much with regard to later adjustment to the illness.

A description of the *worst* attack is also to be sought. It provides indications about the capacities for adjustment under maximal stress and about the scale of the clinical problem and the risk to life. The circumstances of occurrence, duration, and possible presence of postictal phenomena, such as Todd's hemiplegia or aphasia, can give valuable clues to lateralization and localization.

The *setting* in which the attacks occurred may be of considerable significance. Epileptic attacks or nonepileptic paroxysmal events that simulate seizures are often nonrandom phenomena, and the circumstances of occurrence can be important for differential diagnosis and planning of investigations. Points of particular interest include the temporal relation of events to the sleepâ€“waking cycle; for example, was the patient awake or asleep, and, if asleep, did the attack occur at onset of sleep, before or shortly after awakening, or in the middle of the night? In the case of daytime attacks, the following should be determined: Whether the attacks usually occur at a particular time (morning or evening) or apparently at random; the type of activity in which the patient is engaged at the time of seizures (resting, exercising, in bed, at school, playing, in a bath, eating or fasting, standing or reclining, using a computer, watching television or playing a video game, bored, emotionally disturbed, or engaged in a pleasant occupation); and the patient's general state of health (concomitant or recent febrile or other systemic disease). In the case of a child taking antiepileptic drugs on a long-term basis, the temporal relationship of fits to drug ingestion, the possible failure to take one or several doses, and events such as vomiting or other digestive disturbances that may have interfered with absorption of ingested drugs should all be noted.

A *prodrome* is a long-term indication of a forthcoming attack. Prodromes (e.g., changes in behavior, such as irritability, sleepiness, feelings of hunger, sweating, hypothermia, distant feeling, and the like) are mostly absent or of secondary importance. Behavioral changes are more often seen before migraine attacks than before epileptic seizures; hunger and hypothermia can suggest hypoglycemia.

The search for a *stimulus* regularly associated with the occurrence of attacks is of extreme diagnostic interest and consequently should be systematic and thorough. Identification of the regular association of attacks with an immediate stimulus is often of greater value than even a description of the attacks. The significance of the fit may also be better pointed to by the type of stimulus than by the clinical phenomenology of the paroxysm. The *regular* precipitation of attacks by such stimuli as the sight of blood, blood letting, or injections, prolonged standing in hot or confined places, holding breath, or pain from minor trauma, such as bumping one's head, is practically diagnostic of â€œanoxic seizures,â€[15] even when the induced attack is difficult or virtually impossible to differentiate from a convulsive generalized epileptic seizure, as in convulsive syncope.[7,11] Conversely, such precipitating factors as flashing lights or startle strongly favor a diagnosis of epilepsy after such rare conditions as hyperekplexia have been excluded.[3] Certain maneuversâ€"for example, Valsalva's maneuverâ€"can induce attacks that are very difficult to distinguish from seizures but are easily recognizable when the initial phenomena are well described.[2]

The *analysis of the aura* or first symptom of the seizure is so important that detailed questioning is required; the patient and witnesses should be asked to concentrate on that moment. A wide range of symptoms, from vague sensations (especially abdominal and visceral) to highly elaborate motor, sensory, and psychosensorial phenomena, occurs in epileptic seizures,[9,17] but auras can occasionally precede attacks of other types, such as migraine (especially visual aura) or syncope.[4,16] In addition, no description of auras is available with young children. The occurrence of an aura can sometimes be deduced from a child's observed behavior, such as screaming, appearing terrified, and running to his or her mother, or suddenly stopping any ongoing activity and assuming an appearance of preoccupation and concentration. Although such events are often fairly vague, their regular presence indicates that a seizure is probably of localized origin or that any more apparent first symptom is not in fact initial and can be misleading if interpreted without knowledge of previous phenomena.

Reconstitution of the *ictal sequence* itself is difficult because most seizures are brief events with rapidly changing and multiple symptoms. So many things take place in so short a time that even the best witnesses are unlikely to be able to describe all

aspects of the whole sequence. For that reason, monitoring with video in a hospital or, more easily, at home is extremely helpful. It is not, however, a substitute for history taking because it often does not allow a full view of the patient and provides no information on essential clues such as awareness, responsiveness, memory of events, and any cognitive or language involvement. Inquiry about ictal incontinence and tongue biting is traditional, but the presence of these symptoms is neither necessary nor specific for a diagnosis of epilepsy. Although lateral tongue biting is unusual in disorders other than epilepsy, it has been reported occasionally in syncope.[11] The subjective estimation of the *duration* of a paroxysmal attack is very often exaggerated. The person taking the history should attempt to obtain temporal clues, such as the time elapsed before taking the child to the hospital or calling a neighbor for help or phoning the doctor. It is imperative to separate the duration of the active seizure itself from that of the immediate postictal coma, confusion, or sleep and therefore to ask specific questions in this regard. Very often, the duration initially reported includes the whole of the ictal and immediate postictal phases.

The manifestations of the postictal phase and their duration are of interest because they can provide useful lateralizing or localizing clues and indications about the severity of the ictal phase.

Asking witnesses to complement descriptions by miming seizures is often more informative than a purely oral account. Often, miming reveals features that would have easily gone unrecognized, such as asymmetry of posture. The doctor's miming of features of seizures can be of considerable help to witnesses in distinguishing between jerks and vibratory tremor and understanding what an oro-alimentary automatism or different types of head turning look like. Certain types of seizures, such as infantile spasms or other minor seizures, are difficult to recognize, and parents often recognize them only when their features are demonstrated.

Finally, the rate of repetition of the attacks should be carefully recorded, as well as the regularity or irregularity of repetition and the occurrence of clusters. This should be done for each type of seizure.

Patient History

This includes the patient's life and developmental history; aspects of social, behavioral, and cognitive functioning; and the family history, especially of seizures and other neurologic disorders.

Developmental History

Developmental history is recorded along traditional lines, with special emphasis on the perinatal period; milestones, such as age of independent walking and first talking; and school performance, which in older children is particularly useful for the assessment of cognitive functions. A precise history of previous diseases, especially meningitis, encephalitis, and febrile convulsions, including attempts to determine their length, possible lateralization, and the presence of any localized postictal deficit or other episodes of loss of consciousness, is of obvious importance. Any severe or unusual disease should be recorded. It should be remembered that a previous history of seizures or central nervous system disease, however significant, does not necessarily indicate that subsequent paroxysmal events are epileptic.

History of Epilepsy

A history of the epilepsy (once the epileptic nature of the child's seizure has been *authenticated*) should be reconstructed in great detail. Age of onset, initial manifestations, change in frequency and type of seizures, occurrence of episodes of status, presence of deterioration or stagnation (cognitive, behavioral, or both), and any previous investigations should be determined. A precise drug history is of particular importance for a rational treatment, but this is difficult to obtain. It requires considerable effort to collect old prescriptions and determine the duration of drug trials. When available, blood levels of drugs can give precisely dated indications of the adequacy of previous treatments; these should be correlated with the presence and frequency of attacks as well as side effects during the corresponding periods. Family history of neurologic diseases and especially of seizures may be important for diagnosis and prognosis, but it is often difficult to elicit, and the significance of paroxysmal events that occurred many years earlier is often impossible to assess. If medical records, electroencephalographic reports, or other results are available, they should be scrutinized carefully because some types of epilepsy have a strong genetic component.

The Person With Epilepsy

It is essential that the physician gain a sufficient knowledge of the patient as a person. Therefore, the patient's life history, personality, and interests should be reviewed. This will help in assessing the degree of disturbance caused by epilepsy, which varies considerably depending on preferred activities. Persons with active lifestyles, such as athletic individuals, may well find themselves more handicapped than individuals more inclined to reading or a sedentary lifestyle, at least in terms of physical risk. The type of personality may help to predict how a patient will respond to the challenge of epilepsy. The social background will in part determine the sort of explanation and advice given. Assessing the family background and trying to determine to what extent the family may help or represent an additional problem are also important; the attitudes of any other group to which the patient belongs will also be significant. All this information will influence the manner of addressing the patient, the way of conducting the investigations, and the expectation of success in treatment.

The impact of epilepsy on a patient's emotional, professional, and social status is extremely variable, depending on the combination of disease manifestations and the patient's personality and manner of living. Assessment of this impact will largely determine a number of essential decisions, for example, the respective indications of medical and surgical treatment. With children, the disorder affects both the patient and the family. The attitude of parents regarding the risks they are ready to accept and their level of expectations greatly affects their way of coping with the disease. For children and adolescents, school is not only a major part of their present life, but is also a critical determinant of the rest of their existence. Inquiring about school performance is therefore of the utmost importance. Moreover, children with epilepsy who have a satisfactory cognitive level and reasonable capacity for paying attention may be capable of attending a school for normal children, but the real learning problems of some well-behaved children may be overlooked.

Physical Examination

Neurologic Examination

The neurologic examination should take into account the interval since the last seizure. If it is performed within minutes

or occasionally hours after a fit, the physician should look for postictal signs, especially focal signs such as Todd's hemiparesis, even of a minor grade. Transient aphasic symptoms are also important to detect. Care should be taken to separate postictal confusion from true aphasia. Postictal symptoms and signs of localizing or lateralizing significance are not uncommonly the clue to the localized origin of a seizure otherwise reported by witnesses as generalized. When the examination is performed after some time has elapsed since the last seizure, the main objective is to determine whether there are signs of permanent nervous system dysfunction, favoring a diagnosis of symptomatic epilepsy, and if there is evidence for a focal brain lesion. Signs of increased intracranial pressure should be looked for but are rather uncommon. Only undoubted neurologic abnormalities are of value. The so-called soft signs cannot be accepted as sole evidence of brain damage. Additional neurologic signs of interest include language difficulties and possible evidence of drug toxicity such as nystagmus, ataxia, diplopia, or tremor. When appropriate, tests for laterality should be performed because patients with epilepsy related to brain damage have an unusual incidence of left-handedness or mixed laterality, in contrast to patients with idiopathic epilepsy.[14]

General Medical Examination

Skin Examination

Examination of the skin is of particular importance because neurocutaneous syndromes are a frequent cause of epilepsy in children. The presence of cutaneous features of tuberous sclerosis, such as depigmented nevi, fibrous plaques, shagreen patches, or facial angiofibromas, or the presence of a facial flat angioma in the region of the trigeminal nerve, characteristic of Sturge-Weber syndrome, is particularly important. Linear nevus of the face, cutaneous signs of neurofibromatosis, and abnormal pigmentation, as in incontinentia pigmenti or Ito's disease, are also significant.[8]

The growth and general appearance of patients can also provide diagnostic clues. Epilepsy is a major manifestation of many dysmorphic syndromes, for example, Angelman's disease.[18] Body asymmetries are of particular importance. Epilepsy is not rare in association with hemihypertrophy. Facial asymmetry has been reported to be associated with temporal lobe epilepsy.[5,17] Unusual shape and especially size of the skull may suggest craniosynostosis, hydrocephalus, chronic subdural hematoma, or arachnoid cysts.

Eye and Visual Examination

Eye and visual examination should aim to detect papilledema and field cuts associated with focal brain lesions. Ocular motor abnormalities might suggest involvement of the brainstem or floor of the third ventricle. Intrinsic abnormalities such as cataracts, glaucoma, or corneal opacities may indicate the etiology of seizures.

Visceral Examination

Visceral examination should never be neglected and should include a particularly careful cardiovascular examination. The presence of heart arrhythmias or murmurs can suggest syncopal rather than epileptic attacks. Electrocardiographic recording is indicated in selected cases, and measurement of the PR interval should then be performed. Measurement of blood pressure, although often neglected in children, may be the only way of attributing seizures or status epilepticus to arterial hypertension.[6]

Brief Assessment of Cognitive, Social, and Behavioral Functioning

An opinion about the overall level of the patient's functioning in these areas is formed during examination and questioning. It is useful to assess systematically, although informally and rapidly, the more important components of the patient's mental state. The possibility of latent anxiety or depression, even psychosis, should be kept in mind. The level of attention and hyperkinesis is important to judge, as is the general fund of knowledge. The patient's overall behavior and manner of relating to the physician and the attributes of the patient's spouse or family are all very important in terms of diagnosis and therapeutic orientation and should be carefully recorded. They may be of considerable value in planning treatment and in assessing the effects of intervention. A more formal neuropsychologic evaluation is not necessary in most children if school performance and familial behavior are not affected. When there is suspicion of change or deterioration, it is important that a precise baseline be established to allow later comparisons.

Summary and Conclusions

Clinical diagnosis is an intellectual process whereby all available sources of information, from the purely clinical to the highly technical, are integrated with a view to arrive at a meaningful conclusion.[1]

In all fields of medicine, history and physical examination form the essential bases of diagnosis, even though additional information might be required from other sources, such as neurophysiologic and imaging studies and biochemical or other laboratory tests. Such additional information should not be requested in either a predetermined or a haphazard manner, but according to a hypothesis founded on clinical grounds. In this way, time is saved and the costs of investigationâ€”not only in terms of money but also of inconvenience and possible suffering for patients and their familiesâ€”can be considerably reduced while results are improved.

The principles that apply in other fields of medicine are relevant to an even greater degree in epilepsy and other paroxysmal disorders; history taking is by far the most important step in the diagnosis of paroxysmal disorders. Several series give figures of 20% to 30% for false diagnoses of epilepsy.[12] This represents a considerable burden of unnecessary suffering, caused above all by less-than-optimal history taking.

Chapter 71

Laboratory Tests

Ilo E. Leppik

Introduction

Laboratory testing for persons with epilepsy is needed for two reasons: (a) measuring antiepileptic drug (AED) concentrations and (b) monitoring for adverse side effects. Therapeutic drug management is based on the rationale that knowledge of the AED concentrations is necessary to identify the appropriate dose and concentration for an individual patient and monitor treatment to maintain stable therapeutic levels. Measurements of AED concentrations can improve care by avoiding breakthrough seizures, and unnecessary toxicity. AED concentrations can be influenced by a number of factors: (a) pharmacologic, such as changes in product formulation and use of comedications; (b) alterations in physiologic states, such as pregnancy, illnesses, and aging; and (c) noncompliance with AED treatment. The rationale for routine laboratory monitoring for systemic adverse events is based on the assumption that subclinical hepatitis or hematopoietic dysfunction can be detected in asymptomatic patients. However, the cost of performing routine laboratory testing is considerable. As the public becomes increasingly concerned about the cost of health care, physicians can expect to feel more pressure to cut expenses, especially in the area of routine laboratory testing. In facing these pressures, physicians must also consider the overall cost to both patients and society of not performing laboratory tests when they are necessary. This chapter describes a rational approach to the use of laboratory testing in patients with epilepsy.

Monitoring Antiepileptic Drug Treatment

Measurement of antiepileptic drug concentrations is necessary to manage the treatment of epilepsy. Routine measurement of AEDs without a specific purpose is not cost effective and not recommended. There must be a reason for ordering each test. One useful approach is to obtain an AED level when the patient has been titrated to his or her therapeutic goalâ€"no or the fewest seizures with no toxicity. This level then serves as that individual's therapeutic range and is much more useful than the published ranges, which are population derived. Serial AED concentrations in compliant, healthy patients usually do not vary by more than 20%. Thus, if a person has a therapeutic target of 13 mg/L, a level of 10.4 to 15.6 mg/L would fall within this range. However, a level of 18 mg/L, although within the published therapeutic range, may be unnecessarily high. Measurement of a level during a breakthrough seizure can then be very informative. If the level was <10 mg/L, a cause for the decreased concentration must be identified. However, if the breakthrough was associated with a level of 13 mg/L, a lowering of the patient's seizure threshold by worsening of the epileptogenic process or a lowering of the seizure threshold (i.e. use of excitatory substances, sleep deprivation) must be considered, and appropriate changes in management can be initiated. Table 1 lists appropriate times at which to measure AED concentrations.

A number of devices exist for measuring drug concentrations in plasma, serum, saliva, and other biologic samples.[9,12,30] To be approved by the U.S. Food and Drug Administration (FDA), a device for therapeutic drug monitoring must be able to perform with a coefficient of variation of <5%. Although all marketed devices meet this standard under strict testing conditions, the potential for error exists, and unusual results should be repeated.

In the United States, there are laboratories within clinics and within hospitals, as well as central national laboratories. Clinics and hospitals can usually measure concentrations of the older AEDs, usually within hours for emergency situations. Tests are available for all of the new AEDs through central laboratories, but results are usually not available for a few days. Every laboratory in the United States has relations with national laboratories, and so physicians in, say, Minot, North Dakota, or other remote locations can have access to these laboratories. Routine tests measure only the total (bound plus unbound) concentrations. For some highly bound AEDs such as valproate (VPA) and phenytoin (PHT), unbound or â€œfreeâ€ levels may be more informative.

The rationale behind measuring levels is that the serum concentration, specifically the unbound (free) fraction, is in equilibrium with the receptor-site concentrations. This has been verified for the older AEDs, for which serum levels and brain concentrations in animal and human specimens (obtained during surgery) showed close relationships.[10,18,24] However, these relationships have not been established for the newer AEDs. Indeed, for some of these, there appears to be very strong, and in some cases irreversible, binding with the pharmacologically active site. This appears to be the case for vigabatrin and perhaps levetiracetam, for which the pharmacodynamic half-life appears to be much longer than the plasma half-life.

Although a single measurement at steady state when the person with epilepsy has attained the therapeutic goal sets the individual's therapeutic range, subsequent monitoring is for the purpose of assuring that these levels are being maintained in this range. Serial measurements are needed to identify variations from the target AED concentration over time. These can be attributed to pharmacokinetics, changes in physiology, and/or compliance issues.

Table 1 Use of blood tests in monitoring patients with epilepsy

For antiepileptic drugs

1. At steady state, good seizure control, and no toxicity, to obtain a target level[a]
2. Annually, to monitor compliance
3. When a patient has a breakthrough seizure
4. When a patient experiences toxicity
5. When a substance known to affect metabolism is added or removed
6. When there is a change in a patient's physiologic state (pregnancy, burns, renal failure)

Hematologic/hepatic

1. At initiation of therapy
2. Once during the first few months
3. Whenever clinical symptoms occur
4. Annually or less often

[a]Trough measurements are primarily useful for pharmacokinetic studies. Levels drawn for target levels and compliance should be obtained at similar times of day, within 1 to 2 h of each other.

Variability Due to Pharmacokinetics

A number of pharmacokinetic factors can influence the absorption and elimination of antiepileptic drugs. For example, changes in product formulation can markedly alter the absorption of phenytoin. If the preparation is more bioavailable, phenytoin concentrations can increase to levels at which toxic reactions occur.[21,30]

Alteration of gastric or intestinal absorption by food or other drugs may influence the time or extent of absorption. If a product's bioavailability is affected by food,

lowered levels and seizures may occur. This appears to be the case for phenytoin as well.[3,32] Changes in hepatic or renal blood flow can modify the rate of clearance and affect drug concentrations only to a small degree.[6]

Time of sampling can contribute to variability for some AEDs. In general, AEDs with long absorption and elimination characteristics vary little, regardless of time of sampling. Phenytoin has a relatively long absorption time (time to maximal concentration of 9 to 12 hours) because it is absorbed only in the small intestine. It also has a long half-life and nonlinear kinetics (slower elimination at higher concentrations). Thus, the absorption and elimination phases overlap during one dosing cycle, and the concentration differences are small, usually <2 mg/L, between peak and trough levels. On the other hand, carbamazepine and valproate both have shorter absorption times and, during long-term therapy, have elimination half-lives of 6 to 14 hours. This can lead to differences between peak and trough concentrations of as much as 50% or more. Sustained-release preparations for these products have lengthened the absorption phase and have decreased the peak and trough variations.

To be most useful, blood samples should be drawn at the same time relative to dosing. In a clinical setting, this can be accomplished by always scheduling appointments for the same time of day. A reasonable limit is Â±1 hour, which can be attained most of the time. For example, a person with a 3 PM examination usually has blood drawn by 3:30 PM, but any time between 2:30 PM and 4:30 PM is acceptable. Trough concentrations can be quite misleading, especially for AEDs with short serum half-lives. In one institution, it was mandated that carbamazepine levels needed to be >4 mg/L for carbamazepine, and physicians were requested to increase its dose if levels were below this value. Unfortunately, all levels were measured as morning fasting or trough levels, and the mandated dose increases sometimes led to toxicity. The problem was solved by simply changing the time of sampling to approximately 2 hours post morning dose. Through levels for AEDs are widely used, but for therapeutic management of AEDs they can be misleading for agents with short half-lives such as carbamazepine, valproate, and levetiracetam.

Concentrations of AEDs that are metabolized can be altered by the addition or removal of other drugs that are also processed by the liver. These may be other AEDs, drugs used for other disorders, or herbal supplements and foods. For example, St. John's wort, a popular herbal purported antidepressant, is a powerful inducer of cytochrome P3A4, the major isozyme responsible for carbamazepine metabolism, and can significantly lower concentrations of prescription drugs.

Variability Due to Altered Physiology

Any change in homeostasis can alter the absorption or elimination of AEDs. The most commonly encountered situation is that of a woman who becomes pregnant. Of the older AEDs, phenytoin concentrations decrease the most, beginning in the first trimester and decreasing to the lowest levels before labor. Carbamazepine and valproate levels also decrease but to a lesser degree. Of the newer AEDs, lamotrigine levels decrease dramatically, by as much as 200%.[30] There are no specific guidelines for monitoring AED concentrations during pregnancy, but it may be reasonable to obtain a minimum of one measurement at the onset of pregnancy, during the second trimester, and near the time of delivery, or at any time that breakthrough seizures occur or there are symptoms of toxicity.

Phenytoin clearance can be accelerated during various febrile illnesses and also after vaccination.[14,16] Because many AEDs are metabolized by the liver, any condition affecting this organ can influence the concentrations of AEDs. Very little research has been done in this area, and so knowledge of basic principles of metabolism and clinical judgment rather than evidence-based medicine must be relied on when caring for patients with hepatic disease. Burns extensive enough to require admission to a burn unit significantly influence phenytoin, phenobarbital, and diazepam levels.[2] Valproate concentrations can be influenced by head injury.[1] The newer AEDs have not been studied in this regard.

Renal disease or the normal decline in renal function in the elderly necessitates the measurement of AEDs whose elimination is mainly through the kidneys. The formulas that are given to calculate creatinine clearance to adjust doses for gabapentin and levetiracetam cannot substitute for actual measurement of levels. This is because in the elderly, decreases in muscle mass lower the amount of creatinine in the blood, and levels may be in the normal range even when the kidney function is less than in younger persons. In addition, protein binding is greatly affected by renal disease, and the unbound (free) concentration must be measured for highly bound AEDs (phenytoin, valproate).

Table 2 Types of behavior in noncompliance

Medication ingestion
Consistent overcompliance Consistent undercompliance Irregularity Irregularly irregular Sporadically irregular Cyclically irregular Filling prescriptions Medical appointments
Lifestyle
Sleep patterns Alcohol use Psychological stress Exposure to music, strobe lights Drug abuse Adherence to regulations
Intentionality of compliance (patient controlled)
Rational Pregnant women afraid of teratogenicity Compensation related Irrational Fear of medicine Superstition
Structural
Memory deficit Financial problems

Variability Due to Compliance Issues

Noncompliance with antiepileptic drug treatment is a major factor in the recurrence of seizures in patients with epilepsy (Table 2). As many as 50% of all patients with epilepsy are noncompliant to a degree that interferes with optimal treatment.[17,27] Studies using electronic monitors to measure compliance indicate that what might appear to be sporadic seizures can be attributed to missed doses of prescribed drugs.[5] Consequently, proper management of epilepsy requires physicians to identify noncompliant patients, determine the extent of the problem, and devise and monitor an appropriate intervention strategy.

A number of studies have evaluated the variability of serial concentrations of phenytoin and carbamazepine in various settings. In a study of phenytoin, patients in a residential facility were found to have values for the coefficient of variation of <10%.[13] In compliant patients in an outpatient study of

bioavailability during which samples were obtained every 2 weeks and compliance was monitored by pill counts,[13] a few of these patients reported missing an occasional dose several days before the blood sample was taken. This did not significantly affect the coefficient of variation. In the same study, sequential patients at the epilepsy clinic were asked about compliance; a strong correlation was noted between reported noncompliance and a high coefficient of variation. Data from rigorous studies indicate that in most compliant patients the coefficient of variation for carbamazepine is <20%.[8] My experience indicates that similar fluctuations can be expected with valproate.

Based on this experience, use of the percentage of deviation from the mean of two or more levels has been adopted to aid in the evaluation of noncompliance. Although calculation of the coefficient of variation is more accurate, a determination of the percentage of deviation is simpler and more practical for clinical use. In general, deviation of 20% or less from the mean of previous phenytoin, carbamazepine, or valproate concentrations is evidence for adequately compliant behavior. A patient can attain the 20% limit even if an occasional dose is missed. Values between 20% and 45% should raise strong suspicions of noncompliance. Values deviating more than 45% are almost always associated with noncompliance. The larger the percentage, the more marked is the noncompliance (assuming the absence of any factors altering pharmacokinetics, such as a new drug, illness, or altered bioavailability). The percentage of deviation from the mean can be used as a general measure of the degree of noncompliance. For example, a patient with a deviation of Â±25% is less severely noncompliant than one with a deviation of Â±45%, which would have to be considered when assessing the need for intervention to improve compliance.

Serial measurement of AEDs levels is a relatively useful tool for detecting noncompliance. With increasing legal pressure on physicians to certify the safety of a driver's license or a particular work place for a patient with epilepsy, it becomes critical to know that a patient is compliant. Thus, if a patient's antiepileptic drug concentrations fall within the usual therapeutic range but vary from the high to the low end, noncompliant behavior must be suspected. That patient might also be at increased risk for intermittent toxicity or seizures.

Serial measurement of blood levels is relatively crude compared with devices that record each opening of a container of medication daily. Such devices can detect noncompliant behavior lasting only a few days between clinic visits or blood level measurements.[5] However, use of this method is limited to clinical research because of its cost.

Table 3 Laboratory parameters: normal ranges and threshold (â€œpanicâ€) values for antiepileptic drugs

	Normal range	â€œPanic valuesâ€
	Hematologic	
White blood cell count, total	4500â€“10,000/mm^3	<2.0/mm^3

Neutrophils	1500â€“6700/mm^3	<1.0/mm^3
Platelets	150,000â€“350,000/mm^3	<50/mm^3
Hemoglobin	11.5â€“15.0 g/dL	<10.0 g/dL
Hematocrit	34%â€“44%	<28%
	Hepatic	
Transaminase (SGOT)	15â€“40 U/L	>100 U/L
Transaminase (SGPT)	9â€“31 U/L	>100 U/L
Lactate dehydrogenase	60â€“200 U/L	>600 U/L
Alkaline phosphatase	30â€“115 U/L	>300 U/L
Î³-Glutamyl transpeptidase	0â€“65 U/L	None
Bilirubin, total	0.2â€“1.2 mg/dL	>1.5 mg/dL
	Other	
Sodium	135â€“145 mEq/L	<128 mEq/L

SGOT, aspartate aminotransferase; SGPT, alanine aminotransferase.

Table 4 Idiosyncratic reactions to antiepileptic drugs: approximate rates of occurrence[a]

Reaction	CBZ	PHT	VPA	Other AED
Aplastic anemia	2/575,000 (*n* = 65 [61 adults])	A (n [asymptotically	A(*n* = 1â€“2)	A(*n* = ?)

		equal to] ~35)		
Hepatitis	A (*n* [asymptotically equal to] 30)	A (*n* = ~60)	See Table 5	A (*n* [asymptotically equal to] 20)
Pancreatitis	A(*n* = a few)	A (*n* = a few)	A (*n* [asymptotically equal to] 10)	A(*n* = 0)
Exfoliative dermatitis ~30)	A (*n* [asymptotically equal to] 30)	A (*n* [asymptotically equal to] 30)	A (*n* <5)	A (*n* [asymptotically equal to] 30)

AED, antiepileptic drug; CBZ, carbamazepine; PHT, phenytoin; VPA, valproate. [a]Data are based on a review of the literature and hearsay. Data are very incomplete, except for hepatitis related to CBZ and VPA and hematologic disorders related to CBZ. A, <1/100,000 treated patients.

Laboratory Testing for Adverse Reactions

Serious reactions to antiepileptic drugs are rare. They include hepatotoxicity, bone marrow suppression, pancreatitis, exfoliative dermatitis, and other conditions that, if not detected in time, can be fatal. Much emphasis has been placed on routine monitoring of hepatic and hematopoietic factors to detect these serious reactions. However, routine monitoring is expensive and has been discouraged.[22,23] This policy might be appropriate in the case of all antiepileptic drugs except felbamate.

The popularity of laboratory monitoring is based on the assumption that subclinical hepatitis or hematopoietic dysfunction can be detected. However, slight elevations of hepatic enzymes are not unusual, and mild leukopenia is a common side effect in patients treated with antiepileptic drugs. Thus, in addition to being costly, laboratory testing can be misleading, provoke further testing, or lead to inappropriate discontinuation of medication. Table 3 lists the â€œpanicâ€ levels my colleagues and I use as an indication to take immediate action.

The cost of performing routine laboratory testing is considerable. If one assumes that 2.8 million persons are being treated for epilepsy in the United States, that a set of hematologic and hepatic tests costs $50 (conservatively), and that the test is repeated three times a year for each patient, the cumulative cost can be projected to be $420 million. Nevertheless, in the United States reluctance is great to abandon routine laboratory monitoring for two reasons. First, there is the perception that such testing can detect a serious adverse event early enough to prevent a fatal outcome. Second, there is the real concern regarding the medicolegal consequences of not following community practice standards. However, support is growing in the literature for the abandonment of routine monitoring.[4,23]

The precise frequency of serious drug effects from antiepileptic drugs is difficult to determine because of inadequate postmarketing surveillance. Most of the information comes from two sources: (a) reports in the medical literature and (b) information from drug manufacturers supplied to the FDA. A recent search of the Medline database revealed 424 references regarding hepatitis and/or phenytoin, valproate, carbamazepine, phenobarbital, or other antiepileptic drugs. Most of these consisted of isolated case reports, often involving other major complicating factors. A much shorter list of references was generated for hematologic problems.

Tables 4 and 5 list the approximate number of cases, derived from the medical literature, of life-threatening reactions attributable to specific antiepileptic drugs in the United States. These numbers are crude, but they underscore the relatively infrequent occurrence of serious reactions.

Felbamate is the antiepileptic drug with the highest risk for aplastic anemia.[19] During 1994, 32 cases of aplastic anemia were reported in a population of approximately 130,000 to 150,000 treated individuals. Approximately two thirds of these patients recovered. Severe hepatitis developed in approximately 12 to 14 persons. Many neurologists are comfortable with testing every month or two after the first few months of treatment and every 3 months after a year of treatment. There is no evidence that routine monitoring is of any definite benefit. Indeed, if clinical symptoms develop shortly after a normal set of laboratory values has been obtained, retesting is essential.

Carbamazepine was considered to be associated with a high risk of aplastic anemia shortly after its introduction. In a thorough review using an estimated number of persons exposed per year,[26] a rate of two cases of aplastic anemia and one fatality for 575,000 treated persons was calculated. It is interesting that 61 of the 65 reported cases of agranulocytosis or aplastic anemia occurred in adults. Similar data are not available for phenytoin, but such cases have been reported in the literature. Aplastic anemia has rarely been reported in association with valproate use, and well-documented cases of aplastic anemia with phenobarbital or other antiepileptic drugs are rare. Thus, it would appear that the highest risk for aplastic anemia is found in adults exposed to felbamate, and after that in patients taking carbamazepine, but this conclusion must be tempered by lack of reliable data for the other drugs. Even then, the risk of the group at highest risk is very low.

A pattern emerges for the incidence of hepatitis. The group at highest risk comprises infants exposed to valproate in the context of polypharmacy.[7] This may be a consequence of the fact that valproate metabolism depends on both cytoplasmic

and mitochondrial systems, and the relative production of hepatotoxic metabolites is influenced by the amount of drug passing through each system. The proportions of cytoplasmic and mitochondrial metabolism can be influenced by comedication and age-related factors. In addition, the existence of metabolic or neurologic disorders poses a significant risk.[33] The actual number of fatal cases of hepatitis attributable to phenytoin is difficult to determine, but the overall number may be approximately 50. Carbamazepine and other antiepileptic drugs appear to be associated with a lower rate of occurrence of hepatitis. Thus, infants given valproate are the only group at major risk[25]; adults receiving valproate or other antiepileptic drugs are at very low risk.

Other potentially fatal adverse reactions include pancreatitis, serum sickness reaction, Stevens-Johnson syndrome, and other rare complications. Routine laboratory testing for pancreatitis is unnecessary because clinical symptoms of abdominal pain and anorexia are dramatic and lead to specific confirmatory tests.[28] For the other reactions, clinical skills are more diagnostic than laboratory findings.

Table 5 Approximate rate of occurrence of fatal hepatitis from valproate

Monotherapy	Polytherapy	Age
1/7,000	1/500	Infant
1/9,000	1/6,500	Child

0	1/22,000	Adult

Problems of False Positives

Table 3 is a list of laboratory tests performed routinely. The â€œpanicâ€ values are those that trigger an immediate response from the laboratory and are often grounds for discontinuation of a drug.

Use of antiepileptic drugs often leads to values outside normal laboratory ranges. A study of 610 persons with epilepsy between 20 and 40 years of age evaluated the effect of long-term treatment on various laboratory parameters.[11] The findings were that leukocyte counts were significantly lower, with a specific lowering of lymphocytes. In addition, persistent macrocytosis without anemia was noted. In a review of approximately 2,500 white blood cell (WBC) counts in a population of >1,100 patients with epilepsy receiving primarily valproate, phenytoin, carbamazepine, or a combination of these, >17% had WBC counts <4,000/mm^3 and 8 had a WBC count <2,500 (1,800 to 2,400)/mm^3.[15] The 8 cases with â€œpanicâ€ values were reviewed; all were clinically asymptomatic, and in 2 cases the physician discontinued carbamazepine based on laboratory findings. In 1 case, zidovudine was discontinued and the WBC count normalized. In 5 cases, no change was made in treatment. The lowest WBC count was 1,800/mm^3. Other reports documented transient leukopenia in up to 12% of adults and children treated with carbamazepine.

Gamma-glutamyltranspeptidase (GTT) levels are markedly elevated in patients with epilepsy and do not signal hepatic dysfunction. Levels of serum glutamic oxaloacetic transaminase (SGOT; same as aspartate transaminase [AST]) might be more reliable. In one study,[15] approximately 33% of values for >1,100 patients were above normal; in 12 cases the SGOT (AST) values were >100 U/L (normal, 10 to 35). In 8 cases, the elevations were sporadic, that is, the values were in the usual range when the test was repeated. In 4 cases, all on valproate, the drug dose was decreased, and in 1 it was discontinued. All 4 had had clinical symptoms of loss of appetite, malaise, or nausea, which had alerted the clinician to possible problems that led to testing.

Thus, from one study of >5,000 visits involving >1,100 patients who were followed for 24 months, approximately 2,500 measurements of WBC counts and SGOT levels were obtained.[15] The incidence of WBC counts of <2,500/mm^3 was 6.6/1,000 patients, and in only 2 cases was an antiepileptic drug changed based on low WBC count. The rate for â€œpanicâ€ SGOT elevations was higher. Nevertheless, clinical symptoms led to tests that uncovered abnormal values. Thus, overall, routine testing alone uncovered only 2 asymptomatic cases with â€œpanicâ€ values that led to discontinuation of therapy. The approximate total cost of these tests was $125,000 in 1990. It is reasonable to conclude that the cost effectiveness of routine laboratory testing is very questionable. This conclusion is reinforced by the fact that most â€œpanicâ€ values represented false positives, in the sense that they did not lead to modification of treatment but only to additional testing.

Camfield et al. reported similar results from a smaller series.[4] They performed serial testing at initiation of treatment, at 1, 3, and 6 months, and then every 6 months. There were no serious clinical reactions, but laboratory testing was repeated in 6% of cases to confirm abnormal but clinically insignificant results. In a study of 662 adults in whom treatment was initiated with phenytoin, carbamazepine, phenobarbital, or primidone, no clinically significant abnormalities were detected after 6 months.[20]

Antiepileptic drugs, in addition to the major complications listed in Tables 4 and 5, can cause other problems that may be associated with clinical symptoms. Valproate can be associated with thrombocytopenia. This in itself may not be problematic if undetected and asymptomatic. However, the risk for bleeding during injury or surgery might be increased. Carbamazepine is associated with hyponatremia in a substantial number of patients but causes symptoms only occasionally. Elevated ammonia levels can be associated with valproate, but they are often not significant in the absence of clinical symptoms or other laboratory signs of liver failure.

Alternatives to Routine Blood Monitoring

Screening laboratory testing should be obtained to detect any underlying problems before initiating therapy with antiepileptic drugs. These tests can uncover specific problems that, if they developed further, might be incorrectly attributed to the drug. Rarely, however, do they contraindicate use of a medication. Table 6 lists recommended tests.

It can be useful to order a complete blood cell count to check for leukopenia in patients on carbamazepine or a platelet count in patients on valproate 2 to 6 months after onset of treatment. Routine blood or urine monitoring after initiation of therapy is probably unnecessary if the patient is asymptomatic.

Patients in a high-risk group and those unable to communicate must be monitored more closely. The most efficient monitoring system is a high degree of awareness of symptoms that portend serious complications, patient awareness of these symptoms, and rapid assessment of any problems that suggest a rare but potentially fatal complication. However, wide acceptance of less routine testing might be offset by continued liability in the rare but unfortunate cases of serious adverse effects.

P.796

Summary and Conclusions

Monitoring antiepileptic drug levels is not necessary at each clinic visit. It is prudent to determine levels at steady state after good seizure control has been attained to establish a benchmark. This target level can be followed annually, especially at the time of renewal of a driver's license, to ensure that adequate levels are being maintained. Other appropriate times to measure are when a patient is having breakthrough seizures or experiencing toxicity. In addition, whenever therapy with other drugs known to affect antiepileptic drug metabolism is modified, measurement of blood levels should be considered.

For systemic toxicity, the recommendations in the current *Physicians Desk Reference* are less strict than those in previous editions. Screening laboratory testing should be obtained to detect any underlying problems before therapy with antiepileptic drugs is initiated. It might be useful to order a complete blood cell count to check for leukopenia in patients on carbamazepine or a platelet count in patients on valproate 2 to 6 months after onset of treatment. Routine blood or urine monitoring after initiation of therapy is probably unnecessary if the patient is asymptomatic. Patients in a high-risk group and those unable to communicate can be monitored more closely. For patients on felbamate, monthly determination of laboratory parameters is suggested at initiation of therapy and, then at each clinic visit or if symptomatic.

Table 6 Blood tests to be done before initiating treatment with antiepileptic drugs

All patients
Hematology
Complete blood cell count, platelet count, differential
Prothrombin time, partial thromboplastin time (optional)
Serum chemistry
Glucose
Blood urea nitrogen
Calcium
Phosphorus
Magnesium
Creatinine

Urate
Bilirubin
Alkaline phosphatase
Aspartate aminotransferase
Alanine aminotransferase
Total protein Albumin

Specific high-risk patients (based on clinical findings)

Lactate, pyruvate, arterial blood gases
Urine metabolic screen, organic acids
Ammonia
Carnitine
Specific tests for suspected underlying disease

Chapter 72

Physiologic Basis of the Electroencephalogram and Local Field Potentials

GyÃ¶rgy BuzsÃ¡ki

Roger D. Traub

Introduction

Analyses of electric and magnetic fields and imaging energy production in brain structures are the principal instruments in the arsenal of contemporary neuroscience for noninvasive studies of the brain. Three fundamental methods can provide high temporal resolution of neuronal interactions at the network levelâ€"electroencephalogram (EEG), magnetoencephalogram (MEG),[31] and, in invasive experiments, voltage-sensitive, dye-based optical imaging[28] (see Chapters 74, 75, 76, 77, 80, 87, and 90). Each of these methods has its advantages and shortcomings. A common major obstacle of clinical EEG, MEG, and optical imaging methods is that their â€œviewsâ€ are confined mostly to surface events (although MEG, in principle, can provide information about depth events as well[62,63]). However, most network interactions occur in the depth of the cortex. Although imaging methods provide significant spatial resolution, including deep structures in the brain, all of these â€œglobalâ€ methods face the same fundamental questionâ€"the â€œreverse engineeringâ€ problem of signal interpretation.[62] The signals measured by EEG and MEG reflect the cooperative actions of neurons. Therefore, full understanding of the signals recorded by these methods is possible only after their cellular-synaptic generation is explored. Nevertheless, even without a full deciphering of the origin of the recorded signal, EEG and MEG provide useful information about brain operations in health and disease, and EEG evaluation remains the essential method for the diagnosis of epilepsy.

Membrane currents generated by neurons pass through the extracellular space. These currents can be measured by electrodes placed outside the neurons. The field potential (i.e., local mean field) recorded at any given site reflects the linear sum of numerous overlapping fields generated by current sources and sinks distributed along multiple cells. This macroscopic state variable is referred to as local field potential (LFP) if measured by a small electrode in the brain, an electrocorticogram (EcoG) if measured by, for example, subdural grid electrodes, and EEG if recorded from the scalp, or an MEG as monitored with magnetosensor semiconductor quantum interference devices (SQUIDs). LFPs provide experimental access to the spatiotemporal activity of afferent, associational, and local operations in a given structure. Field potential measurements provide the best experimental and clinical tools for assessing cooperative neuronal activity at high temporal resolution. However, without a mechanistic description of the underlying neuronal processes, the mean fields recorded by these methods are a gross correlate of brain activity rather than a predictive descriptor of the specific functional/anatomic events.

Scalp recordings offer only limited information about the structures and neuron groups from which the electrical activity emanates, and the inverse problem does not have a unique solution. The difficulty of source localization using scalp EEG has to do with the low resistivity of neuronal tissue to electrical current flow, the capacitive currents produced by the lipid membranes, and the distorting and attenuating effects of glia, blood vessels, pia, dura, skull, scalp muscles, and the skin. As a result, the EEG recorded by a single electrode becomes a spatially smoothed version of the local field potentials under a scalp surface on the order of 10 cm^2, and under most conditions has little discernible relationship with the specific patterns of activity of the neurons that generate it.[62] The spatial resolution can be improved with intracranial electrodes such as subdural grid electrodes. Nevertheless, because current density, that is, the spatial derivative of current, is sensitive mainly to superficial sources, the signals recorded by scalp or grid electrodes sample mostly the electrical activity that occurs in the superficial layers of the cortex. The contribution of deeper layers is scaled down substantially, whereas the contribution of neuronal activity from below the cortex is, in most cases, virtually negligible. This â€œfish-eye lensâ€ scaling feature of EEG is the major theoretical limitation for improving its spatial resolution.

A straightforward approach to deconvolving the surface-recorded event is simultaneously to study electrical activity on the surface and at the sites of the extracellular current generation in experimental situations. LFP measurements (sometimes referred to as â€œmicro-EEGâ€[68]) combined with recording of neuronal discharges is the best experimental tool available for studying the influence of cytoarchitectural properties, such as cortical lamination, distribution, size, and network connectivity of neural elements, on electrogenesis. However, large numbers of observation points combined with decreased distance between the recording sites are required for high spatial resolution and for making interpretation of the underlying cellular events possible. Progress in this field has been accelerated by the availability of micro-machined silicon-based probes with numerous recording sites.[12,92] The information obtained from the depth of the brain can then assist with the interpretation of the surface-recorded events.

In principle, every event associated with membrane potential changes of individual cells (neurons, glia) contributes to the perpetual voltage variability of the extracellular space. Until recently, synaptic activity has been viewed as the exclusive source of extracellular current flow or EEG. As will be discussed, however, synaptic activity is only one of the several membrane voltage changes that contribute to the measured field potential. Progress during the last decade has revealed numerous sources of relatively slow membrane potential fluctuations not directly associated with synaptic activity. Such nonsynaptic events also may contribute significantly to the generation of local field potentials. Accordingly, this chapter focuses on the cellular origin

P.798

of the extracellular fields. The reviews by HÃ¤mÃ¤lÃ¤inen et al.[31] and Okada et al.[64] provide detailed theoretical background for MEG and SQUIDs and compare EEG and MEG signal detection problems.

Measuring extracellular current flow: A TUTORIAL

Although a variety of sources can contribute to the extracellular current flow (see later discussion), for simplicity, we consider only synapse-mediated events in this section. For the transmembrane potential to change in a given neuron, there must be a transmembrane current, that is, a flow of ions across the membrane. This is the event that one has to spatially localize for the interpretation of the extracellular current or voltage. Opening of membrane channels (or more precisely, an increase in their open-state probability) allows transmembrane ion movement, that is, current flow. LFP (i.e., local mean field) recorded at any given observation point reflects the linear sum of numerous overlapping fields generated by current *sources* (e.g., current from the intracellular space to the extracellular space) and *sinks* (current from the extracellular space to the intracellular space) distributed along multiple neurons.

The term â€œfieldâ€ is often used differently by electrophysiologists and physicists. For the physiologist the field or local field typically means extracellular potential, whereas in physics the gradient of the field is referred to as electric potential. The field is defined at every point of space from which one can derive the force â€œfeltâ€ by an electric charge at that point. The field can be transmitted through volume and is known as volume-conduction. Lower-frequency currents produce, or correspond to, transmembrane currents over larger spatial extent of membrane than are fast signals, partially because the space constant of the dendritic cable is shorter for high frequencies than low frequencies. Furthermore, because the lipid membrane of neurons, glia, and other cells in the brain acts as a capacitive low-pass filter, it offers an easier passage to low-frequency signals than to high-frequency signals. As a result, slow signals, such as postsynaptic potentials, can propagate much farther in the extracellular space than can spikes. In addition, longer-duration events (e.g., excitatory and inhibitory postsynaptic potentials [EPSPs and IPSPs]) have a much higher chance of occurring in a temporally overlapping manner than do the very brief action potentials. Finally, many more neurons display EPSPs and IPSPs than fast spikes in a given temporal window because only a very small minority reaches the spike threshold at any instant in time. For these reasons, the contribution of action potentials to the LFP and especially to the subdural ECoG or scalp EEG in the normal brain is practically negligible. This is not necessarily the case under epileptic conditions, however, when neurons can synchronize within the duration of action potentials. The synchronously discharging neurons create local fields, known as compound or â€œpopulationâ€ spikes.

Excitatory currents, involving sodium (Na^+) or calcium (Ca^{2+}) ions, flow inwardly at an excitatory synapse (i.e., from the activated postsynaptic site to the other parts of the cell) and outwardly away from it. The passive outward current far from the synapse is referred to as a return current from the intracellular milieu to the extracellular space. Inhibitory loop currents, involving chloride (Cl^-) or potassium (K^+) ions, flow in the opposite direction. Viewed from the perspective of the extracellular space, membrane areas where current flows into or out of the cells are termed sinks or sources, respectively. The current flowing across the external resistance of the extraneuronal space sums with the loop currents of neighboring neurons to constitute the local mean field or LFP. In short, extracellular fields arise because the slow EPSPs, IPSPs, voltage-gated active currents, and other intracellular events (see later discussion) allow for the temporal summation of currents of relatively synchronously activated neurons.

Depending on the size and placement of the extracellular electrode, the volume of neurons that contributes to the measured signal varies substantially. With very fine electrodes, LFPs reflect the synaptic activity of tens to perhaps thousands of nearby neurons only. LFPs are, therefore, the electric fields that reflect a weighted average of input signals on the dendrites and cell bodies of neurons in the vicinity of the electrode. If the electrode is small enough and placed close to the cell bodies of neurons, extracellular spikes can also be recorded. Not surprisingly, in such a small volume of neuronal tissue, one often finds a statistical relationship between local field potentials, reflecting mostly input signals (EPSPs and IPSPs), and the spike outputs of neurons.[42] The reliability of such relationship, however, progressively decreases with increasing electrode size, by lumping together electric fields from increasingly larger numbers of neurons. This is why the ECoG or scalp EEG, the spatially smoothed version of the LFP at numerous contiguous sites in a volume, often has a poor relationship to the spiking activity of individual neurons.

In deciphering the current sourceâ€"sink origin of the local fields, we have to go â€œbackwardâ€ from LFP measurement to cellular-synaptic current sources.[57] Current density is the current entering a volume of extracellular space. The current flow between two recording sites can be calculated from the voltage difference and resistivity using Ohm's law, provided that information about the conductance (inversely proportional to resistivity) of the tissue is available. The conductance is a factor of both conductivity and the specific geometry of volume. If at least three linearly spaced electrodes are placed in the brain tissue, one can measure the voltage between the middle electrode and the two side electrodes and calculate the current flow between the pairwise sites. The difference between the respective current flows (i.e., the change over distance) is proportional to current density. More precisely, the current density is a vector reflecting the rate of current flow in a given direction through the unit surface or volume (measured in amperes/m^2 for a surface and amperes/m^3 for a volume).[25,56,60]

To illustrate the utility of the foregoing approach, consider a distant current source relative to the three equally spaced recording sites (Fig. 1). Each electrode will measure some contribution of the field (due to the passive return currents that pass through the extracellular space) from the distant source. Because the source is outside of the area covered by the electrodes, the voltage difference will be the same between the middle and side electrodes. Taking the difference between the voltage differences (voltage gradient), we get a value of zero, an indication that the measured field did not arise from local activity but was volume-conducted from elsewhere. In contrast, if the three electrodes span current-generating neuron groups, the voltage gradients will be unequal and their difference will be large, indicating the local origin of the current. By placing more microelectrodes closer to each other, one can more precisely determine the maximum current source density (CSD) and, therefore, the exact location of the maximum current flow.

Unfortunately, from CSD measurement alone, one cannot conclude whether, for example, an outward current close to the cell body layer is due to active inhibitory synaptic currents or reflects the passive return loop current of active excitatory currents produced in the dendrites. Without additional information that can clarify the nature of the current flow, the anatomic origin is ambiguous. The missing information can be obtained by simultaneous intracellular recording from representative neurons that are part of the population responsible for the generation of the local current. Alternatively, one can record extracellularly from identified pyramidal cells and interneurons and use the indirect spike-field correlations to determine whether, for example, a local current is an active,

hyperpolarizing current or a passive, return current from a more distant depolarizing event. Only after taking these extra steps one can pin down the current sources and sinks and make hypotheses about their synaptic-cellular origin. The combined information is very useful because it provides clues about the synaptic inputs to the same set of neurons whose outputs (i.e., spiking) can also be simultaneously monitored, provided that the recording electrodes are small enough. Once we have information about both the input and output of a small collection of neurons working together, we can begin to understand the transformation rules governing their cooperative action. This approach is the next best thing to the ideal condition when all inputs (synapses) and outputs of each cell are monitored simultaneously and continuously.

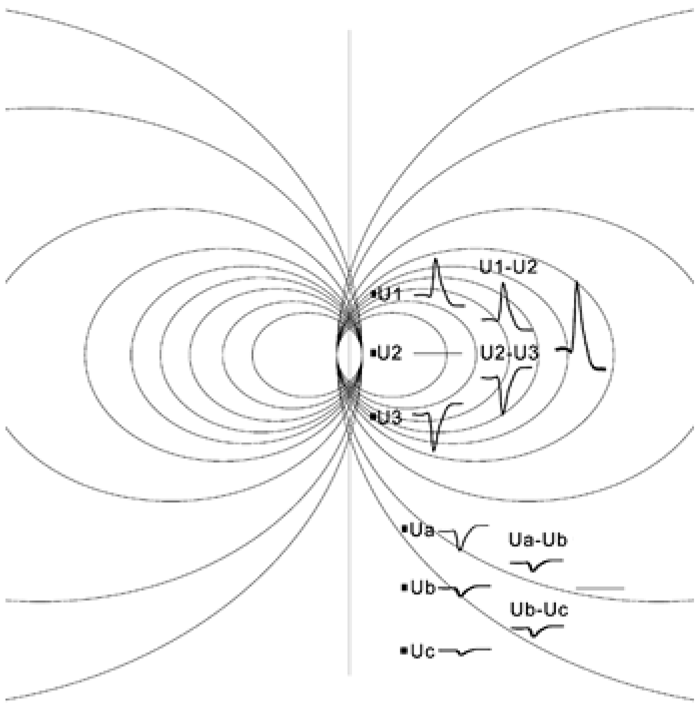

FIGURE 1. Identifying current sources. Current sourceâ€“sink dipole imbedded in a homogeneous and isotropic conductive medium. The density of lines reflects density of currents. The potential generated by the active dipole decays in the medium as the inverse square of the distance (not properly shown proportionally here, for illustrative purposes). The potentials measured at equally spaced locations, relative to an ideal infinite site (reference), are shown as U1, U2, and U3 close to the dipole, and Ua, Ub, and Uc far from the dipole. The differences of the potentials are shown in the middle row and the difference of the differences on the right. In a nonhomogeneous, nonisotropic medium, such as the brain, the current is flow is calculated as the ratio between the voltage (difference) and tissue conductivity (according to Ohm's law). Although dipole-induced voltages can be measured far from the source, calculation of current density by three simultaneously recorded sites is spatially confined and can help to identify the anatomic location of the dipole.

Figure 2 illustrates the necessary steps in the identification of network mechanisms of evoked and spontaneous field events. The example is taken from the hippocampus because it is a simple, three-layered structure consisting of orderly arranged principal cells (pyramidal and granule cells) and interneurons. Therefore, the synaptic interpretation of the extracellular current is simpler than in multilayered structures. Activation of the excitatory associational input by electrical stimulation will depolarize the mid-apical and basal dendrites of pyramidal cells (shown in blue in FIGURE 2). The passive return current will flow out of the cells at the level of the neuronal bodies and distal apical dendrites (shown in red in FIGURE 2) specify where exactly (Figure D or 2E). This change in voltage is reflected by the characteristic depth distribution of field potentials. The extracellular voltage is negative close to the excitatory synapse and positive in the cell body layer. The reason for this is the large depolarization of the dendrite and the gradual decrease of intracellular depolarization toward the soma. This synaptic activityâ€"induced intracellular voltage difference between the dendrites and soma (a â€œdipoleâ€) will result in a current flow across the resistive membrane (arrows in FIGURE 2F). Simultaneous events in many neighboring pyramidal cells will linearly sum and produce an extracellular voltage fluctuation that can be measured with closely spaced electrodes. After determining the resistivity (impedance in case of an alternating current signal) characteristics of the extracellular space, we can calculate the local currents and current densities from the voltage measurements.[25,60]

Increased afferent discharge also activates interneurons, some of which terminate on the cell bodies of the pyramidal cells. For example, the discharging basket cells release gamma-aminobutyric acid (GABA) and activate Cl^- channels, which allows the entrance of the negatively charged ion with resulting hyperpolarization of the pyramidal cell somata. Somatic hyperpolarization, in turn, creates a voltage gradient between the soma and dendrites (inhibitory dipole). The created intracellular voltage difference is the driving force of charges across the cell membrane and the consequent spatially distributed current flow in the surrounding extracellular fluid (FIGURE 2). Note that the direction of current flow is the same as in the case in which the driving force is apical dendritic depolarization (active sink). Because the direction of current flow is identical for dendritic excitation and somatic inhibition, the excitatory and inhibitory currents will sum in the extracellular space, resulting in large-amplitude field potentials. Because the excitation-concurrent somatic inhibition may prevent the depolarization of the axon initial segment and, consequently, the occurrence of action potentials, large-amplitude extracellular current flow can be associated with no spike output from pyramidal neurons. Thus, the relationship between dendritic excitation and spike output of pyramidal cells is highly nonlinear, and is largely determined by the state of inhibition.

Provided that dendritic excitation is strong enough to override somatic inhibition, the cells may discharge. In the simplest case, a Na^+ spike will be generated in the initial segment of several neighboring pyramidal neurons. The large inward current associated with the spikes is reflected by a negative change of the extracellular voltage at the level of the axon initial segment/cell body accompanied by a smaller-amplitude, extracellular positive deflection out in the dendritic regions for the same reasons as described previously for the EPSPs. However, because the spatial location of this event is opposite to the afferent excitation of dendrites, the direction of the extracellular current flow will also be opposite. The contribution of fast spikes to the extracellular mean field is due to the hypersynchronous discharge of many pyramidal neurons (population spike) as a result of artificial stimulation of an afferent bundle. Interpretation of the extracellular events after the population spike is not straightforward, however, due to complex feedback effects of the network and other nonsynaptic events (see later discussion).

Once a circuit, such as that shown in FIGURE 2, has been â€œcalibratedâ€ by electrically evoked potentials, one can move to the next stepâ€"network-level description of the generation of spontaneous EEG events. The tutorial example we use is an intermittently occurring, large-amplitude hippocampal sharp wave (SPW). SPWs are present during immobility, consummatory behaviors, and slow-wave sleep. It is important that the events to be analyzed are clearly separable from other waveforms. After extracting the invariable features of this EEG pattern by averaging or other pattern recognition methods, we convert the

P.800

P.801

simultaneous voltage measurements into a CSD map (Figures 2D and 2E). Note that the distribution of the sinks and sources of SPWs is strikingly similar to the potentials elicited by stimulation of the associational/commissural inputs to the pyramidal cells. Comparison of the spontaneous and evoked events, therefore, allows the conclusion that activation of the same afferent pathways and neurons brings about both events. Indeed, independent experimental work revealed that SPWs in the hippocampus arise from the quasi-synchronous discharge of CA3 pyramidal neurons, the source of associational and commissural afferents to the CA1 region.[11,16] Temporally overlapping activation of converging activity on single CA1 pyramidal cells results in a large depolarization of the dendrites, similar to the depolarization of these cells when the associational pathways are electrically activated. These extra- and intracellular events therefore provide circumstantial evidence that the same neuronal machinery is activated during spontaneously occurring SPWs as during electrical stimulation of the associational afferents.

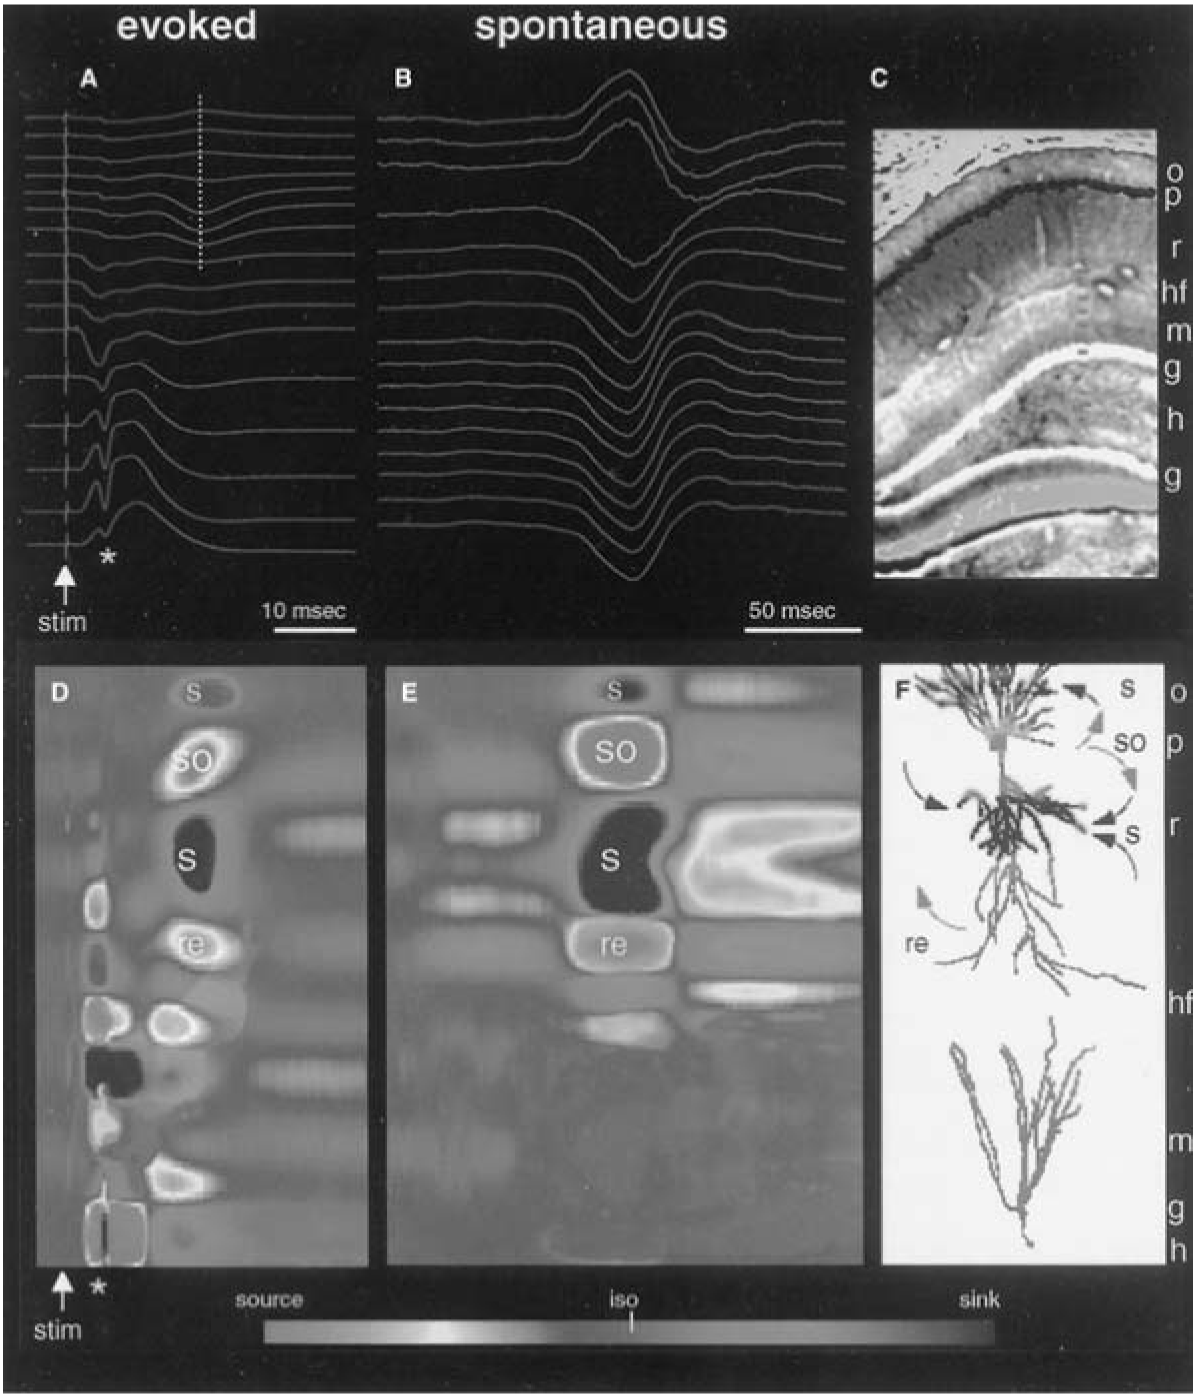

FIGURE 2. Generation of extracellular field potentials. **A:** Simultaneously recorded evoked field responses in the CA1-dentate gyrus axis of the rat hippocampus in response to stimulation of the entorhinal input (stim). The asterisk indicates the population discharge of the monosynaptically activated granule cells. Their discharge, in turn, activates CA3 pyramidal cells (not shown), whose associational collaterals depolarize CA1 pyramidal cells and interneurons. This trisynaptic activation of CA1 pyramidal cells is reflected as a late field event (vertical dotted line). **B**: Spontaneously occurring sharp wave recorded during immobility. The traces are averages of 40 individual events. **C**: A frontal section of the hippocampus indicating the contact sites of the recording silicon probe (*small squares*). o, stratum oriens; p, pyramidal layer; r, stratum radiatum; hf, hippocampal fissure; g, granule cell layer; h, hilar region. **D**, **E**: Current-source density (CSD) maps of evoked

field responses to perforant path stimulation (**D**) and of the spontaneous SPW pattern. Sinks (s, inward currents) and sources (so, outward currents) are indicated by cold and warm colors, respectively. iso, zero-current flow. The time scales in panels A and D, and B and E, are the same. **F**: Interpretation of the current sinks and sources on the basis of anatomic connectivity. Recorded layers are shown on the right of the pyramidal cell (**above**) and granule cell (**below**). Putative active currents are indicated on the right, and passive return (re) currents on the left of the pyramidal neuron. Note identical current sinkâ€"source distribution of the evoked and spontaneous events in the CA1 region (compare panels D and E). Sinks in stratum radiatum and oriens reflect excitation of the apical and basal dendrites of CA1 pyramidal cells, respectively, by the associational (Schaffer) collaterals of the CA3 region. The large source in the pyramidal layer is a combination of active outward current due to hyperpolarization of the soma by the simultaneously activated basket cells (not shown) and passive return currents from the sinks generated in the basal and apical dendrites. The source in the distal apical dendrites (re) is assumed to represent a passive return current due to the active sink in the middle of stratum radiatum. In addition to excitatory postsynaptic potentials, dendritic Ca^{2+} spikes may also contribute to the sinks in strata oriens and radiatum (see FIGURE 4). (From BuzsÃ¡ki G, Traub RD. Generation of EEG. In: Engel J Jr, Pedley TA, eds. *Epilepsy: A Comprehensive Textbook.* Lippincott-Raven Press; 1996, with permission).

The contribution of $GABA_a$ receptorâ€"mediated inhibitory currents is generally believed to be small, based on the assumption that because the Cl^- equilibrium potential is close to the resting membrane potential, the change of the transmembrane voltage is limited. However, in actively spiking neurons, when the cell body is depolarized, the transmembrane potential mediated by $GABA_a$ receptors can be large. Another cautionary note is that inhibition operates also on the dendrites, causing current flow opposite to the direction of excitatory currents. For the identification of excitatory and inhibitory components, represented by the extracellular current flow, a precise knowledge of the anatomic network is essential. Detailed physiologic experiments, including recordings from anatomically identified interneurons and pyramidal cells as well as differential pharmacologic blockage of the excitatory and inhibitory synapses, can provide further knowledge necessary for the proper interpretation of the observed sinks and sources (Fig. 3).[43,44,74] Only when all this knowledge is in place can the extracellular events be interpreted unambiguously.

The strategy just described is, in principle, applicable to any other a priori identified rhythmic or sparse EEG event. Complications arise when several dipoles are involved in the generation of the same EEG patterns, especially when these dipoles are phase-shifted, as is the case in the generation of numerous neocortical patterns (Fig. 4).[14,76,80] Nevertheless, the described strategies have been successfully used in the identification of evoked and spontaneous EEG patterns in the neocortex as well.[18,39,56]

Origin of extracellular currents

Fast (Na^+) Action Potentials

The largest-amplitude intracellular event is the sodium-potassium spike, referred to as the fast (Na^+) action potential intracellularly and as unit activity extracellularly. Individual fast action potentials are usually not considered to contribute significantly to the scalp-recorded EEG, mainly because of their short duration (<2 msec), the low degree of synchrony of spikes in the normal brain, and the high-pass frequency filtering (capacitive) property of the extracellular medium, which attenuates spatial summation of high-frequency events. However, when a microelectrode is placed close to the cell body layer of cortical structures the recorded field potentials contain both extracellular units and summed synaptic potentials. Furthermore, when action potentials from a large number of neighboring neurons occur within a short time windowâ€" for example, during highly synchronous epileptic activityâ€"â€œpopulation spikesâ€

P.802

can be recorded even with relatively large electrodes and in a larger volume (Fig. 2).[3,11,16]

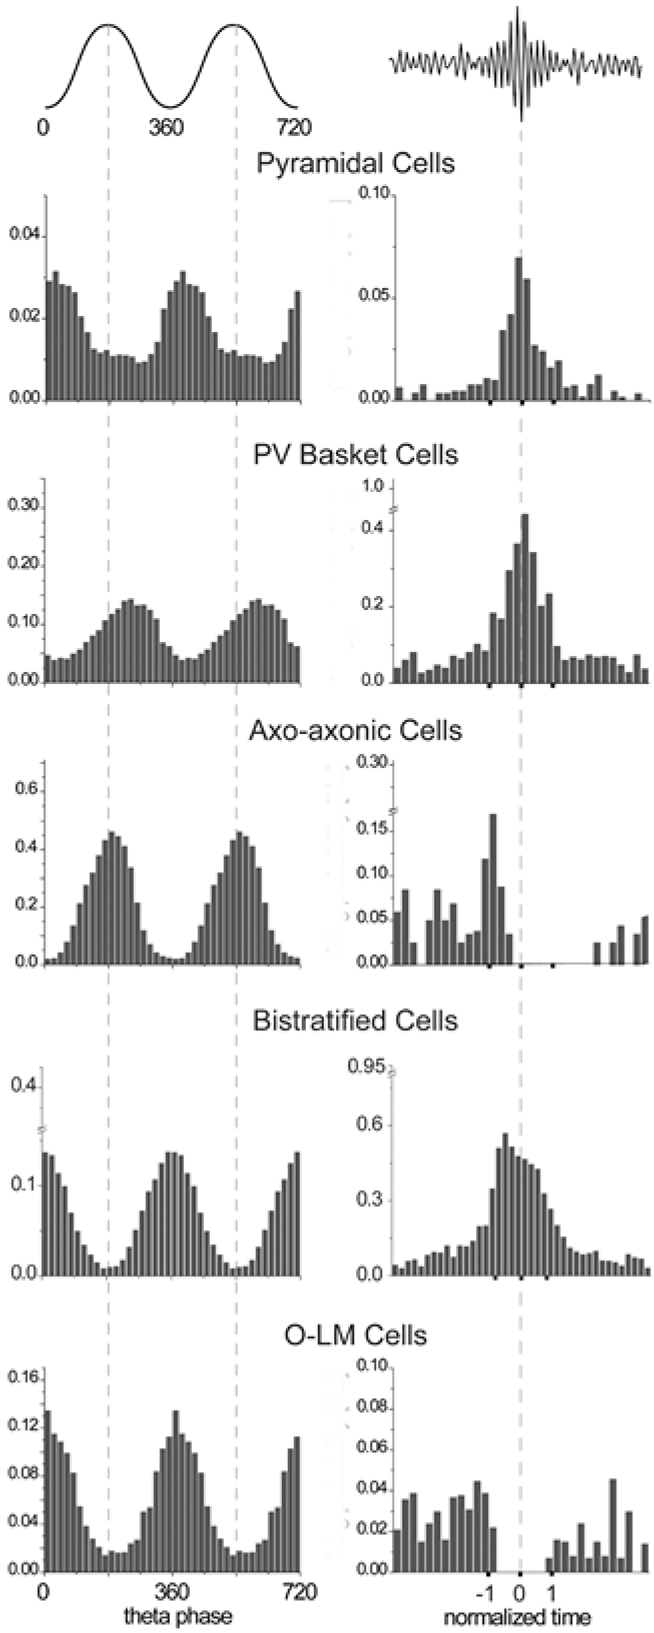

FIGURE 3. Relationship between circuit (axonal targets) and function properties of interneuron classes in the hippocampus. Mean firing probabilities of different cell types during theta (**left**) and sharp-waveâ€"related fast â€œrippleâ€ oscillations (**right**). Distinct classes of anatomically defined interneurons contribute differentially to either theta phase or ripple patterns. O-LM, stratum oriens

interneurons projecting to stratum lacunosum-moleculare. (Adapted from Klausberger T, Magill PJ, Marton LF, et al. FIGURE 4. Variations in the voltage-versus-depth profiles and current-source density (CSD) maps of high-voltage spike-and-wave patterns (HVSs) in the awake rat. **A**: CSD map of a single HVS episode (3-second sweep). The superimposed field traces were recorded from layers II, IV, and VI, respectively. Note the consistent presence of the layer IV sink but the large variability of sinks and sources at other depth locations. **B**: Selected averages of HVS traces and corresponding CSD maps. all, averages of 200 successive events; ppHVS, average HVS with prominent surface-positive spike component; pHVS, average HVS with less pronounced surface-positive component; nnHVS, average HVS with dominant surface-negative spike component and large sink in layers IIâ€"III; nHVS, average HVS with negative spike component in layer IV; DS, average HVS with double spike components at short interspike intervals. Note a prominent delayed sink in layers IIâ€"III in ppHVS and nnHVS. Averages from 40â€"50 traces selected from a 5-minute recording session. Representative single events of the averages are indicated by vertical lines in panel A. iso, baseline isopotential. (From Kandel A, BuzsÃ¡ki G. Cellular-synaptic generation of sleep spindles, spike-and-wave discharges and evoked thalamocortical responses in the neocortex of the rat. *J Neurosci.* 1997;17:6783â€"6797; with permission.)

Synaptic Activity

In most physiologic situations, synaptic activity is the most significant source of extracellular current flow or EEG. The notion that synaptic potentials contribute to the generation of EEG stems from the recognition that for the summation of extracellular currents from numerous individual compartments, the events must be relatively slow.[61] The dendrites and soma of a neuron form a tree made up of an electrically conducting interior surrounded by a relatively insulating membrane with tens of thousands of synapses on it. Each synapse acts as a small battery to drive current, always in a closed loop. Depending on the chemical nature of the neurotransmitter released in the synaptic cleft, the postsynaptic membrane is depolarized (EPSP) or hyperpolarized (IPSP). Excitatory currents, involving Na^+ or Ca^{2+} ions, flow inwardly at an excitatory synapse (i.e., from the activated postsynaptic site to the other parts of the cell) and outwardly away from it. Such an outward current is referred to as a passive return current from the intracellular milieu to the extracellular space. Inhibitory loop currents, involving Cl^- or K^+ ions, flow in the opposite direction. The current flowing across the external resistance of the cortex sums linearly with the loop currents of neighboring neurons to constitute a local mean field (Fig. 2).

Calcium Spikes

Beside the fast Na^+ spike, an important nonsynaptic event in neurons is a wide Ca^{2+}-mediated action potential. These Ca^{2+} spikes are generated in the dendrites and do not necessarily propagate to the soma.[93] Their major role is believed to be to boost synaptic inputs and assist in the plastic modification of synapses.[52,54] The Ca^{2+} spikes represent an inward dendritic current and are large in amplitude (10 to 50 mV). They can occur synchronously with dendritic EPSPs, and for this reason they cannot be simply revealed or separated from EPSPs with extracellular recordings. Because Ca^{2+} spikes are activated by a voltage-dependent mechanism, dendritic depolarization can trigger them.

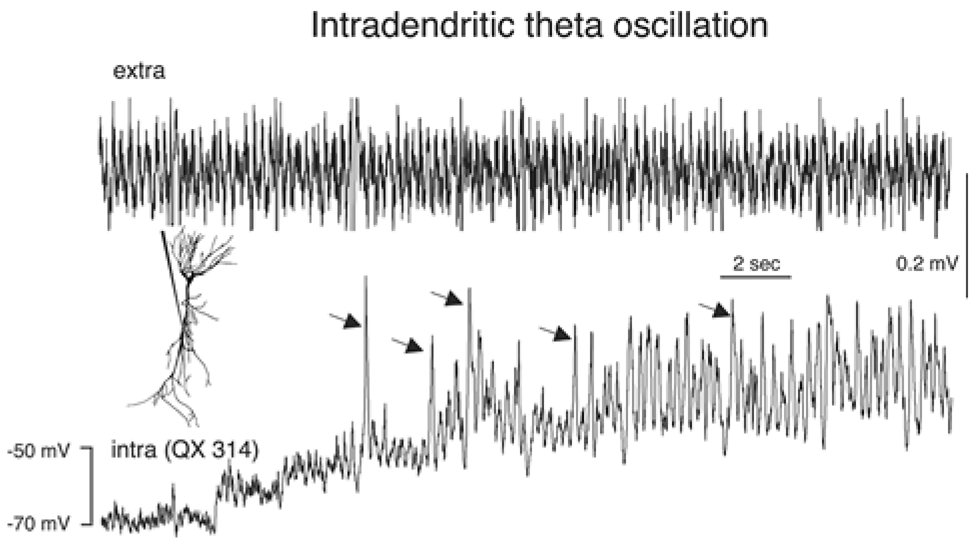

FIGURE 5. Nonsynaptic currents also contribute to the local field potential. Voltage dependence of theta-frequency oscillation in a hippocampal pyramidal cell dendrite. Continuous recording of extracellular (extra) and intradendritic (intra) activity in a CA1 pyramidal cell. Holding potential was manually shifted to progressively more depolarized levels by intradendritic current injection (0â€"0.8 nA). The recording electrode also contained QX-314 to block Na^+ spikes (20 mM). Note the large increase of intradendritic theta oscillation amplitude on depolarization. Some of the putative high-threshold calcium spikes to the phase of extracellular theta in the CA1 pyramidal layer is indicated by arrows. (From Kamondi A, AcsÃ¡dy L, Wang XJ, et al. Theta oscillations in Somata and dendrites of hippocampal pyramidal cells in vivo: activity dependent phaseprecession of action potentials. *Hippocampus*. 1998;8:244â€"261; with permission).

Figure 5 illustrates in vivo recording from a distal dendrite of a hippocampal CA1 pyramidal neuron during theta oscillation.[38] As the dendrite is progressively depolarized by intracellular current injection, the rhythmic synaptic potentials are superimposed on large-amplitude Ca^{2+} events. Are such Ca^{2+} spikes triggered by physiologic stimuli? Recent evidence indicates that this might well be the case. Patterned stimulation of the visual system evoked putative Ca^{2+} events in layer V pyramidal neurons of area 17.[33] Furthermore, intradendritic recordings during spontaneous sharp wave bursts revealed that the amount of physiologic depolarization brought about by the converging active presynaptic afferents to CA1 pyramidal cells is sufficient to trigger voltage-dependent Ca^{2+} spikes.[37]

Such new information, of course, indicates the need for the possible reinterpretation of the extracellular events illustrated in FIGURE 2. Provided that Ca^{2+} spikes occur simultaneously in several neurons near the recording electrodes, these large inward currents can contribute significantly to the field sinks observed in the dendritic layers. The quantitative contribution of dendritic Ca^{2+} spikes to the field EEG has not been determined. They might be quite important in highly synchronous events, such as epilepsy, because synchronous Ca^{2+} spikes in neighboring neurons may be reflected in the field as large sinks. A complicating factor is that, in contrast to EPSPs, Ca^{2+} spikes can actively propagate. Therefore, large dendritic segments and dendritic locations distant from the initiating site might be also involved.

Voltage-Dependent Intrinsic Oscillations

Experiments similar to that shown in FIGURE 5 revealed that when intradendritic depolarization is sufficiently strong, the resonant property of the membrane can give way to a self-sustained oscillation of the voltage, even in the absence of network-driven rhythmic activity. Intrinsic, voltage-dependent slow oscillations and theta frequency resonance have been observed also in somatic recordings of hippocampal pyramidal cells,[48] thalamocortical neurons,[65] stellate cells of the entorhinal cortex,[1] and layer V-VI pyramidal cells of the neocortex.[73] In stellate cells, the main driving force of the oscillation is a persistent Na^+ current,[1] whereas another depolarizing current (I_h) in conjunction with the low-threshold Ca^{2+} current (I_T) is responsible for the maintenance of cellular rhythms in thalamic neurons.[5]

Voltage-dependent oscillatory activation of ionic channels has been shown also in the gamma frequency range. The membrane potential of sparsely spiny inhibitory interneurons in cortical layer IV can sustain a 40-Hz oscillation by sequential activation of a persistent sodium current followed by a slowly inactivating K^+ conductance.[50] Similar intrinsic oscillatory properties have been shown in the intralaminar thalamocortical and GABAergic neurons of the nucleus reticularis neurons in vivo[78] and in the dendrites of hippocampal pyramidal cells.[67] Although these oscillatory membrane currents are small in amplitude, they can nevertheless significantly contribute to the extracellular field.

In most neurons, the voltage-dependent oscillation is below the threshold needed to trigger action potentials. However, when action potentials do occur, they are phase-locked to the depolarizing portion of the oscillatory cycle. Because these intrinsic, oscillatory membrane fluctuations can occur simultaneously in a number of nearby neurons, their contribution to the extracellular EEG can be substantial. This is perhaps best illustrated in the â€œlow-Ca^{2+}, high Mg^{2+}â€ model of epilepsy, when all synaptic activity is completely blocked, and the large, rhythmic extracellular field potentials are exclusively due to the voltage-dependent fluctuation of pyramidal cells, coordinated by ephaptic transmembrane or other nonsynaptic effects.[29,82]

Intrinsic Spike Afterhyperpolarizations

In addition to voltage changes, perturbation of the intracellular concentration of one ion species may trigger influx of other ions by activation of ligand-gated channels. The large Ca^{2+} influx, in association with a dendritic Ca^{2+} spike, is followed by the suppression of fast spikes and hyperpolarization of the membrane due to activation of $Ca2^+$-mediated increase of K^+ conductance in the somatic region.[34,71] These burst-induced afterhyperpolarizations (AHPs) are frequently larger in amplitude and of longer duration than synaptic events. A logical progress of thought is to conclude that they should also be considered as an important source of the extracellularly recorded EEG potential.

Large-amplitude, slow delta waves (1 to 4 Hz) are among the most frequently studied neocortical EEG patterns. These irregular, semirhythmic or rhythmic patterns are most frequently observed during stage 4 sleep in the normal brain. Delta waves occur with largest amplitude in deep (layer V) cortical layers, and they are recorded as negative waves on the neocortical

surface or the scalp. Depth profile measurements in the neocortex of the cat,[17,36,69,70] rabbit,[6,69] and rat[14,90] revealed that surface-negative, deep-positive delta waves during slow-wave sleep correlate with the suppression or cessation of discharges of layer V pyramidal neurons. Intracellularly, the deep-positive waves are correlated with hyperpolarization of pyramidal cells.[2,19] Although the depth profile of the slow delta waves and the associated unit activity are compatible with the hypothesis that the extracellularly recorded delta waves reflect inhibition of pyramidal cells mediated by GABAergic interneurons,[2] all putative, physiologically identified, neocortical interneurons decreased their firing rates during the deep-positive slow waves.[14] An alternative, nonsynaptic explanation of the origin of delta wave generation is based on the summation of long-lasting AHPs of layer V pyramidal neurons.[14,77] During sleep, pyramidal cells of the neocortex often fire bursts in response to rhythmic thalamic volleys,[21,78] and these bursts, in turn, can trigger Ca^{2+}-mediated K^+-conductance changes. The long-lasting nature of AHP combined with disfacilitation from the network favors the summation of outward somatic currents of individual pyramidal cells, resulting in a local positive field in deep layers. Such extracellularly summated currents were hypothesized to form the basis of slow delta EEG waves recorded during sleep.[14] Using whole-cell recordings in vivo, Metherate and Ashe[55] could differentiate between IPSPs and AHPs in cortical neurons of the intact brain. First, they showed, by intracellular injection of Cs^+, that a large part of the delta EEG results from a K^+ current. Second, stimulation of the cholinergic nucleus basalis mimicked the cesium effect. Third, Cs^+ injection blocked the nucleus basalis stimulation effect. These findings support the suggestion that delta waveâ€“concurrent hyperpolarizations result partly from the calcium-activated K^+ current rather than by $GABA_a$ receptorâ€“mediated IPSPs. Overall, these examples illustrate that knowledge of the intrinsic properties of the neurons is as important for the identification of sources of the extracellular ion flow as knowledge of synaptic potentials and anatomic circuitry.

Nonsynaptic Neuronal Effects

Synchronous discharge of large neuronal populations is often associated with large-amplitude extracellular potentials (millivolts to tens of millivolts) and steep voltage versus depth gradients. These large field currents, in turn, can influence the activity of nearby neurons by changing their transmembrane voltage (ephaptic effects). Measurement of transmembrane potential changes (as opposed to potentials relative to a distant ground) indicated that such extracellular current loops can depolarize neurons to spike threshold under certain conditions.[29,82] Computer simulations of multiple neurons embedded in a conductive medium show that such a mechanism is plausible with observed estimates of extracellular resistivity.[83,88] It is important to note that the voltage gradient across pyramidal cell bodies during physiologic SPWs and especially during epileptic or interictal spikes is larger than the experimentally induced voltage gradients that are known to affect cellular excitability. Although direct experimental support is not available yet, one might expect that ephaptic effects could recruit neurons to fire that are otherwise not, or not sufficiently, activated by synaptic inputs alone.[11,24,29]

Gap junctions or electrical synapses[7,20,40] between neurons allow for direct charge transfer not involving the extracellular space. Nevertheless, direct electrical communication can greatly enhance neuronal synchrony and, therefore, network patterns detected by extracellular electrodes. Gap junctions have been suggested to be critical in numerous oscillations, including alpha,[35] gamma,[9,84,86] and high-frequency (150 to 600 Hz) rhythms in both hippocampus and neocortex.[6,83,84,85,94]

Neuronâ€“Glia Communication

The glial syncytium (astrocytes) is connected through gap junctions, which allows the direct spread of current and the diffusion or transport of small molecules. Although the role of concerted changes in membrane potentials of glia in the generation of extracellular current under physiologic conditions has not been studied extensively, recent work on neuronâ€“glia interactions indicates that the glial syncytium can contribute to the slow field patterns in several important ways. Intercellular coupling through gap junctions is required for both propagating Ca^{2+} waves and spreading depression.[58,59] The traveling Ca^{2+} waves, in turn, can trigger calcium influx into neurons.[59] The gliaâ€“neuron dialogue in vivo may be responsible for postictal depression.[8,23,30,32]

The increased $[K^+]_o$ resulting from intensive neuronal activity during epileptic afterdischarge may trigger propagating waves in the astrocytic network reflected by the slowly spreading sustained potentials. In turn, astrocytes at the front of the propagating depolarization wave release more K^+,[46] resulting in a large depolarization of neurons. The ensuing depolarization block of spike generation contributes to the termination of the afterdischarge and is regarded as the cause of the consequent â€œpostictal depressionâ€ of the EEG.[8,81]

DC current fluctuations or ultraslow change of the extracellular voltage cannot be recorded with conventional EEG devices with high-passâ€“filtered inputs. Sensory-evoked responses in scalp recordings with DC amplifiers and nonpolarizing electrodes often contain reliable and relatively long-lasting DC changes, usually referred to as *Bereitschaftpotenzial*[45] or contingent negative variation (Walter). The relatively quick changes in the DC level, such as epilepsy-associated spreading depression,[8] could be identified mistakenly as a slow delta or faster â€œwaveâ€ due to the differential effect of the high-pass filters. These slow potentials may arise from glia, gliaâ€“neuron interaction, or vascular events.[91]

Thus far, we have considered only â€œwell-behavedâ€ single events and provided a bottom-up approach to explaining the extracellular fields from the activity of the neuronal constituents. In the working brain, however, a multitude of (mostly unknown) patterns exists. The bottom-up approach assumes linear operations, and therefore it can be limited in addressing the complex nature of cortical waves. Explanations at the level of networks and systems are also needed.

A system of oscillations is responsible for perpetual EEG activity

A main challenge in cortical neurophysiology is to understand how a useful computation implemented by a relatively small network at a given stage of evolution can be continually implemented when the size of the network grows. The essence of this â€œscaling problemâ€ has to do with the relatively slow conduction velocities of axons and the space and energy limitations of neuronal connections.[47] Growing neuronal networks do not appear to scale linearly, but appear to scale by hitherto unidentified rules.[75] In light of these limitations, a remarkable feature of centrally organized rhythms is their frequency preservation throughout mammalian evolution. All known oscillations in humans have homologous counterparts in monkeys, carnivores, and rodents, and although the frequency ranges can differ somewhat, the variation is within the same order of magnitude. The respective cortical oscillations have similar behavioral correlates, drug sensitivity,[90] and heritability,[72,89] suggesting that they arise from similar mechanisms. Many of the cortical rhythms can sustain high, albeit typically transient, coherence over large spatial distances[10,22,76] despite a

P.805

several-hundredfold increase in the volume of the neocortex from mouse to human. Understanding the spatial scale-invariant preservation of cortical oscillations is a challenging issue for future experimentation and modeling.

Cerebral cortical oscillations range from very slow oscillations with periods of minutes to very fast oscillations with frequencies exceeding 500 Hz, covering a frequency range of at least five orders of magnitude.[41] The neighboring bands often overlap, and boundaries of human scalp EEG bands have been drawn artificially for pragmatic-clinical needs.[79] The historically agreed on frequency bands were largely confined by the limitations of early recording technology. The widely used mechanical recorders limited the upper border of frequencies, and electrode polarization and movement artifacts prevented low-frequency observations.[91]

A useful taxonomy of brain oscillations requires that the individual oscillatory classes represent physiologic entities, that is, that they are generated by distinct mechanisms. A particularly important step in this direction was the discovery of a lawful relationship among brain oscillators: Discrete oscillation bands form a geometric progression on a linear frequency scale and a linear progression on a natural logarithmic scale (Fig. 6).[14,66] An implication of this relationship is that the bandwidth (accuracy of the mean) of the oscillator is proportional to its mean frequency. The numerous brain oscillators fill all frequency bands from ultra slow to ultra fast frequencies without gaps. This noninteger (e ~ = 2.17; the Napierian logarithm, or ln) relationship within the family of brain oscillators has an important consequence. Because e is an irrational number, the phases of coupled oscillators of the various bands vary from cycle to cycle instead of entraining each other for extended periods. Cortical oscillators constantly but only transiently couple and decouple, allowing for an exchange of neuronal information in different regions.[27] In the jargon of nonlinear dynamics, the oscillators are not locked together by a fixed point or attractor (phase), but they attract and repel each other according to a quasiperiodic or weakly chaotic program. Locally emerging stable oscillators are constantly being pushed and pulled by the global dynamics. In reciprocally interconnected networks, temporal ordering of neuronal activity by way of phase-locking can direct the flow of propagation of neuronal activity. The oscillatory network whose neurons discharge earlier can drive the neurons of the trailing network oscillator. By simply reversing the phase offset, the direction of drive can also be reversed without any changes in the connectivity between the networks. The wavelength of a particular oscillation determines the temporal window of processing and, indirectly, the size of the neuronal pool involved. Therefore, different frequencies favor different types of connections and different levels of computation. In general, slow oscillators involve many neurons in large brain areas, whereas the short time windows of fast oscillators facilitate local integration, largely because of the limitations of the axon conduction delays. This anatomic-physiologic limitation can provide an explanation of the observation that a given frequency *f* is spatially correlated over a distance *L(f)* that increases as *f* decreases.[26,62,63]

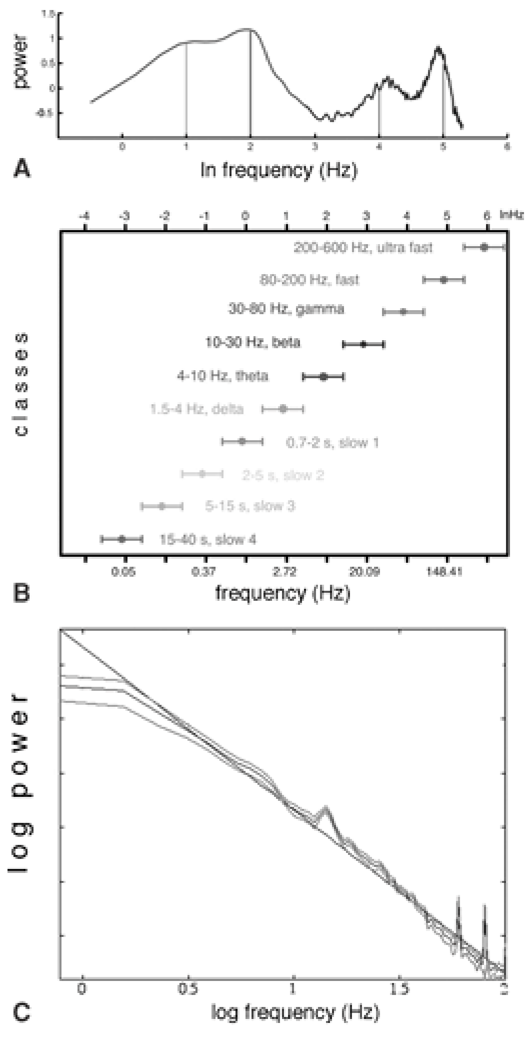

FIGURE 6. An interacting system of brain oscillators. **A**: Power spectrum of hippocampal electroencephalogram (EEG) in the mouse during sleep and waking periods. The spectrum was â€œwhitenedâ€ by removing log slope (see panel C). Note four peaks close to ln integers. Color code band peaks as in panel B. **B**: Oscillatory classes in the rat cortex. Note the linear progression of the frequency classes on the ln scale. For each band the range of frequencies is shown together with their commonly used terms. **C**: Power spectrum of EEG from the right temporal lobe in a sleeping human

subject. Subdural recording. Note near linear decrease of log power with increasing log frequency from 0.5 to 100 Hz. (Adapted from BuzsÃ¡ki G, Draguhn A. Neuronal oscillations in cortical networks. *Science.* 2004;304:1926â€“1929; with permission.)

The ln logarithmic relationship of cortical oscillators gives rise to a perpetual motion of cortical activity. This perpetual activity is nicely reflected by the power law (*1/f*) relationship between frequency and power in all forebrain structures of mammalian brains (Fig. 2).[26] In the frequency-domain (Fourier) plot, the amplitude (square root of power) *A* increases as the frequency *f* decreases, as expressed by the inverse relationship *A* ~ 1/*f*^Î±, where Î± is an exponent. The inverse relationship between frequency and its power is an indication that there is a *temporal* relationship between frequencies: Perturbations of slow frequencies can cause a cascade of energy dissipation at all frequency scales.[4] One can only speculate that this interference dynamics is the essence of the global organization of the cortex at multiple spatial and temporal scales.[15] The 1/*f* scale-invariant feature of the EEG is referred to as â€œpink noiseâ€ or â€œcomplex noiseâ€ in physics, a behavior halfway between disorder with high information content (high entropy, â€œwhiteâ€ or random noise) and certainty or predictability with low information content (low entropy, e.g., harmonic oscillation). It is also the mathematical tell-tale sign of self-organization, implying that the dynamics of the cerebral cortical operations is in a â€œcritical state.â€[3] The physiologic implication of this postulated metastability is that even a very weak transient local perturbation (input) can invade large parts of the network and exert a long-lasting effect, whereas myriads of other inputs remain ignored, depending on the past history of the cortical networks.

The complex (pink) noise view of the EEG implies that the cerebral cortex primarily generates noise. However, as discussed earlier, cortical networks gives rise to several, physiologically defined rhythms in the same frequency range within which the 1/*f* power law applies. In addition, the 1/*f* behavior of the power spectrum is a result of calculating power over a

P.806

long time epoch. However, at any given moment one or few oscillators may dominate, but the frequency versus time orthogonality of the power spectrum does not reveal this. An alternative explanation of the 1/*f* behavior of cortical activity is that it is a result of the perpetual interference of the multiple cortical oscillators. If these oscillators were independent, spectra with multiple peaks would be expected. On the other hand, if the oscillators interact with each otherâ€”an inevitable consequence of the interconnectedness of cortical networksâ€”the frequency, amplitude, and recurrence variability of the oscillators and their interactions might account for the smoothness of the power spectrum constructed from long recordings without a need for generating extra noise. The advantage of such construction is that cortical networks can switch from highly sensitive, scale-free (pink-noise) dynamics to the predictive oscillatory mode that can provide transient autonomy of the involved cell assemblies. The ability rapidly to shift from the metastable state to a highly predictable oscillatory state and back is perhaps the most critical feature of cortical brain dynamics.

It is important to point out that only particular architectures, such as the cerebral cortex, can give rise to spontaneous, self-organized activity with complex dynamics. Self-organization requires regenerative feedback and long-range connectivity. The neocortex with its â€œsmall world-likeâ€ connection architecture[74] and the hippocampus with its random graph-like connectivity[49] meet these criteria. Losing the ability to shift flexibly between the critical state and rhythmicity, these architectures may give rise to hypersynchronous epileptic discharges and the loss of conscious brain operations. In the cerebral cortex, paroxysmal states such as epilepsy usually (but may be not always) depend on recurrent synaptic excitation. Paroxysmal states do occur in other parts of the brain, but of course if there is no recurrent synaptic excitation in those parts, then other mechanisms must be involved.[13]

Summary and Conclusions

The cerebral cortex generates a consortium of interdependent oscillators whose interference pattern appear as spontaneous brain activity. Synchrony of neuronal population is brought about by either external inputs or the self-generated oscillations. Synchronous cooperation of sufficient number of neurons generate extracellular current flow that can be measured by extracellularly placed microelectrodes, subdural electrodes or scalp electrodes. Understanding the processing that give rise to the field requires close monitoring of the neuronal and glial constituents that give rise to the field. Membrane potential fluctuations in all cells can contribute to the field, including EPSPs, IPSPs, voltage-dependent oscillations, afterpotentials and dendritic spikes. Understanding the mechanisms of EEG generation is a central problem because field patterns reflect state changes and provide important clues to the computational â€˜modesâ€™ of the underlying networks.

Chapter 73

Interictal Electroencephalography

Thaddeus S. Walczak

Prasanna Jayakar

Eli M. Mizrahi

Introduction

In spite of the many advances in imaging, digital analysis, and other techniques, routine interictal electroencephalography (EEG) remains central in the diagnosis and management of epilepsy. This should not be surprising. Epilepsy is a disorder of cortical excitability, and interictal EEG remains the most convenient and least expensive way to demonstrate cortical hyperexcitability. Findings indicating abnormal cortical excitability have not changed since the early descriptions. Interpretation of these patterns, however, has evolved in tandem with increased understanding of the natural history of different types of epilepsy, improved study designs, and the issues and opportunities that have emerged in the contemporary care of people with epilepsy. Initial concerns revolved mainly around the relationship between the interictal epileptiform discharge (IED) and the clinical diagnosis of epilepsy. This was usually framed as a problem of sensitivity and specificity, and a thorough understanding of this issue remains important in EEG interpretation. As we learned to view seizures in patients more globally as epilepsy syndromes, EEG findings in patients and close family members became central components in establishing a syndromic diagnosis. As we gained greater understanding of the longer-term course of epilepsy, it became clear that interictal EEG was very helpful in addressing other, nondiagnostic questions that commonly arose. Thus, even in an era of epilepsy care marked by high-resolution anatomic and functional imaging, information provided by routine EEG is more important than ever.

This chapter reviews how interictal EEG is used to address diagnostic and management questions encountered in clinical care of people with epilepsy (Table 1). We discuss how EEG is used to help classify epilepsy syndromes in a general fashion, emphasizing commonly encountered issues and leaving details to the specific chapters describing each syndrome. We also discuss other situations encountered during the treatment of epilepsy in which EEG provides important information.

Electroencephalography in the Diagnosis of Epilepsy

When a patient presents with an unusual spell, the first question the clinician must address is whether the event in question is an epileptic seizure or something else. Although the diagnosis of epilepsy remains a clinical judgment, interictal EEG, interpreted in the context of other clinical data, is often pivotal in answering this question. Two broad ideas must be kept in mind when interpreting interictal EEG in this situation. First, different EEG findings have different degrees of association with epilepsy. Clinicians may encounter any of the finding when considering a diagnosis of epilepsy: interictal epileptiform discharges (IEDs), periodic lateralized epileptiform discharges, generalized periodic epileptiform discharges, focal slowing, diffuse slowing, temporal intermittent rhythmic delta activity and (often) a normal EEG. Of these patterns, only IEDs, the relatively uncommon temporal intermittent rhythmic delta activity, and perhaps periodic lateralizing epileptiform discharges are associated with epilepsy at sufficiently high rates to strongly support the diagnosis of epilepsy. Therefore, understanding specificity and predictive value of the IED is important. Second, lack of these abnormalities or even an entirely normal EEG does not “rule out” the possibility of epilepsy. Therefore, understanding factors affecting likelihood of recording IEDs (sensitivity) is important. These ideas are to some extent affected by the age of the patient and associated clinical condition.

The Interictal Epileptiform Discharge

Definition

IEDs are difficult to describe precisely. However, consensus is widespread that the IED should meet at least the following criteria[20,100]:

1. It must be paroxysmal. This means that it must be clearly distinguished from background activity.
2. There must be an abrupt change in polarity occurring during several milliseconds. This gives the IED its sharp contour and is commonly referred to as the "spikiness" of the IED.
3. Duration must be <200 msec. The Committee on Terminology[20] distinguishes between spikes, which have a duration <70 msec, and sharp waves, which have a duration between 70 and 200 msec. It is not clear that this distinction has clinical utility.
4. The IED must have a physiologic field. Practically, this means that the IED is recorded by more than one electrode and has a voltage gradient across the scalp. This requirement helps distinguish IEDs from artifacts. However, IEDs may have very restricted fields in certain situations (e.g., neonates and the central IEDs seen in benign rolandic epilepsy).

Table 1 Uses of Electroencephalography for Diagnosis and Management of Epilepsy

Diagnosis
Is the paroxysmal event an epileptic seizure?
Is seizure onset focal or generalized?
What epilepsy syndrome best describes the patient's seizure disorder?
Management
What is the risk of recurrence after the first unprovoked seizure?
Is change in behavior due to nonconvulsive status epilepticus?
Is the patient a candidate for epilepsy surgery? What is the area of seizure onset?
How likely are epileptic seizures to recur after antiepileptic drugs are discontinued?

In addition to these necessary criteria, the great majority of IEDs have negative polarity, and many IEDs are followed by a slow wave in the delta range. These two features, although not required, are frequently present and help to distinguish IEDs from other forms of paroxysmal activity. Within the limitations discussed later, IEDs as defined in this manner are highly correlated with epilepsy and rarely seen in normal populations.

Sensitivity: How Often Are Interictal Epileptiform Discharges Seen in Patients With Epilepsy and Seizures?

Prevalence of Interictal Epileptiform Discharges in People With Epileptic Seizures

Sensitivity is an important measure of clinical utility of a test finding. For our purposes, sensitivity of IEDs can be defined as the prevalence of IEDs in people with a diagnosis of seizures or epilepsy determined by other means. Many studies have addressed these issues and allow some general conclusions. However, many factors affect sensitivity, and these must be considered when making clinical decisions.

In three studies of large groups of mostly adult patients evaluated at epilepsy centers, the initial routine EEG demonstrated IEDs in 29% to 55% of patients.[2,50,108] However, serial EEGs performed during varying periods of time ultimately demonstrated IEDs in 80% to 90%.[2,108] Of those patients who had IEDs recorded at some point, 90% had such findings by the fourth EEG.[2,108] If the first EEG demonstrated nonspecific abnormalities but no IEDs, subsequent EEGs were more likely to demonstrate IEDs.[108] Another investigation[135] continuously screened adult patients undergoing video-EEG monitoring for IEDs with standard IED-detection software. Analysis was confined to patients with recorded seizures, allowing a secure diagnosis that was not influenced by the presence of IEDs. No IEDs were detected in 19% of patients, although EEG was screened continuously for an average of 6.9 days.

Studies of patients with single seizures or patients in whom antiepileptic drugs are being discontinued provide some information about the prevalence of IEDs in patients with infrequent seizures (Table 2). Such studies are less likely to be affected by selection bias. From 12% to 50% of this population have IEDs recorded during the initial routine EEG. Nonepileptiform abnormalities are noted in 4% to 45%, and 43% to 74% have normal EEGs. Only one study[131] examined the yield of repeated EEGs in patients with single seizures. Twelve percent of a mostly adult group had IEDs recorded with the first EEG. Electroencephalography was repeated in almost all of those with an initially nonepileptiform study, and an additional 14% had IEDs, resulting in a total yield of 26% after two EEGs. The wide variability in the prevalence of IEDs in these groups with infrequent seizures can be related to a variety of factors, including the study of different populations at different centers and the use of different criteria for the detection of IEDs. The prevalence of normal EEGs was less variable, with five of seven studies finding that about 50% of patients had normal initial EEGs.

Factors Associated With Presence of Interictal Epileptiform Discharges

Interictal epileptiform discharges are recorded more frequently in children than in adults.[2] Furthermore, IEDs are more frequent when epilepsy begins earlier in life.[2] IEDS are more prevalent and more persistent in some epilepsy syndromes such as hypsarrythmia, Landau-Kleffner syndrome, untreated childhood-onset absence, and benign rolandic epilepsy. However, the interictal findings usually form a critical component of diagnosis in these cases, and so such statements may constitute circular reasoning. In adults with partial epilepsy, IEDs are more common when seizures originate in the temporal lobes than when seizures originate elsewhere.[2,135]

Some antiepileptic drugs appear to affect the likelihood of recording IEDs in certain situations.[6,112] Benzodiazepines and barbiturates consistently decrease the prevalence of IEDs acutely. These effects appear to wane with long-term therapy. Withdrawal of barbiturates may be accompanied acutely by the appearance of generalized epileptiform activity or the appearance of noncharacteristic foci of seizure onset. Variable effects on IEDs have been reported with long-term administration of phenytoin and carbamazepine, and no clear trend has emerged. Valproate dramatically suppresses generalized IEDs. In a series of studies, valproate decreased the number of generalized spike-wave discharges in 76% of patients 10 weeks after the drug was started, and the number of generalized spike-wave discharges was still decreased in 57% of patients 1 year after therapy was begun. Photoparoxysmal response was eliminated in 25% of patients with this finding 10 weeks after treatment and in 75% at 1 year after treatment; it is interesting that suppression of photoparoxysmal response persisted even after valproic acid was discontinued and serum levels were no longer detectable. Activation of generalized spike-wave activity with hyperventilation was not affected by treatment at 10 weeks but was eliminated in about half of patients with this finding at 1 year after initiation of treatment.[16,133] Although treatment with benzodiazepines, barbiturates, or valproic acid clearly affects the number of IEDs recorded in certain situations, these drugs are not usually discontinued when no IEDs are recorded and epilepsy is suspected. Atypical IEDs are often seen when barbiturates or benzodiazepines are withdrawn, and the suppressive effect of valproic acid is probably too lengthy to allow safe discontinuation for diagnostic purposes in most cases.

Table 2 Yield of initial electroencephalogram in patients with infrequent seizures

Study	Number of	Age group	With	With IEDs (%)	Normal

	patients		non-IED	abnormalities (%)	(%)
Patients with first unprovoked seizure					
Hopkins et al.[61]	408	Adults	26.8	26.8	46.4
FIRST Group[41]	397	Mixed	50	6	44
Van Donselaar et al.[132]	157	Adults	12	45	43

Kawkabani et al.[70]	177	Adults	34		
Scotoni et al.[115]	213	Children	18	4	78
Patients withdrawing from antiepileptic drugs					
Callaghan et al.[17]	92	Mixed	—	—	74
Shinnar et al.[117]	88	Children	18	—	49
Emerson et al.[36]	68	Children	—	—	50
Specchio et al.[121]	225	Mixed	18	53	29

IED, interictal epileptiform discharge.

Seizure frequency was associated with greater likelihood of recording IEDs in one study,[2] but the opposite was found in another.[135] The first series included many children, whereas the second studied only adults, which may account for the discrepancy. Contemporary studies agree that IEDs occur more frequently in the period immediately after epileptic seizures.[52] Nonetheless a small minority of people with a clear diagnosis of epilepsy will lack IEDs in spite of several routine EEG recordings. There are several potential explanations. IEDs may be infrequent and therefore not detected, even with aggressive sampling. They may be present but not detectable with traditional scalp electrode arrays. IEDs are frequently recorded with intracranial electrodes when results of simultaneous scalp recordings are normal.[1,125] More than 10 cm^2 of brain surface must be involved with an IED before the IED can be detected at the scalp, and fields of IEDs recorded with intracranial electrodes often occupy a smaller area.[1,125] Furthermore, many areas of the cortex, such as the basal frontal and medial temporal regions, are not directly accessible to scalp recording, and IEDs

originating in these regions may not be detected by scalp electrodes. Finally, some patients with epilepsy may have no IEDs even with intracranial recording, although experience suggests that this situation is rare, at least in intractable epilepsy.

Increasing the Likelihood of Recording Interictal Epileptiform Discharges

The yield of IEDs can be increased by activation methods (sleep, sleep deprivation, hyperventilation, photic stimulation, and others; see Chapter 94), by longer EEG recordings, and by employing more electrodes than the routine number used with the 10-20 International System. Each of these may increase sensitivity of interictal EEG in supporting the diagnosis of epilepsy.

The increased yield of IEDs after sleep recordings has been accepted since the early reports of Gibbs and Gibbs.[45] Several reviews provide detailed information.[26,29,35,110] An EEG recorded during sleep will demonstrate IEDs in 40% or more of people with epilepsy in whom EEGs recorded during wakefulness reveal no IEDs. Chloral hydrate is most commonly used to hasten sleep onset. There is no evidence that spontaneous sleep is more effective than sedated sleep; however, sedative drugs, including chloral hydrate, may affect EEG background activity. The majority of studies have shown that 24 hours of sleep deprivation further increase the yield of IEDs by 20% or more after accounting for the increased yield expected with sleep and multiple EEGs.[35] Furthermore, activating effects of hyperventilation and photic stimulation are consistently potentiated by sleep deprivation. Many laboratories employ lesser amounts of sleep deprivation, even though these have not been proved to be as effective.

The occurrence of IEDs and changes in IED distribution and morphology differ depending on epilepsy syndrome and sleep stage. Hypsarrythmia is usually potentiated by sleep, and the EEG becomes increasingly abnormal with deeper stages of sleep; however, the EEG pattern often reverts to normal during rapid eye movement (REM) sleep. Rates of slow spike-wave activity, centrotemporal discharges, and 3-c/s spike-wave activity all increase during deeper stages of sleep. The activating properties of sleep are considered so profound in some of these syndromes that most epileptologists do not consider the EEG evaluation for infantile spasms, Lennox-Gastaut syndrome, Landau-Kleffner syndrome, or benign rolandic epilepsy complete unless a reasonable amount of sleep was recorded. In contrast, the polyspike-wave bursts seen in juvenile myoclonic epilepsy may decrease with sleep and are especially prominent on forced arousal from sleep. Although all studies agree that temporal IEDs are more frequent in non-REM sleep than in wakefulness or REM sleep, there is controversy as to whether frequency is higher in deep or light sleep.[81,109]

Hyperventilation increases the frequency of generalized spike-wave activity in 50% to 80% of patients with absence seizures and often precipitates overt absences, especially in untreated patients.[111] However, altered clinical responsiveness can occur during hyperventilation in the absence of a spike-wave discharge and is a nonepileptic phenomenon observed even in normal children.[39] In contrast, hyperventilation increases the yield of focal IEDs in <10% of patients.[26]

Photic stimulation induces IEDs in 10% of people with epilepsy.[142] More than 80% of such patients have childhood absence epilepsy, juvenile absence epilepsy, juvenile myo-clonic epilepsy, or epilepsy with tonic–clonic seizures on awakening.[142] When partial seizures are activated, clinical features usually suggest a posterior cerebral onset.

An incidental photoparoxysmal response in people without other IEDs or a clear history of seizures can be difficult to interpret. Photoparoxysmal response must be distinguished from the photomyoclonic response and potentiated visual-evoked responses, which are not associated with an increased risk for seizures.[26,79,105,142] Initial studies reported that photoparoxysmal responses persisting beyond the period of photic stimulation were associated with epilepsy, whereas while those limited to the period of photic stimulation were not.[105] However subsequent work has not found this distinction to be useful.[65,120] The very large studies of highly selected airplane crew members report a prevalence of <0.3%.[54] Few adults with an incidental photoparoxysmal response eventually develop epilepsy.[54,114,120] Twin studies of the photoparoxysmal response indicate a concordance of virtually 100%, so the family history should be scrutinized if a photoparoxysmal response is found in someone without seizures. Consequently, most clinicians interpret an incidental photoparoxysmal response conservatively and do not recommend treatment on this basis alone.

IEDs may occasionally be provoked by tactile stimuli; these do not necessarily imply potential epileptogenicity.[76]

Increasing the number of EEGs clearly increases the likelihood of recording IEDs. Salinsky et al.[108] found that approximately 60% of patients studied with up to seven EEGs demonstrated IEDs. About half of these had IEDs in the first EEG, and 90% of these had them after four EEGs. Walczak et al.[135] studied a similar population with continuous detection of spikes and seizures and obtained a somewhat higher yield of 80%. No study has compared the yield of continuous IED detection with that of serial routine EEGs.

Additional electrodes may provide useful information when IEDs are not recorded with the standard 10-20 International System array. This is especially relevant with temporal IEDs. Nasopharyngeal electrodes, true anterior temporal electrodes, and sphenoidal electrodes are all positioned closer to the anterior temporal lobe than are the $F_{7/8}$ electrodes. Several studies[50,51,60,106,107,122] have compared how often temporal IEDs are recorded with these four electrodes. In patients in whom IEDs were recorded at some point during the study, IEDs were recorded in 43% to 58% with the standard electrode array, in 57% to 69% with nasopharyngeal electrodes, in 81% to 90% with true anterior temporal electrodes, and in 75% to 100% with sphenoidal electrodes. More artifacts were seen with nasopharyngeal recordings than with other electrode types. Consequently, nasopharyngeal electrodes have been largely abandoned in favor of anterior temporal electrodes. Sphenoidal electrodes are often used during evaluation for epilepsy surgery but are rarely used during routine EEG. Orbitofrontal electrodes help to record from the frontal pole and nasoethmoidal electrodes from the frontal operculum,[102] and these may be helpful when seizures are thought to originate in the frontal lobe. It is not clear how often such electrodes record IEDs that would not be detected by the standard 10–20 International System electrode array.

Specificity: Interictal Epileptiform Discharges in Nonepileptic Patients

Prevalence of Interictal Epileptiform Discharges in Nonepileptic Patients

Specificity is another important measure of the clinical utility of a test finding. Strictly speaking, the specificity of an IED is defined as the number of individuals not having a diagnosis of epilepsy that do not have IEDs. However, IEDs are rare in people without epilepsy, and so prevalence of IEDs in people without epilepsy is often discussed. All studies of EEGs in large numbers of normal individuals indicate that IEDs are seen in rare individuals without a clinical history of seizures. The likelihood of epilepsy developing in such people appears to be increased, although the likelihood is much less than in patients with paroxysmal clinical episodes who have IEDs. Prevalence of IEDs in nonepileptic individuals is influenced by age, general condition, and recording conditions, among other factors. Only one community-based study is available.[19] Some degree of selection occurred in the remainder.

Table 3 summarizes the available information. Although the studies are few in number and have many limitations, several trends tentatively emerge. In healthy individuals, IEDs are more common in children (2.2% to 3.5%) than in adults (0.2% to 0.5%). Seizures appear to develop eventually in a higher percentage of healthy children with IEDs.[127] In the single study reporting results in hospitalized adults without neurologic or psychiatric disease, prevalence of IEDs was similar to that found in healthy persons.[8] The higher rate in the frequently quoted study of Zivin and Ajmone-Marsan[144] may be attributable to the inclusion of patients who had cerebral neoplasms and underwent craniotomies. The similar rate reported among psychiatric inpatients[15] may be related to the inclusion of patients who were withdrawing from barbiturates or who had anorexia. Interictal epileptiform discharges are more frequent in these conditions and are not necessarily associated with epilepsy.

Types of Interictal Epileptiform Discharges in Nonepileptic Individuals

The types of IEDs seen in normal individuals appear to differ from the types seen in large series of people with epilepsy. Centrotemporal IEDs, generalized IEDs, and the photoparoxysmal response account for the great majority of IEDs found in normal individuals, especially children.[8,19,33,54] On the other hand, focal or multifocal IEDs, especially temporal IEDs, predominate in series of people with epilepsy.[2,37,71] The types of IEDs observed in most nonepileptic subjects with IEDs appear to have a lower association with epilepsy than do other types of IEDs. Centrotemporal IEDs appear to be a heritable EEG pattern with incomplete and age-dependent penetrance.[56] Only approximately 40% of patients with centrotemporal IEDs had epileptic seizures in one large retrospective study.[71] Generalized IEDs occur in approximately 10% of parents and 35% of other family members of probands with both tonic–clonic seizures and generalized epileptiform discharges.[91] The photoparoxysmal response accounts for as many as 63% of IEDs found in individuals without epilepsy.[54] Most studies indicate that seizures develop infrequently in patients with this pattern (see earlier discussion).

Sharp waves or transients are frequently seen in normal neonates and appear to be a normal part of cerebral maturation as revealed by EEG. Frontal sharp transients are isolated sharp waves first present at 34 weeks of conceptional age, with maximum expression at approximately 36 weeks of conceptional age and then with gradual diminution in number and voltage following 44 weeks of conceptional age, and so they are rarely present following 6 weeks postterm. Frontal sharp transients are bilaterally synchronous and symmetric from the time of their first appearance. Focal sharp waves, especially midtemporal sharp waves or sharp slow complexes, can also be normal in premature neonates and perhaps as late as 44 weeks of conceptional age. In normal neonates these are rare in number, random in occurrence, and without persistent focality. The following features suggest that focal sharp waves are abnormal in this age range[23,72,95]: (a) The amplitude of abnormal sharp waves is higher; (b) normal sharp waves occur randomly over the two hemispheres, whereas abnormal sharp waves occur in repetitive runs; (c) normal temporal sharp waves are typically mono- or diphasic, whereas abnormal sharp waves are typically polyphasic with aftergoing slow waves; (d) sharp waves with positive polarity are abnormal, whereas negative sharp waves may be normal; and (e) whereas normal temporal sharp waves may occur in any wake-sleep state in premature infants, they are more common turning transitional sleep in term infants. Temporal sharp waves present in awake term infants are probably abnormal, especially if they are persistent. Overall, the association between IEDs and epilepsy appears to increase as the neonate transitions into infancy and further. There is no information indicating the approximate age at which the degree of association between IEDs and seizures reaches that found in adults, and this is likely to vary depending on the type of IED.

Table 3 Prevalence of interictal epileptiform discharges[a] in individuals without epilepsy

Study	Total number	Age (yr)	General condition	Number with IEDs (%)	Number with IEDs who develop seizures (%)
Eeg-Olofsson et al.[33]	743	1–15	Highly screened normal individuals	14 (1.9)	Not reported
Cavazzuti et al.[19]	3,716	6–13	Screened community-based	131 (3.5)	7/131 (5.3)
Bennet[8]	424	Adults	Healthy flight personnel	2 (0.5)	0/2 (0)

Gregory and Wong[53]	13,658	17–25	Healthy flight personnel	69 (0.51)	1/38[b] (2.6)
Bennet[8]	1,541	Adults	Hospitalized patients; no neurologic illnesses	5 (0.3)	0/2[b] (0)
Zivin and Ajmone-Marsan[145]	6,497	1–74	Hospitalized patients; including neurologic illness	127 (2.0)	20/127 (1.6)
Bridgers[15]	3,143	11–85	Psychiatric inpatients	81 (2.6)	Not reported

IED, interictal epileptiform discharge.

[a]Patients with 6 c/s spike-wave activity were not included, but patients with a photoparoxysmal response (see text) were included in some studies.
[b]Follow-up was not available in all patients with IEDs.

In children, the association between IEDs and epilepsy appears to vary by location, distribution, and morphology. Available studies are retrospective and tainted by selection bias. Nonetheless, the available information and clinical experience indicate that multifocal independent spikes and spikes occurring over the midline, frontal, and anterior temporal regions

are highly associated with epilepsy. Epilepsy occurs in 75% to 95% of cases with such IEDs.[34,71] On the other hand, only about 40% of centrotemporal IEDs and only 50% of occipital IEDs were associated with a history of seizures in a large retrospective study.[71] Occipital IEDs occur after the onset of blindness in infancy; 15% of patients with occipital IEDs were blind in one study.[118] Finally, IEDs tend to cease during follow-up studies in both normal[19] and sick[71,80,129] children who have IEDs; this appears to occur less commonly in adults.[64] Thus, the "cerebral irritability" that seems to be associated with IEDs appears to change with cerebral maturation in many pediatric patients. Clearly, the precise EEG findings and the clinical situation must be carefully considered when the presence of IEDs is used to support the diagnosis of epilepsy in infants and children.

Nonepileptic Conditions Associated With Interictal Epileptiform Discharges

Electroencephalograms recorded during periods of metabolic dysfunction may occasionally reveal IEDs. Triphasic waves, seen in a variety of metabolic encephalopathies, may be difficult to distinguish from generalized epileptiform activity. Focal spikes, multifocal spikes, and diffuse spikes or sharp waves without typical triphasic morphology have been reported in dialysis dementia and hypocalcemia. Seizures are fairly common in these conditions as well, but some such patients with IEDs do not report seizures.[132] Interictal epileptiform discharges may be recorded in nonepileptic patients treated with chlorpromazine, lithium, or clozapine, especially at higher doses. Seizures develop in some, but not all, such patients. The discharges disappear when doses are decreased. These agents also increase the number of IEDs recorded in patients with epilepsy. Electroencephalograms recorded during withdrawal of short-acting barbiturates in nonepileptic patients occasionally demonstrate generalized IEDs or prolonged photoparoxysmal response. This appears to be uncommon with the longer-acting barbiturates.[47] Finally, IEDs in patients without a history of seizures are occasionally seen in cases of cerebral mass lesions, especially abscesses and slow-growing neoplasms.[26] Interictal epileptiform discharges in such situations presumably indicate a higher risk for seizures, but confirmatory follow-up studies are not available.

Summary: Determining the Meaning of the Interictal Epileptiform Discharge

The available information indicates that IEDs are rare in healthy persons and hospitalized patients without neurologic disease and are common in patients with epilepsy. Different types of IEDs appear to have different levels of association with epilepsy, especially in neonates and children. The association between epilepsy and IEDs increases with age. Interictal epileptiform discharges in nonepileptic individuals tend to occur in situations associated with an increased risk for seizures, and seizures subsequently develop in more persons with these findings than in the general population. Clearly, the physician must consider the type of IED and the age and condition of the patient before deciding how much diagnostic significance to attribute to an IED. Furthermore, the "increased seizure tendency" presumably associated with IEDs in some clinical situations may be temporary and not inevitably associated with a long-term risk for seizures, although little information is available to guide the clinician here. Understanding the sensitivity and the specificity of the IED and the factors affecting them will allow proper application of this finding to the individual situation faced by the clinician.

Other Electroencephalographic Findings in Epilepsy

Three paroxysmal patterns meeting criteria for IEDs described earlier have a somewhat lower association with epilepsy than IEDs. Periodic lateralizing epileptiform discharges (PLEDs) consist of sharp waves that are lateralized to one hemisphere

and occur every 1 to 2 seconds. This pattern is usually seen in the setting of an acute irritative structural lesion. The PLEDs attenuate and cease altogether as the patient recovers from the acute event. Seizures occur in about 70% of patients with PLEDs during the acute period.[119] However, at least 20% of such patients have preexisting epilepsy.[119] In three small studies,[113,136,143] epilepsy developed in 23% to 66% of patients without preexisting epilepsy after they recovered from illness associated with PLEDs. Bilateral independent periodic lateralized epileptiform discharges (BIPLEDs) consist of periodic lateralized sharp waves occurring independently and at different rates over the two hemispheres. These are recorded during acute presentation of bilateral or multifocal cerebral disease. In 55% of patients with BIPLEDs, seizures occur during the acute course, and 22% have preexisting epilepsy.[28] Mortality is high, and there is no information on how often epilepsy develops in those who survive. Generalized periodic sharp waves consist of periodic sharp waves occurring synchronously over the two hemispheres. The pattern is recorded in the setting of acute severe bilateral brain damage that is often irreversible. Anoxia is probably the most common etiology; the pattern is also commonly seen in Creutzfeldt-Jacob disease and the late stages of status epilepticus.[128] Association of epilepsy with this pattern is unknown. No data regarding subsequent occurrence of seizures are available because this pattern is associated with a poor prognosis. Epilepsy would appear to be more common in diseases associated with this pattern than in the general population. However, overall occurrence of seizures during or after acute presentation appears to be lower than with PLEDs or IEDs.

Several paroxysmal patterns meet many of the criteria for IEDs but are not associated with an increased prevalence of epilepsy. These include benign epileptiform transients of sleep (BETS), 6-c/s phantom spike-wave, 14- and 6-c/s positive bursts, rhythmic midtemporal theta bursts of drowsiness, subclinical rhythmic electrographic discharge of adulthood, and the midline theta rhythm. A recent review details morphology and clinical associations.[137] Benign epileptiform transients of sleep and 14- and 6-c/s positive bursts occur in >20% of a highly selected normal population and somewhat less frequently in patients with epilepsy. The remaining patterns occur in <3% of referral populations. Controlled studies of these infrequent patterns indicate no association with epilepsy. An experienced electroencephalographer can usually distinguish these patterns from IEDs by careful consideration of morphology, sleep and awake states, and background rhythms. Occasionally, distinguishing between benign epileptiform transients of sleep and temporal lobe spikes, or between 6-c/s phantom spike-wave and the fast spike-wave seen in juvenile myoclonic epilepsy, may be difficult.

Focal slowing or generalized slowing of background rhythms is commonly seen in patients with partial seizures. However, these findings are so common in other neurologic diseases that they cannot be used to support the diagnosis of epilepsy. When continuous focal polymorphic delta activity is present in adults, a focal structural lesion is found approximately two thirds of the time. From 12% to 17% of cases with focal polymorphic delta activity have a history of epilepsy and no structural lesion.[46,87] In children with focal polymorphic delta activity, focal structural lesions are found only half of the time. Twenty-three percent of children with focal polymorphic delta activity have a history of epilepsy and no structural lesion.[89]

Temporal intermittent rhythmic delta activity (TIRDA) is a particular form of focal slowing. In contrast to continuous or intermittent polymorphic delta described previously, monomorphic slow waves of <3 cps occur in brief bursts over the temporal regions. TIRDA is found in only 0.3% of studies recorded in a general EEG laboratory[98] but in more than one fourth of patients evaluated for temporal lobe resection.[44] In contrast to polymorphic focal slowing, TIRDA is highly associated with temporal lobe epilepsy.[44,98,104]

In neonatal EEG, a number of abnormal but nonepileptiform findings are associated with an increased risk of seizures. These risks are not as well quantified as those associated with the IED in adults. Temporal sharp waves, when persistently focal, suggest a lesion or area of focal dysfunction that may be potentially epileptogenic. Similarly, unilateral depression of background can suggest a focal intracranial lesion that increases seizure risk. Central positive sharp waves (also known as positive rolandic sharp waves) suggest periventricular leukomalacia, which is associated with increased incidence of seizures.[12,24] Finally, degree of abnormality of interictal background EEG in neonates is a predictor of seizure risk, especially in high-risk infants[77]; infants with normal background activity are less likely to eventually experience seizures than those with persistent background abnormalities. Of special note is a pattern of modified hypsarrhythmia that can be present in the neonatal period—the suppression-burst variant.[62] This is characterized by periodic bursts of asynchronous high-voltage activity mixed with multifocal spikes and sharp waves. Infants with this pattern experience infantile spasms as well as fragmentary myoclonus, and most eventually develop tonic seizures.

Role of Electroencephalography in the Diagnosis of Epilepsy Syndromes: An Overview

Diagnosis of an epilepsy syndrome is critical for determining correct treatment and prognosis. After a detailed history has been taken, EEG is the most important test in making such a diagnosis. The chapters on the various epilepsy syndromes and other reviews[106,141] discuss specific EEG findings associated with each syndrome in detail. Here we discuss the general principles underlying the use of EEG in diagnosing epilepsy syndromes, briefly summarize important features of various epilepsy syndromes, and describe three common situations in which clinically important distinctions among epilepsy syndromes are based on EEG findings.

General Principles and Summary of Findings

The International Classification of Epilepsy Syndromes is based on two distinctions: (a) between localization-related and generalized epilepsies and (b) between idiopathic and symptomatic epilepsies. The EEG can help to establish which of these categories pertains in a particular case of epilepsy and thus to facilitate the diagnosis of an epilepsy syndrome. Focal IEDs suggest localization-related epilepsies, whereas generalized IEDs suggest generalized epilepsies. The location of the focal IED loosely corresponds to the site of onset of seizures in the localization-related epilepsies; however, there are exceptions (see later section, Role of Interictal Electroencephalography in Evaluating Patients for Epilepsy Surgery). Focal background abnormalities or focal slowing occur in symptomatic epilepsies. Persistent significant attenuation or polymorphic delta activity suggests a structural lesion as the etiology for the symptomatic epilepsy. Diffuse background abnormalities suggest symptomatic epilepsies, whether generalized or localization related. On the other hand, normal background activity argues for an idiopathic epilepsy syndrome. Electroencephalographic findings in the common epilepsy syndromes are summarized in Table 4.

P.815

Table 4 Electroencephalographic features of some epilepsy syndromes

Syndrome	Type of IED	Background	Other

Otahara	Burst suppression	Slowed, attenuated	
Infantile spasms	Hypsarrythmia (multifocal IEDs)	Hypsarrythmia (no parietooccipital rhythm, high-amplitude random focal slow waves); other variants common	Electrodecremental response during infantile spasms
Lennox-Gastaut	Generalized slow spike-wave activity (<2.5 c/s); focal IEDs less common	Diffuse slowing and disorganization	Generalized paroxysmal fast activity during sleep
Absence epilepsy	Generalized 3-c/s spike-and-wave	Usually normal; occasional rhythmic posterior delta activity	Generalized spike-wave activity; activation by hyperventilation
Benign rolandic epilepsy	Rolandic (centrotemporal) spikes; generalized or occipital IEDs occasionally seen	Normal	
Benign occipital epilepsy	Bilateral synchronous occipital spikes or spike-wave activity; amplitude lateralization common	Normal	IEDs activated by eye closure; no activation by photic stimulation
Electrographic status epilepticus during sleep	Continuous slow spike-wave activity during sleep, usually generalized; much less frequently, focal IEDs while awake	Mild diffuse slowing	May be difficult to distinguish from Lennox-Gastaut syndrome by electroencephalogram alone
Landau-Kleffner	Independent bitemporal IEDs	Independent bilateral focal slowing and diffuse slowing	
Juvenile myoclonic	Generalized polyspike wave,	Probably normal; some authors	Photic activation of IEDs common

epilepsy (of Janz)	often >3 c/s	report a midline theta rhythm of questionable specificity	
Progressive myoclonus epilepsy	Generalized spike, polyspikes and waves; also focal or multifocal IEDs in some syndromes	Progressive slowing of background frequencies, especially when dementia is present	Photic activation in some syndromes
Temporal lobe epilepsy	Temporal IEDs; independent bitemporal IEDs in about 25%	Focal temporal slowing; mild slowing of parietooccipital rhythm	
Frontal lobe epilepsy	Frontal IEDs, secondary bilateral synchrony; occasional anterior temporal, multifocal, or no IEDs	Focal slowing uncommon; mild slowing of parietooccipital rhythm	
Occipital lobe epilepsy	Occipital IEDs, independent bioccipital IEDs; occasional temporal IEDs	Focal attenuation of parietooccipital rhythm may occur	Photic activation of seizures may occur

IED, interictal epileptiform discharge.

Clinical Utility of Electroencephalography in Diagnosing an Epilepsy Syndrome: Three Common Situations

Seizures Consisting of Quiet Staring

Staring with unresponsiveness but without automatic activity is a common presentation of epilepsy. These seizure manifestations can be seen in classic absence epilepsy, in the atypical absence of Lennox-Gastaut syndrome, and in complex partial seizures. EEG can provide critical information that aids in diagnosis and treatment. Generalized 3-c/s spike-wave activity (Fig. 1) and a normal background supports the diagnosis of absence epilepsy; slow (<2.5-c/s generalized spike and wave; Fig. 2) together with a slow background supports the diagnosis of atypical absence and suggests Lennox-Gastaut syndrome. Multifocal epileptiform activity, generalized paroxysmal fast activity, and focal paroxysmal fast activity are also common and provide further diagnostic clues.[7,86] Developmental delay and other seizure types may not be very prominent in this syndrome, and so interictal EEG is often very helpful. Finally, a temporal spike or sharp wave (Fig. 3) indicates the presence of complex partial seizures, probably of temporal lobe origin. The medical treatment, surgical options, and prognosis are very different in these three syndromes, so that a correct diagnosis is critical.

P.816

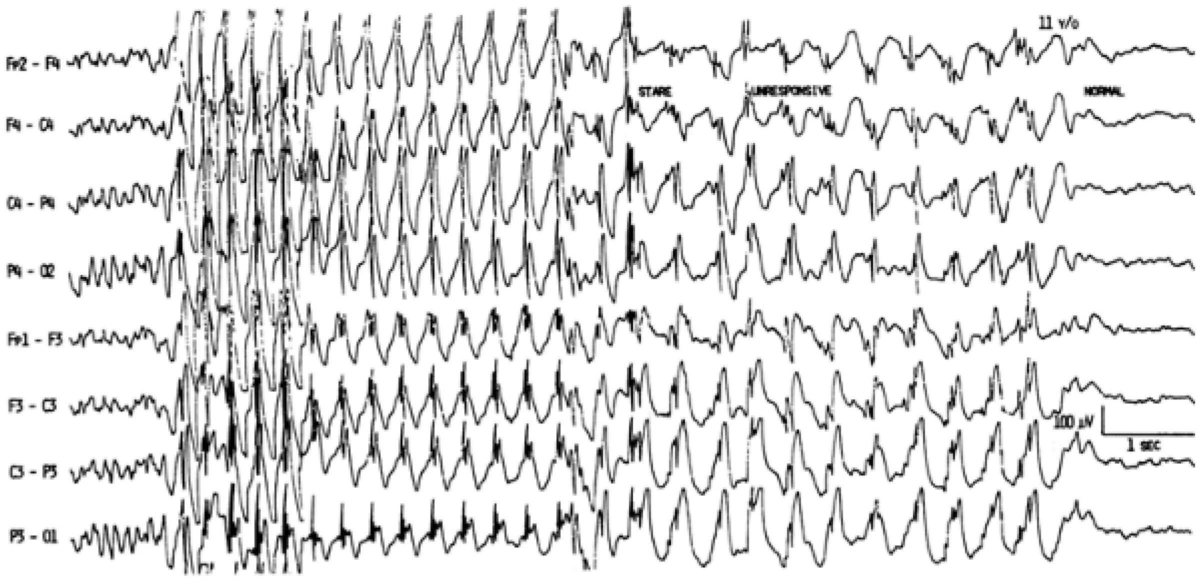

FIGURE 1. Ten-second absence seizure in an 11-year-old with staring spells. Generalized spike-wave activity at 3 to 4 c/s is seen at the beginning of the seizure. The rate gradually slows toward the end of the seizure. The patient was asked to follow a simple command and was unable to do so during the spike-wave discharge. (Courtesy of Dr. Timothy A. Pedley, Columbia University, New York City.)

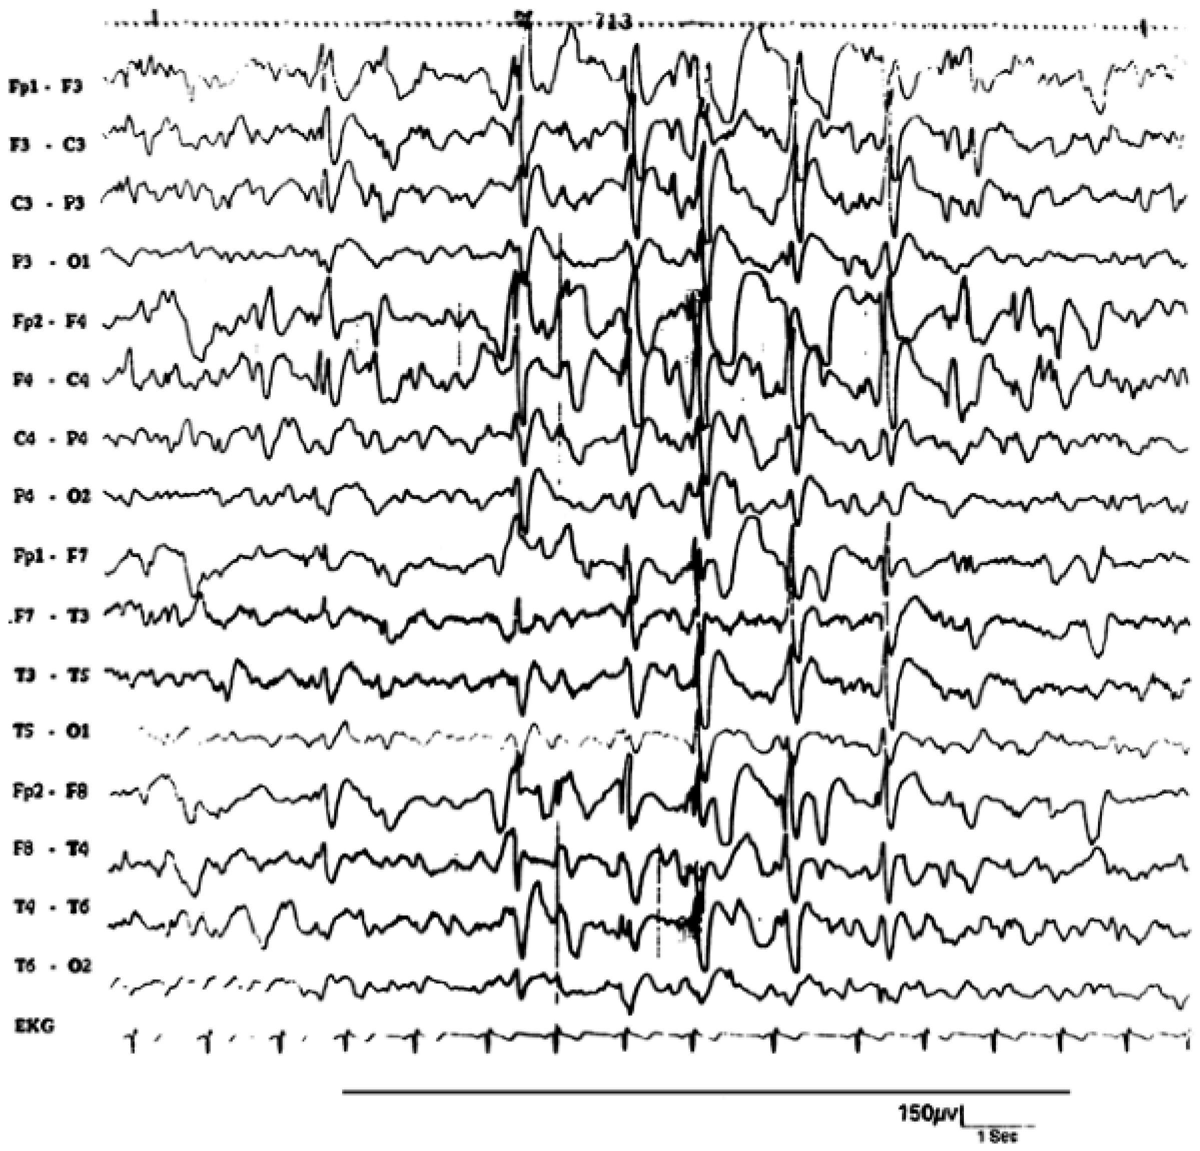

FIGURE 2. Generalized sharp-slow wave ("slow spike-wave") activity.

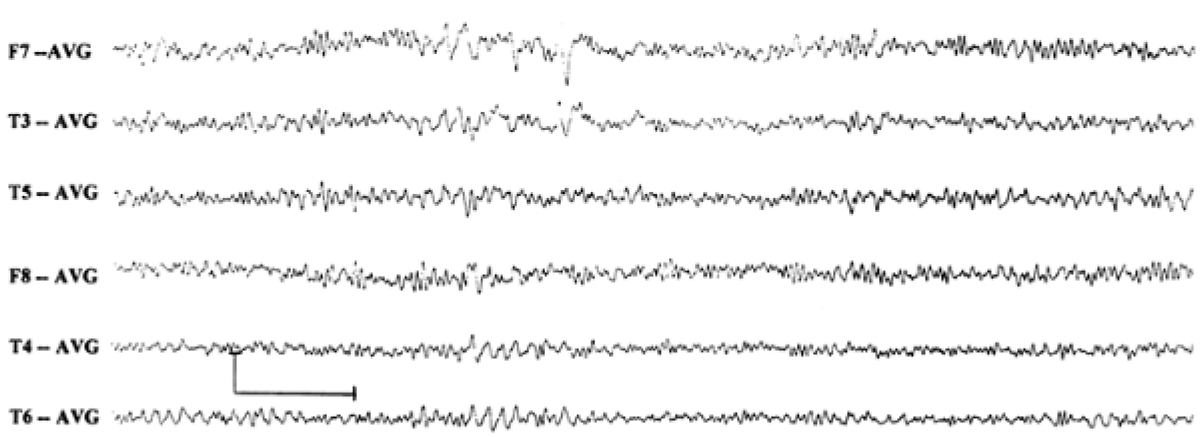

FIGURE 3. Left anterior temporal spikes. Average reference montage is employed, and only temporal channels

on both sides are displayed. Horizontal bar, 1 second; vertical bar, 70 μV.

Primary Generalized Versus Secondarily Generalized Tonic–Clonic Seizures

Epilepsy often comes to medical attention only after a tonic–clonic seizure. Initial manifestations of a seizure are often not witnessed or forgotten. The distinction between primary generalized epilepsy and partial seizures with secondary generalization is clinically important and often cannot be made confidently on clinical grounds alone. Again, EEG provides critical information. Generalized IEDs indicate a generalized epilepsy, and features of the generalized IED suggest specific generalized epileptic syndromes. Focal IEDs indicate localization-related epilepsy. Treatment approach and prognosis differ in these two groups of epilepsy syndromes, and so a correct diagnosis is important.

The EEG distinction between generalized spike-wave activity and secondary bilateral synchrony from one or multiple foci (Fig. 4) is occasionally difficult. The first pattern implies a bilateral synchronous abnormality and an idiopathic generalized epilepsy. The second pattern implies a more focal onset with rapid generalization and raises the possibility of a structural lesion. Shifting focal fragments of the generalized spike-wave often appear during sleep, and this can be misinterpreted as secondary bilateral synchrony. Generalized spike-wave bursts are occasionally recorded in benign rolandic epilepsy or in childhood epilepsy with occipital paroxysms, which can also cause confusion. The following criteria have been offered to distinguish secondary bilateral synchrony from generalized IEDs[100]: (a) Focal IEDs, when present, occur persistently on one area; (b) morphology of the focal IED differs from that of the generalized IED; and (c) focal IEDs clearly and consistently precede and initiate the generalized IEDs or IED bursts. Because secondary bilateral synchrony appears to be less common than primary generalized epilepsy, conservative interpretation is indicated. Simple procedures, such as increasing paper speed, occasionally will make possible the distinction between generalized spike-wave activity and secondary bilateral synchrony. Subtle time differences between IEDs in different regions can be emphasized by with special montage designs, such as reference subtraction.[66]

Nocturnal Attacks With Drooling in Children

Children are occasionally seen with a history of drooling, facial twitching, and unresponsiveness occurring at night. Diagnostic possibilities include the rolandic seizures of benign rolandic epilepsy and complex partial seizures of temporal lobe epilepsy. Drooling and facial twitching often occur during the latter. A careful history taken from an alert child or parent occasionally indicates that consciousness was preserved, that unresponsiveness was a consequence of anarthria, or that peculiar oral sensations preceded the seizure. All of these features would favor a diagnosis of rolandic seizures. However, such a precise description is rarely available. Once again, EEG provides critical information. A centrotemporal spike focus (Fig. 5) supports the diagnosis of benign rolandic epilepsy, whereas an anterior temporal focus usually indicates temporal lobe epilepsy. The distinction is important because the prognosis differs significantly in the two syndromes.

Not all patients with centrotemporal spikes have benign rolandic epilepsy,[31,57,71,88] although how often centrotemporal IEDs indicate symptomatic localization-related epilepsy is unclear. Both classic descriptions[57,82] and computerized analysis of voltage topography[53] indicate that the IED of benign rolandic epilepsy is oriented tangentially. The negative pole typically lies near the junction of the rolandic and sylvian fissures, and the positive pole is more broadly distributed over the frontal regions bilaterally. Gregory and Wong[53] confirmed that the IEDs of benign rolandic epilepsy have this sort of tangential distribution, whereas the IEDs of partial symptomatic seizures have a radial distribution. Others have noted that the IEDs of benign rolandic epilepsy are stereotyped, whereas centrotemporal IEDs of symptomatic localization-related epilepsies demonstrate greater variability in field. Focal background abnormalities are common in symptomatic epilepsy[89] and are not present in benign rolandic epilepsy. These differences, age of the patient, and the clinical situation usually allow a distinction between “benign” and “malignant” centrotemporal IEDs. Nor is the distinction between centrotemporal IEDs and midtemporal IEDs with some suprasylvian representation always straightforward with routine electrode arrays. The $T_{3/4}$ electrodes of the 10-20 International System actually lie near the junction of the sylvian and rolandic fissures. Recording to inactive reference always demonstrates that the amplitude of

IEDs seen in benign rolandic epilepsy is maximal over $C_{3/4}$ or $C_{5/6}$ rather than $T_{3/4}$.[79] Electrodes below the standard temporal 10-20 placements may allow more direct recordings from the temporal cortex and help to make this distinction as well.

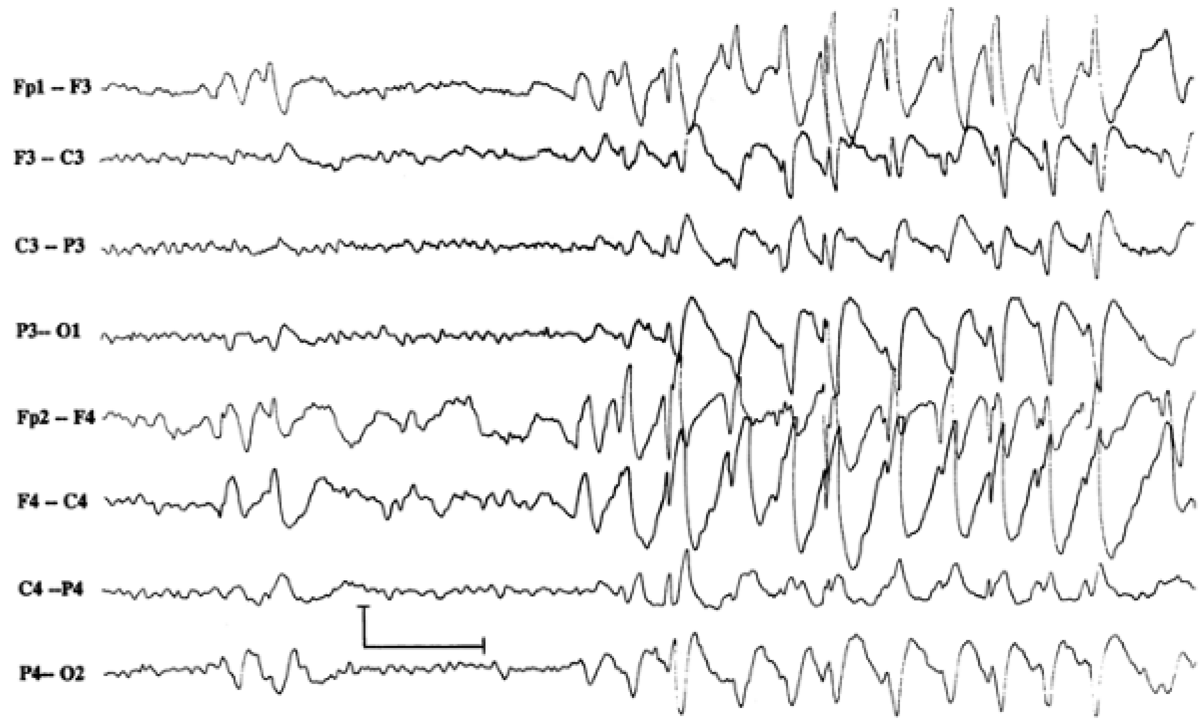

FIGURE 4. Secondary bilateral synchrony. Right frontocentral slowing and an independent right frontocentral sharp wave are noted. The next frontocentral sharp wave leads into a burst of secondary bilateral spike-wave activity, which is better organized over the right hemisphere. The patient had sustained traumatic injury to both frontal lobes, and posttraumatic epilepsy subsequently developed. Horizontal bar, 1 second; vertical bar, 70 µV.

Role of Electroencephalography in Assessing Cognitive Decline in People With Epilepsy

Electroencephalography can also be useful in distinguishing various causes of cognitive decline in people with epilepsy. Possible causes include antiepileptic drug toxicity, development of a degenerative syndrome associated with epilepsy, evolution of a neoplasm, or nonconvulsive status epilepticus. If baseline EEG is available, development or worsening of background slowing over time suggests either antiepileptic drug toxicity or the development of a degenerative syndrome (e.g., progressive myoclonic epilepsy). The appearance of new focal polymorphic delta activity raises the possibility of a new structural lesion. Both focal and diffuse slowing can be seen postictally. In large groups of patients, these changes almost always revert to baseline within 1 hour[69]; encephalopathic changes lasting as long as 10 days, however, have been rarely reported.[11] Previous EEG findings must be reviewed before focal delta activity can be considered significant in people with epilepsy because 12% to 23% of recordings in these patients demonstrate focal slowing without structural lesions.[46,87,89] Finally, nonconvulsive status epilepticus must always be suspected when responsiveness or alertness deteriorates in a person with epilepsy. Only EEG can confirm this diagnosis. Electroencephalographic evaluation is especially useful when postictal impairment is unduly prolonged because nonconvulsive status epilepticus or frequent subclinical seizures are more likely in this situation.

In children, IEDs may occur very frequently, blurring the differentiation between interictal and subclinical electrographic seizures. Such EEG abnormalities are often associated with adverse developmental and cognitive, behavioral, or psychiatric symptoms. It is not clear that treatment with antiseizure medications directed at decrease of IEDs is helpful. However, more definitive treatment of underlying etiologies (e.g., focal malformations of cortical development or hypothalamic hamartoma) is widely recognized as improving these comorbidities. The association between IEDs and autistic/behavioral dysfunction in general and the role of antiepileptic medications in treatment are even less well defined.[101,126]

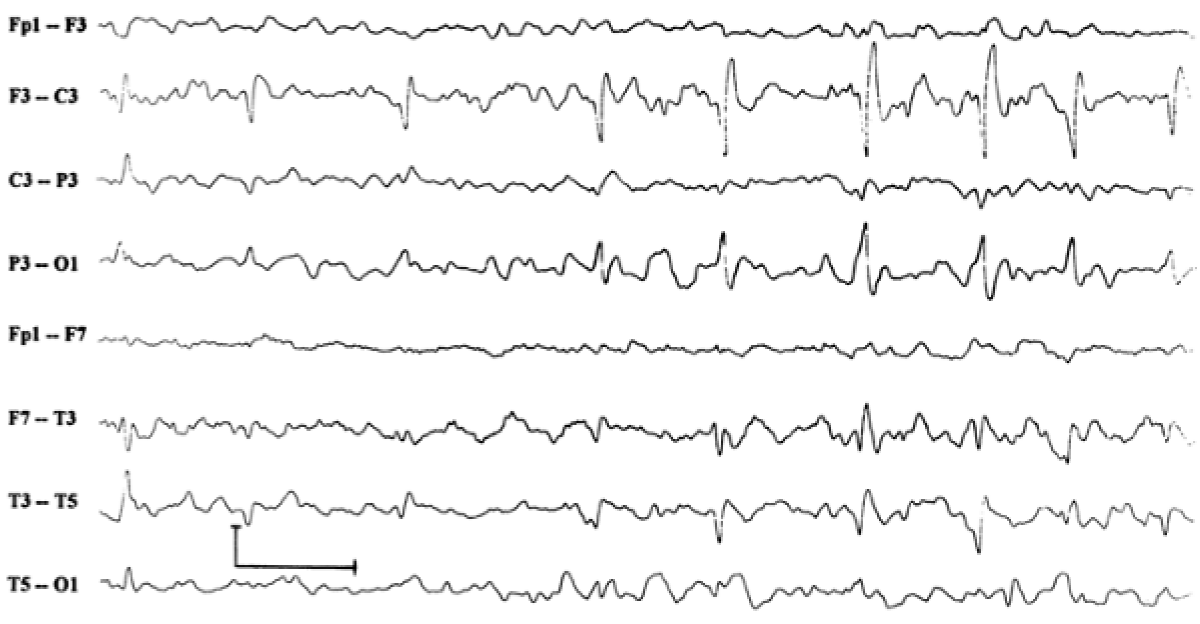

FIGURE 5. Centrotemporal spike in a 12-year-old with a clinical diagnosis of benign rolandic epilepsy. Only left hemispheric electrodes are displayed. Horizontal bar, 1 second; vertical bar, 70 μV.

Role of Interictal Electroencephalography in Evaluating Patients for Epilepsy Surgery

Adults

Resective epilepsy surgery aims to remove the area of seizure onset if it is safe to do so. Interictal EEG defines the irritative area, that is, the cortical area capable of generating IEDs. There is some overlap between irritative areas and areas of seizure onset, and so interictal EEG is used to find potential areas of seizure onset. Temporal lobe epilepsy is the most common localization-related epilepsy; consequently, anterior temporal lobectomy is the most commonly performed resective epilepsy surgery. In large surgical series, 74% to 92% of patients with unilateral anterior temporal IEDs had remission or significant improvement.[30,134] In these patients scalp interictal EEG appears reliably to define the area of seizure onset. However, unilateral anterior temporal IEDs by themselves can be misleading.

P.819

First, the duration of EEG sampling and sleep stage, among others,[21,109] determine the likelihood that IEDs are unilateral. Second, up to 25% of surgical candidates who have independent bitemporal seizure onsets found with intracranial recordings also have unilateral anterior temporal IEDs with scalp EEG.[58] Finally, anterior temporal IEDs have been reported in patients with seizure onset in lateral temporal neocortex[32] or orbitofrontal neocortex.[103,139] Voltage distribution with dipole modeling[32] or the use of sphenoidal electrodes[103] can help to distinguish between these possibilities. However, limited studies of these additional techniques have not yielded clinically useful rules.

More than 25% of potential candidates for resective epilepsy surgery have independent bitemporal IEDs.[58,103,134] In these patients, the probability that seizures originate independently from the two temporal lobes appears to be higher.[21] Nonetheless, 73% to 83% of patients with independent bitemporal IEDs recorded with scalp EEG have all seizures emerging from one temporal lobe after seizures are recorded with intracranial electrodes. Independent bitemporal seizures are more much likely when lateralization of temporal IEDs is <80%.[21,120]

IEDs appear to be less useful for localization in extratemporal epilepsies. In one study of 34 patients with intractable epilepsy cured by frontal lobe resection, only 9% had focal IEDs, and only 33% had regional IEDs that were thought to point to the frontal lobe.[103] Multifocal IEDs or secondary bilateral synchrony were common. Localization and lateralization appeared to be even less accurate in children. Other studies report similar findings.[40,85] Less information is available regarding seizures with occipital lobe onset. In three series of patients with seizures thought to emerge from the occipital regions (total 70 patients), occipital IEDs were seen 32%, 50%, and 63% of the cases, respectively.[13,78,140] Anterior temporal IEDs and secondary bilateral asynchrony were common. Independent bitemporal IEDs occurred in 31% to 40% of cases.[13,140] Similarly, in parietal lobe epilepsy, IEDs are localized to the parietal regions in less than half of the cases and are rarely the only abnormalities. Diffuse or bilateral independent temporal IEDs are common.[74,138]

Why are IEDs less localizing in the extratemporal epilepsies? There are several reasons. Opercular and interhemispheric cortex accounts for proportionally more of extratemporal cortex and is further removed from scalp electrodes than dorsal convexity. Cortical regions generating the IED may be larger, more variable, and overlap with seizure-onset area less well in the extratemporal epilepsies. Finally, white matter pathways mediating IED propagation may be more extensive and variable in extratemporal epilepsies.[37,103] A better understanding of the electrical pathophysiology of the IED in the various epilepsy syndromes would help in interpreting the localizing information that IEDs provide.

The usefulness of nonepileptiform focal changes in defining the seizure onset area has been less extensively examined. One study found that focal polymorphic delta was highly lateralizing in patients with unilateral mesial temporal sclerosis being evaluated for epilepsy surgery but was less useful in patients with bilateral mesial temporal sclerosis.[43] Temporal intermittent rhythmic delta appears to have a higher lateralizing and localizing value (see earlier discussion). Others have examined asymmetries of beta activity induced by intravenous barbiturates.[38,73] Such asymmetries occur in 23% to 66% of patients evaluated for epilepsy surgery and 37% to 54% of patients with mesial temporal sclerosis. False lateralization appears to be rare with visual assessment of scalp recordings.

Children

There is consensus that an EEG must be interpreted in the context of a child's cerebral development. Although partial seizures in children of school age that are associated with a localized epileptogenic zone are generally approached in the same manner as seizures in adults, the situation is different in early childhood. Maturational changes may lead to migration of the focus or appearance of new ones, and serial EEG studies are required to demonstrate consistency of the focus.[25]

Table 5 Electroencephalographic predictors of recurrence after first unprovoked seizure

Study	Population	IEDs	Non-IED abnormalities	Any abnormality	Comments
Annegers et al.[4]	Mixed	NR	NR	+	In idiopathic seizures only
Hopkins et al.[61]	Adults	0	0	0	

Shinnar et al.[116]	Children	0	NR	+	Trend toward IED predicting recurrence
Hauser et al.[56]	Mixed	+	0	0	Only generalized IEDs predicted recurrence
FIRST Group[41]	Mixed	+	NR	NR	
Van Donselaar et al.[132]	Adults	+	+	+	
Scotoni et al.[115]	Children	+	NR	+	

IED, interictal epileptiform discharge.
+, factor associated with increased risk; 0, factor not associated with increased risk; NR, effect of factor on risk not reported.

Multifocal epileptiform discharges raise concern about potentially multiple areas of seizure onset, but some of these

children may still be good surgical candidates. Typical examples are children with tuberous sclerosis, in which seizures may arise from a single tuber even when IEDs are multifocal and magnetic resonance imaging (MRI) reveals many tubers. Runs of repetitive IEDs may help to identify the candidate tuber in this situation.[75]

Another important scenario in early childhood occurs when focal lesions are associated with multifocal independent IEDs, diffuse IEDs, or even hypsarrythmia. Resection of lesions may eliminate the IEDs,[103] leading to the conclusion that IEDs in this situation do not represent multiple areas of increased seizure tendency. Rather, the IEDs appear to represent a functional electrical irritability of the whole cortex that is induced by the focal lesion and is apparently related to a particular stage of cerebral development. Thus, multifocal or diffuse IEDs do not appear to argue as strongly against a single area of seizure onset in immature abnormal cortex as they do in older children and adults.

A note of caution is warranted in a heterogeneous group of focal epilepsies in childhood that are not amenable to surgical care. These include genetically based partial epilepsies and those associated with progressive neurologic disorders requiring specialized investigations. Interictal EEG plays an important role in defining these situations.

Electroencephalographic Findings and Risk of Recurrent Seizures

The likelihood of seizure recurrence is the most important issue in deciding whether to treat with antiepileptic drugs after the first seizure. Five of six representative studies (Table 5) found that EEG abnormalities of any sort are associated with an increased risk for seizure recurrence. Three of the five studies found that presence of IEDs was associated with an increased risk for recurrent seizures. In one other study, a trend toward increased recurrence was noted in patients with IEDs. The risk for recurrence with the various types of IEDs was separately reported in only two studies. Hauser et al.[56] found that only generalized IEDs were associated with increased risk for recurrence. Shinnar et al.[116] did not find that different types of IEDs carried different levels of risk. A meta-analysis found that EEG findings provide useful prognostic information beyond that obtained by diagnosis of epilepsy syndrome, which is itself strongly influenced by EEG results.

These statements are not correct, however, when considering risk of unprovoked seizures following a febrile seizure. Nonspecific EEG abnormalities, usually generalized slowing maximal in the occipital regions, are common following a febrile seizure. Neither generalized slowing nor IEDs increase risk for further febrile seizures, unprovoked seizures, or subsequent epilepsy.[42,127,130] EEG has no demonstrated role in evaluating children with typical febrile seizures.

Likelihood of seizure recurrence is also a central issue when a suitable seizure-free period has elapsed and discontinuing antiepileptic drugs is being considered (see Chapter 7). It is reasonable to expect that EEG abnormalities are associated with an increased risk for relapse after discontinuation of antiepileptic drugs. It is not clear what features of the EEG evaluation would be most helpful. Results at time of first seizure, results at time of antiepileptic drug withdrawal, or change between these two could be considered. Again, it is reasonable to expect that IEDs would be more predictive than presence of other abnormalities. Finally, it is reasonable to ask whether the EEG provides unique information, separate from the diagnosis of the epilepsy syndrome.

Available information partially answers these questions. Electroencephalographic abnormalities increase risk for seizure recurrence in almost all studies (Table 6), although the strength of the effect ranged widely. Several studies examined risks associated with different types of IEDs. In the Medical Research Council study of antiepileptic drug withdrawal,[90] only generalized IEDs in patients with tonic–clonic seizures indicated increased risk for relapse significantly (relative risk, 1.37). Similarly, when antiepileptic drugs were discontinued following 3 years of seizure control in a group of children, generalized IEDs recorded immediately prior to discontinuation doubled the risk of seizure recurrence but centrotemporal IEDS did not.[3,14] However, another pediatric series[117] found that focal or diffuse slowing or IEDs were associated with relapse in univariate analysis. With multivariate analysis, four of six variables predicting relapse were EEG-related: (a) an association between age at first seizure and slowing, (b) presence of IEDs of any type, (c) presence of slowing, and (d) improvement in EEG at withdrawal compared with EEG at diagnosis.

It is not immediately obvious whether the value of EEG in determining whether to discontinue antiepileptic drugs comes from its contribution to the diagnosis of epilepsy syndrome or from its ability to measure "seizure susceptibility" at the time of medication discontinuation. Recent multivariable analyses simultaneously considering EEG findings at the time of medication withdrawal, previously established epilepsy syndrome

P.821

diagnosis, and other factors suggest that IEDs at time of discontinuation predict the risk of recurrence independent of epilepsy syndrome, at least in children.[14,117]

Table 6 Electroencephalographic predictors of relapse after withdrawal from antiepileptic drugs

Study	Population	Abnormality at withdrawal	With abnormality who relapsed (%)	Definition of abnormality
MRC Trial[90]	Mixed	+	NR	Features analyzed individually
Callaghan et al.[17]	Adults	+	70%	IEDs, focal slowing

Shinnar et al.[117]	Children	+	35%	Features analyzed individually
Emerson et al.[36]	Children	+	57%	IEDs, "paroxysmal slowing"
Andersson et al.[3]	Children	+	43%	IEDs
Specchio et al.[121]	Mixed	+	NR	IEDs

IED, interictal epileptiform discharge.
+, factor increases risk for relapse; NR, information not reported.

Summary and Conclusions

Even in the era of high-resolution imaging, interictal EEG provides unique and critical information in the evaluation of people with known or suspected seizures. Interictal epileptiform discharges are highly correlated with epileptic seizures in the great majority of patients. Situations in which the presence of IEDs should be interpreted more cautiously are relatively uncommon and fairly well defined. Types of IEDs and other EEG abnormalities are somewhat less specific when the purpose is diagnosis of an epilepsy syndrome. This is in part because the epilepsy syndromes are often not precisely defined and because interictal EEG plays a critical role in the definitions that have become generally accepted. The usefulness of EEG in predicting seizure relapse is increasingly clear. Finally, limitations of interictal EEG in defining seizure onset area are becoming better defined so that the information provided by interictal EEG during evaluation for epilepsy surgery can be properly used.

It is remarkable that the EEG provides so much useful information. The fact that much of our knowledge is empiric—that is, derived from observed associations between easily recognizable waveforms and certain clinical situations—can be attributed to our imperfect understanding of the pathophysiologic underpinnings of the different forms of epilepsy and the associated cerebral electrical abnormalities. We do not understand exactly how damaged brain generates an IED or a sustained epileptic seizure, and so it should not be surprising that the relationship between epilepsy and IEDs is imperfectly defined. As further studies delineate the electrical, neurochemical, and genetic underpinnings of human epilepsy, empiric EEG investigations will become more focused. Contemporary digital and statistical techniques can then be applied more effectively so that interpreting clinicians can make full use of the wealth of information available in the interictal EEG.

Chapter 74

Ictal Electroencephalogram

Michael R. Sperling

Robert R. Clancy

Introduction

This chapter reviews the electroencephalographic features of seizures. The electroencephalogram (EEG) is an indispensable tool for studying seizures and is often the only means by which a diagnosis of epilepsy can be unequivocally established or seizures accurately classified. It supplies unique information about seizures that is not provided by any other physiologic method. Depending on the EEG technique, the spatial resolution ranges from 1 mm to several centimeters. Its recording characteristics allow the resolution of brief transients lasting a few milliseconds, yet comfortably allow the examination of events like seizures that last for minutes or hours.

Several questions about seizures can be answered using the EEG. The EEG verifies that the event in question is an epileptic seizure and not something else. It helps to classify the type of seizure, defining whether it is partial or generalized. Often, the EEG helps to pinpoint where seizures arise in the brain. The frequency of seizure occurrence and the effectiveness of therapy can be gauged with EEG.

This chapter first discusses the rationale and methods for recording seizures, then illustrates and describes the types of seizures seen in neonates, children, and adults. The EEGs shown here have mainly been recorded with scalp electrodes because seizures recorded with intracranial electrodes are amply illustrated in a subsequent chapter.

Rationale for Recording Seizures

Differential Diagnosis

There are many types of episodic events (see Chapter 68). Some are seizures, whereas others might be pseudoseizures, syncope, paroxysmal movement disorders, transient ischemic attacks, night terrors, somnambulism, narcolepsy, fugue states, or transient global amnesias, among others.[23] Although the medical history often helps to establish the diagnosis, it is not always adequate for the task. The history at times is misleading, and data must be obtained from other sources to arrive at a diagnosis. Ultimately, one can be confident of the diagnosis only when the episode is witnessed and physiologic recordings are made. Interpretation of the EEG recording is generally enhanced by simultaneous analysis of the behaviors that occur during the spell, although that is not always necessary.

Because seizures are characterized by paroxysmal changes of the brain's electrical activity, the diagnosis of a seizure can be confirmed with certainty by demonstrating those changes during the event in question. Seizures that produce impairment in consciousness or bilateral movements such as tonic–clonic seizures, tonic seizures, and complex partial seizures nearly always appear in the scalp EEG. However, there are certain circumstances in which the electrical signature of a seizure is not seen in the scalp EEG, even if a seizure has occurred:

1. During some seizures, the brain's electrical activity may be completely obscured by muscle and movement artifact. Whereas this sometimes prevents physicians from reaching a firm conclusion, the diagnosis of an epileptic seizure can still be offered if the pattern of muscular contractions is stereotyped (as in tonic–clonic seizures) or if it is followed by postictal slowing of EEG frequencies.
2. The scalp EEG usually does not show ictal discharges during simple partial seizures because of their

restricted potential fields.[21,69] Whereas this is especially true of simple partial seizures arising in medial, basal, and interhemispheric cortex, this is often true of convexity simple partial seizures as well. Even when simple partial seizures produce bilateral movements (e.g., supplementary motor seizures), a scalp EEG correlate is often lacking.

3. The scalp EEG, on rare occasion, also fails to detect ictal discharges during complex partial seizures, particularly when they originate in a frontal lobe.[38,78] Intracranial EEG generally eliminates these problems, and with adequate spatial sampling, seizures should appear in the EEG recorded by electrodes directly in contact with the cortex from which the seizures originate.

Occasionally, it is useful simultaneously to record other physiologic parameters along with the EEG when trying to diagnose episodic events. For example, the electrocardiogram (ECG) may reveal a primary cardiac rhythm disturbance, which then secondarily produces changes in the EEG. Blood pressure, muscle, and eye movement can also be studied if they might be helpful. Finally, the events in question can be provoked to help arrive at the diagnosis. For example, suggestion can be used to elicit a pseudoseizure while simultaneously recording the EEG, or tilt-table testing might reproduce vasodepressor syncope.

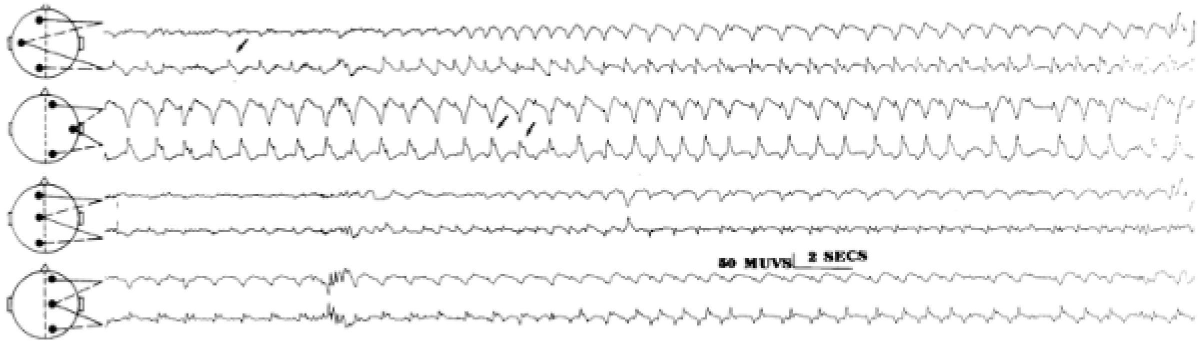

FIGURE 1. Neonatal seizure. This electroencephalogram was recorded from a 1-day-old, full-term infant boy who showed an acute neonatal encephalopathy, including seizures after a placental abruption. Two ongoing, independent electrographic neonatal seizures are apparent in the temporal-central regions (see text for details). The calibration mark in this and subsequent neonatal rhythm strips is 7 μV/mm and 2 seconds.

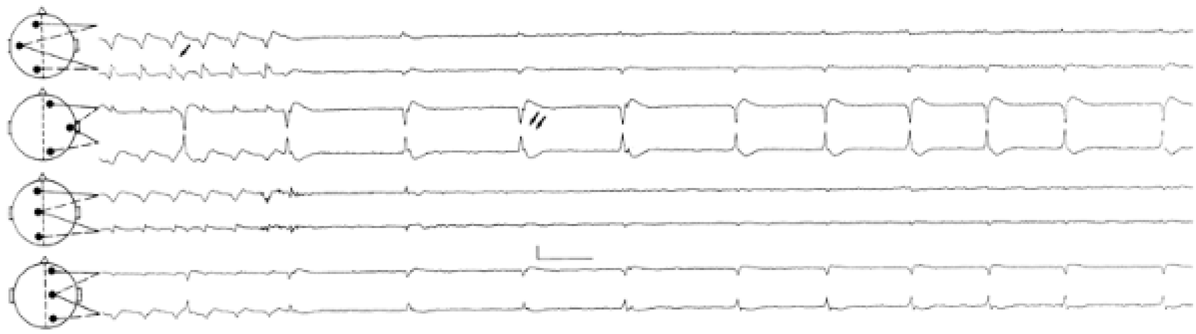

FIGURE 2. Neonatal seizure. This electroencephalogram was recorded from the same patient as in FIGURE 1, at a slightly later time. The very end of an electrographic neonatal seizure appears at T3, and periodic

lateralized epileptiform discharges recur invariantly at T4-C4 (see text for details).

Case Report

A 19-year-old woman had a history of absence seizures since the age of 12 years. They had never been completely controlled and, at the time of her latest evaluation, occurred three to four times daily. They came without warning and had no postictal confusional state, and she believed that they lasted between 10 and 20 seconds. She had taken ethosuximide (Zarontin) for the previous 7 years. She had normal developmental milestones and intelligence, and was a college student at a prestigious university at the time of her evaluation. Her medical history was significant only for well-controlled asthma, and no one in the family had a history of seizures. The neurologic examination was entirely normal. Her interictal EEG showed brief, 3- to 4-Hz generalized spike-and-wave bursts, mainly in light stages of sleep.

P.826

A decision was made to try to stop the seizures because of her dissatisfaction with her condition. First, the dose of ethosuximide was increased without benefit. She next tried valproic acid (Depakene) alone, then a combination of ethosuximide and valproic acid, then valproic acid and methsuximide (Celontin), then valproic acid and acetazolamide (Diamox), then valproic acid and clonazepam (Klonopin), and then trimethadione. With each drug or combination, she complained of persistent seizures and often had sedation, tremor, or some other side effect. Midway in the course of adjusting her medication, another EEG was obtained. This again showed interictal generalized spike-and-wave discharges.

Because therapy had failed, she had continuous EEG recording to study the seizures. During a 4-hour morning session, she complained of two absence seizures. Although she appeared briefly to stare, the EEG remained normal. She was informed that her seizures were not epileptic in nature, and psychogenic seizures were diagnosed. Ethosuximide was restarted and psychotherapy begun. Her complaints of seizures stopped, and she had no further complaints of seizures for the next 4 years of follow-up. After the seizures resolved, her asthma became more severe, requiring several hospitalizations in the next few years.

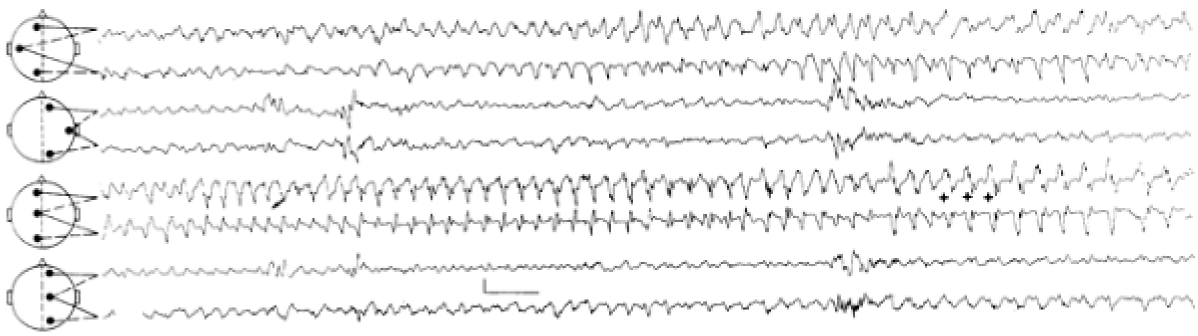

FIGURE 3. Neonatal seizure. This electroencephalogram was recorded from a comatose, 1-day-old, full-term infant boy who was being treated by extracorporeal membrane oxygenation for severe respiratory distress syndrome due to meconium aspiration syndrome and perinatal asphyxia (see text for details.)

FIGURE 4. Simple partial seizure of right temporal lobe origin. **A:** The record begins with the patient awake, with eye blinks and frontalis muscle artifact. Midway through the page, rhythmic sharp waves appear in the right temporal region at approximately 3 Hz. In the anterior to posterior chain (channels 1–4), they phase-reverse at F8 (between channels 1 and 2). In the transverse chain, the phase reversal is less well defined, although it is apparent between channels 10 (C4-T4) and 12 (S2-S1). The sharp waves progressively increase in amplitude while simultaneously diminishing in frequency. When they appear, a bilateral desynchronization and attenuation of the alpha rhythm are seen, probably related to arousal. **B:** As the seizure continues, the sharp waves evolve in frequency and amplitude while the spatial extent of the field remains relatively constant. The discharge increases in frequency in the 5 seconds prior to seizure termination (*arrow*). The ictal activity does not spread to the contralateral hemisphere, and the patient remains conscious and in full contact during the entire seizure. Note the subtle increase in heart rate during the course of the seizure, due to either hypothalamic activation or heightened arousal. Although this patient felt this aura midway through the surface electroencephalographic (EEG) manifestation, awareness may precede, coincide, or follow its scalp EEG appearance in others. (Note: bar = 1 second in this and all subsequent figures.)

FIGURE 5. Complex partial seizure of right temporal lobe origin. **A:** This sequence illustrates a typical complex partial seizure of temporal lobe origin. The seizure begins with rhythmic 8- to 8.5-Hz sharp waves in the right basal temporal region, with a crisp right sphenoidal phase reversal (*arrow*). Because of the steep field gradient between T4, S2, and S1, the activity is best seen in the transverse chain. The same activity, although much reduced in amplitude, is seen in the anterior-to-posterior chain as well (channels 1–4), and it becomes clearer toward the end of this page. Note the progressive increase in amplitude of the sharp waves as the seizure continues. There is a subtle increase in the amount and rhythm of the theta- and alpha-frequency waves in the left hemisphere leads at the same time. This probably reflects invasion of the ictal discharge in that hemisphere. **B:** The seizure continues (*arrow*) with a gradual slowing of the sharp wave frequency, seen best in T4-S2 and S2-S1. In the anterior-to-posterior chain, the rhythmic sharp waves phase-reverse between channels 1 and 3 or 1 and 2 as the field varies, which is characteristic of mesial temporal lobe seizures. The ictal activity in the left hemisphere is subtle compared with the right, but rhythmic alpha-frequency waves are present that were not seen in the interictal state. **C:** On this page, the right sphenoidal sharp waves vary more in amplitude and frequency (*arrow*), and semirhythmic delta activity becomes prominent in the right hemisphere, although it is noted in the left-sided derivations also. **D:** The rhythmic sharp waves stop early in this page (*arrow*), marking the end of the seizure. Immediately afterward, lateralized postictal slowing, consisting of prominent delta activity in the right temporal region, appears. This last page also illustrates how physiologic artifact from eye blinks and muscle contraction help to diagnose a seizure and to characterize the behavior. This last page contains at least eight eye blinks in 7 seconds after the seizure stopped. In contrast, no eye blinks are seen on the first two pages once ictal activity appears, and only two blinks are seen in panel C. This lack of blinking correlates with a motionless stare, noted during some complex partial seizures. The high-frequency activity in channels containing the right temporal leads (F8, T4, T6, S2) is muscle artifact, which reappeared immediately after seizure cessation. It had been present before the seizure early in panel A and disappeared once the seizure began. Hence, the seizure produced a decrease in muscle tone, further confirming concomitant behavioral change, had no observer been present.

FIGURE 6. Left occipital complex partial seizure. **A:** This seizure begins with low-amplitude 9-Hz waves (*arrow*). The patient was eating prior to seizure onset, and the record shows muscle artifact caused by chewing. **B:** The seizure continues with an occipital alpha-frequency discharge (*small arrow*). Several seconds after the start of the page (*large arrow*), higher-amplitude sharp waves appear in the temporal regions, with mid- to anterior temporal phase reversal. This represents anterior spread of the seizure and the development of an independent ictal discharge in the temporal lobes at a different frequency from that of the occipital lobe.

This case illustrates the usefulness of EEG recording to clarify a diagnosis. In retrospect, it would have been prudent to perform EEG recording of her seizures much earlier. Her physician was swayed by the abnormal interictal EEG, and, in all likelihood, she did have epilepsy at one time and may still have had a tendency for seizures. Arriving at a diagnosis of pseudoseizures allowed for institution of appropriate therapy.[37] The subsequent worsening of the asthma reveals the need for illness that motivated the complaints of absence seizures, and it may be suggested that ongoing psychotherapy is required.

Classification

Once seizures are diagnosed with certainty, the type of seizure should be determined. The classification of seizures and the epilepsies is reviewed elsewhere, and here it suffices to remind the reader that seizures typically fall into one of two categories—generalized or partial. Generalized seizures begin more or less simultaneously throughout the cortex, whereas partial seizures begin focally and spread to a variable extent. This distinction is important because it helps to determine which of the epilepsy syndromes a particular patient has, influences the choice of medication, and ultimately affects prognosis. The history and interictal EEG usually suffice for reasonable diagnostic confidence. However, should a patient fail to respond to therapy or experience adverse side effects to a number of medications, recording of seizures with EEG not only can confirm the diagnosis of epilepsy, but it also can establish the classification to ensure that appropriate therapy is prescribed. EEG recording, particularly when behavior is studied, greatly furthers this aim.

Generalized seizures begin with a number of character-istic patterns that are apparent in the scalp EEG: Typically, generalized spike-and-wave discharges (e.g., absence or tonic–clonic seizures), generalized paroxysmal fast activity (e.g., tonic seizures), a diffuse electrodecremental response (e.g., atonic seizures), or a generalized frontally predominant slow wave (e.g., atonic seizures). Because partial seizures begin focally, one

P.827

might reasonably assume that the EEG shows a focal onset in a frequency domain when they begin. This often happens and, in theory, should always be present. However, technical limitations in recording methods make demonstration of a focal seizure onset either impractical or unattainable. Some seizures spread so quickly —within a few milliseconds—that localized onset cannot be demonstrated, despite the best of modern technology. Other seizures begin in "buried cortex," that is, cortex hidden from the recording electrodes. These seizures are detected only once they have spread elsewhere in the brain, and the propagation may be so diffuse that a focal start cannot be seen. Fortunately, the EEG patterns of partial seizures

P.828

usually differ sufficiently from those of generalized seizures that they are diagnosed with reasonable confidence, even though a focal onset is not seen. Nevertheless, there still remain some occasions when seizures cannot be definitively classified.

Case Report

A 22-year-old man complained of seizures that began at the age of 15 years. He had a prior history of an uncomplicated febrile convulsion. His seizures began with a feeling of lightheadedness lasting several seconds, and then he became unresponsive and motionless for approximately 20 seconds. He had been treated unsuccessfully with phenytoin (Dilantin) since his seizures began and still had several per month. No one in his family had a history of seizures. Neurologic examination was normal, and an interictal EEG was normal.

The phenytoin was discontinued and carbamazepine (Atretol, Tegretol) was begun. The seizures continued unabated, perhaps slightly increased in frequency. Another interictal EEG was normal. Because of nausea at higher doses, the carbamazepine was stopped and phenobarbital (Arco-Lase, Bellergal-S, Donnatal, Quadrinal, Mudrane, Rexatal, Solfoton) was begun. The seizures continued.

He then had continuous EEG recording to capture seizures. During one of his typical seizures, the EEG showed a prolonged run of generalized, 4- to 5-Hz spike-and-wave discharges. Valproic acid was then begun, and his seizures stopped.

This case illustrates how ictal recording, by classifying seizures, can help. Once it was realized that this patient had generalized epilepsy, appropriate medical therapy could then be used successfully to treat the seizures.

Localization

There are two reasons to localize seizures. The first reason is scientific. By directly studying seizures and characterizing how they begin, spread, and end, one can better understand epilepsy. Planning for epilepsy surgery provides the main clinical reason to localize seizures. If a surgical procedure is planned, it is first necessary to establish whether all seizures come from one region and, if so, to identify the specific region of cortex that gives rise to the seizures. Whereas evaluation for epilepsy surgery involves performing a variety of tests, recording seizures with

P.829

P.830

P.831

either scalp or intracranial EEG still offers the most direct means of identifying the tissue to be resected. Seizures can be localized either with scalp (extracranial) electrodes or with intracranial electrodes. It is important to recall that both extracranial and intracranial EEG can be misleading with regard to localization. Just as partial seizures might not appear to be localized in some EEG recordings or might not appear at all (as discussed previously), a “clear-cut” localization can at times be misleading if the propagation of an ictal discharge is seen first, rather than its initiation. For example, a seizure might start in the occipital lobe but spread rapidly to the temporal lobe and falsely appear to begin in the temporal lobe in the scalp EEG.

Quantification

The last of the major clinical reasons to record seizures is to quantify their rate of occurrence. Many people do not know when they have had a seizure or how often they occur. A prolonged recording session can define how often seizures occur, thereby providing a gauge of the effectiveness of therapy. For example, absence seizures may occur dozens of times per day in small children, and a 24-hour recording can establish whether medication levels are sufficient. Examination can be made of the relationships between seizure occurrence and the time of day or month, the different stages of sleep, and medication levels, among other factors.

Methods for Recording Seizures

Electrodes

Extracranial Electrodes

Most types of EEG electrodes that are employed for interictal EEG recording are also suitable for recording seizures. The only requirements are that the electrodes be suitably placed to detect the electrical activity of the brain and that they be reasonably secured so that they do not fall off or move too much during a seizure. The electrodes most often used for extracranial recording are attached to the scalp (placed in the 10/20 system, its intermediate placements, or more inferiorly).[61] Collodion should be used to maintain optimal contact and minimize movement. Sphenoidal electrodes are inserted medially beneath the zygoma to record from basal temporal structures[67] and are sometimes useful for detecting basal temporal lobe spikes and localizing temporal lobe seizures.[57] Nasopharyngeal electrodes are too unstable to use for recording seizures. Extracranial electrodes are subject to significant limitations. These include limited spatial resolution and inability to detect activity from deep cortex (such as basal cortex, including basal orbitofrontal, temporal, and occipital

P.832

cortex; interhemispheric cortex; and activity within the depths of sulci).

In addition, EEG electrodes record some physiologic artifacts that may sometimes aid in diagnosis. These include characteristic patterns of muscular contraction, changes in heart rate, and alteration in eye blinking. For example, whereas the muscle artifact of a tonic–clonic seizure may completely obscure the EEG, the pattern of muscular contractions is so stereotyped that the EEG is diagnostic. Subtle increases or decreases in tonic muscle activity help to establish whether electrographic seizures have an associated subtle change in behavior. The cessation of eye blinking often heralds the onset of many temporal lobe complex partial seizures; this observation is readily made in the EEG. Most seizures induce an increase in heart rate, sometimes even before the seizure produces a conscious response, and this is often recorded in the EEG.

Intracranial Electrodes

These are used to localize the source of seizures when noninvasive methods are inadequate.[27,40] They lack many of the limitations of scalp and other extracranial electrodes and are discussed at length in a separate chapter. Briefly, they include electrodes that can overlie the dura, known as *extradural electrodes*; electrodes that overlie the pia and are beneath the dura, known as *subdural electrodes*; and electrodes that enter the substance of the brain, known as *intracortical* or *depth electrodes*. Electrodes may also be inserted through the foramen ovale to record from the mesial temporal lobe from an epidural location. They are more sensitive to small field potentials than with scalp EEG and serve to localize seizures when noninvasively obtained data are inadequate. They may often show a well-localized seizure onset, even when scalp EEG recording is nonlateralizing.[40] A more complete discussion can be found in Chapter 171.

Other Electrodes

Electrocardiography (ECG) recording is usually done along with EEG. At times, an electromyogram (EMG) may be recorded, using surface electrodes glued to the skin. These help to define artifacts in the recording environment and so assist in interpreting the EEG.

Electroencephalographic Recording

The EEG should be recorded using standard filter settings (low-frequency filter, 1.0–1.6 Hz, and high-frequency filter, 70 Hz). If excessive movement is present, the low-filter settings can be increased to reduce sway; reducing the high-frequency filters rarely clarifies the situation. Montages should incorporate at least 16 channels and should include bipolar montage configurations in anterior-to-posterior and transverse directions (at times, referential montages are useful supplements). Paper records should be displayed at 30 mm/s. When digitally recording the EEG, the sample rate should be at least 200 Hz.

Seizures can be recorded in the EEG in a routine laboratory setting, on an outpatient ambulatory basis, or in an inpatient unit. Routine laboratory recording allows for behavioral

P.833

P.834

P.835

P.836

testing but suffers from technical and time constraints. Ambulatory recording eliminates the time limitations, but video is not available, and technical problems are not immediately remediable. An inpatient unit permits the most comprehensive and technically satisfactory recording, although at greater expense than the other methods. Automatic spike and seizure detection programs employed during long-term monitoring reduce the amount of EEG that must be directly reviewed by the electrophysiologist and, therefore, are useful means of performing data reduction while simultaneously enhancing detection capabilities.

FIGURE 7. Frontal lobe complex partial seizure. **A:** This page immediately precedes seizure onset. Frequent interictal sharp waves are present at F4, C4, and F3. These wane in the last 2 seconds of this page. **B:** The sharp waves are replaced by irregular theta and delta discharges in the first several seconds of this page. In the last few seconds, an obvious ictal discharge consisting of rhythmic 9- to 10-Hz sharp waves appears (*arrow*), maximal at F4, suggesting right frontal localization. **C:** The seizure continues, but no definite ictal discharge is seen in the electroencephalogram. Toward the end of this page, high-amplitude rhythmic delta discharge appears. This is accompanied by a notable increase in tonic muscle artifact, indicating a behavioral change. **D:** The seizure continues with rhythmic theta- and delta-frequency activity. Contractions of the temporalis muscles show as phasic muscle artifact in the latter portion of the page.

FIGURE 10. Seizure onset demonstrated with intracranial electroencephalogram. **A:** A discrete (focal) seizure onset is seen in the right amygdala (*arrow*). The seizure begins with rhythmic triangular sharp waves that are confined to the amygdala. **B:** This regional onset seizure contrasts with the previous seizure in that a more widespread onset is seen in both amygdala and hippocampus. Rhythmic spiking (*arrow*) is seen in electrodes recording from amygdala and mid pes hippocampus, with some reflection of the spikes in the posterior pes electrode and reflection of the slow wave in the parahippocampal gyrus. AMYG, amygdala; AP, anterior pes hippocampus; L, left; MG, mid parahippocampus gyrus; MP, mid pes hippocampus; MT, middle temporal gyrus; PG, posterior parahippocampus gyrus; PP, posterior pes hippocampus; R, right.

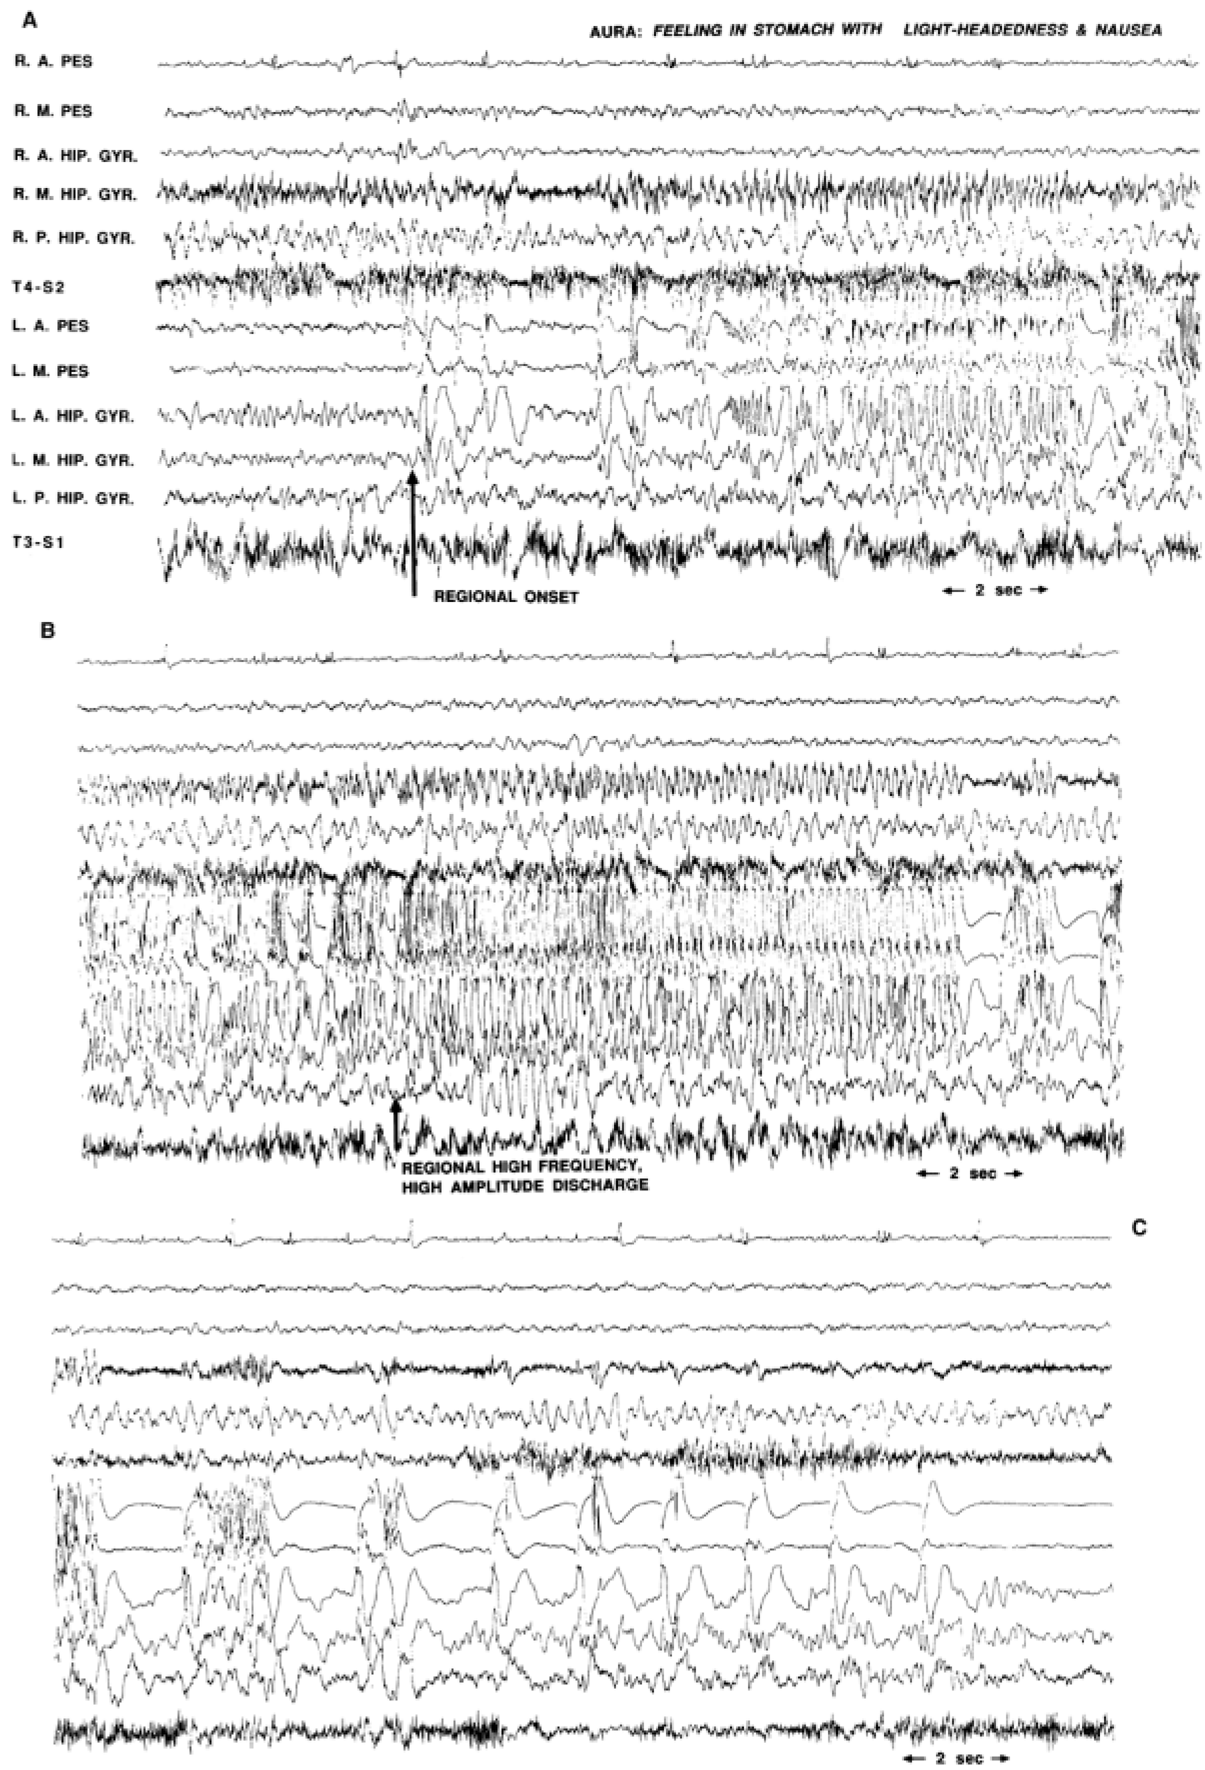

FIGURE 11. Mesial temporal simple partial seizure recorded with intracranial electrodes. **A:** The seizure begins with regional high-amplitude spiking (*arrow*) for several seconds. This is followed by the development of regional fast activity in the latter portion of the page. **B:** The regional discharge progressively slows in

frequency while increasing in amplitude. The extracranial channel (*bottom channel*) shows a rhythmic pattern, although the fast spiking present in the depth electrodes cannot be seen. Toward the end of the page, the discharge is interrupted by transient suppressions. The seizure does not spread to the contralateral hemisphere but remains confined to the left mesial temporal lobe. **C:** The pattern of ictal fast activity and suppression continues initially, although the fast activity is then replaced by spikes. The seizure ends with flattening in the anterior mesial channels. A. HIP. GYR., anterior hippocampus gyrus; A. PES, anterior pes hippocampus; L, left; M. HIP. GYR., mid hippocampus gyrus; M. PES, mid pes hippocampus; P. HYP. GYR., posterior hippocampus gyrus; R., right.

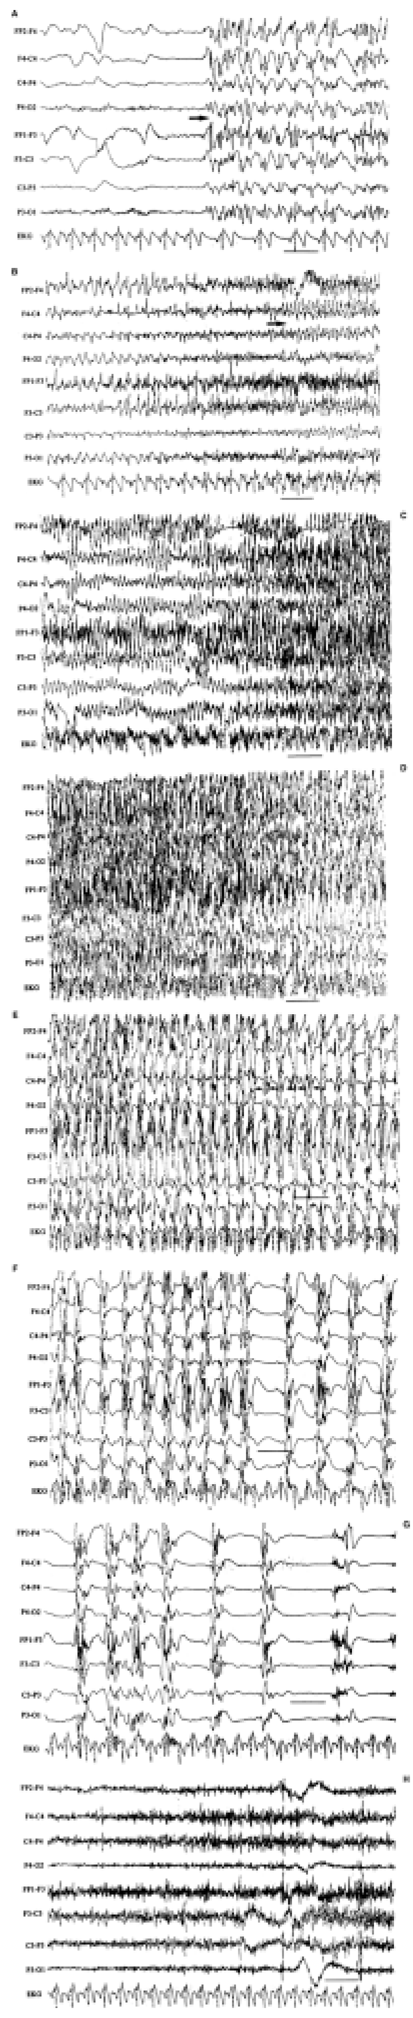

FIGURE 12. Generalized tonic–clonic seizure. **A:** The seizure begins with a generalized spike-and-wave burst (*arrow*) that is replaced by polyspike and wave. **B:** The polyspike and wave is succeeded by generalized continuous fast activity, which is the start of the tonic phase of the seizure. The latter half of this page begins to show tonic muscle artifact indicative of a generalized increase in continuous muscle contraction. **C:** The fast activity, at 8 to 10 Hz, continues with progressive increase in muscle artifact. **D:** During this segment, the tonic phase continues. The electroencephalogram cannot be seen because it is completely obscured by muscle artifact. Slow waves start to appear in the last second of this page, heralding the onset of the clonic phase. **E:** The clonic phase now predominates. Bursts of muscle contractions are interrupted by pauses (coexistent with the slow wave), with a gradual diminution of the frequency of muscle contractions. **F:** The clonic phase shows increasing intervals between contractions, with occasional long pauses between jerks. **G:** The clonus becomes less frequent, and suppressions of increasing duration are seen. **H:** The seizure is now mostly ended. This page shows a mild tonic phase that lasted 30 to 40 seconds in this patient. This subtle tonic phase typically follows tonic–clonic seizures and is succeeded by loss of muscle artifact and profound background amplitude attenuation and slowing.

FIGURE 13. Absence seizure. **A:** This absence seizure begins abruptly with a generalized spike-and-wave discharge at 3.5 Hz (*arrow*). The discharge continues with a slight diminution in frequency. **B:** As the seizure continues, the frequency of the discharge gradually slows, and the seizure terminates with a series of slow waves (*arrow*), seen best in the channels in the lower half of the page.

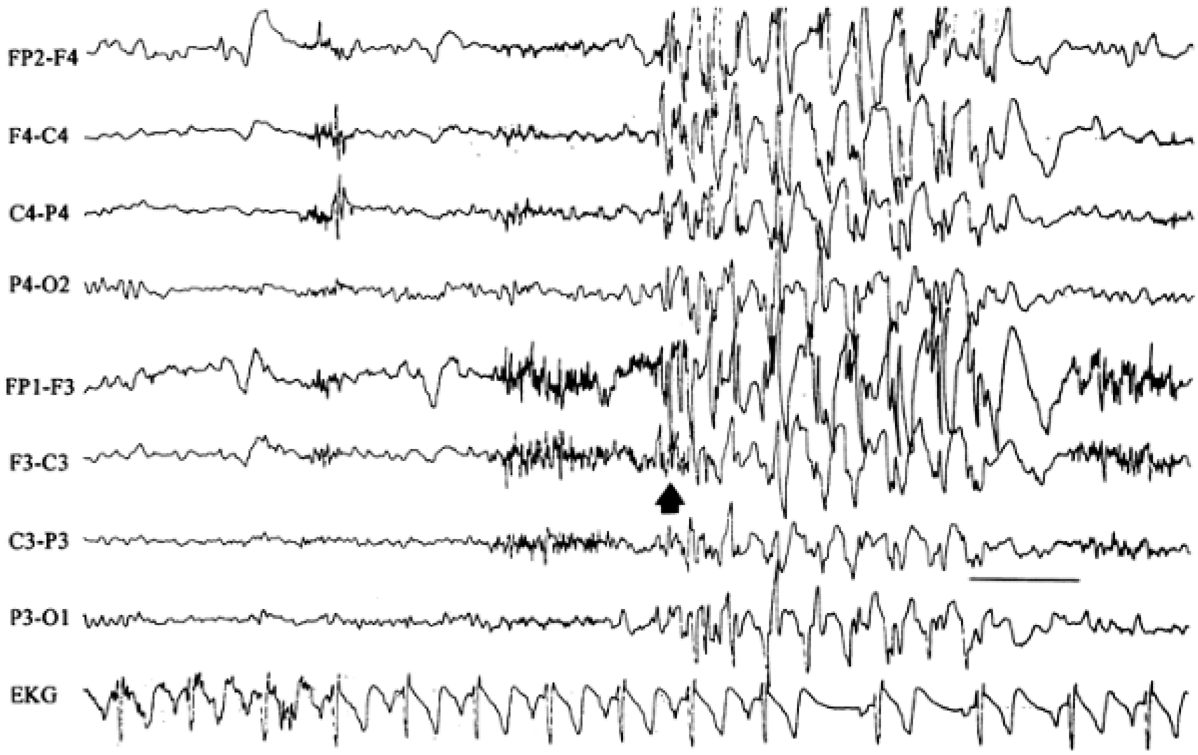

FIGURE 14. Atypical absence seizure. This brief seizure begins with a burst of generalized polyspikes (*arrow*) that are interrupted at irregular intervals by slow waves. This seizure lacks the regularity of the preceding absence seizure (Fig. 11), with its machine-like spike-and-wave repetition rate.

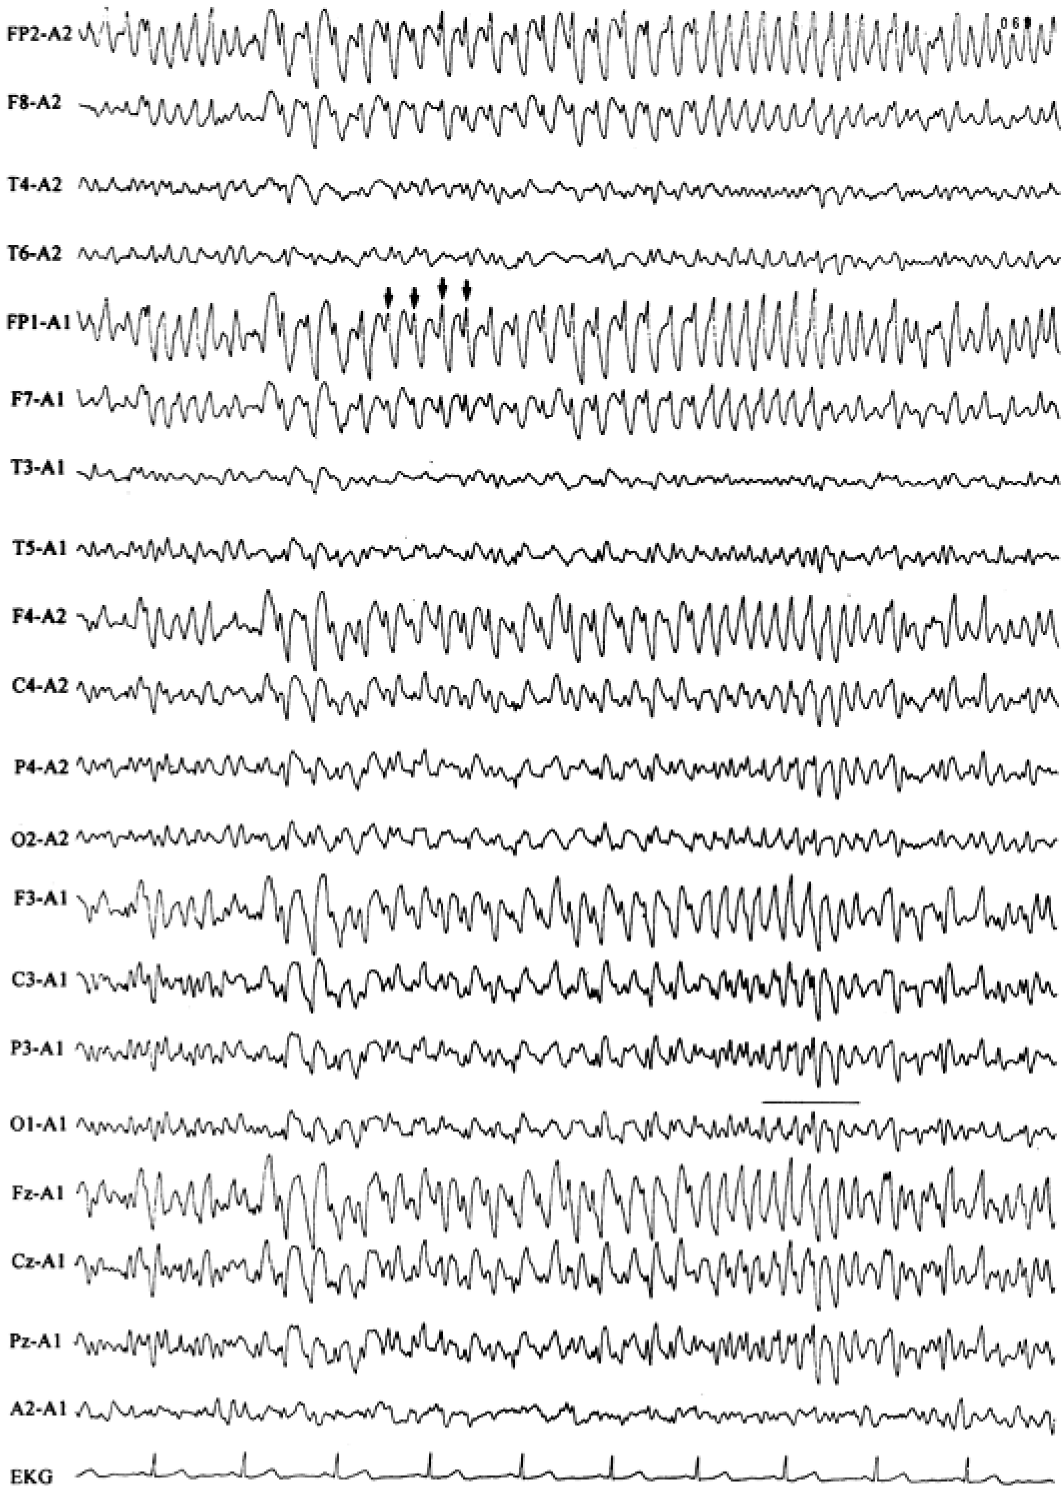

FIGURE 15. Continuous spike-and-wave state (absence status; spike-wave stupor). Spike-and-wave discharges at 4 Hz occupy part of this page (arrows highlight the spikes), whereas rhythmic theta at approximately 5 Hz predominates at other times.

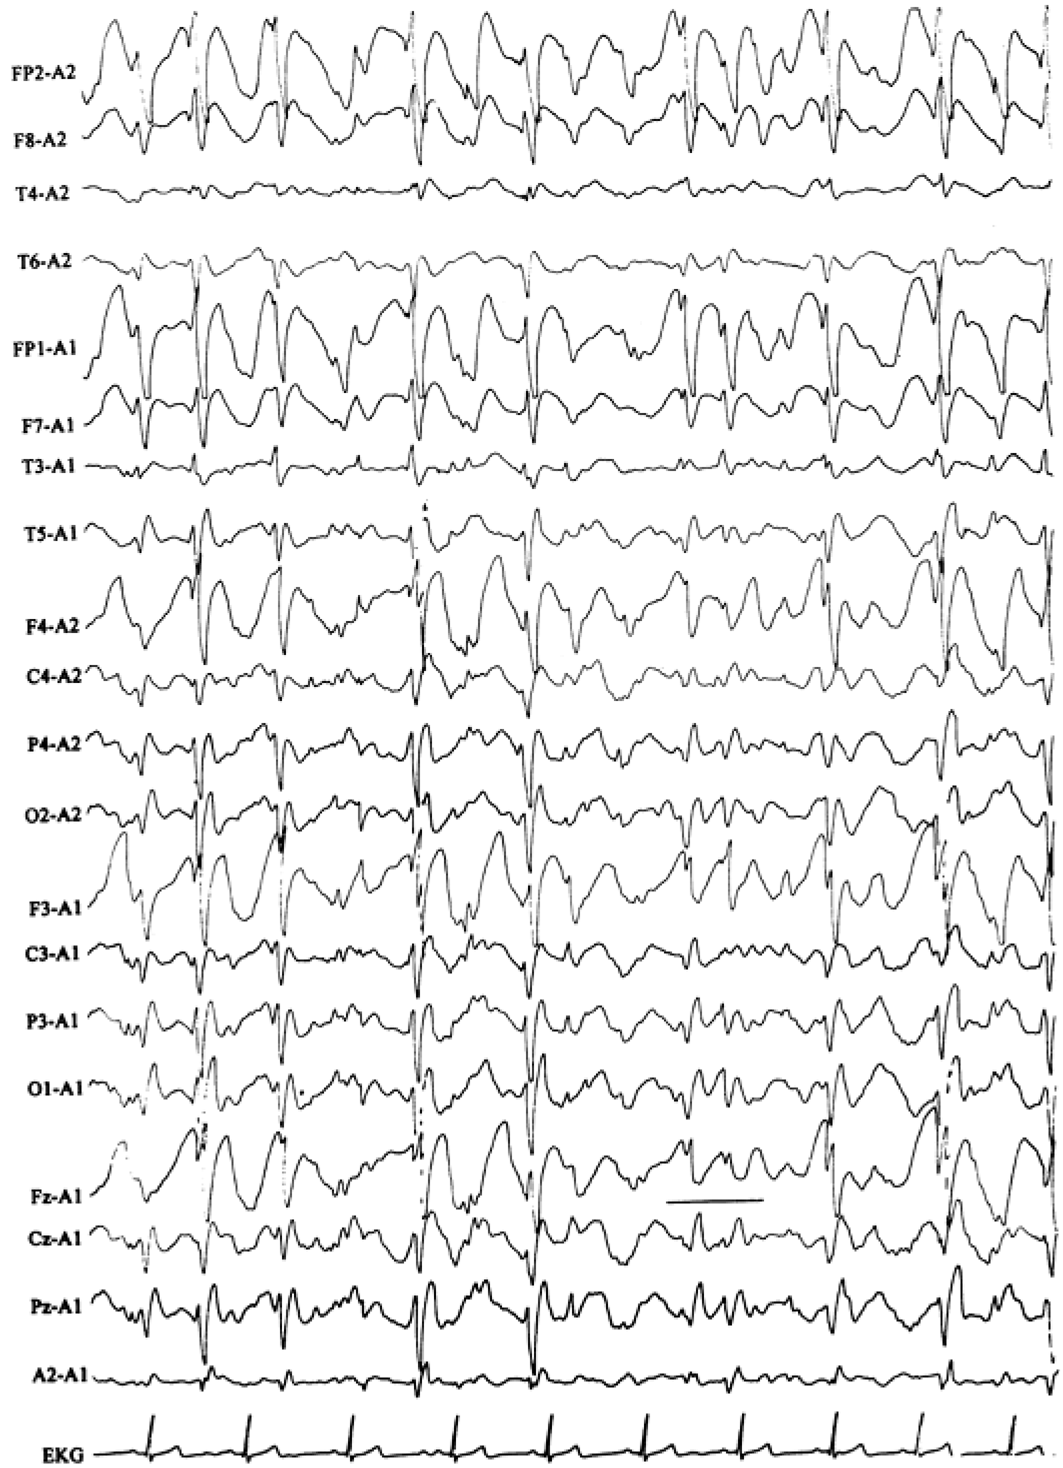

FIGURE 16. Interictal electroencephalogram from a patient with symptomatic generalized epilepsy. This shows high-amplitude generalized slow spike-and-wave discharges arrhythmically and at 1.25 to 2.0 Hz superimposed on a diffusely slow background.

Limitations of Electroencephalographic Recording

Seizures often produce abnormal movements such as blinking, chewing, jerking, and stiffening, among others. These movements can obscure portions of the EEG recording and sometimes may render an EEG uninterpretable. Scalp EEG suffers from other limitations. When recording from scalp electrodes, the EEG signal is filtered variably, depending on frequency (fast frequencies are attenuated more than slow frequencies);

spatial signal averaging takes place; volume conduction occurs; and signals from perpendicularly oriented superficial cortex predominate.[52] To be visible with scalp electrodes, a large volume of cortex must display synchronized activity. The scalp and skull serve as spatial averagers, further hindering EEG interpretation. In addition, deep cortex (e.g., interhemispheric, basal frontal, temporal, and occipital cortex) is often too distant for scalp electrode detection of potentials. Finally, the orientation of the dipole in EEG is critical, so that only orthogonally oriented potentials are visible.[52] Consequently, the standard scalp EEG may record from as little as one third of the cortex. For all of these reasons, many EEG events, including some interictal discharges and seizures, do not appear in the scalp EEG.

Using intracranial EEG eliminates muscle and movement artifact, but these electrodes suffer from "tunnel vision." They record from a limited amount of cortex, and the electrode placement biases the results.[27] For example, a seizure can be localized only to the cortex in which electrodes have been placed; because it is impossible to put electrodes everywhere, mislocalization must occasionally occur.

Enhancing Seizure Occurrence

Because seizures usually occur infrequently and unpredictably in most people, the EEG must often be recorded for a long time before a seizure occurs. Certain methods can be used to increase the likelihood of seizure recurrence. Stress, either emotional or physical (e.g., sleep deprivation), sometimes helps to

bring on a seizure. Anticonvulsant medication taper more reliably induces seizures, so this is commonly employed. This is safest when reserved for the inpatient setting. It should be performed cautiously to avoid status epilepticus and secondarily generalized seizures.

Neonatal Seizures

The behaviors and activities of the newborn infant are regulated by a variety of innate neurobiologic mechanisms that govern the natural rhythms of life. Sleeping, waking, feeding, crying, and quiet visual exploration wax and wane as the infant's biobehavioral state cycles through an orderly progression of predictable state changes that appear and evolve as the nervous system matures from the preterm to the term infant and beyond. Healthy newborn infants possess an inherently modest repertoire of motor activities and behaviors commensurate with their limited maturity. There are also a number of paroxysmal behaviors that the healthy newborn can display, such as tremors, jitteriness, benign apnea-bradycardia, rapid eye movement sleep activities, and startles. These arise suddenly and unexpectedly against the background of the normal unfolding of the activities and behaviors dictated by the infant's biobehavioral state. Neurologically compromised neonates may also display an assortment of abnormal paroxysmal postures, movements, or behaviors that must be distinguished from their innocent counterparts.

Neonatal seizures are a common phenomenon encountered in the care of the newborn infant.[3,15,17,73,74] Historically, neonatal seizures were diagnosed on clinical grounds alone and were classified by their most visually conspicuous features as subtle, clonic, tonic, myoclonic, or autonomic. In more recent times, there has been a growing appreciation of the limitations of diagnosing neonatal seizures on clinical grounds alone and an increased recognition of the role of EEG in confirming and characterizing epileptic-based seizures in the newborn infant.[22,36,41,51,74] Specifically, not every clinical "neonatal seizure" is simultaneously accompanied by a coincident electrographic seizure, and, conversely, many electrographic seizures recorded in the newborn arise subclinically.[13,18,48,77] Such occult electrographic seizures, those subclinical electrographic seizures unaccompanied by simultaneous clinical seizures, constitute a significant fraction of recorded electrographic seizures.[77] Furthermore, there are common circumstances in the newborn nursery in which the use of neuromuscular blocking agents such as pancuronium bromide (Pavulon) renders the patient clinically neurologically unassessable due to the iatrogenic paralysis. EEG examinations performed to provide a measure of neurologic assessment during therapeutic paralysis may capture electrographic seizures that were clinically unexpected.[28] Consequently, the electroencephalographer must be familiar with the basic characteristics of the electrographic neonatal seizure (ENS) and alert to their possible presence when reviewing neonatal EEGs performed for any reason.

Common Scenarios to Recording Neonatal Seizures

The majority of clinically witnessed neonatal seizures appear in the acutely ill newborn.[43,45,58] As such, they are examples of *reactive* seizures that arise in the context of intercurrent medical or neurologic illnesses that provoke the many signs of an acute neonatal encephalopathy. In this context, EEGs may be performed to provide a measure of neurologic assessment because the degree of EEG background abnormality may serve as a useful, accurate barometer of neurologic outcome.[2,5,14,30,33,39,50,54,56,63,64,70,71,72] EEG

P.838

examinations may also be conducted to understand the nature of clinically witnessed neonatal "seizures."[19] That is, the EEG may confirm whether certain abnormal clinical paroxysms ("seizures") are founded on a specific epileptic mechanism.[48] Clinical "seizures" that are uniquely time-locked to electrographic seizures thus may be regarded as examples of "*epileptic*" neonatal seizures.[76] On the other hand, clinical "seizures" that do not coincide with electrographic seizures may be regarded as a type of "*nonepileptic*" seizure, including so-called automatisms, brainstem release phenomena, and other poorly understood abnormal reflex behaviors.

Infants who require the use of neuromuscular blocking agents are usually acutely ill and may have experienced significant episodes of hypoxia or ischemia.[28] Because the clinical neurologic examination is unfruitful in this setting, the EEG is employed to measure the reaction of the cortex to the illness at hand. Electrographic neonatal seizures are not uncommon in this setting and must be carefully searched for in the interpretive process.

Although the majority of neonatal seizures are provoked by intercurrent illness, there are examples of *very early onset epilepsy* in the sense that these conditions feature unprovoked seizures in the absence of an underlying trigger. These infants are prone to recurrent attacks of epileptic seizures due to a persistent underlying "lowered seizure threshold." For example, certain forms of cerebral dysgenesis may announce their presence, with or without accompanying outward somatic signs of multiple congenital anomalies, by unprovoked neonatal seizures. Thus, this version of the "well neonate with seizures" may actually be harboring pachygyria or a form of holoprosencephaly. Some neurocutaneous disorders may also feature very early onset seizures. When tuberous sclerosis penetrates the individual deeply and severely, the result can include conspicuous neonatal neurologic dysfunction and seizures from the earliest hours of life. The organoid nevus syndrome, another neurocutaneous disorder, also possesses a very broad spectrum of penetrance and may appear in an extreme form in the neonatal period featuring neonatal seizures.

There are two dramatic but relatively rare epilepsy syndromes of the neonate that merit special mention.[1] Both are regarded as examples of "malignant" forms of epilepsy, in that they feature multiple types of refractory and debilitating seizures in the setting of pronounced psychomotor retardation and may lead to early death. Early myoclonic epileptic encephalopathy (EMEE) is characterized by early-onset

P.839

unprovoked neonatal seizures, stimulus-provoked myoclonus, other clinical seizure types, bulbar dysfunction, and a very abnormal EEG background. The syndrome known as *early infantile epileptic encephalopathy* (EIEE) features tonic seizures as the core clinical ictal phenomenon, a markedly abnormal EEG background, early transformation into a form of infantile spasms with hypsarrhythmia, and a possible association with overt cerebral dysgenesis. There are other examples of less notorious unprovoked neonatal seizures, such as *benign familial neonatal seizures*, that also represent a kind of neonatal-onset epilepsy and underscore the rich variety of disorders that may rise to the surface in life's earliest moments.[4,44,60]

Ideally, the neonatal EEG should be interpreted with this general background of information at hand. Furthermore, knowledge of the physical condition of the patient is an immense aid to an understanding of the confounding influences of rhythmic artifacts, such as mechanical ventilation, extracorporeal membrane oxygenation (EMCO), or even the nurse "patting" the baby.

P.840

Background Cerebral Electrical Activity

In neonatal EEG, the background activity refers to the ongoing, moment-to-moment unfolding of the electrographic activities and rhythms generated by the cerebral cortex. The EEG background changes substantially, depending on the infant's biobehavioral state. Thus, there are dramatic differences in the visual appearance of the neonatal EEG, depending on whether the infant is awake, dream sleeping, or quietly sleeping. This is no different in principle from the more familiar EEG state changes recorded in adults or older children.

The EEG background may also be affected by the presence of any disorder that disturbs the functional integrity of the central nervous system (CNS). During the evolution of conditions such as bacterial meningitis, the degree of EEG background abnormality may range from a minimal amount to an advanced abnormal state, such as burst-suppression or isoelectricity. Several schemes for organizing observed EEG background abnormalities have been suggested, but they differ somewhat on exact classifications.[14,39,50,64,74,77] However, most distill the wide range of observed findings into the broad categories of “normal to mildly abnormal,” “moderately abnormal,” and “markedly abnormal.” Although these broad groupings are not very specific from the viewpoint of the etiology or identity of the disorder, they are useful for gauging the severity of the impact that the disorder has imposed on the CNS.

Electroencephalographic Seizures

The EEG background is the stage on which the *process* of the electrographic seizure conducts itself. The electrographic seizure is an *event* in which abnormal EEG patterns and waveforms evolve in time and location. In many patients, it is also possible to describe the *behavior* of electrographic seizures. In this sense, many infants' seizures behave as a *series* of relatively brief (i.e., a few minutes) attacks separated from each other by variable-length periods of interictal EEG background.[12] Because most neonatal seizures arise in acutely ill, encephalopathic infants, it is quite common to encounter abnormalities of the interictal EEG background, ranging in degree from minor to severe.

An electrographic seizure is a discrete event with a definable beginning, middle, and termination.[12] Consequently, it can be considered as a transient phenomenon that can wax and wane. However, in the field of neonatal EEG, the concept of so-called EEG transients actually refers to a wide array of specific, short-lived, named waveforms in the premature and term neonate. Delta brushes, rhythmic temporal theta activity, encoches frontales, positive rolandic sharp waves, and positive temporal sharp waves are all—strictly speaking—examples of EEG transients that convey markedly different kinds of information about the functional condition of the cortex.[6,10,11,16,34,46,53] The distinction between the electrographic seizure as a transient event and these other individual waveforms as EEG transients should remain in mind.

There is a variety of descriptors that helps to define and quantify the ENS, including location(s), duration, morphology, and amplitude. These attributes are distinctive in the newborn, but some have analogous counterparts in the “mature” EEG.

Location

A fundamental observation about ENSs is that they essentially always arise *focally*. The ENS is, by its nature, a partial seizure. Although it is true that generalized, synchronous and symmetric, spike-and-slow wave discharges have been rarely encountered, they are an extreme exception to the rule. The exact site of origin of an individual ENS may vary within an individual. The midtemporal regions (T3 and T4) are probably the most common locations of origin of ENSs. Certainly, ENSs have been recorded from all brain regions, and so care must be exercised to ensure that the chosen neonatal montage is spatially comprehensive, including sampling from the midline vertices (Fz, Cz, and Pz).

Electrographic neonatal seizures that always originate from the same, single location are called *unifocal*. There is usually no special information conveyed by the knowledge of the location of onset of such a single focal seizure. It does not necessarily indicate the existence or location of a restricted brain abnormality. However, if repeated ENSs always arise from the same single location, it is fair to question whether a focal or lateralized structural CNS lesion exists. For example, in the setting of an embolic neonatal stroke, a brief wave of repetitive seizures often arises, such that all of the individual electrographic seizures have their spatial origin in the same location. In other neonates, multiple seizures originating from different brain regions are recorded, illustrating the case of “multifocal” onset seizures. For the purpose of an operational definition, the description *multifocal* should require at least three independent generators involving both hemispheres. For example, the locations Fp3, O1, and T4 satisfy the criteria for “multifocality.”

Electrographic neonatal seizures are not always spatially stationary. Once they arise, they may leave their site of origin and migrate to remote locations, even to the contralateral hemisphere. This is commonly matched with an evolution of the morphology of the ictal waveforms as they progress from one location to another. Some neonates display the interesting phenomenon of simultaneous but independent focal electrographic seizures. In this instance, careful examination of the tracing shows two or more coincident electrographic seizures arising from independent foci and evolving at their own pace.

Duration and Temporal Profile

The typical duration of an individual ENS is about 2 to 3 minutes.[12] There is much variability in seizure duration within and between individuals, but most are relatively brief. Occasionally, a single, extremely long, uninterrupted seizure is encountered, such that the strict conventional definition of electrographic status epilepticus (i.e., ≥30 minutes) is satisfied. The minimal duration of an event that qualifies as an electrographic seizure is debatable.[65] Certainly, many agree that a single, sharp EEG transient, even if it implies a “lowered seizure threshold,” would not be adequate to be designated as an actual seizure. How long does the event have to last to be considered a seizure? In common practice, a minimum duration of 10 seconds has been specified in several published studies, but this duration

P.843

was chosen as much for convenience as for any substantial neurobiologic reason.[12,63,65]

Because of the variable and often very high rate of subclinical electrographic seizures in the neonate, the true temporal profile of neonatal seizures' abundance as a function of time has not been studied by clinical observation. Unfortunately, there has been no universal definition or criteria for neonatal *status epilepticus* adopted into general use by neonatal neurologists or electroencephalographers. The usual definition of status epilepticus requires an uninterrupted seizure lasting at least 30 minutes or recurrences of seizures between which the patient's mental status remains abnormal. Surely, determination of mental status in the neonate is elusive and not a suitable clinical endpoint for the definition of status epilepticus. Furthermore, by their nature, most ENSs tend to behave as relatively brief but recurrent events. One study offered a reasonable but arbitrary definition of electrographic status to be present if 50% or more of the tracing was occupied by an electrographic seizure. Status was present, by that definition, in 27% of the 81 infants studied.[31] Because most examples of neonatal

P.844

seizures arise in acutely ill infants, it is common to observe an initial burst of seizures in the first 2 to 3 days of the illness.[8,32,35,75] The seizures gradually wane (usually in parallel with the administration of an antiepileptic drug [AED]) during the first week of the illness and eventually terminate completely. It is certainly true that many of those affected eventually develop chronic postnatal epilepsy in the conventional sense, but the acute seizures tend to disappear, even after an initially explosive beginning. Consequently, a significant number of critically ill neonates are actually experiencing electrographic status epilepticus for days, perhaps at a time when they have just suffered a serious acute encephalopathy. There is no suitable information on the natural history of neonatal seizure abundance during the first days and weeks of an acute illness. This would require continuous video-EEG monitoring for many days without the administration of an AED. Instead, most current data are culled from much briefer samples of video-EEG recordings obtained randomly in the early hours of the illness. The emphasis should remain on the fact that although the term *neonatal seizures* is commonly used, the real situation is actually “electrographic status epilepticus” in many more patients than is widely appreciated.

P.845

Morphology

The morphology of the ENS is noted for its rich variety. Ictal waveforms can assume many appearances, ranging from simple sinusoidal waveforms of any frequency (i.e., beta, alpha, theta, or delta activity) to complex, bizarre ictal patterns.[80] One of the hallmarks of the genuine article is the *evolution* of morphologies demonstrated within an individual seizure or between seizures. In contrast, one of the clues that a suspected “electrographic seizure” is artifactual is the recognition that the morphology is fixed and invariant. Such monotonous, albeit rhythmic, patterns commonly arise from noncerebral sources such as repetitive electrode “pops” (capacitance discharges), pulse artifact, ballistocardiographic effects, mechanical pumps, respirators, or even “patting” the baby.

Amplitude

The typical ENS evolves in amplitude as well as in waveform morphology. It is common for the seizure to first appear at relatively low voltage and gradually to increase as the event unfolds. In contrast, the termination of a seizure may be abrupt, and the voltage may precipitously truncate from a high value to zero. On the other hand, some seizures gradually wind down and show an orderly progression of lower voltages until their final termination.

Examples of Neonatal Seizures

The principles that describe the usual properties and behaviors of the ENS can be illustrated by several specific examples. FIGURE 1 is a rhythm strip that features a number of electrographic properties of a typical ENS. The most conspicuous feature of this tracing is the presence of two simultaneous but independent ENSs. In the left midtemporal and occipital regions (T3 and O1), the beginning of one ENS is shown (*arrow*) as surface-negative, low-voltage, sharply contoured slow waves that quickly evolve in frequency, amplitude, and waveform morphology. Notice that the waveform morphology becomes more complex with the passage of time, especially in channel T3-O1, and that the frequency slows as the amplitude

progressively builds, a very common property of the ENS. At the same time, another ENS is in progress that is most conspicuous in the right midtemporal area (T4) (*double arrows*). The second rhythm strip on the same patient at a slightly later time (Fig. 2) shows the last 6 seconds of an ENS at T3 (*arrow*), whereas periodic lateralized epileptiform discharges (PLEDS) appear invariantly at T4-C4 (*double arrows*). Careful inspection of their homologs (T3-C3) show faint, low-amplitude, surface-positive potentials that are time-locked to the main negative deflections, creating a positive–negative dipole across the cortical surface. Surface-positive EEG activity can appear in a variety of forms in the neonate but is rarely encountered in EEGs recorded from more mature individuals. In general, PLEDs are not considered to be an electrographic seizure per se in neonatal electroencephalography but convey the same connotation as PLEDS in older individuals, namely, the presence of a relatively acute, destructive CNS lesion.[47,62]

Another example of an ENS is provided in FIGURE 3 to show an evolving complex waveform at C3-T3 (*arrow*). As the seizure progresses, the ictal pattern becomes progressively more complex, and the seizure converts polarity from surface-negative to surface-positive. Notice also that the seizure is confined to the left hemisphere. The EEG background in the right hemisphere is largely unperturbed by any seizure activity but does show markedly excessive discontinuity and a paucity of richness of the normal background patterns and rhythms anticipated in healthy neonates of this conceptional age.

Partial Seizures in Children and Adults

Seizures Recorded With Scalp Electrodes

Many of the basic definitions and rules hold true once an individual has matured past the neonatal stage. Seizures still represent paroxysmal discrete events with beginnings, middles, and ends, although the duration might sometimes be measured in hours or days rather than in seconds or minutes.

Temporal and spatial evolution of the ictal discharge is usually seen, and seizures may give rise to changes in either behavior or perception, or may remain subclinical and asymptomatic. Seizure onset may be described as discrete (or focal), regional, hemispheric, or nonlateralized. Discrete (focal) onset is that confined to a single scalp electrode or to one or two intracranial electrode contacts; these imply a highly restricted area of seizure origin. Regional onsets when using scalp electrodes refer to a lobar onset but with a spatial extent of several centimeters. Hemispheric onset refers to an ictal discharge that is clearly lateralized but whose broad voltage field maxima make further localization impossible. A nonlateralized seizure is one in which ictal discharges appear at seizure onset in both hemispheres, with approximately equal vigor in the scalp EEG or simultaneous onset in both hemispheres with intracranial EEG, without regard for amplitude or frequency of the ictal discharge.

A variety of EEG features are present during seizures that aid in classifying and defining them.[24,26,68] Partial seizures have a number of distinctive characteristics. Often, a focal onset to the seizure is seen in the scalp or intracranial EEG, but this is not a constant feature. Many partial seizures propagate so rapidly that the initial detection of localized ictal activity with conventional methods is not possible; in these cases, the earliest observed ictal changes may be widespread over either an entire hemisphere or within both hemispheres. Nonetheless, the pattern of electrical activity during the seizure usually provides a clear sign that the seizure is partial and not generalized, as shown in this section. Partial seizures may begin with ictal discharges of any frequency (delta, theta, alpha, or beta) and are sometimes heralded by either an increase or a decrease in interictal spike rate.[26,79] The initial ictal activity may be focal or diffuse. The typical pattern is one of waxing and waning frequencies, subtle or prominent lateralized amplitude maxima during parts of the seizure, and postictal slowing of background frequencies.

Simple partial seizures have a restricted field that favors detecting a localized abnormality. However, most do not appear in the scalp EEG[21,40,69] because the summated background activity tends to overshadow the small fields of such seizures. Intracranial EEG has a higher yield, yet nearly half of simple partial seizures are not detected with modern techniques.[69] FIGURE 4 shows a simple partial seizure from the temporal lobe that does appear in the extracranial EEG. This has many of the characteristics of a partial seizure. It begins focally in one temporal lobe, with sharp waves that evolve in frequency while remaining confined to one hemisphere. It is also relatively brief—most simple partial seizures last less than 1 minute.

In contrast, complex partial seizures typically show a more complicated picture.[7,24,79] They nearly always spread to the contralateral hemisphere, so that bilateral ictal changes are seen, usually last longer (often 2–3 minutes), display more spatial evolution, and more often produce postictal slowing. FIGURE 5 shows a well-localized temporal lobe complex partial seizure. This begins with an alpha-frequency discharge, and although it would be considered localized and discrete, it is obvious that the contralateral hemisphere contains abnormal frequencies indicative of subtle ictal invasion. Very often, by the time the scalp EEG shows the ictal discharge in a temporal lobe seizure, the seizure has spread beyond the hemisphere of origin.[67] The characteristic evolution of frequencies occurs in this seizure. The lateralized postictal slowing is also a common feature of partial seizures. A relatively slow frequency at onset (in theta and slow alpha ranges) is more characteristic of temporal lobe seizures of mesial temporal origin. In contrast, neocortical seizures often start with higher frequency activity in the alpha or beta bands in the scalp EEG.

Figure 6 shows a complex partial seizure with a subtle ictal onset and prominent secondary distant propagation. The seizure begins with low-amplitude alpha-frequency activity in the left occipital lobe (the source of seizures in this patient). Once the seizure spreads anteriorly to the temporal lobes, a more vigorous ictal discharge pattern appears, with prominent bilateral temporal activity, maximal on the right. This temporal lobe discharge appears at a different frequency than the

simultaneously occurring occipital discharge, demonstrating that the different lobes of the brain may seize somewhat independently during a seizure. Had the early occipital activity not been noted, temporal lobe localization of the seizure might otherwise have been suggested. Other complex partial seizures differ from the two previous examples in that the initial activity is not well localized at onset. The same type of rhythmic activity, although present, is bilateral in distribution, without clear laterality or with only subtle asymmetry. The lack of clear localization in the ictal scalp or intracranial EEG recording simply reflects the technical limitations of current of EEG technology and does not preclude the presence of a focal restricted epileptogenic zone. The EEG does not always permit the precise demarcation of the time of seizure onset, and EEG patterns during seizures may not always appear to be "ictal." Moreover, the scalp EEG may sometimes suggest misleading localization of the site of seizure origin.

Figure 7 illustrates these points. It shows cessation of actively firing interictal sharp waves before the seizure starts, but the seizure appears to develop gradually over several seconds without a clear-cut demarcation between interictal and ictal states. The ictal activity, once apparent, phase-reverses at F4, suggesting right frontal localization. As this seizure progresses, the conspicuous ictal rhythmic discharge (Fig. 7B) is replaced with irregular delta and theta activity (Fig. 7C) that is not obviously ictal, although subsequent pages show more rhythmic and clearly ictal activity. This patient was ultimately studied with intracranial electrodes, which showed seizure onset in the left frontal lobe; resection of that area eliminated seizures. Consequently, the early right frontal localization suggested by the scalp EEG was misleading. It is important to note that this "localized" activity was present several seconds after seizure onset and reflected ictal propagation.

The variability of seizure propagation is further illustrated in FIGURE 8. This seizure begins in the left temporal lobe. After approximately 10 seconds of a left temporal ictal discharge, the seizure terminates there. However, the ictal activity then continues in the right temporal lobe, to which the seizure had spread before stopping on the left side. This "ping-pong" effect is more often seen with intracranial EEG recording and further emphasizes the caution with which scalp seizure patterns should be viewed.

As noted, the EEG may not always show an obvious ictal discharge during portions of some seizures. During other partial seizures, no conspicuous ictal discharge may ever be seen, even though a localized abnormality is present. Epilepsia partialis continua serves as a prototype for this, with only irregular slowing in the EEG, despite ongoing focal motor seizures. FIGURE 9 demonstrates this finding. The clinical manifestation in this patient was left facial twitching, yet irregular, semirhythmic delta and theta discharges were the sole EEG manifestations. The segment shown here was taken from a time when the delta activity was at its most rhythmic, yet it still never exhibited temporal or spatial evolution, and the rate of twitching never correlated with EEG frequencies.

Seizures Recorded With Intracranial Electrodes

These are discussed more fully in Chapter 171 and are the subject of a comprehensive review elsewhere.[66] In addition to conventional visual analysis, computerized techniques have been applied to the intracranial EEG to aid in its analysis.[20,29] A few examples of seizures recorded with intracranial electrodes are shown here to further illustrate some key points. As noted previously, intracranial electrodes are less subject to physiologic artifact and, being closer to the source, show a fuller picture. Intracranial electrodes have much greater spatial resolution and can demonstrate a highly localized seizure onset if one is present. In FIGURE 10A, the seizure begins focally (discrete onset) in the right amygdala, without concurrent ictal discharges 5 mm distant in the presubiculum or in other hippocampal areas or parahippocampal gyrus. FIGURE 10B shows a regional seizure onset, with more widespread ictal spiking in amygdala and hippocampus. Although it is not restricted to a few millimeters like the previous example, this seizure is still localized far more accurately than would be possible with extracranial electrodes. Many patients have well-localized seizures like these, yet their scalp EEG may be nondiagnostic.

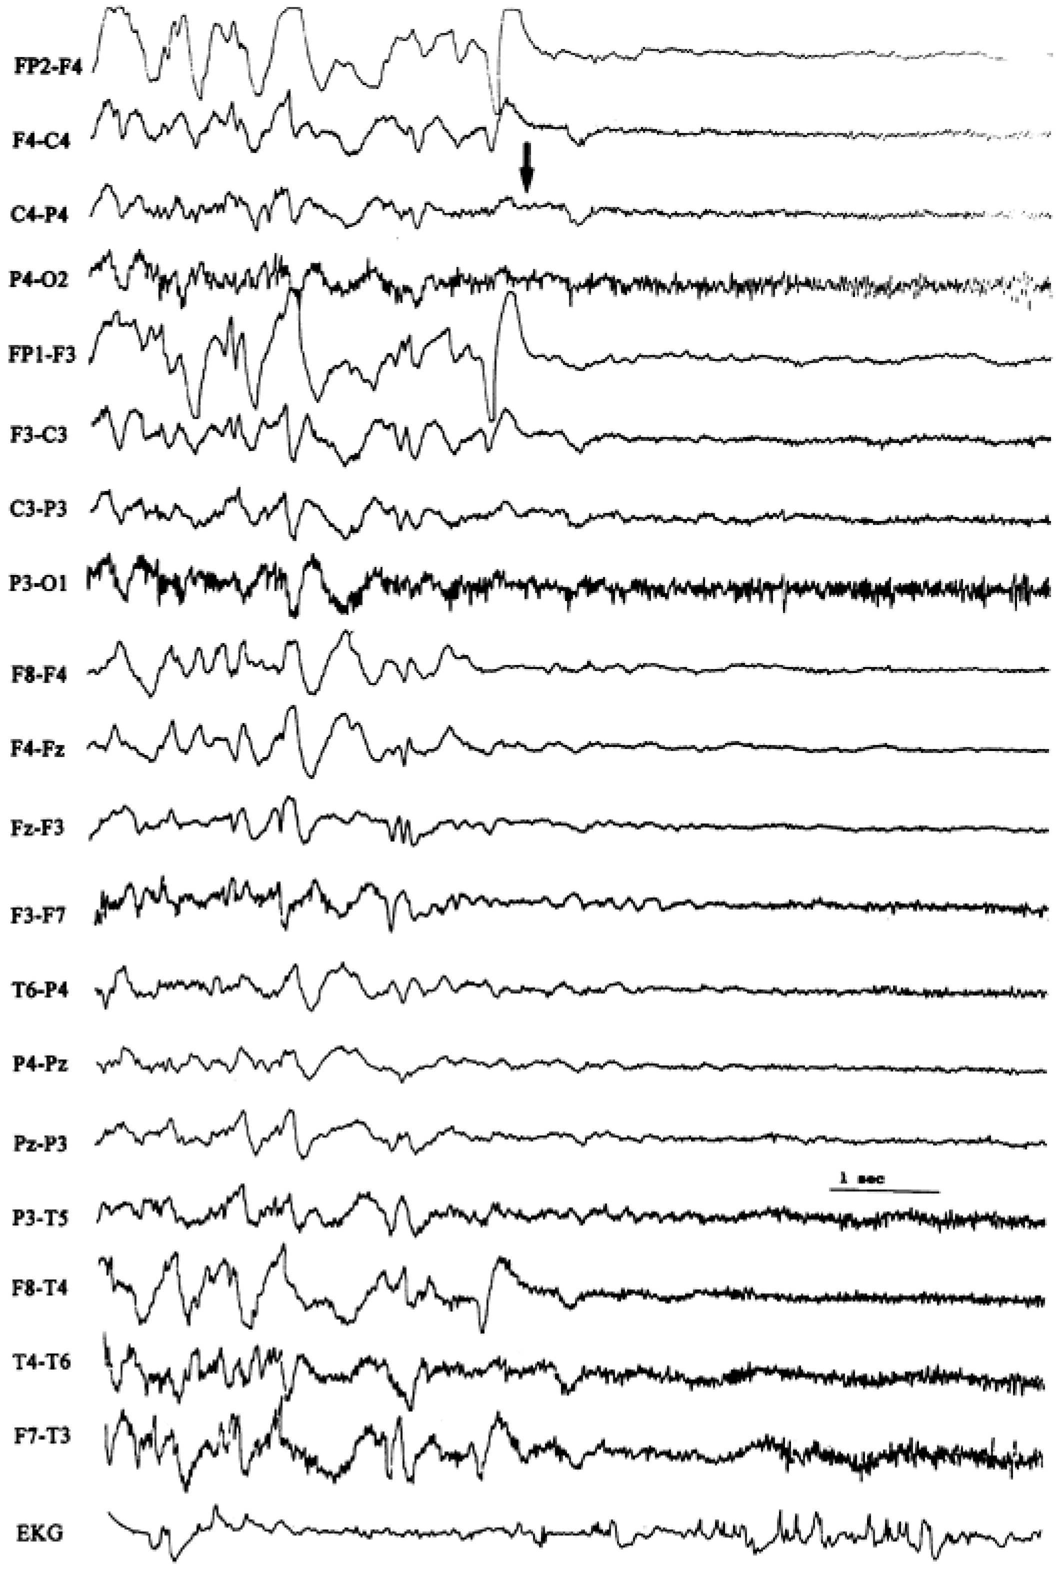

FIGURE 17. Atonic seizure characterized by sudden loss of posture and falling. The electroencephalogram shows a diffuse attenuation (*arrow*) following an eye blink. The amount of muscle artifact is somewhat reduced compared with that present before the seizure, and the accompanying clinical behavior was a loss of postural tone. It should be noted that a complete loss of scalp muscle activity is not required to diagnose an atonic seizure because tone in postural muscles may not mimic that of all scalp muscles.

Figure 11 shows a simple partial seizure, recorded with intracranial and extracranial electrodes. The EEG shows the early and clear localization made possible by intracranial EEG

P.850

recording. In contrast, the extracranial derivations (midtemporal and sphenoidal leads) contain a large amount of muscle artifact, which hides the first half of the seizure. Moreover, the evolution of the ictal discharge can be readily seen without interference from muscle artifact or the scalp's spatial averaging of extraneous potentials. This seizure also highlights the difficulty of determining precisely when some seizures begin. Standard interpretation would place seizure onset in FIGURE 11A at the time when the rhythmic spiking first appears because the background was previously quiescent. This type of activity in other circumstances, however, might be indistinguishable from interictal spike discharges, and the development of fast activity several seconds later might be considered firmer evidence of a seizure. This figure shows the progressive changes in frequency and amplitude of the electrographic discharge. Note the similarities of the EEG activity in this seizure to the pattern of muscular contractions in FIGURE 12. The profound flattening in the EEG in the anterior and middle pes hippocampus commonly follows even brief seizures and usually lasts less than 1 minute.

Generalized Seizures

Generalized seizures involve large parts of both hemispheres more or less at once and do not have a localized onset. They presumably reflect a generalized disturbance of cortical function, either on a genetic basis or from diffuse injury (discussed elsewhere). Several distinct EEG patterns appear in generalized seizures that are related to the underlying cause of the epilepsy. Seizures arising in patients with idiopathic generalized epilepsy usually begin with generalized spike-and-wave discharges or a burst of generalized polyspikes. Patients with symptomatic generalized epilepsy have a broader variety of ictal onset patterns, although a generalized spike and slow wave, generalized slow wave, generalized fast activity, or generalized attenuations

P.851

are usually seen. Subsequent ictal EEG findings depend on the seizure type. During absence seizures, the spike-and-wave pattern continues; during tonic seizures, the generalized fast activity persists. Tonic–clonic seizures show an evolving spike pattern consonant with the muscular contractions.

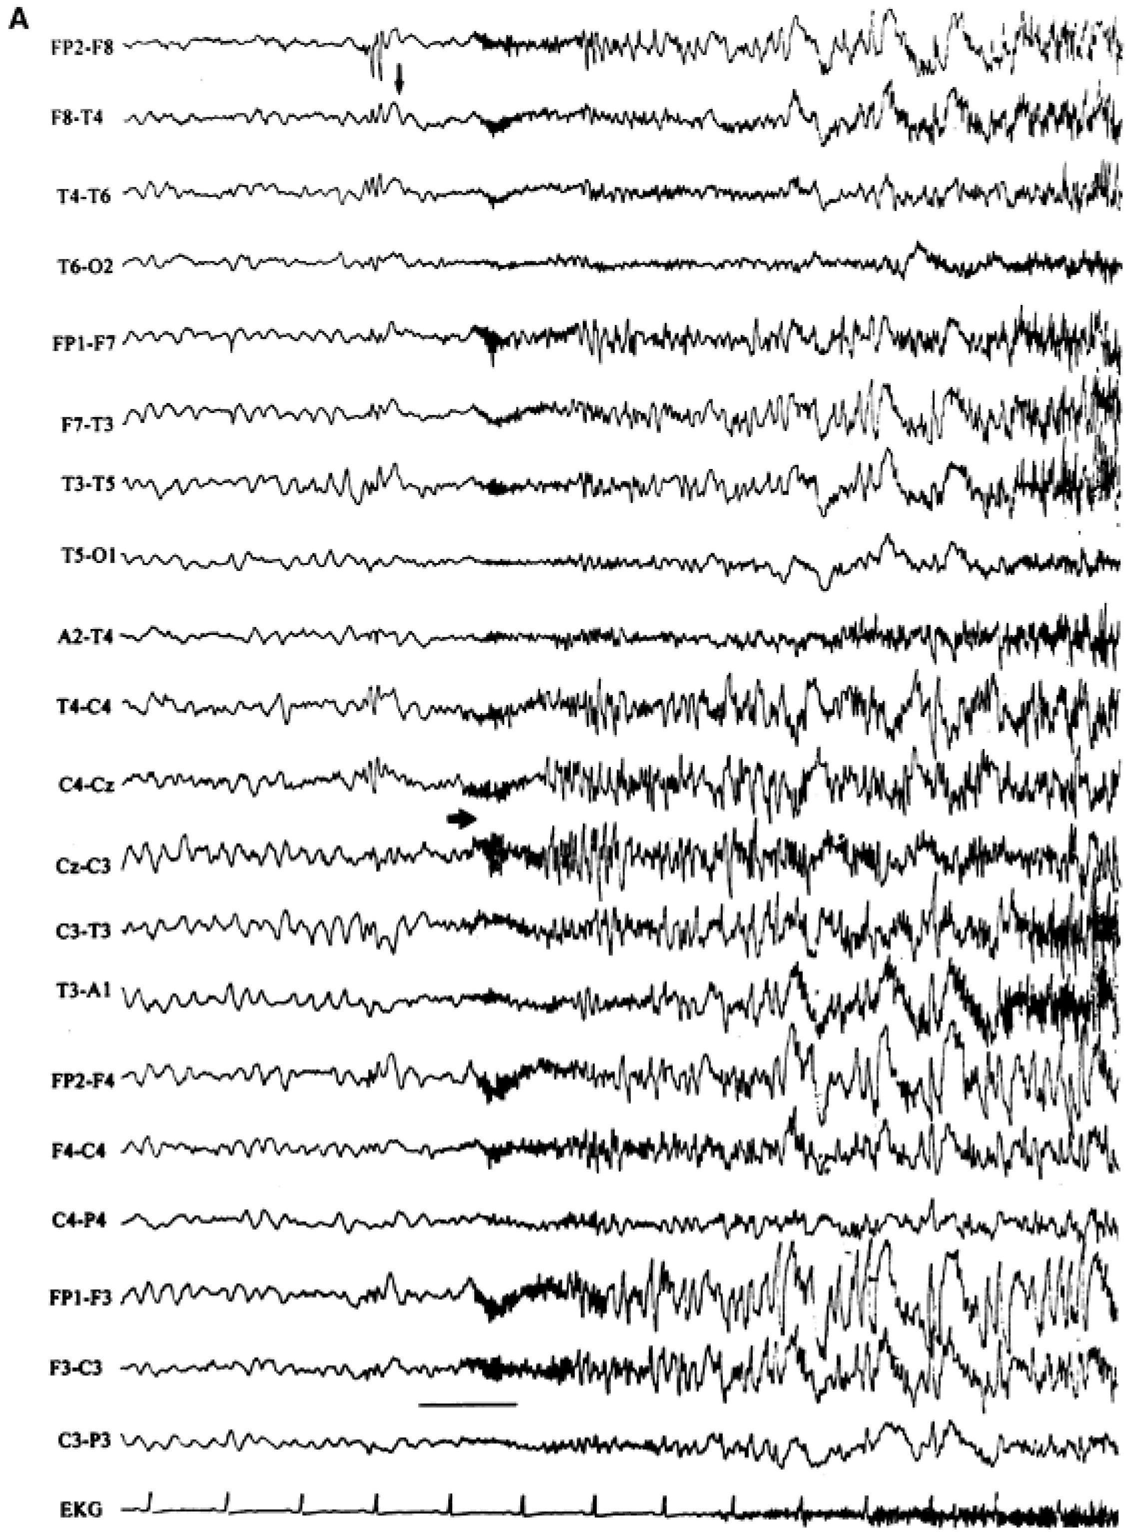

FIGURE 18. Tonic seizure. **A:** The seizure begins with a sudden amplitude attenuation (*small arrow, top*), which lasts <1 second. An immediate buildup of beta activity then occurs (*large arrow, middle*). This progressively increases in amplitude and slows in frequency. Muscle artifact appears in the last 2 seconds of the page. **B:** This page continues where the other stopped. It shows the rapid increase in muscle artifact consistent with a generalized increase in muscle tone. The muscle contraction lasts for approximately 4 seconds, then ceases for 2 seconds. The muscle artifact resumes, but the patient is no longer stiff and begins to move about, although he is confused. The underlying electroencephalographic background shows excess delta at this time, although the large amount of movement artifact hampers interpretation of the record.

Figure 12 shows a typical tonic–clonic seizure in a patient with idiopathic generalized epilepsy with a strong family history of epilepsy. The seizure begins with a generalized spike-and-wave burst that is replaced by repeated polyspike and wave discharges. This is followed by the tonic ictal discharge with continuous spikes. Slow waves of progressively longer duration gradually intrude and interrupt the spikes for the clonic phase of the seizure. The seizure ends with profound background suppression and slowing in both hemispheres. After the first 10 seconds or so, muscle artifact fills the EEG, and cerebral activity cannot be seen. The pattern of muscular contraction is so characteristic of an epileptic seizure as to be diagnostic; this evolution of activity cannot be voluntarily produced.

Absence seizures have varying characteristics.[42,55] Typical absence seizures (Fig. 13) usually begin with a generalized, frontally predominant spike-and-wave discharge at 3.5 to 4 Hz that gradually slows to 2.5 Hz by the end of the seizure.[59] Absence seizures often show increasing spike amplitude in the first two or three discharges, as shown here. Seizure offset, while relatively quick, also often reflects a "build down," with one to three rhythmic slow waves of diminishing amplitude following the last spike discharge. There is no significant postictal slowing of the background after absence seizures, corresponding to immediate regaining of full control of mental faculties. Atypical absence seizures may show somewhat more irregular spike-and-wave or polyspike-and-wave discharges, sometimes at initial higher frequencies. FIGURE 14 demonstrates an atypical absence in a patient with juvenile myoclonic epilepsy, a generalized polyspike initiating the seizure. Myoclonus may also be accompanied by a brief (<0.5 second) generalized spike-and-wave discharge identical to that seen at the start of the atypical absence seizure.

P.852

A less common form of absence seizure is that of the continuous spike-and-wave state. Episodes of "absence status" or "spike-wave stupor"[25,42] occur in the juvenile and childhood absence epilepsies. Patients in this state display impairment of consciousness ranging from stupor to full alertness with only subtle cognitive defects. FIGURE 15 shows the EEG of a patient in a continuous spike-and-wave state who displayed only mild confusion. The EEG oscillated between 4-Hz spike-and-wave and a rhythmic theta state for many hours.

Patients with symptomatic generalized epilepsy and multifocal brain injury often have atonic or tonic seizures.[9] These seizures are usually relatively brief, lasting from 5 to 30 seconds. The interictal EEG in these individuals characteristically shows diffuse background slowing, generalized slow spike-and-wave (frequency <2.5 Hz), and multifocal spikes[9] (Fig. 16). Atonic seizures may begin with a generalized spike or sharp wave (with or without a slow wave), a generalized slow wave, or simply a diffuse attenuation of the background EEG with or without low amplitude fast activity. FIGURE 17 illustrates an atonic seizure, starting with the last pattern, a generalized attenuation without increased fast activity. In contrast, a characteristic feature of tonic seizures is the progressive buildup of generalized fast activity (15–30 Hz), which may be preceded by a spike-and-wave or a slow wave or may appear without antecedent. The seizure is usually followed by a brief period of postictal background slowing. FIGURE 18 illustrates the typical evolution of a tonic seizure, with a progressive increase in amplitude of generalized fast activity and muscle artifact accompanied by the gradual slowing of the frequency of the ictal discharge. The tonic phase may be followed by a brief (10- to 20-second) period of confusion with diffuse background slowing in the EEG or generalized arrhythmic slow spike-and-wave discharges.

Summary and Conclusions

The EEG has enabled us to gain valuable insights regarding the fundamentals of epilepsy and has proven invaluable in diagnosing and treating patients. The ictal EEG remains

P.853

irreplaceable for many clinical questions. However, much remains to be learned, and more investigative studies are needed. Whereas careful EEG studies must still be done, the addition of newer physiologic methods should improve our understanding of seizures and their treatment.

Chapter 75

Electroencephalography in the Intensive Care Unit

Thomas P. Bleck

Lawrence J. Hirsch

Paul M. Vespa

Introduction

Intensive care units (ICUs) employ physiologic monitoring equipment to detect potential problems, aid in rapid diagnosis, and guide therapy. Although the equipment available in most general ICUs allows sophisticated monitoring of cardiac and pulmonary variables, the most important organ for functional outcome, the brain, is typically monitored only by physical examination. Additional monitoring devices are used in special circumstances. Intracranial pressure (ICP) monitoring has been available since the 1960s and brain tissue oxygen and brain temperature monitoring since the 1990s. Microdialysis of the brain extracellular fluid can be performed, but the time lag between the equilibration of dialysate and the generation of results prevents changes in management in real time. Other devices, such as probes that provide continuous regional measurements of cerebral blood flow, are becoming available in a few research centers. By far the most widely available techniques for monitoring the brain, however, are electrophysiologic, primarily electroencephalography (EEG), but also including evoked potentials (EPs) and event-related potentials (ERPs).

The most common current indication for electrophysiologic monitoring is refractory status epilepticus (RSE).[1] Once a patient fails to awaken after first-line therapy for status epilepticus (SE), EEG monitoring becomes necessary because a substantial percentage of patients will enter a state of electrical-mechanical dissociation in which motor activity ceases but the EEG continues to show ongoing seizure activity. It is no more conscionable to attempt treatment of RSE without EEG monitoring than to treat complex cardiac arrhythmias without electrocardiographic monitoring. In the coming years, neurologists should ensure that such monitoring is available in all centers that treat such patients.

Technical Considerations

Performing EEGs in ICUs using standard EEG equipment has long been viewed as a challenge for both the technologist and the interpreter. The electrical environment of the ICU is commonly viewed as hostile because the large number of devices produces electrical interference, mechanical artifacts, or both. Attention to detail, however, such as keeping electrode wires parallel to each other and away from cables carrying mains current can reduce many artifacts. Technologists may not be able to eliminate all physical artifacts, such as those produced by mechanical ventilation, but they can provide the interpreter with accurate information about the timing of extracerebral events so that they are not misinterpreted as being of brain origin. Simultaneous video recordings are helpful for identifying artifacts and avoiding misinterpretation. In the modern era, fears about compromising patient electrical safety are largely unfounded because all devices attached to a patient are electrically isolated, and the ground electrodes placed on the patient's skin are virtual grounds that are not physically connected to the equipment chassis or the earth. Thus, there is no longer a prohibition against placing more than one ground electrode on a patient (assuming that all of the devices are properly isolated). ICU staff members involved in patient care still need to understand the possibility of microshock hazard, but they should also be aware that contemporary vascular devices that could provide a current path through the heart are also electrically isolated.

The large numbers of tubes, catheters, and other devices attached to the patient may seem intimidating to EEG technologists accustomed to working in the EEG laboratory, but with assistance from the patient's nurse, it is almost always possible to achieve good electrode attachment with acceptable scalp impedances. Many patients will have scalp wounds or monitoring devices that may require some creativity in electrode placement. In such circumstances, it is often not possible to position all electrodes at standard International 10–20 System locations. If the interpreter is aware of the alternate location, this does not pose a significant problem. For brief studies, saline paste is adequate unless the patient is very diaphoretic. For longer recordings, electrode attachment using collodion or similar substances is preferred. However, EEG electrodes produce artifacts in computed tomographic (CT) and magnetic resonance (MR) images, and the presence of any wire loops inside the MR magnet may cause inductive heating, with the attendant risk of burns. Although several groups are developing CT- and MR-compatible EEG electrodes,[16,19] there are still no readily available and practical MRI-safe and non–image-distorting electrodes.

Several types of devices are available that can record EEG activity in some manner. The standard against which these should be judged is the regular digital EEG machine, recording activity from at least the 18 usual locations of the International 10–20 System. The device employed should store the raw EEG signal recorded against a common reference electrode so that montages of choice can be reformatted off-line. Simultaneous recording of the electrocardiogram (ECG) is crucial, and the system should also be capable of recording other polygraphic variables such as airflow, chest movement, electromyographic (EMG) signals, and eye movements. Video recording capability is important for the identification of artifacts, especially during prolonged recordings when a technologist will likely not be present for the bulk of the recording. A reliable system for recording medications and other interventions is also a necessity. Having the data automatically downloaded to a network server for analysis and archiving is very useful.

A variety of less capable devices have been developed with a view toward use in both the operating room and

the ICU. One of the earliest, the cerebral function monitor, provides a single channel of EEG for visual analysis. The signal is derived from two electrodes, usually placed over the parietal regions, and filtered to diminish low (<2 Hz) and higher (>15 Hz) components. The device displays the amplitude of the signal remaining after filtering. The tracing is displayed on a chart recorder at a low paper speed. The effect of seizures on this signal is unpredictable, and the manufacturer (Lectromed) does not suggest its use for seizure monitoring.

Later versions of the small EEG monitor include the amplitude-integrated EEG (aEEG) monitor (Brainz Instruments) and the BIS monitor (Aspect Medical). The aEEG device is designed for neonatal intensive care units; it displays and stores two channels of EEG along with the corresponding amplitude-integrated tracings at a lower sweep speed. The current version of the BIS monitor provides displays of EEG and EMG activity as well as a number calculated from the EEG, derived from a single bipolar frontopolar derivation. The algorithm for calculation of this "BIS number" is proprietary, but it appears to be heavily influenced by the presence of periodic suppressions in the EEG. According to the manufacturer, a normal waking EEG should produce a number of 100; surgical anesthesia produces a number between 60 and 40; a suppression-burst pattern causes the number to fall to near 20; and an isoelectric EEG yields a number of 0. Similar devices are now in development, and their ultimate role in ICU monitoring will require study and experience. None of these devices is intended to detect seizures; rather, their purpose is to assess and track EEG background activity.

The Moberg Neurotrac was an eight-channel EEG monitor that could display and store raw EEG along with a variety of computed parameters. The most useful of these was the compressed spectral array (CSA), discussed later. Its flexible display and its ability to store 24 hours of EEG on a removable hard drive made it a very useful device, but the slow microprocessors of the 1990s prevented its wide adoption.

Although continuous monitoring of all ICU patients with altered awareness may be the ideal, compromises are usually necessary because of too few monitoring devices, technologists, or electroencephalographers. Claassen and colleagues showed that nearly 20% of the ICU patients they monitored had seizures, and >90% (101/110) of these had purely nonconvulsive activity that would have been missed without EEG monitoring.[8] Eighty-eight percent of these seizures were detected in the first 24 hours of monitoring and another 5% on the second day.

Data Analysis and Management

Recording 24 hours of continuous multichannel EEG with simultaneous video is now a trivial matter, but it poses substantial challenges in monitoring, interpretation, and data archiving. EEG *monitoring* implies that someone knowledgeable is observing either the raw EEG or the results of some computer program running in real time designed to detect events or trends of possible pathophysiologic significance. Such events may be seizures, but they could also be runs of focal slow waves, periods of voltage attenuation, or a change in a derived value such as the ratio of delta to alpha activity, which appears to be valuable in the prediction of vasospasm in patients with subarachnoid hemorrhage (SAH). Such observation needs to be done in real time to provide the intensive care staff with the timeliest information with which to manage the patient. However, becoming a skilled electroencephalographer requires years of training and experience. In addition, patients being monitored in ICUs often display EEG activity that is not commonly seen in other settings and may thus present interpretive difficulties.

Seizure detection software is sometimes used to assist the bedside staff in determining whether changes in the EEG are ictal in origin. Because such software was not developed with the ICU patient in mind, it may have difficulty with either the EEG consequences of many of the drugs administered in the ICU or with some of the unusual rhythmic artifacts that may occur in the unit. Furthermore, seizures in encephalopathic patients tend to have more gradual onsets and offsets and slower frequencies, characteristics that make them more difficult to distinguish from background EEG, particularly the abnormal backgrounds found in these patients. Thus, the output of this software cannot substitute for experienced analysis of the EEG. Other analytic approaches involve data reduction at the bedside using CSA or density spectral array (DSA) displays to aid ICU staff in detecting seizures. In contrast to routine EEG practice, CSA is often able to detect seizures in patients being treated with sedative drugs for SE or to improve their ability to tolerate mechanical ventilation. In such patients, the spectral edge frequency (the frequency envelope that includes 95% of the power in the EEG) is often in the range of 1 to 2 Hz. A seizure may shift the spectral edge frequency to 10 Hz, which causes an obvious change in the activity displayed, thus alerting the staff. One must have access to the raw EEG, however, to confirm that this was actually a seizure rather than an artifact or a transient emergence from sedation.

Because an experienced electroencephalographer is usually not available much of the time in most ICUs, many units rely on a combination of ICU physician and nursing interpretation at the bedside, with later off-line review by an electroencephalographer. The diagnostic accuracy of this approach is unknown. To decrease the time between data acquisition and interpretation, network transmission of the EEG from the ICU to the EEG laboratory, or the EEG reader's office or home, is very useful. However, this off-line interpretative service only constitutes a retrospective check when therapies have been altered based on the local interpretation. Thus, it is incumbent for the critical care staff to become as proficient in EEG interpretation as they can.

The vast amount of data generated by continuous video-EEG monitoring creates archiving problems. The percentage of the acquired data that contains events of interest is usually small, but the time involved in selecting and archiving these events is often prohibitive. Although the cost to archive the data to DVD media is relatively low, the space eventually consumed to store the DVDs suggests that in routine practice some attempt should be made to preserve only clinical or electroencephalographic events of note. As memory storage capability continues to improve, it may soon become practical to simply store all EEG data on large servers.

The Electroencephalogram in Status Epilepticus

The electroencephalographic appearance of SE varies with the type of SE and its duration. Unfortunately, attempts to classify the types of SE have not yet yielded a consensus. Table 1 presents one classification, which will be used in this chapter.

Table 1 Classification of Status Epilepticus (SE)

Type of SE (synonyms)	Characteristics	Comments
Generalized	May begin with discrete seizures	Partial seizures with secondary

convulsive SE (GCSE)	that progress through a reasonably predictable sequence (see Table 2)	generalization are typically included here rather than adding another category
Simple partial SE	Focal SE with retained awareness, such as continuous focal jerking of one limb (epilepsia partialis continua)	The focus may be too small or deep to be detected with standard scalp electroencephalogram
Myoclonic SE		May be the consequence of diffuse anoxia or the end-stage of a progressive myoclonus epilepsy
Nonconvulsive SE (*subtypes in italics*)		Encompasses all other forms of SE
Complex partial SE	Continuous or repetitive complex partial seizures	Sometimes manifested as rhythmic theta activity over the temporal regions without sharp activity; may become generalized later
Absence SE	Long runs of generalized 3-Hz wave and-spike activity (electrographic characteristics may vary slightly with the nature of the underlying epilepsy)	Seen in those with chronic epilepsy with absence seizures; in contrast to absence syndromes in general, the SE form often occurs in adults
Subtle SE	Slight clinical manifestations such as nystagmus	Perhaps a consequenc of a long duration of ictal activity prior to detection or in those with an underlying encephalopathy

Table 2 Electroencephalographic stages of generalized convulsive status epilepicus

Stage	Description	Likelihood of response to initial veterans therapy in the administration cooperative Trial (%)
1. Discrete seizures	Typical generalized seizure (with or without focal onset) followed by	75

	postictal slowing	
2. Waxing and waning activity	The frequency and amplitude of ictal activity increases and decreases but it is not replaced by postictal slowing	30
3. Continuous seitzure activity	The frequency and amplitude of the discharge are constant	24
4. Continuous seitzure activity punctuated by flat periods	Periods of suppression interrupt the ictal activity	8
5. Periodic discharges	An endstage with single bisynchronous generalized sharp waves occurring at approximately 1, usually on a relatively flat background	7

Treiman and colleagues derived the stages listed in Table 2 by observations in humans and confirmed them in experimental models of SE.[24] Although there has been considerable controversy about the development of periodic discharges as the end-stage of human SE and their clinical significance,

P.857

others have made similar observations.[11] Some patients with periodic discharges have suffered severe diffuse anoxic injury, and rare patients with this finding have prion diseases or subacute sclerosing panencephalitis. The most reasonable approach appears to be to treat patients who present with periodic discharges after resuscitation who do not have clinical or electrographic seizures for their anoxic injury (e.g., considering induced hypothermia[21]) and to reserve treatment for SE for those patients with clinical or electrographic seizures. As can be seen in Table 2, SE patients who have a periodic pattern are very unlikely to respond to conventional anticonvulsant drugs, so therapy would require agents typically used for RSE.[2] However, this question has not been answered by an appropriately designed and powered clinical trial. Furthermore, anoxic patients being treated with hypothermia may seize while receiving neuromuscular junction blockade, which suggests that EEG monitoring should be performed in this group.[22] Although a periodic pattern after anoxia has often been held to augur a poor prognosis, this may not be true with therapeutic hypothermia.[15] The same is probably true of myoclonic SE after an arrest, which

P.858

has commonly been said to mark a very poor prognosis[28]; this contention needs reexamination with contemporary therapy.

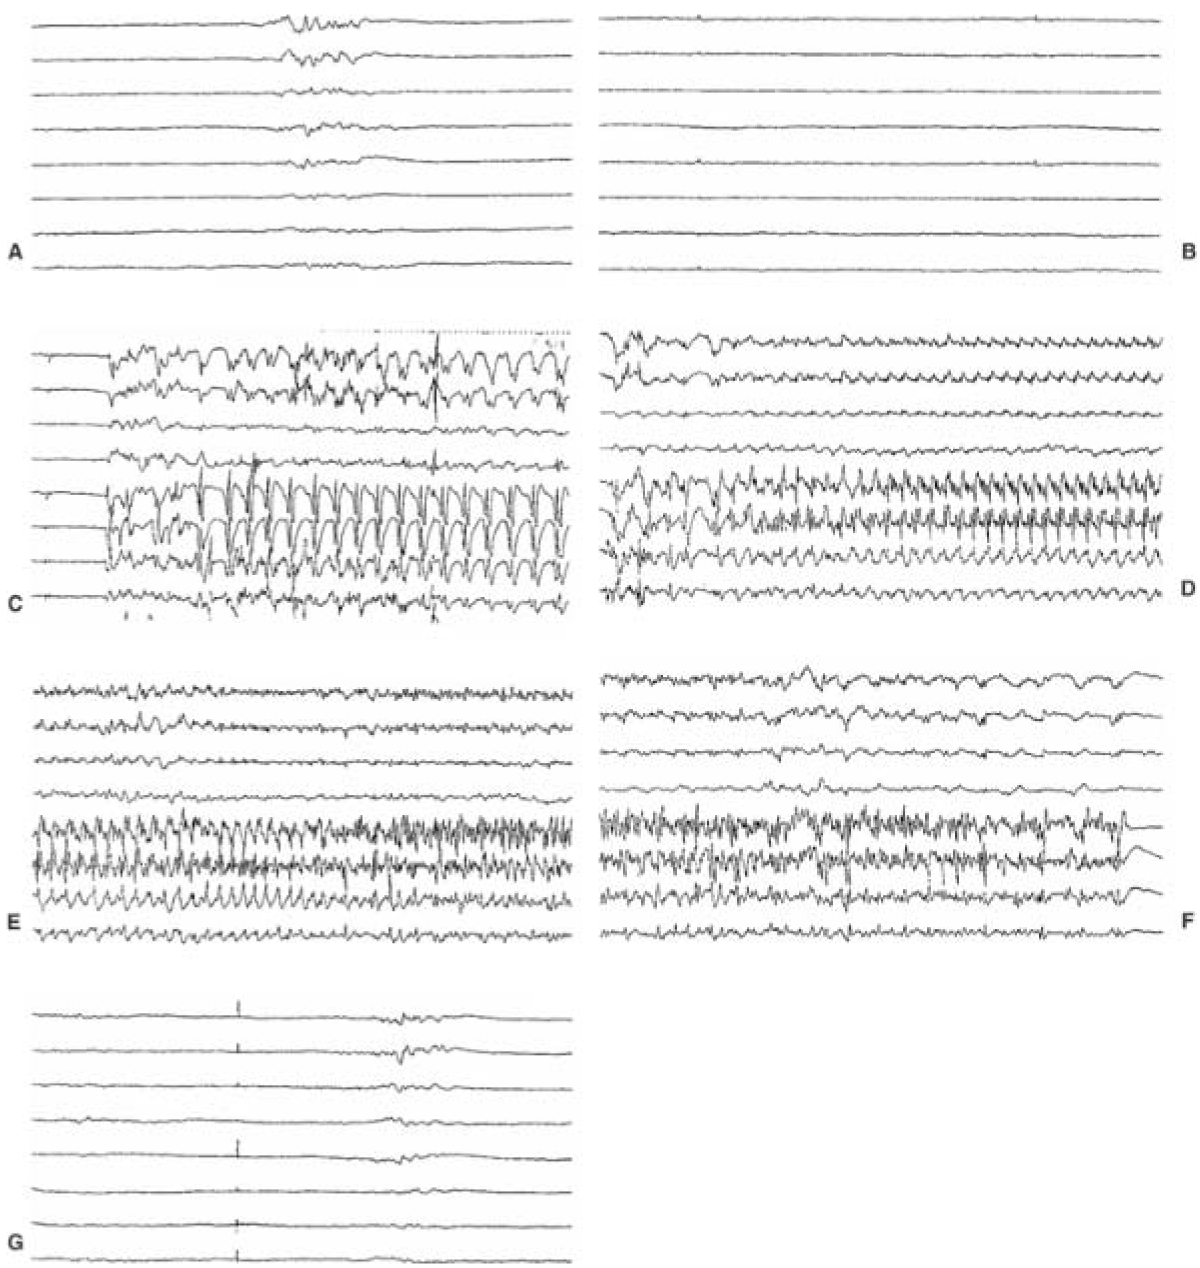

FIGURE 1. Seizure occurring in the setting of a suppression-burst background. Seventy seconds of continuous electroencephalogram recorded from a motionless patient receiving pentobarbital for refractory status epilepticus. Bipolar anteroposterior montage; channels 1–4, left temporal; channels 5–8, right temporal. Each panel displays 10 seconds.

In the past, some authors suggested that the physiology underlying the suppression-burst background pattern, typically when induced by high-dose barbiturates, prevented the generation and propagation of a seizure. When such patients are continuously monitored, however, subclinical seizures are often discovered. One such example is presented in FIGURE 1. Seizures can even arise from complete suppression.

Table 3 presents some suggested criteria for a definitive diagnosis of nonconvulsive seizures; in clinical practice, there are many equivocal cases.

As continuous EEG monitoring has become technically easier, a baffling array of previously rare or unknown electrographic findings has been recorded from ICU patients. A classification of those that appear potentially ictal has been proposed for research purposes[12]; the reader is encouraged to consider this classification for clinical use as well.

Table 3 Criteria for Nonconvulsive Seizures

Any pattern lasting at least 10 s satisfying any one of the following three primary criteria:

Primary criteria

1. Repetitive generalized or focal spikes, sharp waves, spike-and-wave, or sharp-and-slow wave complexes at ≥3/s.
2. Repetitive generalized or focal spikes, sharp waves, spike-and-wave, or sharp-and-slow wave complexes at ≥3/s and the secondary criterion.
3. Sequential rhythmic, periodic, or quasiperiodic waves at ≥1/s and unequivocal evolution in *frequency* (gradually increasing or decreasing by at least 1/s, e. g., from 2/s to 3/s), *morphology*, or *location* (gradual spread into or out of a region involving at least two electrodes). Evolution in amplitude alone is not sufficient. Change in sharpness without other change in morphology is not adequate to satisfy evolution in morphology.

Secondary criterion

Significant improvement in clinical state or appearance of previously absent normal electroencephalograptic (EEG) patterns (such as posterior dominant rhythm) temporally coupled to acute administration of a rapidly acting antiepileptic drug. Resolution of the "epileptiform" discharges leaving diffuse slowing without clinical improvement and without appearance of previously absent normal EEG patterns would not satisfy the secondary criterion.

Source: From Chong DJ, Hirsch LJ. Which EEG patterns warrant treatment in the critically ill? Reviewing the evidence for treatment of periodic epileptiform discharges and related patterns. *J Clin Neurophysiol*. 2005;22:79–91. This is a modification of the criteria initially proposed by Young et al.[29]

One characteristic of electrographic seizures is their repetitive nature, even when the activity itself is not clearly ictal. FIGURE 2 presents such a case. Some electrographic events may be triggered by sensory stimuli, causing confusion regarding their nature as ictal, evidence of a change in the patient's level of consciousness, or artifactual.[13] It is now quite

P.859

clear that unequivocal electrographic seizures, and less commonly focal clinical seizures, can be repetitively triggered by nonspecific alerting stimuli in many encephalopathic patients (Fig. 3).

The Electroencephalogram in Other Critical Neurologic Illnesses

In recent years, EEG monitoring has been applied to larger groups of critically ill patients; in addition to detecting previously unrecognized seizures, this monitoring provides information of substantial therapeutic and prognostic significance.[3] Table 4 presents some suggested indications for EEG monitoring in the ICU.

Subarachnoid Hemorrhage

Labar and colleagues reported that early forms of quantitative EEG monitoring (single-channel CSA and trend analysis) could predict the development of delayed ischemia (cerebral vasospasm) in patients with subarachnoid hemorrhage (SAH).[18] Subsequent work by Vespa and colleagues has extended these observations, focusing on the variability of relative alpha activity in the continuously monitored quantitative EEG.[25] Their observations suggest that cerebral vasospasm can be detected by EEG about 2 days before clinical symptoms appear and about 1 day earlier than an increase occurs in the transcranial Doppler blood flow velocity measurement. Quantitative EEG changes preceded transcranial Doppler or angiographic detection of vasospasm by at least 2 days in 10 of 14 patients, and quantitative EEG was 100% sensitive for angiogram-defined vasospasm (19/19) with a positive predictive value of 76%.

Claassen and colleagues studied this and other quantitative EEG parameters in SAH patients and found that the most useful quantitative EEG measure was the poststimulation alpha/delta ratio.[7] They also detected nonconvulsive SE (NCSE) in at least 8% of unresponsive SAH patients and noted the poor outcome in this group.[10] Other findings carrying a poor prognosis are periodic epileptiform discharges and the absence of sleep architecture.[6]

Phenytoin is commonly administered for seizure prophylaxis in SAH patients. In this setting phenytoin, however, is associated with a plethora of complications.[20] EEG monitoring represents a reasonable way of detecting and treating subclinical seizures in this group of patients rather than relying on a prophylactic approach.

Head Trauma

Vespa and colleagues studied 94 patients with moderate or severe head trauma and found seizures in 22%; 6 developed SE.[26] Seizures were exclusively nonconvulsive in just more than one half of the patients with seizures.

Intracerebral Hemorrhage

Intracerebral bleeding raises serious concerns for long-term epileptogenesis because of irritative effects of iron on the cortex. Because the majority of intracerebral hemorrhages (ICHs) occur in subcortical structures, however, the utility of prophylactic approaches in this population is also uncertain. In a study of 63 patients with ICH, Vespa and colleagues detected electrographic seizures in 28%; a comparison group of patients with large ischemic strokes had a 6% incidence of electrographic seizures.[27] Seizures in the ICH group were associated with increased periclot edema and midline shift and a trend toward worse outcome, even after controlling for ICH size.

Complications of Nonneurologic Critical Illnesses

Clinically apparent seizures complicate about 3% of nonneurologic critical illnesses.[4] In one unselected series of comatose patients in a medical intensive care unit without any clinical suspicion of seizure activity, Towne and colleagues found that 8% were in nonconvulsive SE as diagnosed by a standard EEG.[23] Using continuous EEG monitoring, Connell and colleagues determined that 20% of infants in a neonatal ICU were having seizures; almost half had no clinical manifestations.[9] The percentage of pediatric or adult ICU patients in which altered awareness is due to intermittent seizure activity, often superimposed upon some other type of encephalopathy, is unknown.

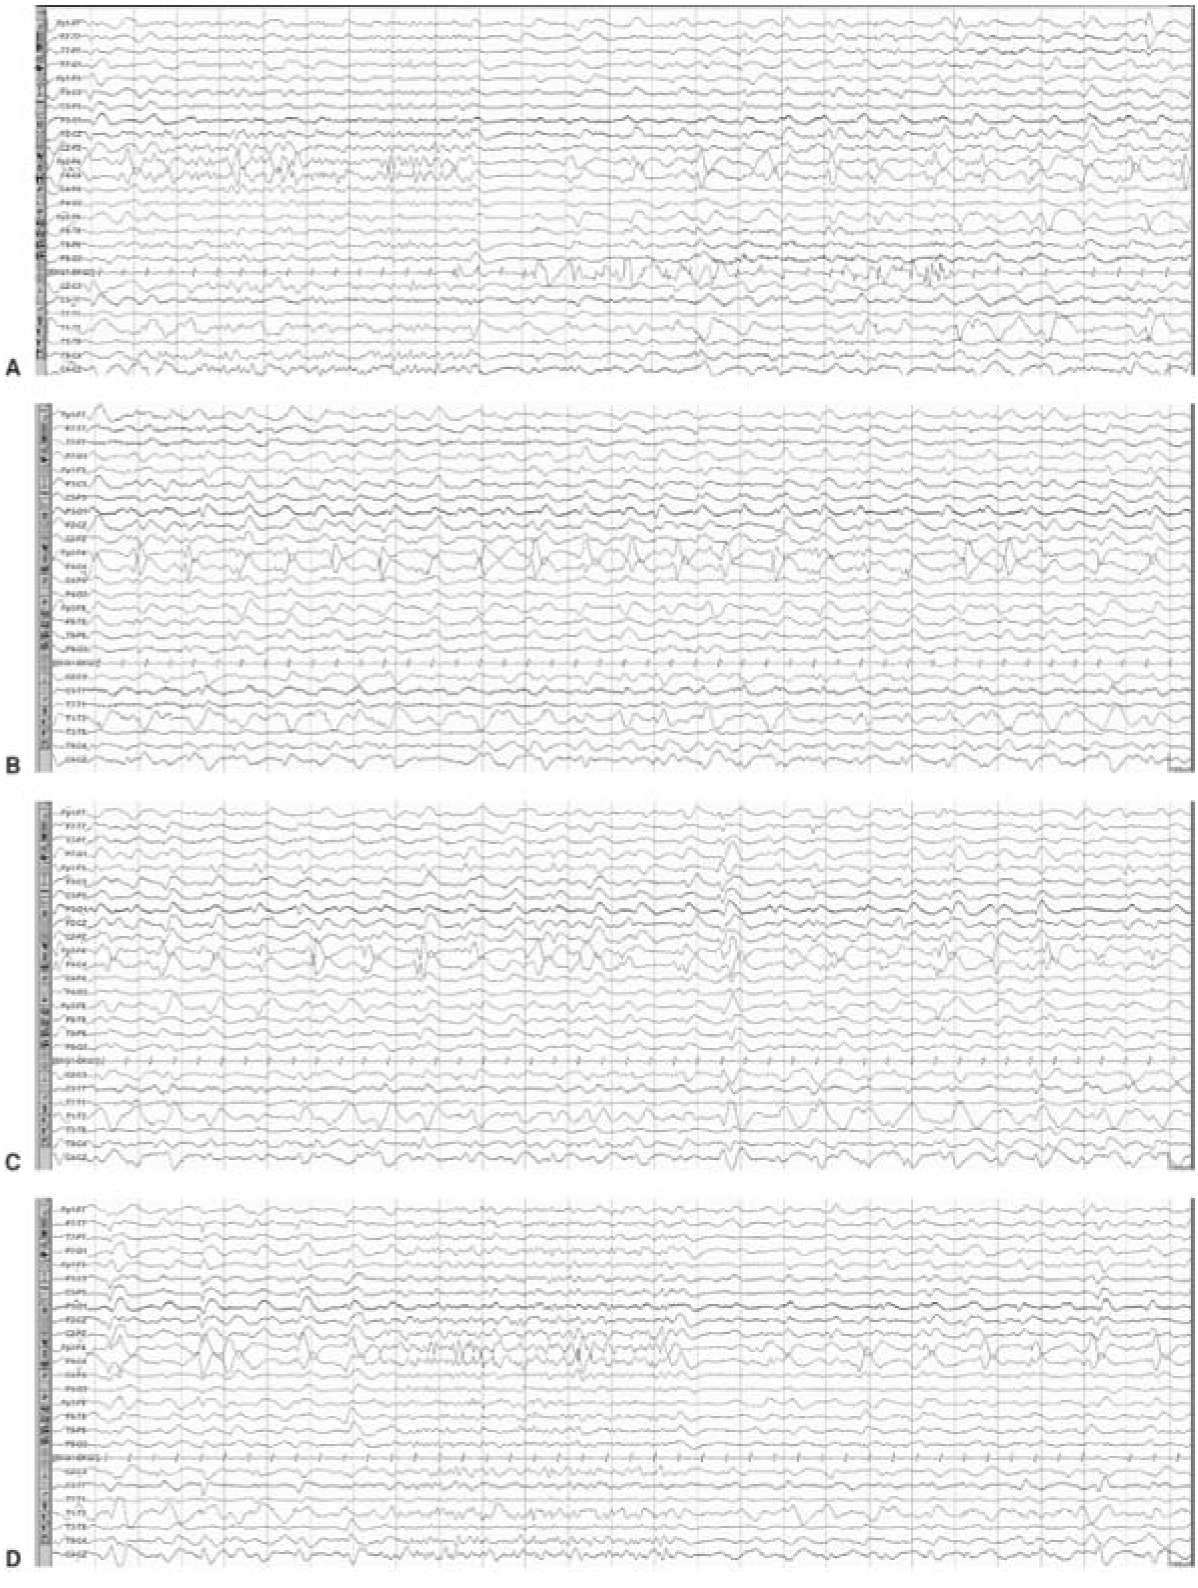

FIGURE 2. Repetitive seizures arising from the right frontal region in a patient with encephalitis. The onset consists of fast activity near F4 (panel A, repeated in panel D); after 8 seconds, there is widespread desynchronization, with the subsequent evolution of periodic sharp activity, which spreads to involve the entire cortex. The pattern then repeats itself until terminated with propofol.

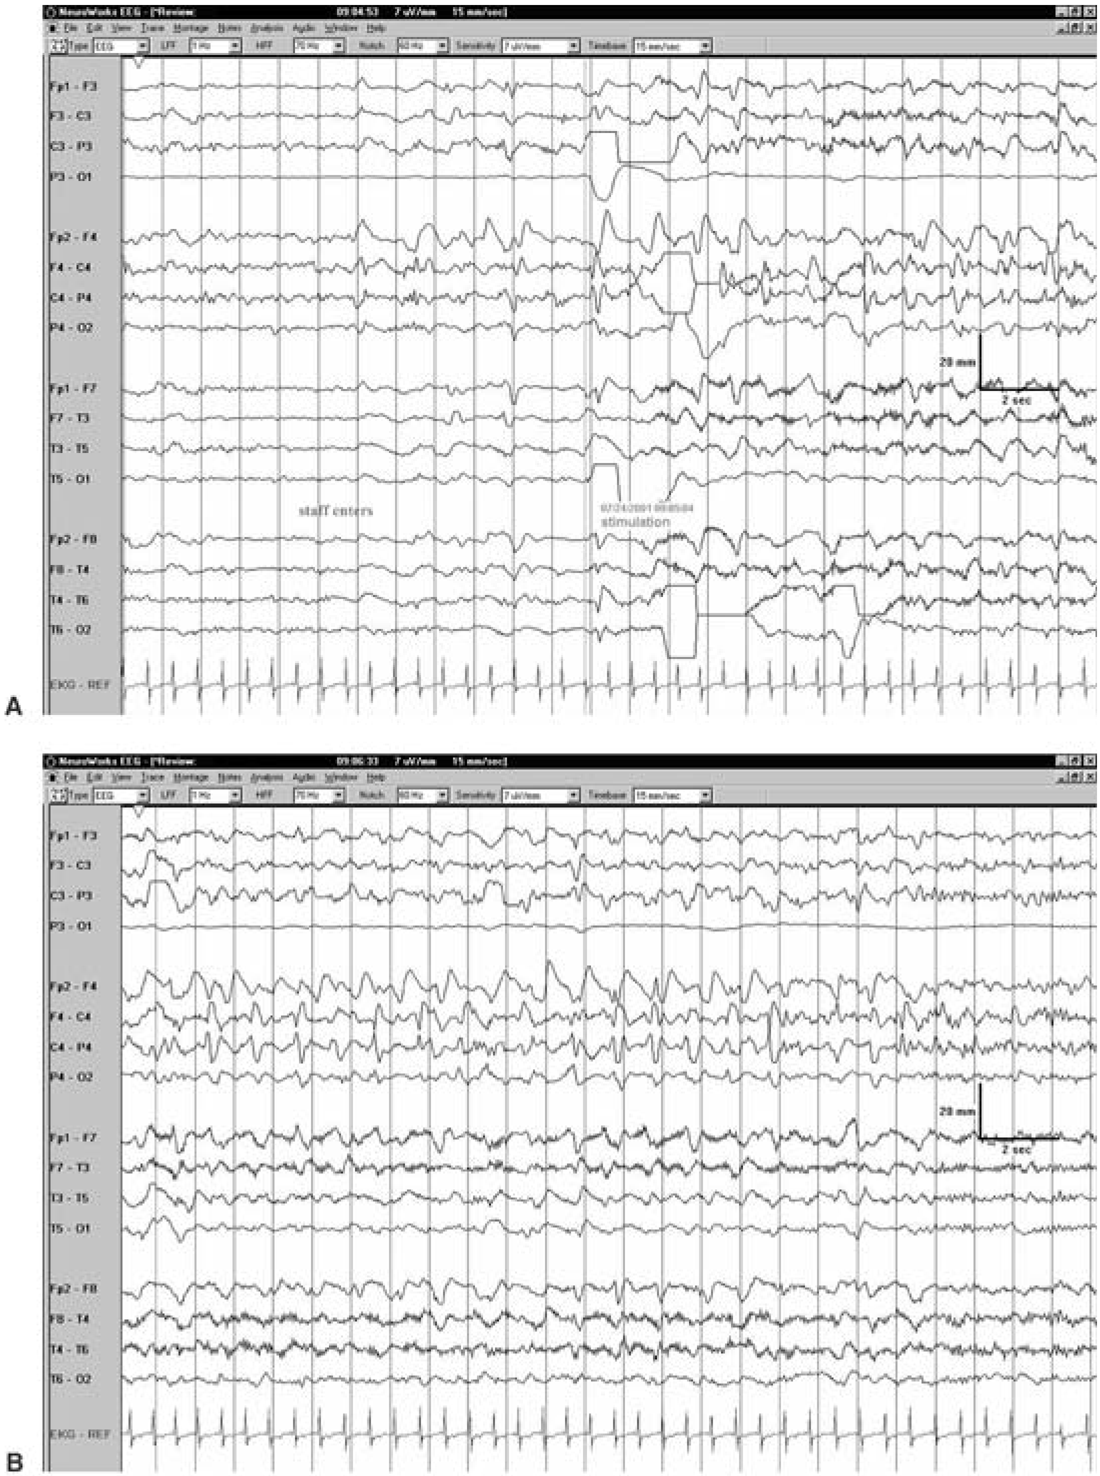

FIGURE 3. Stimulus-induced rhythmic, periodic, or ictal discharges (SIRPIDs). **A:** Before and during stimulation. **B:** After vigorous stimulation (80 seconds after A). A 61-year-old patient with a recurrent right frontal glioblastoma multiforme. Stimulation consistently elicited periodic lateralized epileptiform discharges, maximal at C4 (right central), with some underlying rhythmic delta and bilateral spread. After vigorous or repetitive stimulation, this pattern often became a focal ictal-appearing pattern, as shown in panel B. There was no clinical correlate. [From Hirsch LJ, Claassen J, Mayer SA, et al. Stimulus-induced rhythmic, periodic, or ictal discharges (SIRPIDs): a common EEG phenomenon in the critically ill. *Epilepsia*. 2004;45:109–123.]

Summary and Conclusions

The most common indication for EEG monitoring in the ICU is refractory status epilepticus. Technical improvements in EEG machines and software make monitoring safer and easier to interpret, but skilled technologists are still essential. The

P.860

P.861

P.862

electrographic patterns of status epilepticus, as well as transient events and background activity, are often different in the ICU patient population compared with other patient groups.

Patients with particular critical illnesses may specifically benefit from EEG monitoring. The development of vasospasm in subarachnoid hemorrhage is often suggested by EEG changes a day or more before clinical changes are noted or other modalities yield abnormal findings. Patients with head trauma or intracerebral hemorrhage develop nonconvulsive seizures more frequently than had previously been suspected. Nonconvulsive status epilepticus contributes to coma in about 8% of ICU patients without previously suspected neurologic disease.

Table 4 Indications for Continuous Electroencephalographic Recording

1. Detection of subclinical seizures
    a. Fluctuating mental status
    b. Unexplained alteration of mental status
    c. Acute or remote supratentorial brain injury with altered mental status
    d. After convulsive status epilepticus
2. Characterization of spells
    a. Episodic posturing; other paroxysmal or repetitive movements
    b. Subtle twitching, nystagmus, eye deviation, hippus, chewing
    c. Paroxysmal autonomic spells including tachycardia or hypertension
3. Assessment of level of sedation and following trends
4. Management of burst-suppression in anesthetic coma
5. Detection of ischemia (particularly if continuous electroencephalographic review and alarms are utilized)
    a. After subarachnoid hemorrhage
    b. During and after vascular neurosurgical or interventional neuroradiologic procedures
    c. In patients with hemodynamic lesions and borderline flow
    d. in other patients at risk for in-hospital acute ischemia
6. Prognostication

Chapter 76

Electroencephalogram Mapping and Dynamic Analysis

Peter K. H. Wong

Fernando H. Lopes da Silva

Introduction

In its simplest use, mapping of the scalp electroencephalogram (EEG) provides a convenient display of instantaneous scalp topography, usually that of resting background or interictal spike activity. In more complex forms, the scalp EEG data are subjected to mathematical manipulation as prescribed by a theoretical model. The result is a variety of parameters capable of characterizing the input data, albeit always within limitations imposed by the model. In between these two approaches is a large variety of methods using quantitative analysis.

In the clinical arena of epilepsy diagnosis, EEG analyses seek maximally to extract information pertaining to the epileptic discharge so as to facilitate the understanding of the underlying focus and its current and future behavior. The final purpose is then to use such information for earlier and more accurate diagnosis, which, in turn, can facilitate appropriate treatment and management. This is of particular importance when surgical resection is contemplated.

With spike discharges, the routine EEG tracing provides good visual information regarding spike morphology, scalp localization, and temporal changes (see Chapter 73). It is generally accepted that more useful information might be available but undiscovered. This drives the search for better and more productive display techniques, usually based on computer software algorithms. However, there is no consensus on what technical approaches are useful or acceptable. It is appropriate to observe that newer algorithms and theoretical models tend to be viewed with skepticism. This view has some valid basis, in part generated as a reaction to schemes that purport to make instant clinical diagnoses of various kinds based only on scalp recordings, without the need for clinical assessment. Such computerized diagnostic “aids” have been proposed for differentiating depression from dementia, for example. One is well advised to exercise caution with any such device.

We hope that by increasing the understanding and knowledge base of prospective users, choice of methodology and utilization can be made based on sound neurophysiologic considerations. Toward this end, this chapter reviews selected techniques and results.

Methodology

General Aspects: Electroencephalography and Magnetoencephalography

Electroencephalographic signals reflect the dynamics of the electrical activity generated by populations of neurons (see Chapter 72). This activity is caused by ionic currents flowing through neuronal (and glial) membranes between the intra- and the extracellular space. These signals can be measured at a considerable distance from the sources when two conditions are satisfied: (1) the responsible neurons are regularly organized in space and (2) they are activated in a rather synchronized fashion. As regards the first condition, the cortical neurons form the main sources of EEG potentials because they are arranged in palisades perpendicular to the cortical surface and are activated by synapses distributed in a regular way along their soma-dendritic membranes. According to this spatial organization, their synaptic activation causes the generation of potential fields with a dipole layer configuration. The second condition, synchronization of neuronal populations, is important because in this way, potential fields can be generated that are sufficiently strong to attain the necessary signal-to-noise ratio to be recordable at a distance. The main factor responsible for the synchronous activity of populations of neurons also has a structural basis. It consists of the fact that the neurons within these populations form interlocked networks through excitatory and inhibitory synaptic connections. These populations of interconnected neurons form the macroscopic sources of EEG signals. The neuronal ionic currents not only generate electric fields; they also give rise to magnetic fields. The latter constitutes the magnetoencephalogram (MEG) (see later discussion and Chapter 78).

Although EEG and MEG are caused by the same elements, in practice the two types of signals differ: (1) The EEG is a relative measurement needing a reference electrode; this does not apply to the MEG; (2) the MEG is a signal that consists of the magnetic fields oriented perpendicular to the skull that are caused by current dipoles tangential to the cortical surface, whereas the radial components do not contribute significantly to the MEG signal; the EEG signal is a measure of both tangential and radial components; (3) the MEG pattern of activity is more focal than the corresponding EEG pattern because the former is much less dependent on variations in resistivity of the volume conductor.

Sampling in Time and Space

Electroencephalographic signals are continuous variations of electrical potential as a function of time and space. The same applies to the variations of magnetic fields that form the MEG signals. In practice, these signals must be digitized to be quantified and analyzed. First we consider this question in terms of the variable *time*. This implies that the signals have to be sampled at a certain rate and that their amplitude has to be quantified. These operations must take place in such a way that all important information contained in the signals is preserved. Accordingly, the Nyquist sampling theorem has to be satisfied: If the signal has a frequency spectrum with an upper limit f_N, the signal should be sampled at a frequency at least equal to

P.864

$2f_N$. This means that care should be taken that the signal does not contain frequency components $>f_N$ to avoid aliasing, that is, all frequency components $>f_N$ should be zero. Thus, before sampling, all frequency components $>f_N$ should be eliminated by appropriate filtering. For most EEG-MEG signals, a quantitization into 4096 amplitude levels (i.e., 12-bit precision) is appropriate and commonly available. In practice, however, the Nyquist criterion, although a minimally necessary condition, is not sufficient for displaced signals, and a sampling frequency of $>3f_N$ should be used.

Another aspect of the temporal properties of EEG-MEG signals that has to be taken into consideration here is that the statistical properties of these signals can change as a function of time (i.e., nonstationary properties). However, they can be subdivided into representative segments, or epochs, that are quasistationary. A precise definition of the duration of these epochs cannot be given in general terms because it depends on the subject's condition. Nevertheless, it has been shown[20,30] for EEG signals recorded in a general population that 90% had time-invariant properties for epochs of about 20 seconds, whereas <75% remain time invariant after 60 seconds. This means that it is, in general, safe to choose epochs with a duration of 10 to 20 seconds to avoid deviations from stationary behavior.

Sampling in space must obey the same general rules as sampling in time. However, it is much easier to grasp the meaning of a frequency component in the time domain than one in the spatial domain. What is the spatial frequency of a given EEG signal? This can be accounted for by considering a model of a source within a volume conductor, which will cause a potential distribution at the surface of the conductor. Using Fourier analysis, we can represent this potential distribution as a spectrum of spatial frequencies. The sharper the potential distribution, the higher are the corresponding spatial frequencies. It is important to know the upper limit of this spatial frequency spectrum to estimate how sampling in space should take place in an optimal way. If the sampling in space is not appropriate, an aliasing error will be introduced. In general terms, the traditional 10–20 system can be sufficient to sample in space most potential distributions that are rather widespread and smooth, but not those distributions that are highly focal and change abruptly with distance. Some practical questions posed by sampling this kind of potential distribution, in which a high spatial resolution has to be achieved, are discussed later.

Two other fundamental issues need to be further understood—volume conduction and the “inverse problem.” The former is a physical phenomenon that smears or blurs the EEG signal as a result of the different layers of tissues interspersed between source and electrode (brain, cerebrospinal fluid, skull, muscle, fat). The result is added uncertainty about the EEG source. The "inverse problem" refers to the process of inferring the source characteristics from the recorded EEG signal. Fundamentally, this problem has no clear or unique mathematical solution, and is the reason for the general skepticism about dipole localization methods (DLMs; see later discussion). Certain mathematical simplifications that are implicit (e.g., the number of sources, the configuration being small and localized rather than as a layer) might not be clinically appropriate. Experience with application to known problems (e.g., somatosensory-evoked potentials, visual-evoked potentials, known epileptogenic lesions) allows some general understanding of its capabilities and limitations, which can guide its use under certain circumstances.

The detection of specific signals in the background EEG, whether occurring spontaneously, such as epileptiform spikes, or evoked by sensory stimuli, is not only an important general problem in electroencephalography, but it is also relevant for the estimation of the parameters of the equivalent dipole sources. This is a classic problem of detection of signals in noise. The background EEG represents the noise term. To optimize the detection, it is important to know the statistical properties of the noise, that is, the background EEG. Knowledge of these statistical properties is necessary to estimate the confidence limits of equivalent dipole parameters and to design optimal noise filters to improve the signal-to-noise ratio. The spatiotemporal covariance matrix of the background EEG differs with frequency band. For the frequency bands 5 to 8 Hz and 13 to 30 Hz, it was found experimentally that the variance is a function of electrode distance that is compatible with a generator model consisting of random dipoles with a spherically symmetric distribution. However, for the alpha (9 to 12 Hz) frequency band, such a distribution is not adequate, and a localized model consisting of one or more clustered dipoles has to be assumed. These estimates of the statistical properties of the background EEG have practical implications because they allow the construction of maximum likelihood estimators for evoked potentials/magnetic fields based on the spatiotemporal covariance matrix of the background signals.[7]

High-Resolution Electroencephalography and Magnetoencephalography

The condition in which the highest possible spatial frequencies are achieved can be represented by a source consisting of a radial dipole situated in the cortex, that is, close to the surface of the volume conductor. This may correspond to the source of an epileptiform spike located in the cortex. If one uses the traditional 10–20 system (interelectrode distance of about 4.5 cm), the aliasing error in such a case is 6%. To reduce this error to the more adequate level of 1%, one must reduce the interelectrode distance to 3.2 cm, which corresponds to at least 64 electrodes.[49] Gevins and Bressler[14] indicated that sampling with 128 electrodes (interelectrode distance of 2.25 cm) might be indicated in some cases. A comprehensive system, called the *10% system*, includes electrodes halfway between each of the principal 10–20 system electrodes.[6,61] Electroencephalographic signals recorded according to such a system using a large spatial sampling frequency are called *high-resolution EEGs*.

The technique, developed by Gevins et al.,[15] combines large spatial sampling (>100 electrodes) with a method that minimizes the blur distortion that takes place in the transfer from the cortical surface to the scalp. For the deblurring operation, these authors use a realistic finite-element model of the subject's head using the structural information provided by the magnetic resonance imaging (MRI).[37] The scalp and skull volumes are approximated by tetrahedral finite elements having the physical properties characteristic of the different layers of the head. These authors' algorithm searches for the optimal potential distribution at the cortex that provides the best-fit forward solution to the measured scalp distribution, using this volume conductor model. Deblurring is equivalent to a high-pass filtering operation in the spatial domain. Therefore, it can enhance high spatial frequencies and introduce spurious results; this can be avoided by applying spatial filtering techniques (smoothing) to the scalp recordings.

Static and Propagated Fields

In the earlier discussion, we considered EEG-MEG signals as being generated by static sources. However, this is not necessarily the case. Particularly in epilepsy, we can encounter evidence for the propagation of electrical activity over the cortex. We can distinguish two main problems that arise when the propagation of epileptiform activity from a focal area must be analyzed: The first is to determine whether there are multiple independent sources; the second is to determine, in case that related sources exist, whether the activity of one source occurs in a fixed time sequence in relation to that of another source. In the latter case, a time delay can be expected between the signals due to the finite propagation velocity of electrical activity in the brain.

A classic way to estimate the degree of association between two signals and the corresponding time delay is to calculate the correlation coefficient as a function of time shift between the two signals. This is called the *cross-correlation function*. Alternatively, we can deal with this problem in the frequency domain by estimating the coherence and phase functions. In short, the coherence function expresses how each frequency component of one signal is related to the corresponding frequency component of the other signal. The delay can be estimated by calculating the slope of the phase spectrum. This method was used in electroencephalography to analyze the propagation of epileptic seizure activity, initially by Brazier[4] and in a systematic way by Gotman,[18,19,20] Gotman et al.,[22] and Lieb et al.[45,46]

A limitation of these methods is that they provide unambiguous results only if the relationship between the signals is linear. This is not necessarily the case for epileptic seizure activities. Therefore, methods have been proposed that are not restricted to the case of linear relationships. One of these uses the average amount of mutual information, which was introduced into the analysis of epileptiform activity by Mars and Lopes da Silva[50] and Mars et al.[51] Later, Pijn et al.[63,65] introduced a method for estimating the relationship between two signals that always applies, regardless of whether or not it is linear. This is a form of nonlinear regression analysis because it describes the dependence of a signal on another one in a general way, independent of the type of relation between the two signals. This measure was called h^2. If the relationship is linear, h^2 approximates the cross-correlation coefficient r^2. This method was applied to EEG signals recorded during epileptiform seizures by Fernandes de Lima et al.[13] and Pijn et al.[63] A particularly interesting application of this method is in the analysis of epileptiform seizures recorded from simultaneous intracranial electrodes, with the aim of estimating the localization of an epileptogenic focus and the spread of seizure activity in patients being assessed for a possible surgical intervention. Typically, at the beginning of a seizure, considerable differences were encountered between r^2 and h^2, indicating the presence of nonlinear relations between signals recorded from different sites. In practice, it is appropriate to apply the following procedure to estimate the degree and type of interdependence between EEG and MEG signals recorded simultaneously. First, compute the values of r^2 and h^2 as a function of time delay for a number of representative epochs. From these values, we can draw conclusions regarding the linearity or nonlinearity of the relationship. Second, estimate the corresponding time delays. In this way, we can obtain a valid interpretation of the EEG-MEG signals regarding the presence of propagated epileptiform activity.

Simple Voltage Maps: Spike Topography

An example of interictal spikes can be found in children with benign epilepsy with central temporal spikes (BECTS). A similar term, *benign rolandic epilepsy of childhood* (BREC), was used in the past to refer to the same syndrome. This syndrome occurs from 3 to 16 years of age and has an EEG focus in the centrotemporal or rolandic region. There is a particular topography displayed by the peak of the negative spike, namely, a pattern with simultaneous negativity and positivity in a distinctly tangential pattern.[24] Further analysis of this patient population led to the observation that there were two subgroups, depending on the clinical presentation. One subgroup tended to have a more benign presentation, whereas the other tended to have one that was less benign.

It was also observed that the spike topography was correlated with these groupings: A tangential field was associated with the benign group, whereas a nontangential (or radial) field was associated with the less benign group. For convenience, these two subgroups will be labeled *typical* and *atypical BECTS* because the former fulfills the criteria of typical BECTS, whereas the presence of abnormal neurologic findings in the latter coexists with otherwise typical seizure symptoms and EEG features.

Figure 1 illustrates spikes from both groups. Gregory and Wong[25] studied 366 children with rolandic spikes to determine whether the tangential field had any clinical significance. Clinical factors studied included development history, school performance, intelligence, total number of seizures, and neurologic findings. Patients with nontangential spikes tended to show a greater degree of abnormality in the aforementioned clinical areas. That study was based on a visual determination of spike topography from the tracing, without requiring more sophisticated computer hardware. It was speculated that such tangential discharges might represent a benign functional focus whose identification can be differentiated from those rolandic spikes associated with nonbenign clinical presentation.

In a study of 48 children with an EEG rolandic spike but no other EEG abnormalities outside of the rolandic region and no diffuse or progressive brain disorder, van der Meij et al.[53] analyzed the rolandic spike with respect to whether there were associated seizures and, if so, what type of seizures they were. Using dipole source analysis parameters, they did not find any differences in the rolandic spike-and-wave complexes. If they took into account the presence (in some cases) of an initial spike preceding the rolandic spike-and-wave complex, they were able to conclude that this pattern was associated with a greater probability of seizures. On this basis, they hypothesized that this preceding spike is generated by a group of neurons that cause seizures and that the rolandic spike-and-wave complex is not strongly related to clinical symptomatology. More recent results have suggested that this syndrome may not be adequately modeled by a simple fixed point source.[27]

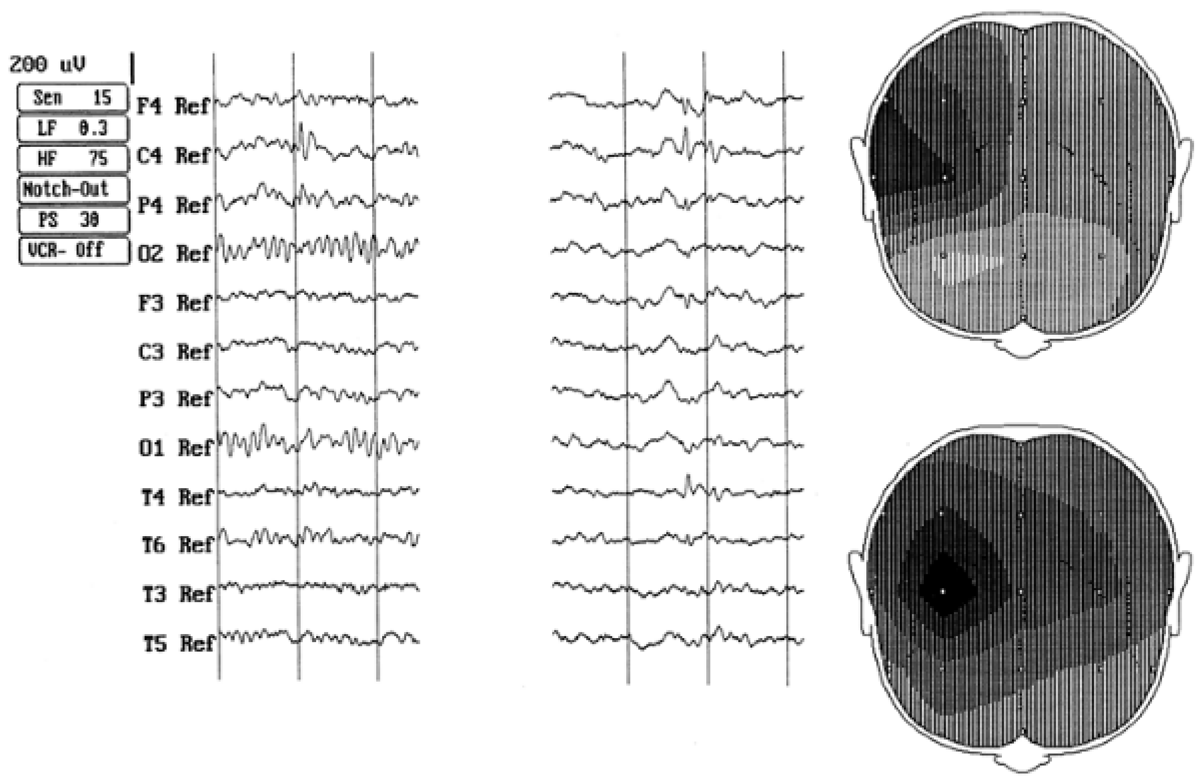

FIGURE 1. Examples of electroencephalogram s and maps of radial and tangential spikes. Tracing: left, radial; right, tangential; grid lines 1 second apart; ref, linked cheeks; negative up. Maps: top, tangential (T4-F4); bottom, radial (C4); nose-down vertex view; right, patient's left. Color scale: white, positive; black, negative.

Decomposition of Spikes

A segment of scalp EEG containing a single spike discharge might represent the aggregate of electrical activity from more than one source. In the presence of a high signal-to-noise ratio, as may be present with averaged spikes,[24] it is possible to decompose this aggregate using mathematical techniques. The assumption is that such objective mathematical decomposition can represent separate physiologic sources, with no guarantee that such an interpretation is accurate or even appropriate. Nevertheless, the results can be useful in providing a measure of the electrical characteristics of the spike generators or sources. On this latter point, Wong[84] reviewed the use of source behavior information in distinguishing populations of epileptic foci. FIGURE 2 is an example of an analysis using singular value decomposition (SVD).[26] Principal component analysis can also be used to achieve substantially similar results, although SVD makes spatial displays more directly available.

From FIGURE 2, one can see that the original spike segment shows a complex topography over the right frontocentrotemporal area, with the predominant negative spike peaking earliest at F4, then slightly later at C4, then still later at T4. Simultaneously with the F4 negative peak is a smaller, positive peak at T6. Under such careful scrutiny, there are, therefore, tangential and radial components within the single spike, lending to the suspicion that this was a complex spike, with perhaps complicated multiple generators. The decomposed features (1 and 3) provide mathematical (and objective) evidence of two separate sources, overlapping spatially but with distinct topography (tangential and radial). These two presumed separate sources might well originate from cortical areas with different clinical symptomatology.

P.866

Notwithstanding the cautionary note regarding the interpretation of each component as being from a separate source, such a hypothesis could be generated and tested against collected patient populations for verification, with particular emphasis on the clinical symptomatology and electroclinical correlations.

Kobayashi et al.[33] reported being able to isolate separate epileptic components from spike and slow wave complexes using independent component analysis (ICA). They proposed that these components might represent separate cortical regions. Such a possibility would be of interest in the identification and surgical resection of the presumed neocortical focus. However, Unsworth et al.[74] defined the criteria for the EEG data required for the ICA procedure to be reliable and interpretable. They concluded that it was not appropriate to apply ICA or source localization from independent components in four common types of childhood epilepsy. They also listed some preconditions before such analysis can be valid.

Source Models

The technique of source modeling (or the *dipole localization method* [DLM]) can be applied to interictal spikes (see also Chapter 78). Here, the implicit assumptions are that there is a limited number of well-defined electrical generators whose mass occupies a small volume in space (i.e., discrete source) and whose electrical signals are accurately recorded by the scalp electrode array. Generally speaking, DLM is an exercise in force-fitting the mathematical model onto the recorded scalp data, the objective being to achieve the best mathematical fit (based on a goodness-of-fit measure). Either a particular time point or a segment of EEG can be chosen for this fitting process. The former produces a moving dipole solution, whereas the latter is a spatiotemporal solution.[8,9,10,11,83,84,85,89,90] Evoked potential waveforms have similarly been analyzed.[1,68,86,87]

It has to be borne in mind that DLM has limitations based on its assumptions. A common pitfall is to use an inordinately large number of sources in the model, which will guarantee a “perfect” mathematical fit. Mathematical adequacy does not guarantee accurate or physiologically appropriate results from DLM. Thus, the choice of the number of dipoles in the model should be made on appropriate electroclinical grounds. In reality, multiple dipole models are inherently more difficult to execute and less amenable to valid physiologic interpretation.

Constraints on the mathematical computation using anatomic knowledge can be extremely helpful in restricting solutions and in increasing the chances of meaningful results. Knowledge of the exact head and brain shapes, skull thickness, tissue layers, presence of foramen, and so on improves the quality and accuracy of the model. Gevins et al.[15] used corrected and aligned MRI images to recreate a realistic head model, which was used to calculate cortical current flow patterns. These closely approximated actual cortical surface recordings made during surgery. Nunez[60] discussed an approach to realistic models and experience with DLM. Such realistic head models allow mathematical models to follow closely the brain volume but do not provide further detail, for example, at the gyrus and fissure level.

Such localization applied to the somatosensory-evoked potential has produced good anatomic and physiologic agreement. Results with interictal spikes have been less ideal, likely attributable to the less-defined source configuration present in different epileptic foci. By careful selection of patient material, particularly partial epilepsy (while avoiding generalized discharges like spike-and-wave complexes), the assumption of a discrete generator can be adequately satisfied. Under these circumstances, DLM can serve not only as an acceptable localization tool, but also as an objective measure to characterize the electrical properties of the focus. Ebersole and Wade[11] used the inclination angle of the calculated dipole in patients with complex partial seizures as a measure of improvement after temporal lobectomy. Their hypothesis was that this angle reflects the location of the generator (mesial temporal or lateral temporal cortex), and thus has predictive value for postsurgical outcome.

In BECTS, calculated sources showed a clustering at the rolandic area, as expected. A study of the variability of source locations (i.e., their stability index) indicated that the "typical" group had a greater stability index than did the "atypical" group.[82] If the individual components of these spikes were separately analyzed (i.e., the initial sharp negativity and positivity, and the aftercoming slow wave) using a single-dipole model, the goodness of fit of each component showed an interesting profile. For the typical group, all three components were adequately fitted by a single-dipole model. For the atypical group, the negative and positive peaks were adequately fitted by a single dipole, but the slow wave was not.[84] This singular behavior of the slow wave in the atypical group suggests a different source configuration, one that requires the assumption of a widespread or diffuse source, an extended dipole sheet, or even multiple sources. It could not have been generated by a single discrete source. Regardless of which explanation is correct, the results suggested that source configurations of the interictal spike can differentiate between typical and atypical groups.

In this manner, mathematical models can supply additional information on the interictal focus. The computed solution provides a measure of source characteristics that can be very helpful in the formulation of a hypothesis regarding the epileptic focus.

More recently, the use of accurate MRI images with gyral pattern information has been explored, lending hope to a "realistic gyral model" to provide a finer degree of anatomic realism amenable to mathematical solutions.[1] Potentially, this technique can greatly enhance the accuracy achieved by a large variety of mathematical imaging techniques. These are not yet in common use. Other recent developments include new modeling approaches.[88]

The experience with multichannel MEG is now considerable. Stefan[70] reported that magnetic source localization compared favorably with EEG and electrocorticography (ECoG) recordings and volumetric MRI measurements. Further analysis of focal epileptic activity was made using "dipole cluster quantification," demonstrating additional useful information on the spatial distribution of the underlying excitation process—in their case, in the temporal lobe. Such information was found to be useful in the workup of presurgical candidates, particularly to guide the implantation of invasive recording electrodes.

Methods for the automatic analysis of large numbers of spontaneously occurring epileptiform paroxysms on MEG records based on spike clustering combined with averaging of similar spikes and subsequent dipole modeling can simplify the laborious work of manual spike classification and yield useful results regarding the clinical neurophysiologic assessment of epileptic patients.[76]

Nakasato et al.[58] compared MEG, EEG, and ECoG methods for seizure localization in complex partial epilepsy. By studying a large number of interictal spikes in each modality, they concluded that MEG was superior to EEG (more consistency), by virtue of better agreement with ECoG, MRI lesion location, and surgical outcome. Generally, when viewing such comparative studies it is important to ensure that the same recording parameters had been used for both MEG and EEG. An obvious one is spatial sampling density (number of recording sensors used) because it is obvious that comparing results from 128-channel MEG with 32- or 64-channel EEG would be inappropriate.

Dynamic Analysis: Linear and Nonlinear Correlations

The classic method for the quantification of background EEG signals is by way of frequency spectra, usually based on Fourier analysis. Accordingly, the relationships between simultaneously recorded EEG signals are analyzed by way of cross-correlation functions or coherence and phase spectra. Incidentally, higher-order spectra (e.g., bispectra) are used to estimate nonlinear interactions.

However, these methods do not take into account the possibility that EEG signals are generated by neuronal networks with nonlinear dynamical properties. The hypothesis is that the irregular patterns presented by EEG signals can correspond to the expression of complex nonlinear dynamical systems. This is interesting because it is known that systems with complex nonlinear properties that are both deterministic and low dimensional can exhibit complex oscillations, which in some cases can be considered chaotic. Whether the latter correspond to deterministic chaos is, in most cases, neither mathematically proven nor relevant to the specific problem under discussion here. What is important is to note that EEGs are, in general, muitivariable, nonstationary, and complex nonlinear signals.

Mathematicians have developed quantitative measures for identifying these kinds of systems. These measures include, among others, the correlation dimension and the Lyapunov exponents. Most commonly, the algorithm of Grassberger and Procaccia[23] has been used to find evidence for the presence of nonlinear dynamics in EEG records. This algorithm provides an estimate of the correlation dimension and has been widely used in EEG analysis (see Pritchard et al.[67] for review). Although the initial investigations have led to the claim that normal EEG signals can have low-dimensional chaotic dynamics, the application of more sophisticated techniques has shown that under normal conditions, most EEG signals, recorded under normal conditions, cannot be distinguished from filtered noise.[73]

Nevertheless there is evidence for nonlinear dynamics in EEGs recorded *during epileptic seizures* in animals and humans, obtained by comparing the correlation dimension of the real EEG signals with that of surrogate data obtained by randomizing the phases of the corresponding Fourier coefficients.[3,5,64,65,66,75,79] Thus we can state, in general terms, that seizure activity, in most cases, is highly nonlinear and low dimensional, whereas interictal EEG is high dimensional and only weakly nonlinear.[71] Therefore, the change in correlation dimension occurring at the beginning of an epileptiform seizure, which differs from that of normal EEG epochs, might indicate a transition in the dynamic state of the underlying networks.

How the transition between interictal and ictal takes place is a question of paramount importance in epilepsy. Stam[71] noted that there are two aspects of this transition: (1) changes in local dynamics and (2) changes in interregional coupling. The former may reflect one or more bifurcations from a high-dimensional dynamical state characteristic of the normal state to another,

P.870

low-dimensional state typical of an epileptic seizure. The transition may occur according to different scenarios: (1) abruptly, as in the case of absence seizures arising "out of the blue"[72]; (2) induced by an external stimulus, as in reflex epilepsies[62]; and (3) in a gradual way by a series of bifurcations culminating in a pre-ictal and, finally, an ictal state.[37,38,39,77,78,80] Regarding the second aspect of the transition, the general assumption is that an increase in coupling between brain areas is characteristic of seizures.[40] However, in some types of seizures a decrease in coupling can initially occur.[57,59,81] The studies carried out in patients, mostly with temporal lobe epilepsy, suffer from the important limitation of being based on a relatively small number of electrodes that, in general, do not provide satisfactory spatial sampling of the brain areas involved in the epileptic process. Thus, more detailed analyses of these brain systems based on adequate sampling in space and time are necessary to obtain a reliable insight into the evolution of the coupling between different brain areas at the onset and during epileptic seizures.

An even more controversial issue is whether the dynamical state of the brain systems involved in the generation of epileptic seizures, as revealed in EEG recordings, may provide a reliable indication of a *pre-ictal state*. The question, in practice, is whether measures derived from these EEG recordings could be used to anticipate or predict seizures. Assuming that epileptic seizures correspond to a state of increased synchronization, at least between some brain sites, one might expect that this increase of synchronization can gradually evolve in the pre-ictal state, and this gradual change might be detectable by appropriate analysis methods. After some early studies reporting that nonlinear dynamical EEG measures (e.g., Lyapunov exponents) might change some time before the onset of a seizure,[28,29] in the late 1990s a number of papers reporting that epileptic seizures could be predicted using nonlinear EEG measures appeared that had a large impact in the scientific and clinical communities,[12,52] leading even to an editorial comment in *Nature Medicine*.[69] A considerable number of studies followed these seminal papers, which were reviewed by several authors involved in this research line.[28,40,42,43,47,48] The initial perspectives were, however, too optimistic. One of the limitations of the early studies is that they were based on small sets of selected EEG data and did not include solid statistical evaluations of sufficiently long records. Furthermore, many of these studies used only specific EEG measures and did not analyze a comparative assessment of different methods of EEG analysis. Recently an issue of *Clinical Neurophysiology* (March 2005) published a useful collection of papers on this issue. The study of Mormann et al.[57] reports a second-generation study attempting to evaluate in a comprehensive way the predictability of seizures using 30 EEG measures, both linear and nonlinear, applied to long-term intracranial EEG recordings lasting over days. The authors concluded that a *pre-ictal period* can be identified and that a combination of univariate (e.g., Hjorth mobility and complexity) and bivariate (e.g., cross-correlation coefficient, Hilbert mean phase coherence, wavelet mean phase coherence) measures offers the most promising approach in seizure anticipation. It is important to emphasize that the direction of the change of the phase coherence, a measure of synchronization, can vary with electrode site, and it can increase at some sites while it decreases at adjacent sites. In addition, in an analysis of intracranial long-term EEGs in patients with mesial temporal lobe epilepsy Le Van Quyen et al.[40] found that phase synchronization can be used to characterize a pre-ictal state, although this is controversial.[31]

Recently the issue of the changes in dynamical properties of the EEG in the course of the process of transition toward an epileptic seizure has been explored using a different approach. Instead of analyzing the spontaneous EEG, the activity evoked by stimulating with bursts of pulse trains, applied intermittently during long periods lasting even days by way of intracranial electrodes, was used.[32] The EEG measure that showed the most significant performance was a quantitative measure of spectral phase demodulation, the relative phase clustering index (rPCI). In interictal periods, large values of rPCI recorded from specific sites were correlated with the most probable seizure onset sites, and large values of rPCI from certain locations were correlated with shorter time intervals to the next seizure, whereas small values were associated with much longer time intervals. This indicates that this approach might be relevant to estimating the probability of occurrence of epileptic seizures within a given time, at least in patients with mesial temporal epilepsy.

The studies of dynamical changes in EEG recorded in the course of the transition from the interictal to the ictal state, however, have been empirical without an appropriate theoretical framework, based on solid experimental data indicating how the activity of neuronal networks responsible for epileptic behavior develops in the course of time. This is an important limitation. A promising theoretical approach in this respect is that of Wendling et al.,[80] who proposed relevant models of such neuronal networks. More work along these lines is needed.

Generator Considerations

In the clinical consideration of seizures, it is important to ask whether the ictal generator is different from the interictal one(s). Conventional epileptology teaches that these generators are different and that the only reliable localization is by the study of ictal data, often from invasive recordings (cortical grids and depth electrodes). In practice, discussion usually proceeds to involve other possible foci, areas that were not recorded from. This issue is bound to arise, and a satisfactory resolution can be achieved only when there is convincing and converging evidence toward a particular generator/focus or, conversely, of multiple foci, so as to render focal surgical resection nonviable. The complexity of ictal localization is compounded by the fact that the focus might initiate a seizure accompanied by very low amplitude signals that can be recorded only by nearby depth electrodes. If no electrodes had been placed there, such signals would be lost. The first recorded ictal signals, then, might well be secondarily generated as a result of propagation. Such a scenario might well be present with temporal lobe foci, in which the seizures originate from the deep hippocampus or amygdala and propagate to the superficial temporal cortex.

There is evidence that the generators responsible for interictal discharges might overlap with ictal generators; this line of reasoning has been particularly supported by the findings of Ebersole[8] and Ebersole and Wade.[11] In fact, this should not come as a complete surprise if one considers that seizure surgery (temporal lobectomy and cortical resection) is guided by intraoperative interictal spike discharges. The obvious difficulty here is that there may be different types of interictal discharges recorded in a given patient from multiple scalp locations. This is in part a by-product of the ease of obtaining interictal spikes as compared with ictal episodes. Perhaps if one were to always insist on having an equally large number of ictal episodes, one would well appreciate the diversity of ictal patterns in the same given patient. Of course, this is not easily accomplished because ictal recordings usually require expensive hospitalization for many days under the direct supervision of skilled personnel using sophisticated equipment.

Expanding the horizons for the foregoing discussion, one can consider how other modalities image a seizure focus—computed tomography (CT) or MRI atrophy, positron emission tomography (PET) hypometabolism, single-photon emission tomography (SPECT) hypervascularization, functional

MRI (fMRI) enhancement, and so on. Each modality demonstrates a particular and unique aspect of the (interictal) behavior of the epileptogenic area. Therefore, it is not surprising that each modality might describe different aspects of this common epileptogenic area and that the resultant localizations from these techniques might not overlap completely. It follows that localization by interictal spikes falls into the same situation and should not be treated differently. It is necessary for any localization technique to have its measurement result well defined (i.e., variability and reproducibility). Therefore, serial scalp recordings must have been done with a complete cataloging of all interictal foci, their spike topography, and their morphology. For scalp recordings, quantitative descriptions are superior to qualitative descriptions and can be based on one of the aforementioned mathematical techniques.

In the final analysis, it is not relevant how localization is determined and whether mathematical models are "accurate" (whatever this means) when compared with a given standard. Rather, it is physiologic parsimony of model with clinical observations that is relevant, so that all available clinical information can be explained. The clinician can then confidently use the model (whether it be derived from MRI, PET, EEG, etc.) to make a diagnosis, infer behavior, and predict future outcome.

Such multimodality models require the coregistration of findings into real brain space. Currently, each modality obtains data and displays results in a particular manner, and it is difficult to make comparisons: Scalp EEG might be displayed using a two-dimensional flattened-scalp topography, whereas PET and CT create three-dimensional images of brain slices. Magnetic resonance imaging is a true three-dimensional anatomic display due to its resolution and software capabilities.

Recently, the co-registration of EEG and fMRI has become technically possible.[2,16,17,21,34,44] Nevertheless co-registration of different techniques poses difficult problems of interpretation. The goal should be for brain regions or structures to be identified with confidence when comparing across modalities, and not pixel locations, as shown on the computer screen from each modality. For other recent examples of co-registration see Moran et al.[56] and Mirkovic et al.[55]

A note of caution: There are readily available mathematical models that purport to yield source localization accuracy to within millimeters. These models claim to be able to identify activity as coming from very specific and small brain structures, based on parameters (e.g., 20 recording EEG electrodes) that most electrophysiologists would not associate with such accuracy. Lantz et al.[35] demonstrated the level of caution required before making conclusions from such analyses (see also Lehmann et al.[41] and Michel et al.[54]).

Summary and Conclusions

Quantitative analyses allow objective characterization of electromagnetic signals from spontaneous interictal spike discharges and ictal patterns. Such techniques are still being developed, but they appear at least to have good electroclinical correlations, which is encouraging. Current techniques lend themselves to the formulation of specific hypotheses and their application to clinical studies. There is still tremendous potential for making significant advances in the recovery of more information from the EEG-MEG signals.

Chapter 77

Polygraphic Recordings

Carlo Alberto Tassinari

Guido Rubboli

Introduction

Polygraphy is a general term that refers to the simultaneous recording of multiple physiologic measures. The main purpose of polygraphic investigations is to provide a correlation between the phenomenology of a behavioral manifestation and a set of physiologic parameters. The polygraphic study must be tailored to each clinical problem to select the parameters relevant to the nature and the characteristics of the manifestation being investigated. Several books and chapters have reported a list of the different variables that can be monitored polygraphically.[38,56,104,133]

In the study of epilepsy, polygraphy helps to determine the occurrence and characteristics of the modifications of different physiologic functions associated with changes in the electroencephalogram (EEG) and the temporal relationship with the EEG events. Data obtained by means of polygraphy can be extremely useful for describing the symptomatology of epileptic seizures, defining the clinical characteristics of different epileptic conditions, clarifying the physiopathogenetic mechanisms of epileptic conditions, establishing and verifying diagnostic hypotheses, and monitoring and evaluating the action of drugs. This chapter outlines some applications of polygraphic techniques to the study of epilepsy—in particular, its motor manifestations.

Technical Aspects

Currency

Polygraphic recordings are usually performed using modified EEG apparatus. An appropriate number of channels is required, either to collect sufficient information to localize abnormalities or to adequately record polygraphic data. Standard EEG machines usually employ a set of alternating current (AC) amplifiers to collect the data. However, this type of amplifier limits the possibility of recording constant or slowly varying signals (such as those produced by blood pressure, respiratory parameters, or electrodermal resistance). The availability of one or more direct current (DC)-coupled amplifiers can allow the collection of signals whose magnitudes or frequency characteristics range outside those provided by the standard EEG AC machines.

Methodology

The following parameters are relevant to epileptic seizures that can be monitored by means of polygraphic recordings.

Electroencephalogram

Data are collected following the standard procedure for EEG recording. The number of recording channels and the montage used depend on the characteristics of the clinical situation being investigated.

Electromyogram

Surface electromyogram (EMG) activity is obtained by applying two electrodes over the muscular belly of the recorded muscles. To allow collection of high-frequency EMG signals, a short time constant (0.03 second or less) to reduce artifacts caused by movement or sweating and minimum filtering are necessary. Simultaneous EEG and EMG recording can provide useful information to verify the existence of correlations between cortical and muscular events. Analysis of latency between EEG and EMG events, which was once difficult and imprecise by visual inspection of data on paper, can be performed more precisely and reliably by using computerized polygraphic systems that collect the neurophysiologic signals in a digital format and allow off-line processing and analysis of the data. Recording of EMG activity from antigravity muscles can be useful for investigating modification of the muscular tone associated with paroxysmal discharges. Disorders such as tremor or myoclonia require the monitoring of muscular activity of both agonist and antagonist muscle groups.

The inherent limitations of surface EMG, including difficulty recording from a deep or a single muscle without the interference of nearby muscles, loss of high-frequency muscular activity, and inability to obtain single-motor-unit activity, mean that there is only a gross correlation between the EEG and the compound activity of a single muscle. For analysis of the effect of epileptic activity on the single motor unit, needle EMG recording is indicated.

Electrooculogram

Eye movement recording is usually performed by placing two electrodes at the outer canthi to record horizontal movements and one electrode above and the other below one eye to record vertical movements.

When only one electrooculogram (EOG) channel is available, two electrodes can be used, one placed above the outer canthus of one eye and the other placed below the outer canthus of the opposite eye. Other systems have been proposed, including using infrared-detecting cells mounted on a spectacle frame together with an infrared-emitting diod[43] or employing piezoelectric sensors.[53] Electrooculography is particularly useful for detecting artifacts induced by eye movements, investigating lambda waves, studying ocular manifestations correlated with EEG paroxysms, such as in cases with epileptic nystagmus,[58,103] and scoring sleep stages in polysomnography. Computerized methods for removing the EOG artifacts using the EOG signal have been extensively described by Barlow.[5]

P.874

Electrocardiogram

Electrocardiograms (ECGs) can be easily recorded with an EEG device by placing two electrodes on the chest wall or—to obtain a lead I derivation—on the right and left arms. Sensitivity must be adjusted by switching from microvolts per millimeter to millivolts per millimeter; bandwidth ranges from 0.8 to 60 Hz. Simultaneous recording of EEG and ECG allows the detection of pulse and ECG artifacts contaminating the EEG tracing.

Respirogram

Respiratory activity can be monitored either by measuring the changes in thoracic volume due to respiratory movements or by detecting the flow of air through the nostrils and the mouth. Modifications of chest volume can be measured using a strain gauge attached to a piece of elastic forming a band around the chest. Variations of chest circumference due to respiration stretch the elastic band, causing a change in resistance in the strain gauge. Change in resistance can be measured by means of a DC-excited Wheatstone bridge circuit. This system requires that the patient remain still because chest size in moving individuals can change independently from respiration.

Another method for monitoring respiratory activity is to detect the air flow through nostrils and mouth by means of a thermocouple, which generates a current whenever warmed, or by a thermistor, which requires a constant-current source and reproduces changes of temperature as variations of resistance. Both thermocouples and thermistors must be placed between the nostrils and the mouth to detect differences in temperature between inspired and expired air. All of these methods require a long time constant (0.6 or 1 second) and filtering of high frequencies.

Electrodermal Response or Electrodermogram

Electrodermal (EDG) response, also referred to as *electrical skin resistance*, *galvanic skin reflex* or *response*, and *psychogalvanic reflex*, is a change in resistance and the generation of a potential between areas containing many sweat glands and areas almost devoid of them, due to modifications of sweat gland activity. Change in resistance is also called the *Fere effect*; the generation of a potential is called the *Tarchanoff response*. The Fere effect and the Tarchanoff response are probably two measures of the same phenomenon, both being affected by cholinergic modulation.[70]

Measurement of EDG response is performed by placing one electrode in the palm of the hand or on the sole of a foot and another in an area without sweat glands (such as the back of the hand). Another method is to place both electrodes on the dorsal surface of the forearm 5 to 6 cm apart. Recording must be performed using the longest time constant available with the maximum high-frequency filtering. Measurement of the skin potential, which appears as a DC potential (Tarchanoff response), is quite easy; however, it is unstable due to the possible occurrence of an offset potential at the electrode–skin interface and is difficult to control and distinguish from the EDG. For these reasons, measurement of change in skin resistance is more appropriate.

In normal individuals, resistance recorded from two electrodes on the hand ranges from 20 kΩ to perhaps 0.2 MΩ. If the autonomic nervous system is malfunctioning, resistance can reach values of >1 MΩ. Variations of EDG by measuring the Tarchanoff response during sleep in normal individuals and in patients with epilepsy have been described by Broughton et al.[16] Arousal is associated with a decrease in resistance and relaxation with an increase in resistance. Evident EDG modifications were observed—especially during sleep—and were associated with temporal lobe interictal discharges and brief generalized discharges of polyspikes (Fig. 1).

Blood Pressure Monitoring

Blood pressure can be monitored invasively by introducing a microcatheter in the radial artery. The microcatheter is connected with a pressure transducer to polygraph preamplifiers. DC recording is required. It is possible, via microcatheter, to obtain blood samples for blood gas measurements. A preferable method for monitoring blood pressure is a noninvasive assessment based on the computerized processing of instantaneous blood pressure modifications, which are collected by a plethysmographic system applied, usually, to the middle finger of the hand.

Micturition Recorder

A micturition recorder is a device that allows the detection of enuresis or loss of urine due to a convulsive seizure. Broughton[37] designed a system consisting of two long electrodes, in separate nylon sheaths, placed parallel with and close to one another in a serpentine shape close to the urinary meatus. The signal recorded, using a high upper-frequency response and a short time constant, is a 50-Hz artifact (60 Hz in North America). As soon as the patient urinates, the first drops of urine create a conductive path between the two electrodes that causes the disappearance of the artifact.

Body Movement Detectors

Systems for signaling body movements are usually based on displacement transducers, accelerometers, or actigraphy monitors. These systems can be applied to the bed of the patient—especially when the aim is to detect seizures during sleep[131]—or to body parts. A wrist accelerometer can be extremely useful for monitoring movements during sleep,[60] identifying different types of movements (tremors, myoclonia),[72] and differentiating EEG activity from movement artifacts.[18] Actigraphs are small, wrist-worn devices (usually about the size of a wristwatch) that measure movements; they are equipped with a microprocessor and an on-board memory that can allow off-line analysis and display. Actigraphy monitoring is particularly useful in the study of sleep and circadian rhythms.[2,64]

Gastrointestinal Activity Monitoring

Motility of the gastrointestinal tract was studied by means of EMG recording of the duodenal activity[116] using bipolar platinum electrodes. This study investigated modifications of duodenal motility in relation to wakefulness, sleeping (Fig. 2), and ictal activity (Fig. 3). Cherubini et al.[20] polygraphic techniques, including monitoring of EMG activity of intestines in cats, to investigate the effects of pharmacologically induced generalized epileptic seizures on intestinal motility.

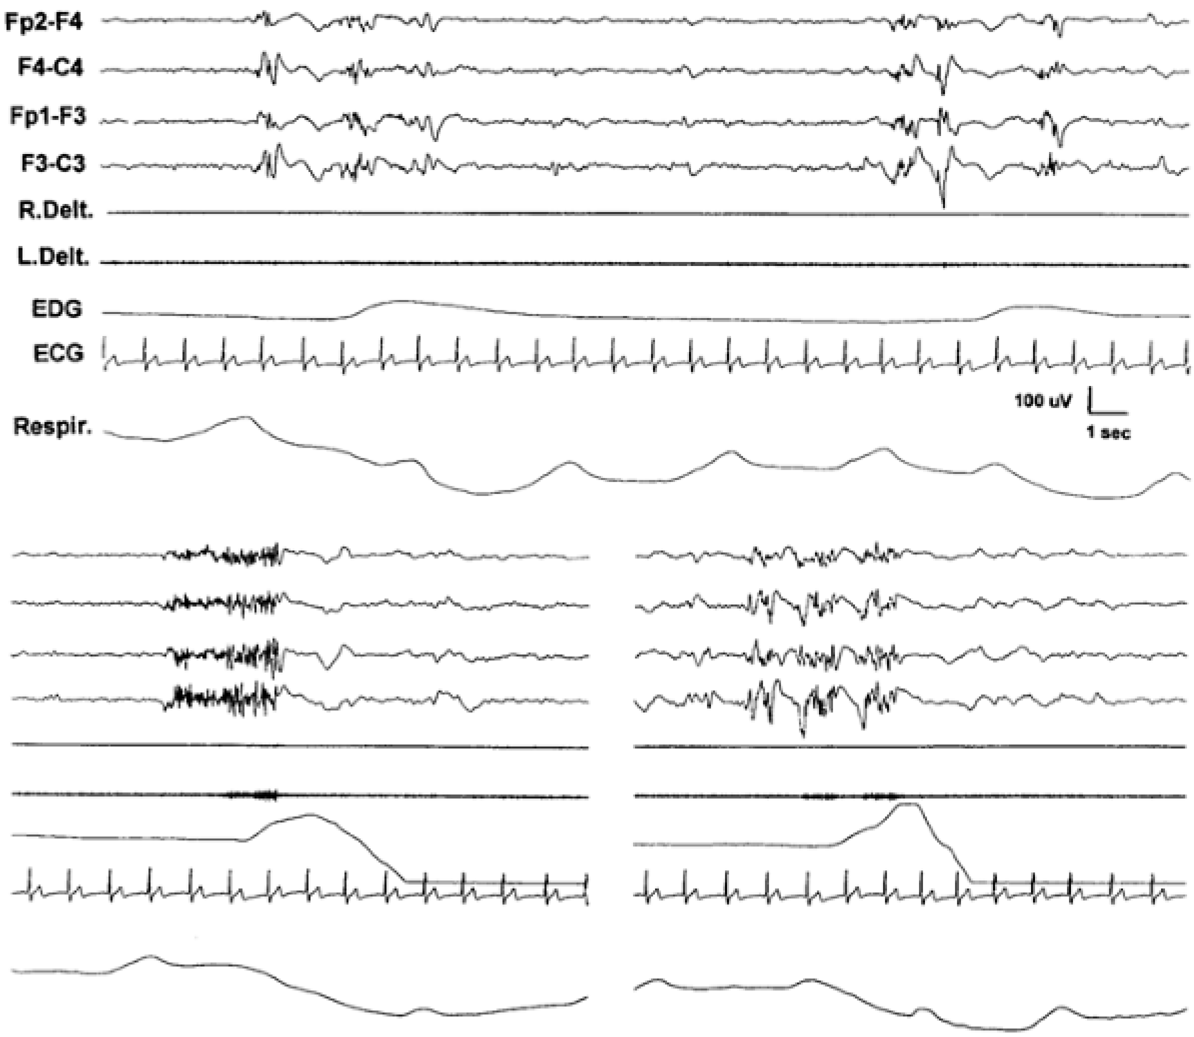

FIGURE 1. Modifications of electrodermogram (EDG) associated with paroxysmal electroencephalogram (EEG) activity during sleep. **Upper:** Slight EDG changes, indicating a modification of skin potential (Tarchanoff effect), occur as the only manifestation associated with diffuse polyspike-wave activity (note the absence of EMG changes in the deltoids and of modifications of electrocardiogram [ECG] and respiratory rate). **Lower:** Fast rhythmic activity of polyspikes accompanied by a more significant EDG modification, mild contraction on the left deltoid, and change of respiration. L. Delt, left deltoid; R. Delt., right deltoid; Respir., thoracic respiration.

Polysomnography in Patients With Epilepsy

The term *polysomnography* refers to polygraphic recordings of sleep/wake cycle in subjects with sleep disorders. Technical or methodologic aspects of these techniques applied to the study of sleep have been addressed in specialized books and monographs.[15,59,61,128] In patients with epilepsy, the role of sleep in facilitating seizures and in activating interictal EEG paroxysmal abnormalities is well known. On the other hand, epileptic seizures can be responsible for modifications of sleep architecture. The relevance of the relationship between epilepsy and sleep has been acknowledged.[28,102,132] Sleep polygraphic studies in epilepsy can be extremely useful for diagnosis and for understanding some of the physiopathologic mechanisms of sleep and epilepsy.[5a]

In epilepsy, polysomnographic studies can be indicated for two reasons: (a) to investigate the presence of disturbances

P.875

of vigilance or sleep in patients with epilepsy and (b) to identify and analyze paroxysmal interictal activities, detect nighttime seizures, and evaluate the influence of epilepsy on sleep.

Altered alertness in patients with epilepsy can be due to several factors that are either related or unrelated to the epilepsy. Frequent nocturnal seizures altering sleep structure, antiepileptic treatment, and epileptogenic lesions affecting anatomic structures related to vigilance can cause excessive sleepiness in patients with epilepsy. Polysomnographic studies can document the possible occurrence of sleep disorders, such as sleep apnea, and other respiratory disorders, nocturnal myoclonus, or restless leg syndrome.

When the goal of polysomnography is to document nighttime seizures or to investigate the relationship between sleep and epilepsy, a higher number of EEG channels is required than for standard polysomnography. Overnight polysomnography can be helpful to discriminate between epileptic and nonepileptic nocturnal episodes,[12,37,49,55,74,77,101,120] characterize and classify nocturnal epileptic seizures,[8,75,110] establish the occurrence of electrical status epilepticus during sleep,[107,108] identify the primary focus in localization-related epilepsy by investigating topography of paroxysms during rapid-eye-movement (REM) sleep,[71,89] and analyze the behavior of interictal discharges during sleep.[8,25,27,33,36,66,84,125,126]

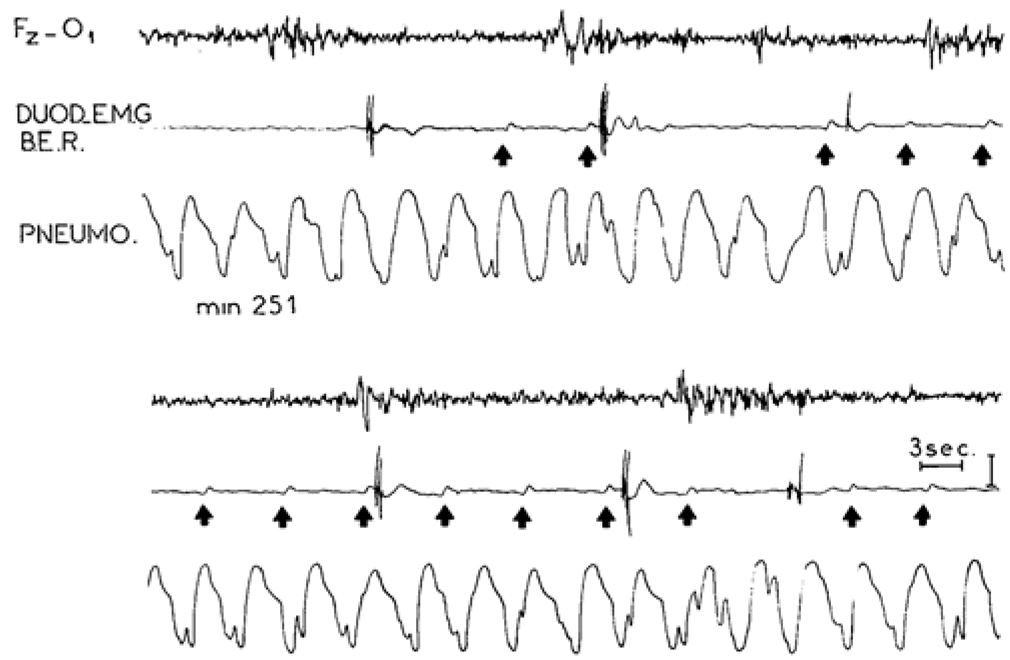

FIGURE 2. Sleep polygraphic tracing with duodenal electromyogram (EMG) recording in a normal individual. Basal electrical activity can be associated with bursts of muscular potentials accompanying duodenal contractions (*arrows*). No constant relation is observed between duodenal electrical activity and K complexes. DUOD E.M.G. BER, duodenal EMG demonstrating basal electrical activity; PNEUMO., respirogram.

Polygraphic Studies in the Investigation of Epileptic Motor Manifestations

Motor phenomena are often the most overt clinical aspects of an epileptic seizure. However, when one is relying solely on clinical data, the patterns of muscular activations can be difficult to characterize and analyze. Mild contractions or sporadic muscle twitchings can often be missed by an observer. Polygraphy with recording of surface EMG activity can be extremely

P.876

P.877

useful in identifying and characterizing even subtle and apparently subclinical muscular manifestations and correlating these movements with EEG activities.

Analysis of Motor Phenomenon

Surface EMG recording can provide information regarding the modality of muscular contraction, which can allow distinctions to be made among different types of motor phenomenon. All of the following types of muscular phenomena can occur, either in isolation or in various combinations, to constitute the clinical manifestations of the different types of epileptic seizures.

Myoclonus

A positive myoclonus is characterized by a massive, shock-like muscular contraction involving one or more body segments. It appears in the EMG as a brief burst of muscular potentials (Fig. 4), synchronous on agonist and antagonist muscles, with or without an EEG correlate. The opposite phenomenon, a "negative" myoclonus, is a brief interruption of a tonic muscular contraction (Fig. 4), sometimes clinically indistinguishable from the positive myoclonus.[94,123] When associated with a paroxysmal EEG event, a *negative myoclonus* is defined as "epileptic negative myoclonus" (Fig. 5).[48,106,122] Negative myoclonus, defined as an interruption of tonic muscular activity for <500 msec without evidence of preceding myoclonia, was recognized in 2001 as a seizure type by the Task Force of the International League Against Epilepsy on Classification and Terminology.[13]

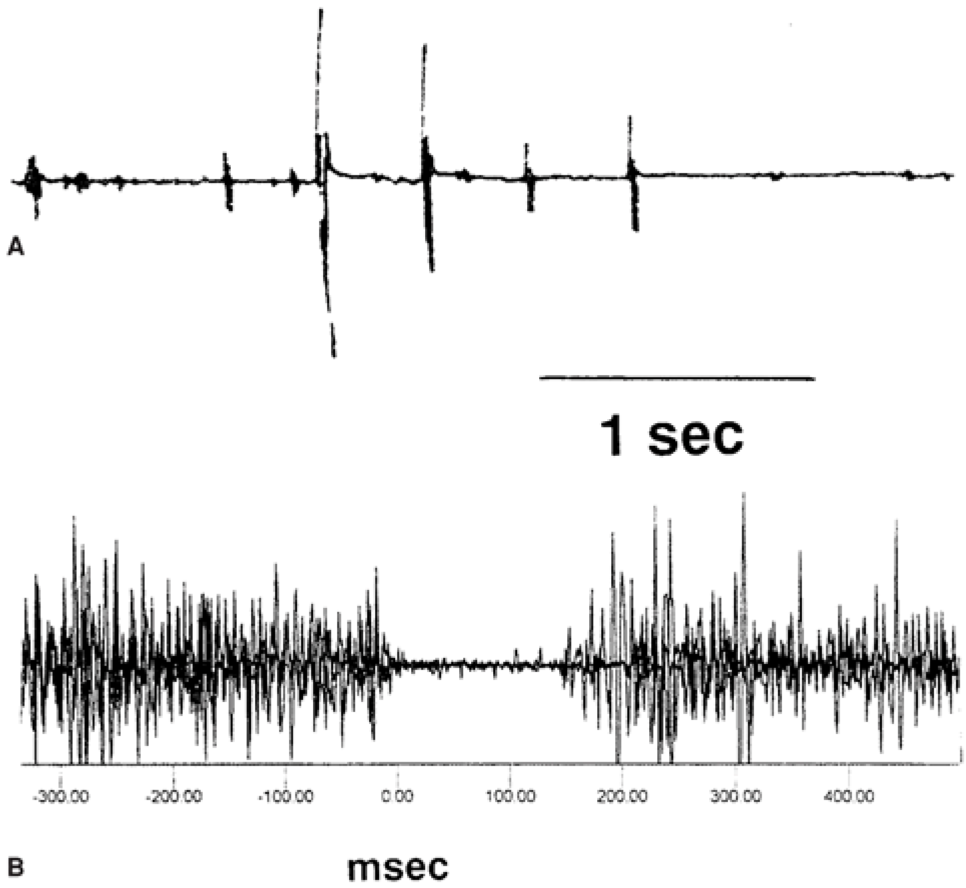

FIGURE 4. A: Positive myoclonus. **B:** Negative myoclonus.

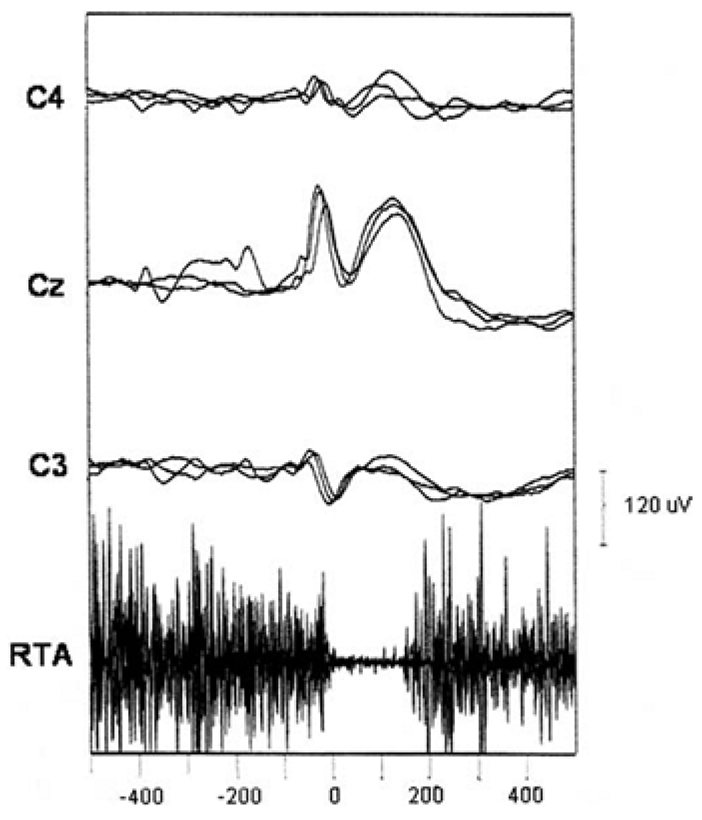

FIGURE 5. Epileptic negative myoclonus. Superposition of three polygraphic segments illustrating a spike-wave complex on Cz, slightly spreading to C3 and C4, associated with epileptic negative myoclonus in right tibialis anterior (RTA), in a child with benign partial epilepsy of infancy. The onset of the electromyogram silent period in RTA precedes the onset of the slow-wave component on Cz, suggesting that the muscular inhibition is related to the spike and not to the slow wave.

Spasm

A spasm, which appears as a massive but slow contraction reaching a climax and progressively decreasing, more often than not involves axial and proximal muscular groups. Indeed, polygraphic recordings with multiple EMG leads have demonstrated that epileptic spasms can occur with a complex pattern of muscular activation, with the involvement of cranial as well as limb and axial muscles. This complex pattern of contraction can appear clinically similar in different spasms, although with variable sequences of muscular recruitment (Fig. 6).[10,134] On the EEG, spasms can be devoid of any modification of tracing or they can be associated with flattening, diffuse low-voltage fast activity,[42] or a slow wave.[34,46]

Tonic Contractions

Tonic contractions consist of slow, sustained contractions maintained over time and involving several muscular groups. They are usually associated with fast recruiting EEG activity.

Clonic Contractions

Clonic contractions are characterized by a series of jerks, appearing on the EMG as hypersynchronous muscular potentials. They can vary in amplitude, symmetry, frequency, and topography and are often related to contralateral EEG spikes.[42]

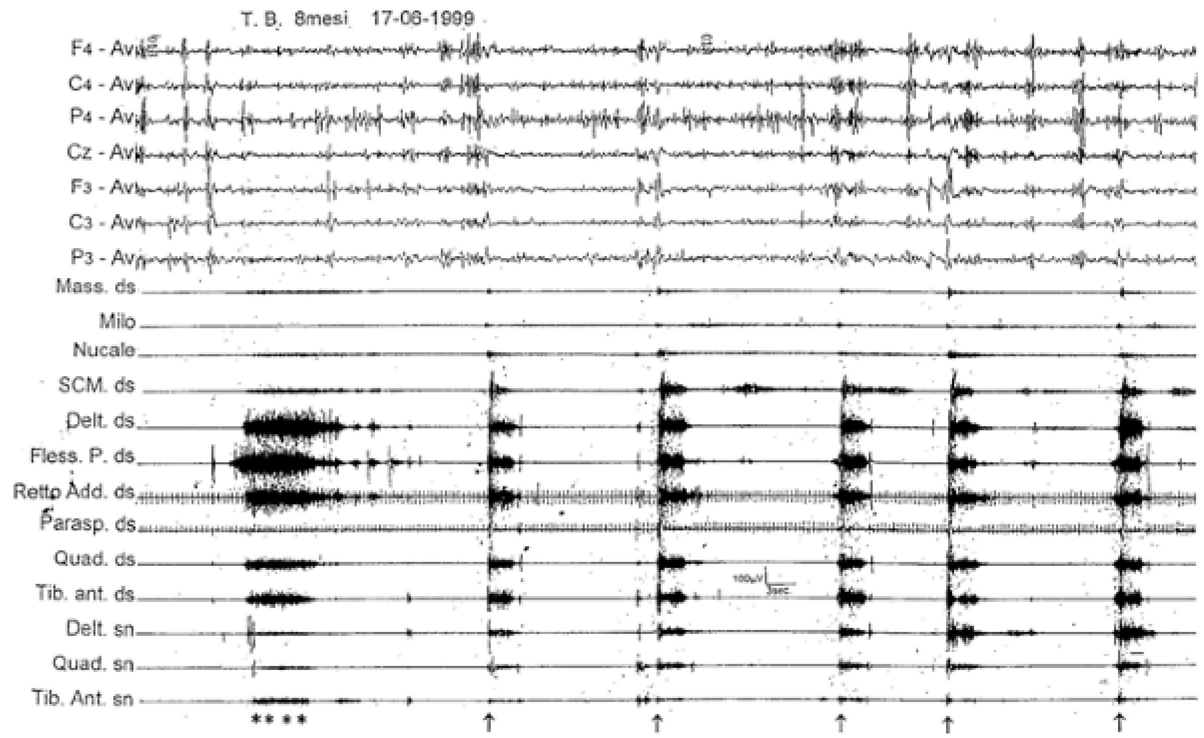

FIGURE 6. Polygraphic recording of a cluster of spasms (*arrows*) following a brief tonic seizure (*asterisks*) in

an 8-month-old child with severe epileptic encephalopathy associated with cortical dysplasia. The multichannel electromyogram recording shows the involvement of cranial, trunk, and limb muscles with a quite reproducible pattern. A slow complex associated with the spasms is detectable in the electroencephalogram (horizontal time scale: 3 s). Delt., deltoid; ds, right; Fless. P., wrist flexor; Mass., masseter; Milo, mylohyoideus; Nucale, splenium capitis; Parasp, paraspinal muscles; Quad., quadriceps; Retto Add., rectus abdominis; SCM., sternocleidomastoideus; sn, left; Tib.ant., tibialis anterior.

Atonic Phenomena

Atonic phenomena can appear as a sudden global or focal loss of muscular tone, characterized polygraphically by an abrupt flattening of the EMG activity. They are associated with different types of EEG paroxysmal discharges (generalized spike- or polyspike-and-wave, diffuse fast rhythmic spikes, bilateral synchronous fast waves intermixed with slow waves) or with no EEG changes at all.[42]

Analysis of Motor Pattern

Polygraphy can be extremely relevant for defining the characteristics of a motor manifestation during a seizure in terms of (a) the relationship with the concomitant EEG activity, (b) muscular groups involved in the seizure, (c) the temporal succession and the time course of the activation of motor patterns during the seizure, and (d) the presence of a stereotypic motor pattern across different seizure types.

Generalized Tonic–Clonic Seizures

Polygraphic recordings make it possible to characterize the complex manifestations of generalized tonic–clonic seizures, which are composed of a more or less stereotyped sequence of motor phenomena.[9,29,38,40] This sequence consists of an initial tonic phase of sustained muscular contraction lasting 10 to 20 seconds and involving all skeletal muscles. This phase is responsible for the characteristic body attitude (a flexion followed by a longer extension phase). A diffuse vibratory contraction follows this initial phase, and clonic manifestations follow next. The clonic manifestations consist of brief, maximal flexor contractions of the whole body, with the interval between the jerks becoming progressively longer. It is interesting that polygraphic recordings have demonstrated that, just a few seconds after the last clonic jerk, a new tonic phase usually reappears, as intense as the first one but with different topographic distribution, involving mainly facial and masticatory muscles.[42]

The EEG correlates of a tonic–clonic seizure are usually represented by an initial desynchronization, sometimes preceded by generalized bursts of polyspike-and-waves, followed by a recruiting rhythm. These are intermixed with slow waves of decreasing frequency and increasing amplitude that correspond, at a certain point, with the interruption of the tonic massive contraction and with the onset of the clonic manifestations. A flattening of the EEG activity follows, which represents the phase of “cortical extinction” and lasts several seconds (see Chapters 47 and 74).

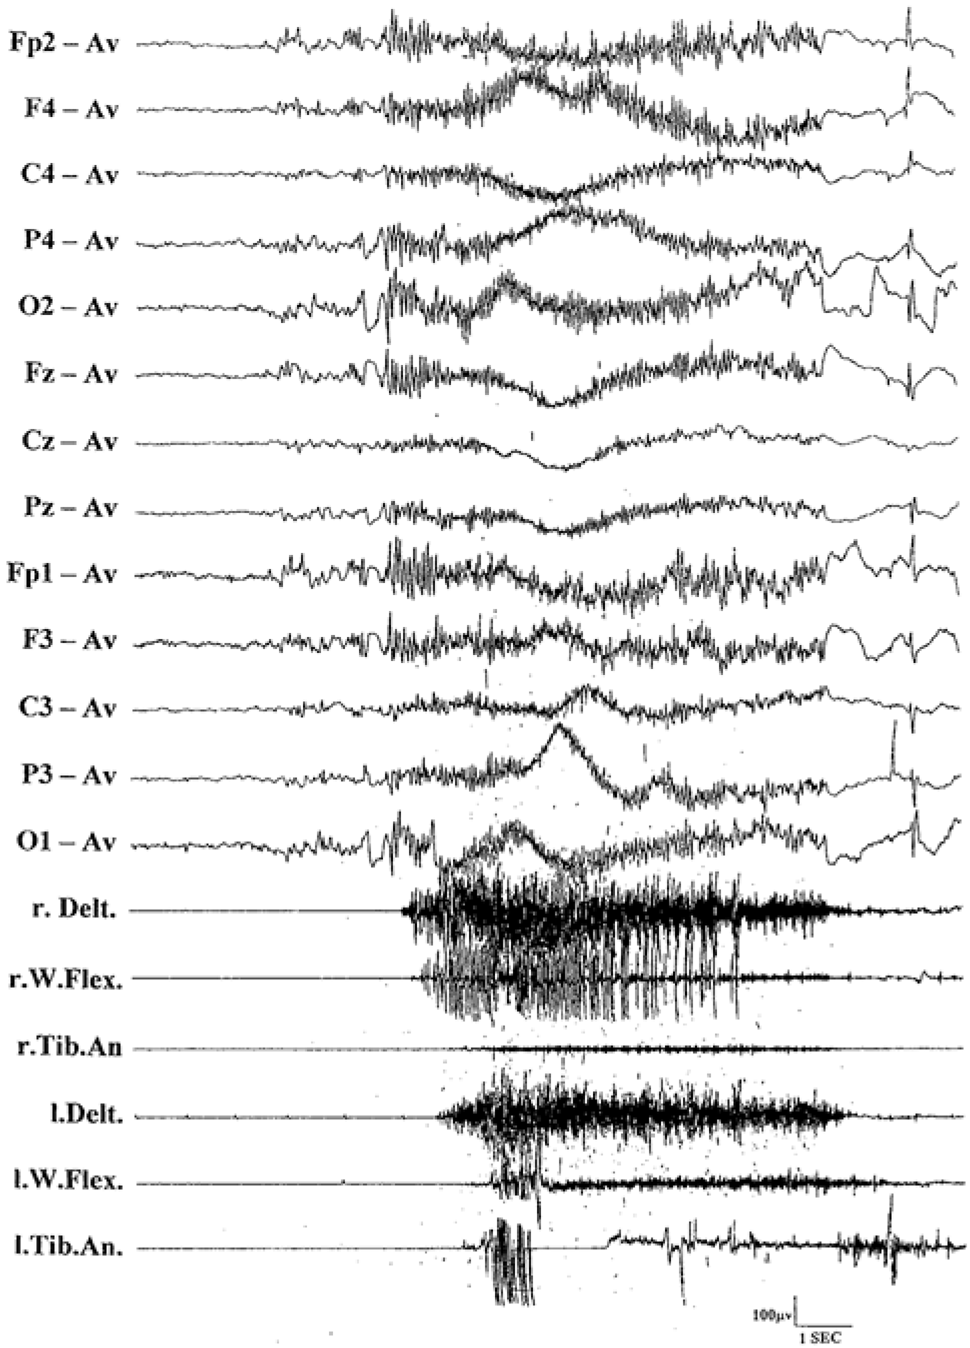

FIGURE 7. Tonic seizure. The bilateral tonic contraction, more prominent in both deltoids, is associated with a fast rhythmic polyspike activity. Delt., deltoid; l, left; r., right; Tib. An., tibialis anterior; W. Flex., wrist flexor.

Tonic Seizures

Clinical features of tonic seizures consist of a brief (5 to 20 seconds) muscular tonic contraction accompanied by impairment of consciousness and involving, with varying degrees of intensity and extension, distinct muscular groups (i.e., the head and trunk or the limb girdles and, to a lesser extent, the legs) or the whole body.[19,40,41,42] The associated polygraphic findings are represented by different EEG patterns such as (a) flattening of the tracing, (b) fast activity (around 20 Hz) of progressively increasing amplitude, and (c) recruiting rhythmic discharge at about 10 Hz, sometimes of high amplitude from the onset. The EMG leads show an interference pattern in all involved muscles corresponding to the tonic contraction (Fig. 7). Different

P.879

patterns of muscular activation can be observed according to the duration of the seizure: When it lasts a short time, the contraction is maximal at the onset, then decreases; when it is of longer duration, a progressive increment of the muscular activity reflects the increasing intensity of the contraction. In global tonic seizures, an axial preponderance of the muscular activation is evident. Asymmetry of the tonic contraction or the occurrence of myoclonia at the end of the tonic manifestation can be observed. Tonic seizures are often associated with autonomic changes, such as modifications of heart and respiration rate, mydriasis, vasomotor phenomena, increase in intravesicular pressure, and positive electrodermogram responses (see Chapter 52).[19,40]

Myoclonic Absences

In myoclonic absences, the appearance of a generalized 3-c/s spike-and-wave discharge lasting up to several seconds is associated with myoclonic jerks (see Chapter 240). These jerks are particularly evident in the upper limbs and are polygraphically characterized by myoclonic potentials that, a few seconds after the beginning of the discharge, are superimposed on a progressively increasing tonic muscular contraction, which mainly involves the shoulders and the deltoids and results in the abduction and elevation of the upper limbs (Fig. 8).[109,118] With extra leads, facial muscles and the mentalis and orbiculus oris muscles can be observed for twitchings synchronous with the spike-and-wave complex. Oscilloscopic analysis of the EEG/EMG correlation has demonstrated that the positive transient of the 3-c/s spike-and-wave complex[137] is correlated with the appearance of the myoclonic jerks. Latency between the myoclonic jerk and the spike on the EEG is 15 to 40 msec for the upper limbs and 50 to 70 msec for the lower limbs. The myoclonic bursts are followed by a brief (60 to 120 msec) silent period that interrupts the tonic contraction (Fig. 9).[109]

Juvenile Myoclonic Epilepsy

Polygraphy can be extremely useful for supporting a diagnosis of juvenile myoclonic epilepsy, in which brief myo-clonic jerks—particularly in the upper limbs—are associated with polyspike-and-wave complexes at a frequency of 3 to

P.880

P.881

P.882

3.5 c/s (see Chapter 244).[54,99] Computerized polygraphic recordings have shown that myoclonic potentials in juvenile myoclonic epilepsy are related to a cortical positive potential encompassed in the polyspike discharge of the polyspike-wave complex.[73]

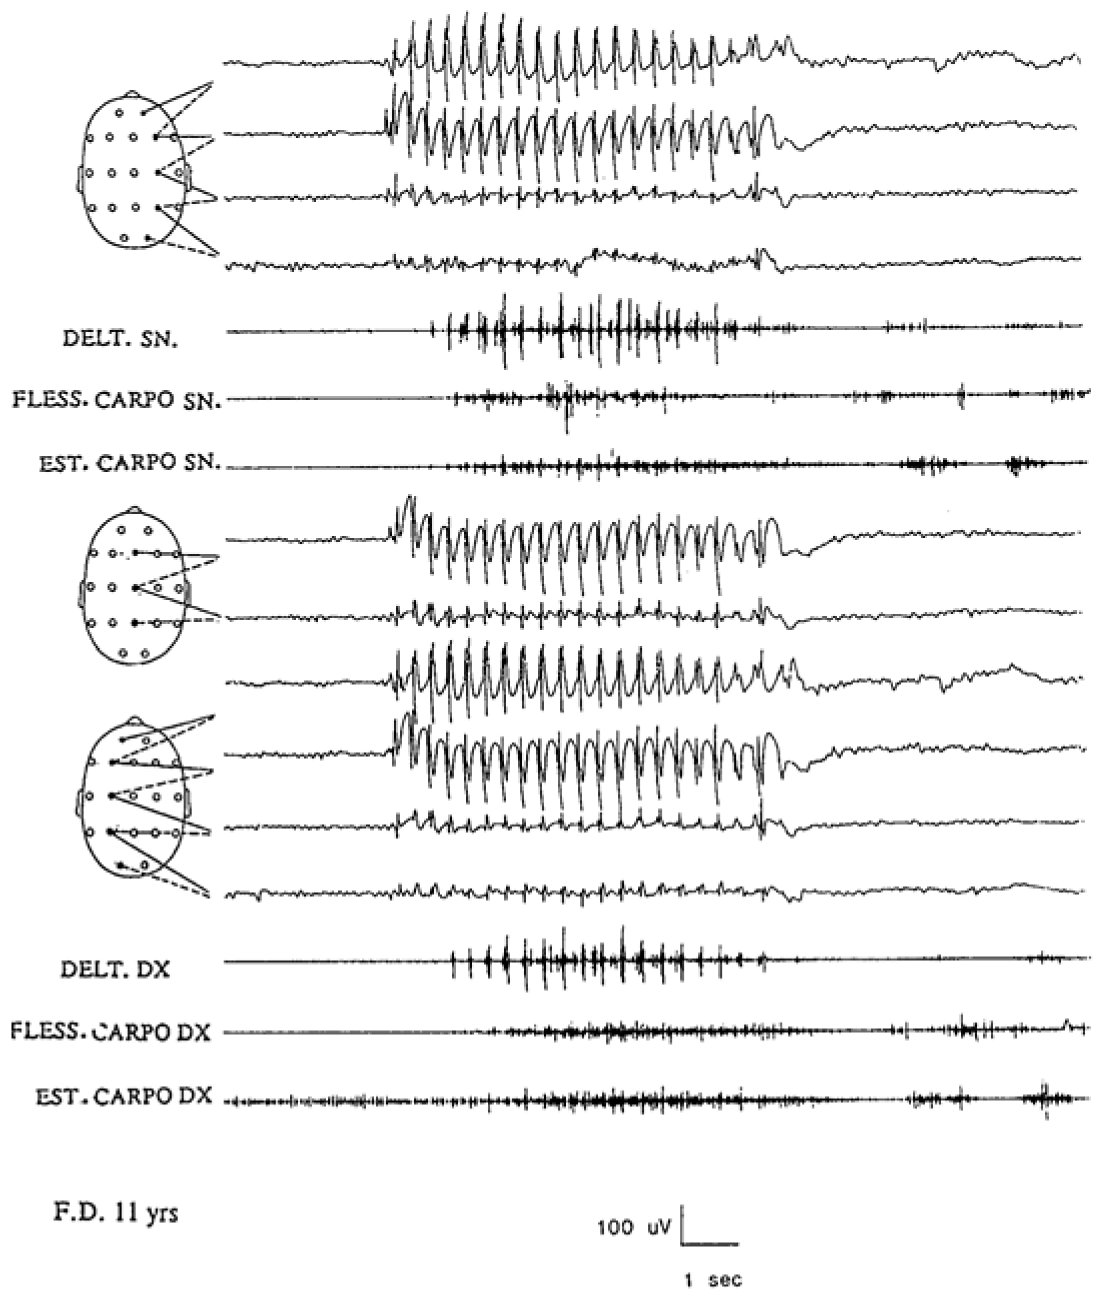

FIGURE 8. Myoclonic absence. A 3-c/s generalized spike-and-wave discharge is accompanied by rhythmic myoclonic jerks in the upper limbs, particularly evident on the deltoids, occurring at the same frequency of the spike-and-wave complexes and progressively associated with a tonic contraction. DELT. SN. and DELT. DX., left and right deltoid, respectively; EST CARPO SN. and EST. CARPO DX, left and right extensor carpi, respectively; FLESS. CARPO SN. and FLESS. CARPO DX, left and right flexor carpi, respectively.

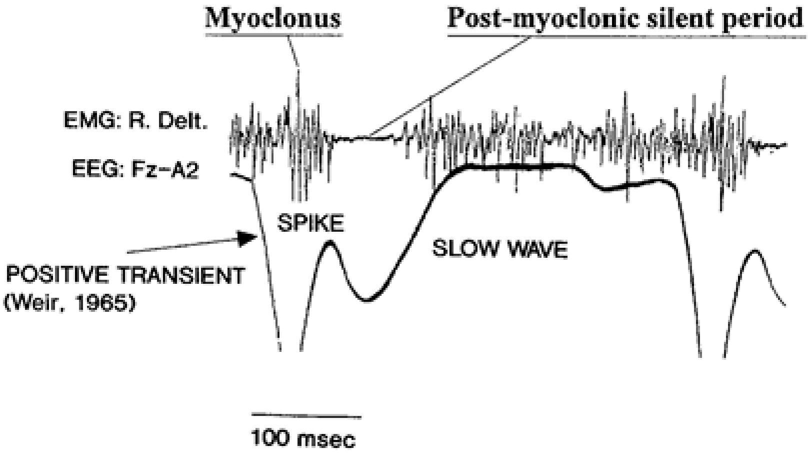

FIGURE 9. Electroencephalographic (EEG)/electromyo-graphic (EMG) correlation on oscilloscope of the spike-and-wave complex and associated muscular events in myoclonic absences. The myoclonic potential is associated with a positive transient preceding the spike and is followed by a postmyoclonic EMG silent period. R. Delt., right deltoid.

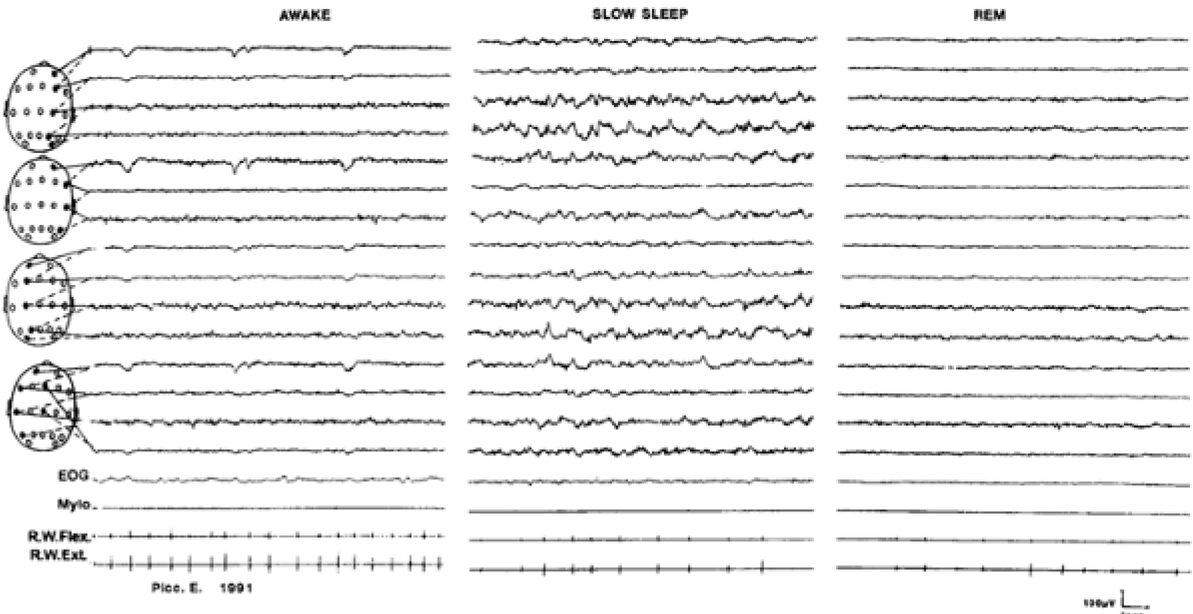

FIGURE 10. Rhythmic contractions of the right upper limb in a case of epilepsia partialis continua. No evident electroencephalographic activity was correlated with the myoclonic jerks. Note the persistence of myoclonia, although with some modulation of frequency, during sleep. EOG, electrooculogram; Mylo, mylohyoideus; R.W. Ext., right wrist extensor; R.W. Flex, right wrist flexor; REM, rapid eye movement.

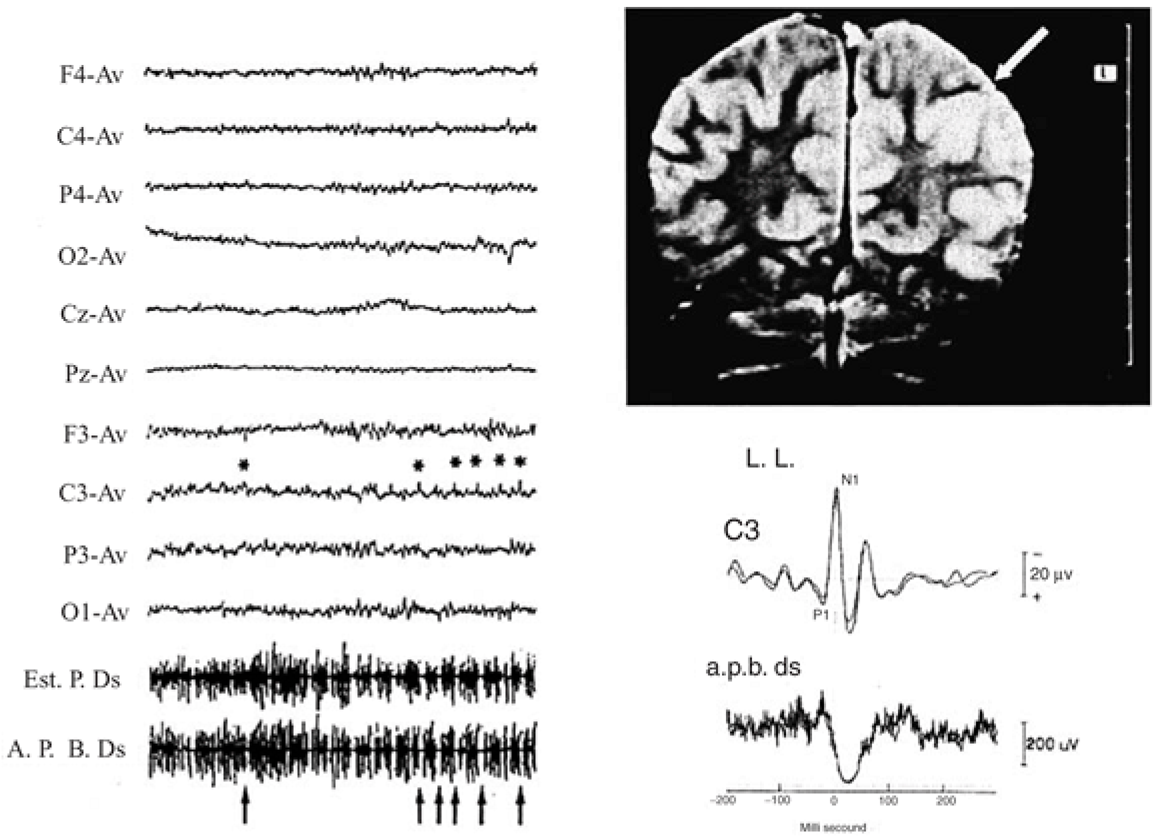

FIGURE 11. Left: Subcontinuous epileptic negative myoclonia (*arrows*) in the right wrist extensor (Est.P.Ds) and right abductor pollicis brevis (A.P.B.Ds) associated with small-amplitude spikes (*asterisks*) in the left central region in a patient with focal epilepsy associated with left parietal focal cortical dysplasia (indicated by the arrow in the magnetic resonance image shown in the right upper panel). **Lower Right:** Average of the C3 spikes triggered at the peak of the spike and rectified electromyogram (EMG) of the right abductor pollicis brevis (a.b.p. ds). No positive myoclonia precedes the onset of the brief EMG silent period associated with the C3 spike.

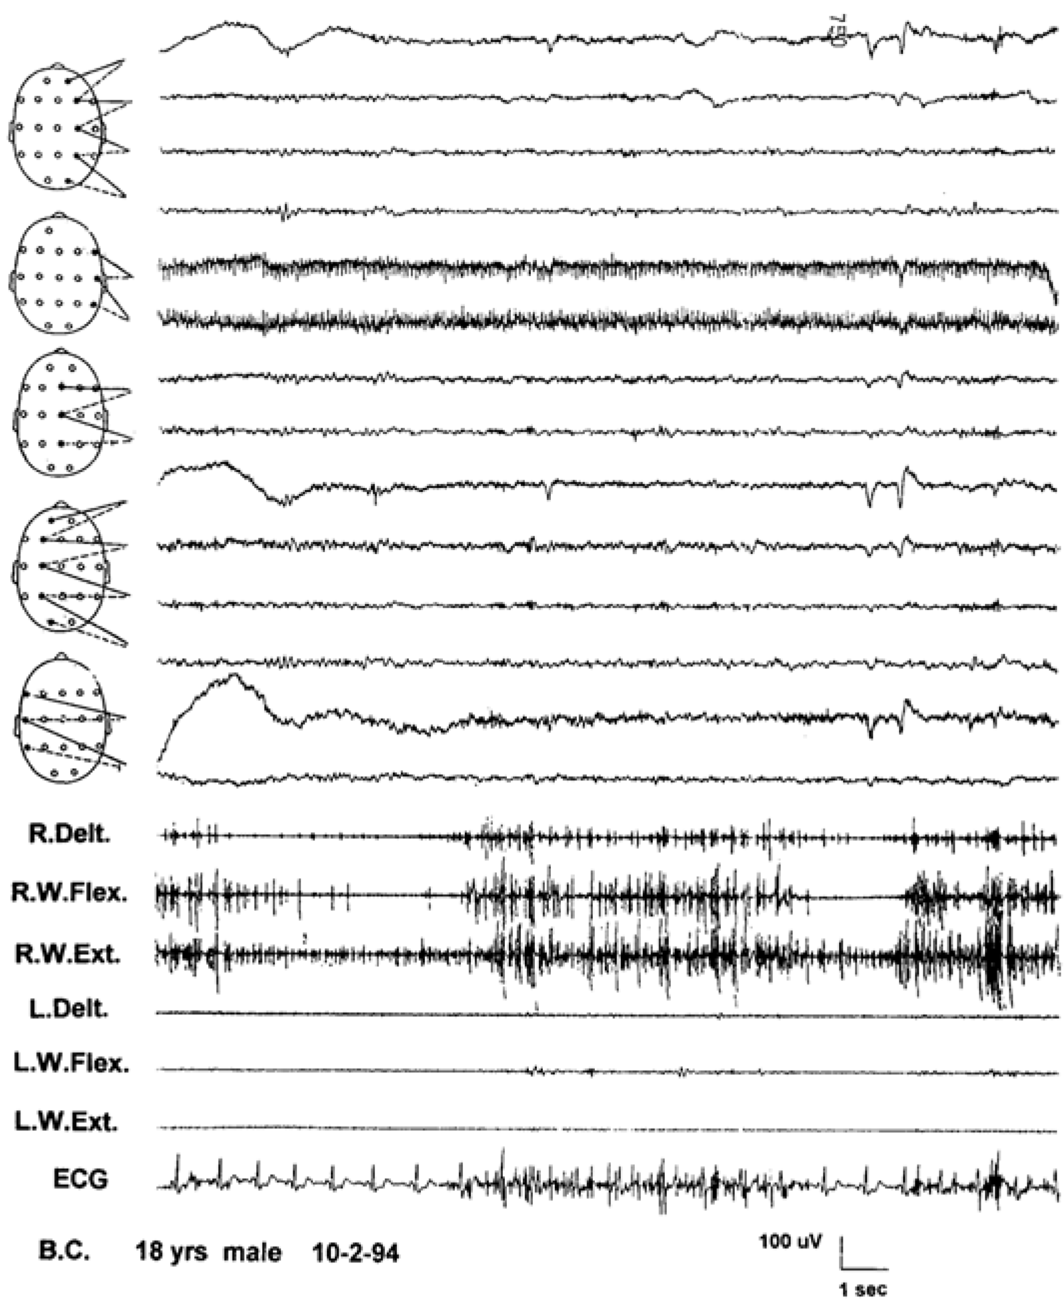

FIGURE 12. Action myoclonus in the right upper limb of a patient with progressive myoclonus epilepsy. The patient was asked to touch with his right index finger the tip of the index finger of the examiner. Muscular contraction in the right arm is fragmented by myoclonic potentials, intermixed with brief silent periods. No evident electroencephalographic modifications were associated. L. Delt., left deltoid; L.W. Ext., left wrist extensor; L.W. Flex., left wrist flexor; ECG, electroencephalogram; R.Delt. right deltoid; R.W. Ext., right wrist extensor; R.W. Flex., right wrist flexor.

Epilepsia Partialis Continua

In cases of epilepsia partialis continua, polygraphic study allows the analysis of the rhythm, intensity, rate, and distribution of the muscle jerks.[127] Myoclonic EMG potentials can be associated on the EEG with slow focal abnormalities, focal paroxysmal discharges, or no evident paroxysmal activity (Fig. 10) (see Chapters 61 and 243).

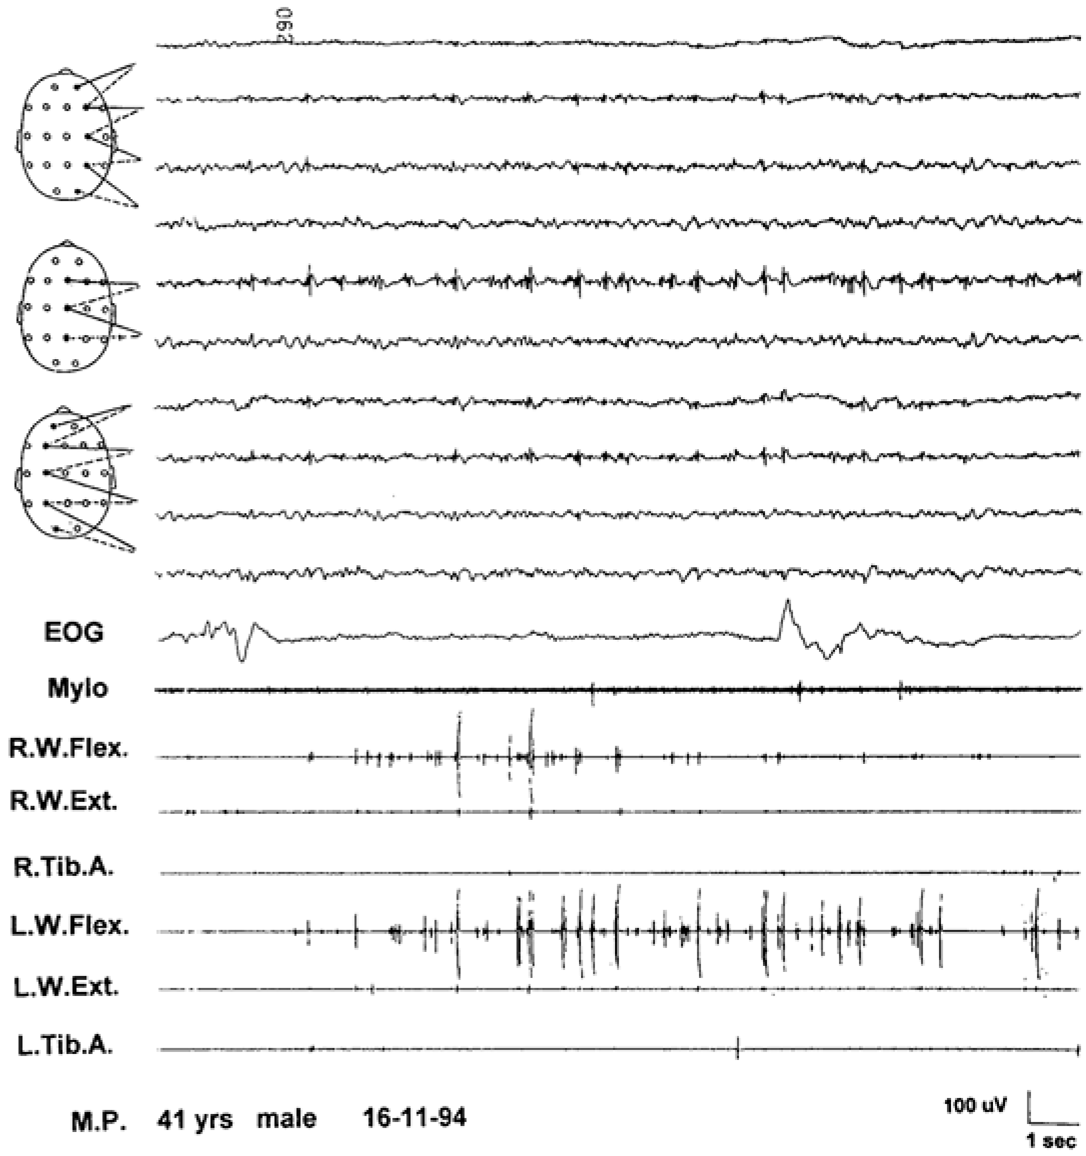

FIGURE 13. Polygraphic recording during rapid-eye-movement (REM) sleep in a patient with Unverricht-Lundborg disease. The tracing is characterized by fast spikes at the vertex, diffusing to parasagittal regions, and abundant, erratic myoclonic jerks, inconstantly related to the vertex spikes. EOG, electrooculogram; L.W. Ext., left wrist extensor; L.W. Flex, left wrist flexor; L. Tib. A., left tibialis anterior; Mylo, mylohyoideus; R.W. Ext., right wrist extensor; R.W. Flex, right wrist flexor; R. Tib. A., right tibialis anterior.

Epileptic Negative Myoclonus

Some patients with epilepsy can present with a clinical picture resembling epilepsia partialis continua, characterized by frequent, subcontinuous jerks, evident when the patient maintains a posture, or by a tonic contraction (Fig. 11). Polygraphic recordings can be crucial in defining the exact nature of this motor disorder, which can be caused by subcontinuous epileptic negative myoclonia (i.e., brief lapses of the muscular activity time-locked to paroxysmal EEG activity).[48,106,122] In epileptic negative myoclonus, the interruption of the muscular activity occurs synchronously on agonist and antagonist muscles; when epileptic negative myoclonus is focal, involving one or both limbs on the same side of the body, it is usually associated

P.883

with a contralateral EEG spike located in the centroparietal region. Epileptic negative myoclonus can be found in a wide spectrum of epileptic conditions—idiopathic, cryptogenic, and symptomatic (see also Chapter 277).[122]

Progressive Myoclonic Epilepsies

The polygraphic features of progressive myoclonus epilepsies, such as Unverricht-Lundborg disease, consist of constantly present action myoclonus, characterized by high-amplitude EMG potentials of short duration (20 to 30 msec), which are synchronous on agonist and antagonist muscles. These are followed by an EMG-silent period lasting 40 to 120 msec (rarely up to 300 msec) (Fig. 12). The myoclonic bursts and the silent periods are inconstantly related to EEG spike-and-waves and polyspike-and-waves.[113] Myoclonic seizures in Unverricht-Lundborg patients are characterized by generalized myoclonia, predominant proximally in the upper limbs, with varying rhythm and associated with generalized, symmetric polyspikes or polyspike-and-waves. Lafora disease is characterized polygraphically by the presence of abundant, asymmetric, asynchronous, subtle myoclonia at rest, diffuse to all muscular groups, usually without an EEG correlate.[81,110] In the progressive myoclonus epilepsies, intermittent photic stimulation is very effective in eliciting fast polyspikes and polyspike-and-waves associated with massive myoclonic jerks (see also Chapter 252).[81,112]

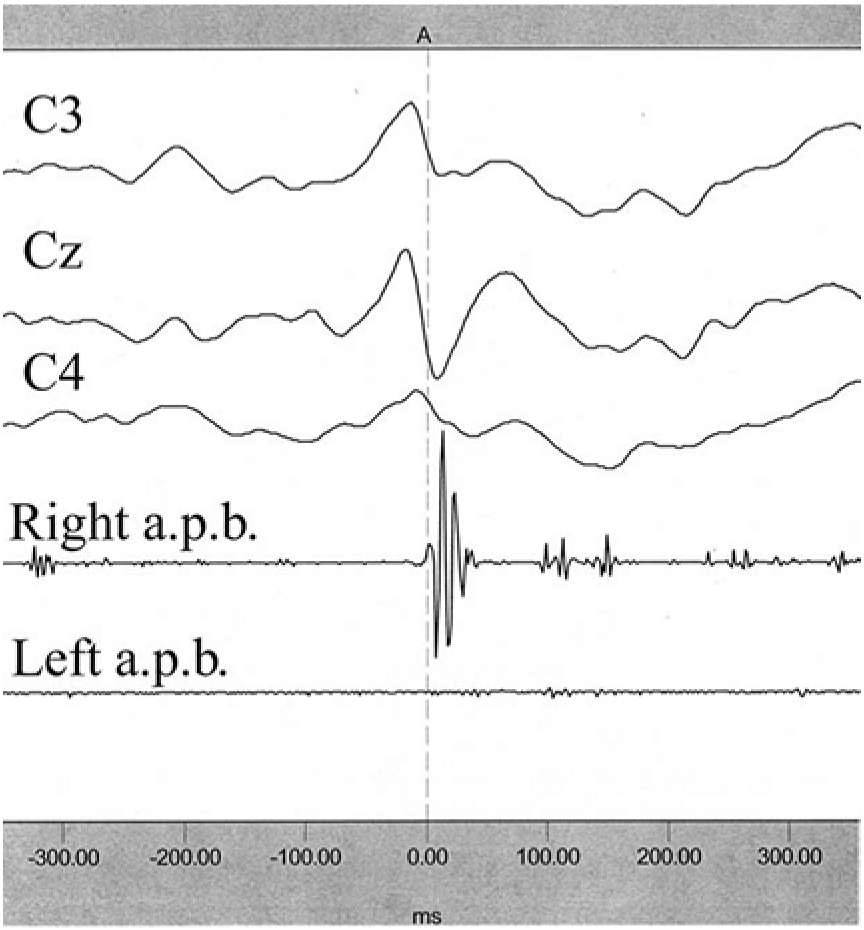

FIGURE 14. A patient with Lafora disease. Jerk-locked averaging triggered from the onset of the myoclonic potential in the right abductor pollicis brevis (Right a.p.b.) showing a premyoclonic electroencephalographic potential in the left central region and on the vertex (number of averaged myoclonia = 125). Left a.p.b., left abductor pollicis brevis.

Evolution of Motor Manifestations in Relation to Sleep–Wake Cycle

Epileptic manifestations are entrained to the sleep–wake cycle in a consistent number of epileptic conditions (see Chapters 187 and 188). Accordingly, epileptic motor phenomena can show modifications in the transition from wakefulness to sleep. Photosensitivity and light-induced myoclonus are decreased in non-REM sleep,[23,69,80] whereas discordant results—perhaps due to differences in medications and stimulation procedures and indicating either a decrement or an increment of

photosensitivity-related myoclonus in REM sleep—have been reported.[23,52,69,90,135]

Lennox-Gastaut Syndrome

In patients presenting with Lennox-Gastaut syndrome (see Chapter 241),[41] nocturnal tonic seizures can recur so frequently during non-REM sleep that they produce a tonic status epilepticus, which is characterized polygraphically by a progressive attenuation of tonic motor manifestations, paralleled by a worsening of the vegetative parameters and by an impairment of consciousness between seizures. The situation can deteriorate into a coma-like state, with autonomic derangement and mild motor phenomena, such as raising of the hands and slow eye movements. An adequate polygraphic monitoring can be of utmost importance for the diagnosis and treatment of such a condition. Patients with Lennox-Gastaut syndrome can also show minor nocturnal seizures, which are associated with eye-opening spells, head nodding, and changes in cardiac and respiratory rate. Sometimes these seizures are uncovered only by means of polygraphic recording, represented by generalized polyspikes, fast recruiting rhythms, or slow spike-and-wave discharges.[4,19] A disruption of sleep architecture has been reported in patients with Lennox-Gastaut syndrome.[1,4]

Epilepsia Partialis Continua

Polygraphic studies during sleep have demonstrated modifications of myoclonic phenomena in different pathologic conditions. Epilepsia partialis continua is usually characterized by the persistence of focal myoclonic jerks, which modulate only in intensity and frequency, across all sleep stages (see Fig. 10).[65]

Unverricht-Lundborg Disease

In Unverricht-Lundborg disease, sleep studies demonstrate (a) lack of activation of generalized paroxysmal discharges and (b) appearance of focal multiple fast spikes occurring in repetitive bursts, localized over the midline and centroparietal regions, and occurring more frequently during REM sleep, particularly when eye movements are abundant. These fast spikes can be time-locked to myoclonic jerks, particularly in those muscles that show a striking action myoclonus during wakefulness (Fig. 13).[111,113,120]

Lafora Disease

In Lafora disease, sleep organization is extremely altered, with the different stages barely recognizable: paroxysmal activity does not seem to increase during sleep; diffuse multiple fast spikes show variable amplitude and topography and can be intermixed with fast activity, and posterior spikes persist during slow sleep and can show an enhancement during REM sleep.[112,120]

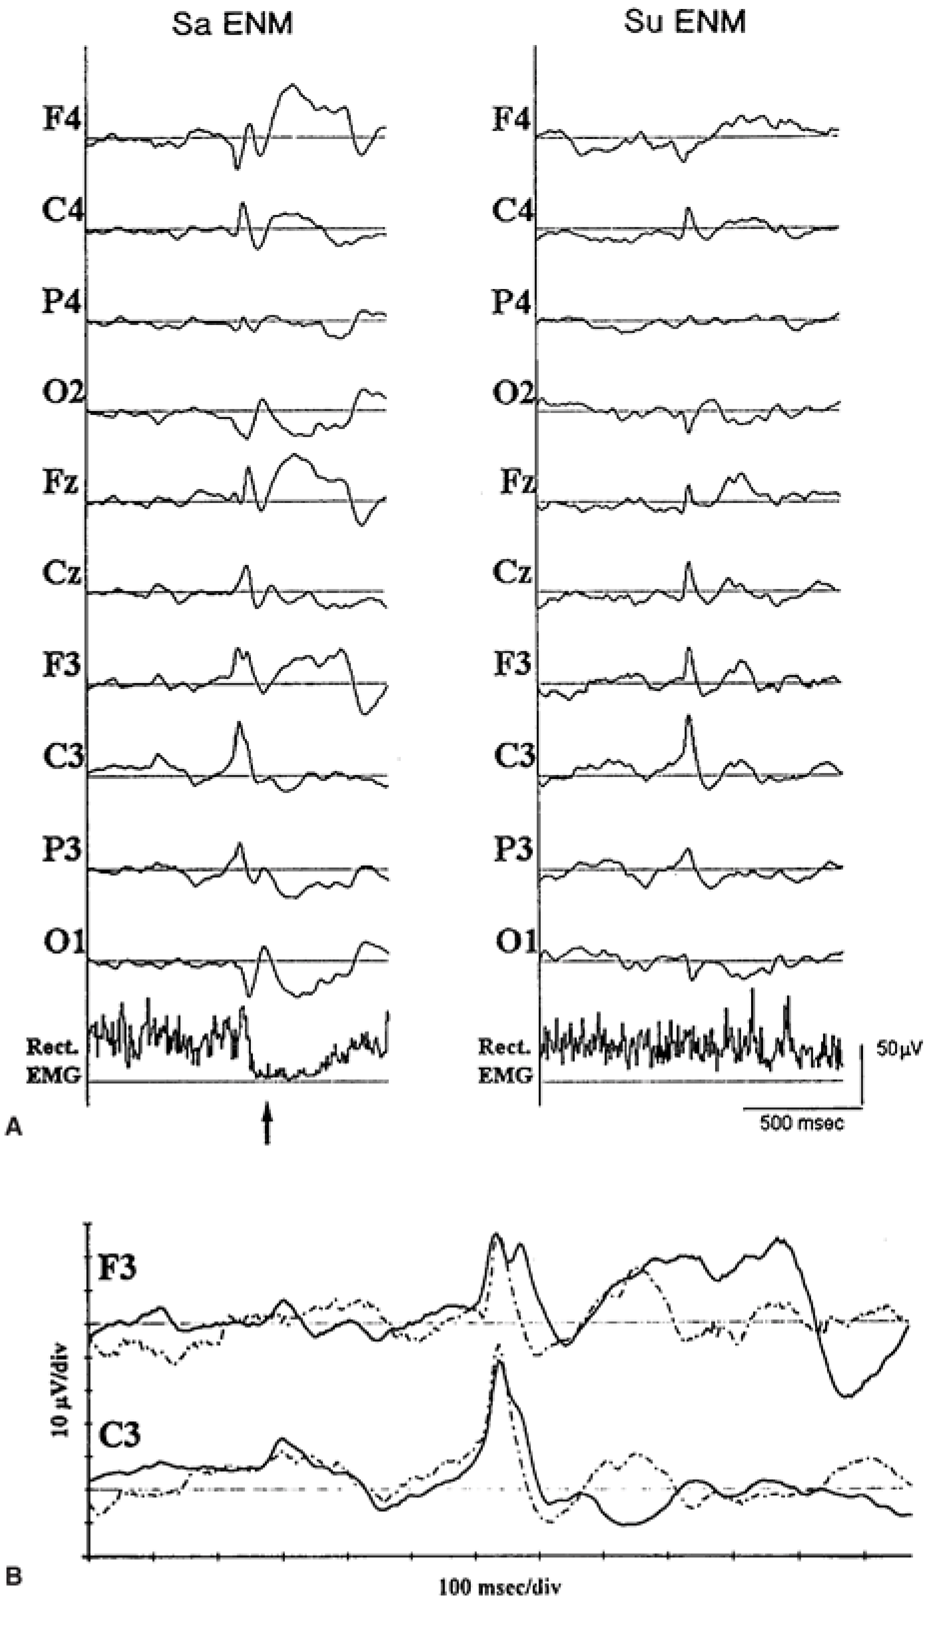

FIGURE 15. Digital electroencephalographic (EEG)/electromyographic (EMG) recording in a patient with epileptic negative myoclonus in the right upper limb. **A:** On the left, averaged spikes (n = 25) associated with epileptic negative myoclonus (Sa ENM); on the right, averaged spikes (n = 22) unrelated to epileptic negative myoclonus (Su ENM). The bottom channel shows rectified EMG activity of the right wrist extensor. Epileptic negative myoclonus appears as a brief flattening of EMG activity (*arrow*). **B:** Superposition of averaged Sa ENM (*solid line*) and of averaged Su ENM (*broken line*) at F3 and C3. Note the presence in Sa ENM of a "double spike" in F3 due to a frontal component related to the occurrence

of epileptic negative myoclonus absent in Su ENM. Negative is up. Average potential reference montage. (From Rubboli G, Parmeggiani L, Tassinari CA. Frontal inhibitory spike component associated with epileptic negative myoclonus. *Electroencephalogr Clin Neurophysiol*. 1995;95:201–205, with permission.)

Myoclonic Encephalopathies

Myoclonic encephalopathies can be properly investigated by means of sleep polygraphy to detect myoclonus during sleep when other associated abnormal movements that occur in wakefulness disappear.[27] In patients presenting with myo-clonic epilepsy with ragged red fibers (MERRF), sleep polygraphic studies showed the occurrence of vertex and central spikes, absence of physiologic EEG elements of stage II sleep, and persistence of generalized paroxysmal activity as in wakefulness.[82] Sleep polygraphic investigations can be relevant in the study of aminoacidopathies, in which multifocal

paroxysmal abnormalities and suppression burst patterns are inapparent during wakefulness but are unveiled by sleep.

Computer-Assisted Analysis of Polygraphic Signals

The introduction of computerized techniques has provided new tools for the analysis of polygraphic data. The main field of application in epilepsy has been the simultaneous collection and processing of EEG and EMG signals. This allows for detection of cortical correlates associated with muscular phenomena not identifiable with standard polygraphic techniques and for more precise determination and quantification of the temporal relation between cortical and muscular phenomena.

Jerk-Locked Averaging

One such technique, a computerized EEG averaging technique called *jerk-locked averaging*, was applied to polygraphic data by Shibasaki and Kuroiwa.[95] Jerk-locked averaging is triggered

by an EMG pulse, which is represented by a myoclonic potential, and permits cortical correlates associated with muscular events to be extracted from background EEG activity (Fig. 14). This allows different types of myoclonus to be characterized in terms of presence or absence of a cortical correlate and according to the latency between the cortical correlate and the myoclonic jerk.[96,97]

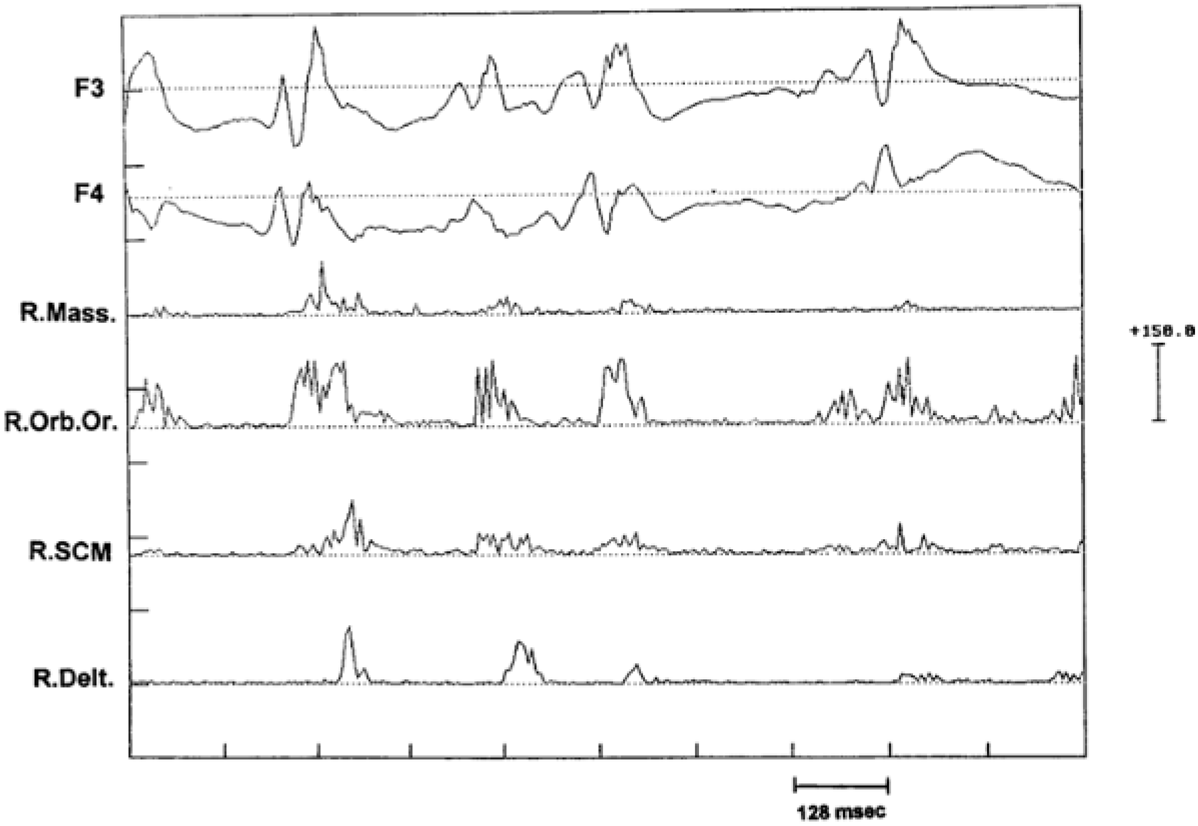

FIGURE 16. Single sweep (1,280 msec) of prolonged computerized electroencephalographic (EEG)/electromyographic (EMG) recording showing myoclonic potentials associated with a spike-and-wave discharge. Each spike-and-wave complex is associated with a myoclonic contraction. Note the sequential activation of the right orbicularis oris, followed by the right masseter, the right sternocleidomastoideus, and the right deltoid, in each myoclonic jerk. EEG activity is recorded with average potential reference. EMG activity is rectified. Negative is down. R.Delt., right deltoid; R.Mass., right masseter; R.Orb.Or., right orbicular oris; R.SCM., right sternocleidomastoideus.

Silent-Period Locked Averaging

A similar technique, triggered not by a myoclonic jerk but by the onset of an EMG silent period on a background of a tonic contraction, was introduced by Ugawa et al.[130] Known as *silent-period locked averaging*, this technique allows different types of negative myoclonus, including asterixis, to be identified and associated with cortical events.

Spike Averaging

Spike activity associated with different muscular events can be investigated by means of EEG computerized systems with an extra channel for polygraphic signals and displaying the topographic distribution over the scalp of the EMG related-cortical potentials. These techniques have been adopted to investigate paroxysmal activities associated with epileptic negative myoclonus.[57,88] Through the finding of a frontal spike component that suggests the involvement of inhibitory frontal areas in the generation of negative motor phenomena (as subsequently demonstrated by intracerebral electrical stimulation[86]), spike-averaging procedures have demonstrated that spikes associated with epileptic negative myoclonus differ from spikes without epileptic negative myoclonus (Fig. 15).[88]

Quantitative Analysis of Electromyography

A quantitative analysis of EMG signals can be performed by rectification and integration of EMG wave forms.

These techniques allow the area between the EMG tracing and the baseline to be calculated. The area varies according to modification of amplitude, frequency, and duration of the potentials, which provides a quantification of EMG activity.

Multichannel Electromyography

Multichannel computerized EMG recordings with only a few EEG channels can analyze the pattern of sequential activation of different muscular groups that participate in a sudden motor event (i.e., a massive myoclonic jerk) (Fig. 16) or in the complex motor manifestations characterizing focal seizures involving motor areas[67] (Fig. 17). Analysis of the temporal

sequence of the onset of contraction in different cranial and limb muscles has allowed a distinction to be proposed between cortical and reticular myoclonus.[50,51,85]

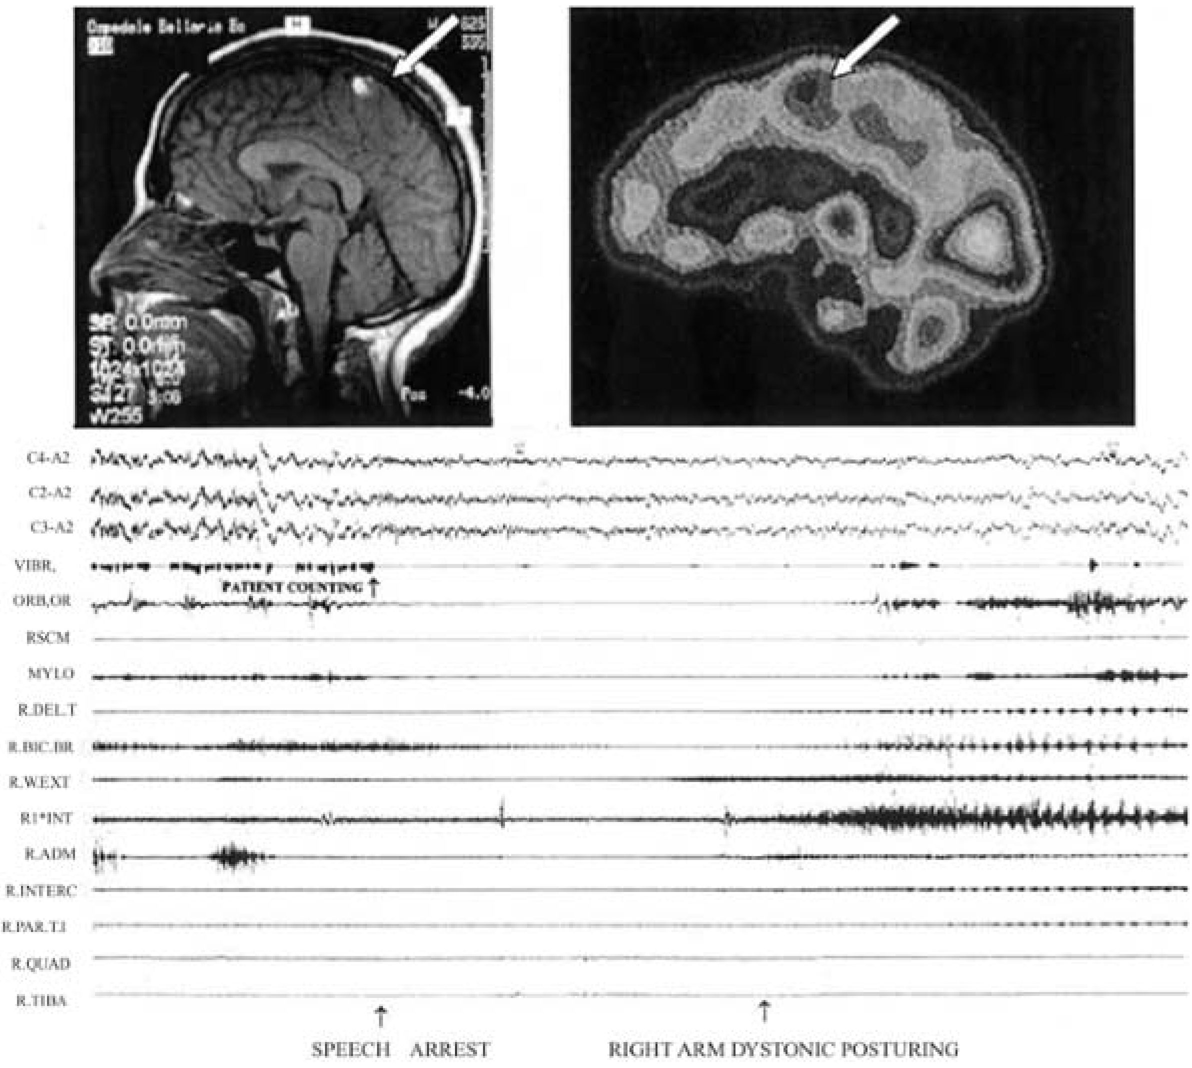

FIGURE 17. Polygraphic recording of a focal seizure originating from the left frontomesial region in a patient with left frontomesial neoplasia (indicated by the arrow in the magnetic resonance image in the left upper panel). Ictal single-photon emission computed tomography showed focal hyperperfusion in the mesial aspect of the frontal lobe just anterior to the neoplastic lesion (*right upper panel*). Polygraphic recording showed, as soon as the electroencephalographic activity at the vertex and central leads was modified by the paroxysmal discharge, a speech arrest (the patient stopped counting aloud) and muscular inhibition in all the electromyographic channels, suggesting early involvement of frontomesial "negative" motor areas. Then a tonic contraction (evident in the right wrist extensor and first interosseus muscles) associated with a dystonic posturing of the right arm appeared, followed by clonic contractions in the right upper limb and trunk muscle.

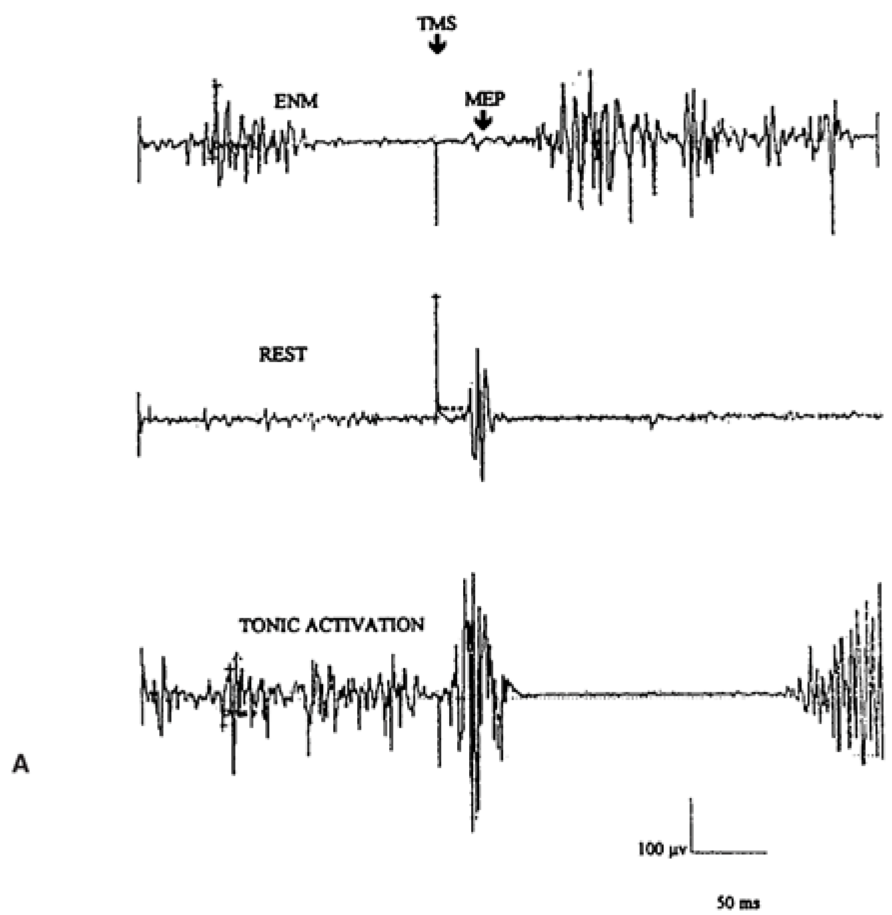

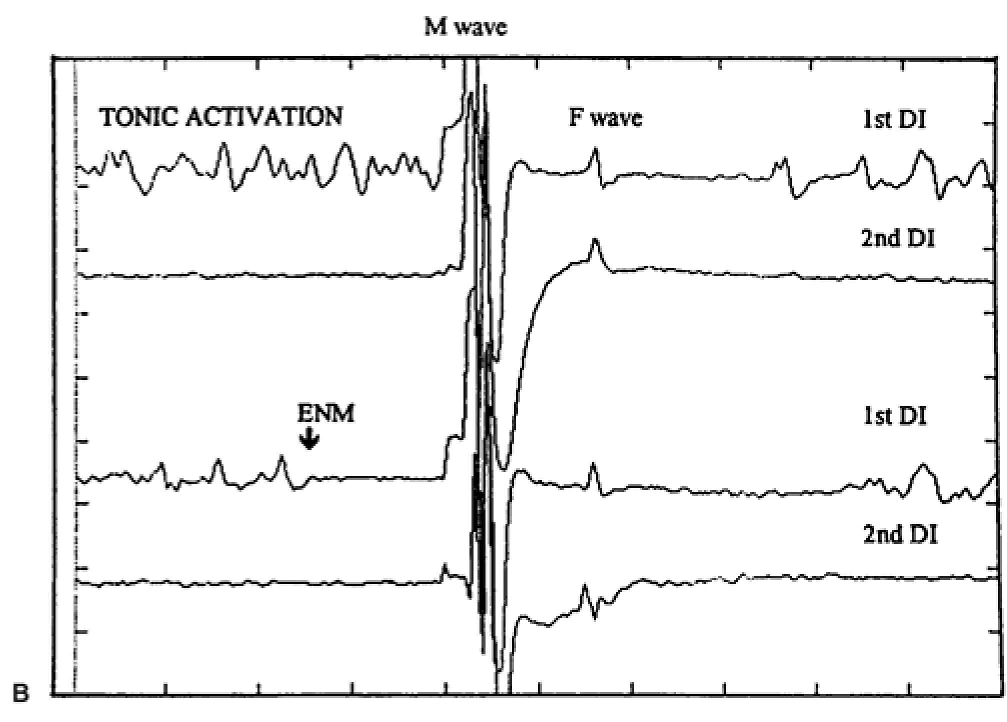

FIGURE 18. A: Cortical excitability during epileptic negative myoclonus (ENM) assessed by transcranial magnetic stimulation (TMS). During ENM, motor-evoked potentials (MEPS) were consistently depressed as compared with rest and tonic activation conditions. **B:** Spinal excitability during ENM evaluated by F-wave study. The upper pair of traces show M response and F wave during tonic activation, recording from the first and second dorsal interosseus (DI); the lower pair of traces demonstrate preservation of F wave during the EMG silent period of ENM, suggesting an unaltered spinal excitability. (From Tassinari CA, Rubboli G, Parmeggiani L, et al. Epileptic negative myoclonus. In: Fahn S, Hallett M, Marsden CD, eds. *Negative Motor Phenomena. Advances in Neurology*, vol. 67. New York: Raven Press; 1995:181–197, with permission.)

Combination Recordings

Investigations on the modulation of the motor system during ictal and interictal paroxysmal discharges can be performed by combining polygraphic recordings with techniques able to assess cortical (e.g., transcranial magnetic stimulation) and spinal (e.g., H reflex, stretch reflex, F wave) excitability. During epileptic negative myoclonus, an inability of transcranial magnetic stimulation to evoke a motor response, associated with the preservation of the F wave, suggests a cortical origin for this motor disorder (Fig. 18).[122] In patients with severe partial epilepsies and falling seizures, H-reflex and motor-evoked potentials are unmodified during slow spike-and-wave complexes, whereas they appear to increase during subclinical fast polyspike discharges. A similar facilitation can be observed at the beginning of tonic seizures, when the EMG is silent. During the ensuing tonic contraction, H-reflex and motor-evoked potentials are further enhanced, decreasing consistently only in the postictal phase. In contrast, 3-c/s spike-and-wave discharges of typical absences or evoked by intermittent photic stimulation do not alter motor-evoked potentials or the stretch reflex.[124]

Polygraphic Investigations in the Study of Reflex Epilepsy

In reflex epilepsies, seizures are elicited by some specific stimuli or events (see Chapter 257).[6,68,121] Polygraphy can be useful in defining the stimulating factor and documenting the correlation between the triggering condition and the seizure. Arseni et al.[3] documented the role of proprioceptive stimuli in eliciting and blocking convulsive seizures. Scollo-Lavizzari and Tassinari[91] provided polygraphic evidence in one patient of simple partial motor seizures involving body parts that had been actively or passively moved. Polygraphy can be a useful aid in discriminating between movement-induced seizures and attacks of

paroxysmal choreoathetosis and in proving the nonepileptic nature of a startle response (Fig. 19).[76,79] Polygraphy has also documented seizures related to the act of eating a meal and characterized by occurrence of myoclonic jerks or head drops.[21,32]

Tassinari et al.[124] presented a polygraphic demonstration of the mechanism of induction of seizures by hand waving in a patient with self-induced seizures. In this patient, the intermittent light stimulation resulting from the rhythmic movement of the hand in front of the eyes elicited a bilateral spike-and-wave discharge. Photic reflex myoclonus in progressive myoclonus epilepsies has been investigated with jerk-locked averaging techniques applied to computerized polygraphic recordings showing the combined participation of the visual and motor cortex in the genesis of this type of reflex myoclonus.[87,96]

The occurrence of extreme somatosensory-evoked potentials following tapping of the extremities of the four limbs has been reported[116]; polygraphic recordings, including a marker channel reporting the tapping artifact, allow observation of the correlation between the tactile stimulus and the cortical spike.

Polygraphy as an Aid in the Differential Diagnosis of Epileptic and Nonepileptic Episodes

Recurrent and transitory episodes of cerebral disturbance are not necessarily epileptic. Definition and characterization of the episodes by means of polygraphic techniques can help to determine the etiology and pose the correct diagnosis. Two main groups of episodes can mimic epileptic seizures: (a) episodes of syncopal or cardiac nature and (b) pseudoseizures.

Syncope and Cardiac Dysrhythmia

Because syncope and epileptic seizures can share some common characteristics (e.g., loss of consciousness, dilation of pupils, opisthotonus, clonic jerking, salivation, incontinence),[35,39] clinical description alone is inadequate in identifying the correct etiology. Polygraphic studies with simultaneous recording of EEG and ECG, therefore, can be helpful for differential diagnosis.[35] Twenty-four-hour ambulatory recording systems that can monitor EEG and ECG activity in unrestrained conditions can be extremely effective in demonstrating the cardiac nature of syncopal episodes (Fig. 20).[14,30,62]

Because of the longer duration of EEG recording, ECG monitoring during EEG recording has a higher probability of detecting cardiac abnormalities than does routine ECG.[31] Monitoring of ECG during EEG recording, therefore, should be encouraged in a routine setting. If an altered ECG is found, episodic cerebral symptoms due to cardiac arrhythmia can be suspected. However, because cardiac arrhythmia can represent a secondary event associated with epileptic seizures, the finding does not necessarily imply that the patient suffers from syncope rather than epilepsy.[129] It should also be remembered that when prolonged ECG monitoring is performed, there is a relatively high incidence of cardiac dysrhythmia in an asymptomatic population.[22]

Ambulatory cassette EEG/ECG systems can allow the investigation of the instant heart rate by measurement of the R-R interval during spontaneous seizures. Smith et al.[100] observed impressive seizure-to-seizure similarities in heart rate profiles when multiple partial seizures were recorded. In long-duration records, identification of heart rate profile changes could be useful in detecting seizures that are either not indicated by the event marker or not accompanied by overt EEG modifications. Analysis of the ECG tracing in the polygraphic recording and its modifications and correlations with EEG can be an important diagnostic aid in cases of Q-T interval prolongation,[47,105] Jervell and Lange-Nielsen syndrome,[93] and Romano-Ward syndrome.[83,136]

Pseudoseizures

Recognition of pseudoseizures has always been and continues to be a diagnostic challenge for epileptologists. A number of clinical features of pseudoepileptic and true epileptic (particularly complex partial) seizures are similar, rendering diagnosis based solely on clinical observation extremely difficult. Unequivocal documentation of EEG epileptic modifications associated with the episodes, therefore, is necessary. A normal routine EEG does not exclude epilepsy, nor does it confirm pseudoseizures. Although recording of a pseudoseizure during EEG can be crucial for the diagnosis, this is an infrequent occurrence. Therefore, diagnosis of pseudoseizures often requires intensive monitoring. Ambulatory cassette EEG can allow for prolonged recording in the patient's environment and quantification of the episodes.[78] However, several drawbacks (e.g., reduced spatial sampling over the scalp due to a limited number of channels, lack of patient and family cooperation, artifacts, or poor-quality recording) can render analysis of the recording unreliable.

Intensive monitoring with closed-circuit video-polygraphic systems can help in the differential diagnosis of pseudoseizures. Pseudoseizures usually last longer than do epileptic seizures, and alpha activity can persist throughout the episode.[63,92] Surface EMG channels show muscular activity corresponding to the gross and polymorphous movements that occur during pseudoseizures. Although true epileptic seizures can present bizarre and chaotic clinical manifestations as well, compared to pseudoseizures, they tend to show a more stereotyped clinico-polygraphic pattern. In the postictal phase, an immediate recovery of alpha activity and an abrupt arrest of the muscular artifacts are clues that the nature of the episode is nonepileptic. Simultaneous EEG/ECG recording, either during ambulatory cassette EEG or video-polygraphic monitoring, can provide additional helpful information. Whereas tachycardia or bradycardia can occur during epileptic seizures, only tachycardia has been reported in pseudoseizures.[92]

Polygraphic Monitoring of the Effects of Antiepileptic Drugs

Polygraphic monitoring can be useful when drugs are parenterally administered, especially during intravenous treatment for status epilepticus. Recording of EEG activity is necessary to evaluate the effectiveness of treatment and the rapidity and duration of its effect. Some drugs, such as benzodiazepines and phenytoin, require monitoring of vital functions when given by injection.

Because benzodiazepines have been reported to cause hypotension or respiratory depression, several authors,[7,17] recommend blood pressure and respiration monitoring during administration. However, these adverse effects are probably more likely to occur when benzodiazepines are given in conjunction with another central nervous system depressant or with concomitant organic cerebral damage.[115]

Another reason to use polygraphy with benzodiazepines is that the drug can uncover focal paroxysmal activities. Electroencephalographic recording after benzodiazepine administration, therefore, can provide information about the localization of the epileptic focus. Polygraphic recording is mandatory when benzodiazepines are injected to treat clusters of tonic seizures in patients with Lennox-Gastaut syndrome. A paradoxical effect consisting of precipitation of tonic status epilepticus has been reported following benzodiazepine injection.[11,117]

Intravenous administration of phenytoin requires monitoring of blood pressure, ECG, and respiration due to the possible occurrence of hypotension, heart block, and respiratory depression, especially when injected rapidly in elderly patients.[24,44] Polygraphy has also been used to document antimyoclonic effects of alcohol intake in patients with progressive myoclonic epilepsy.[45]

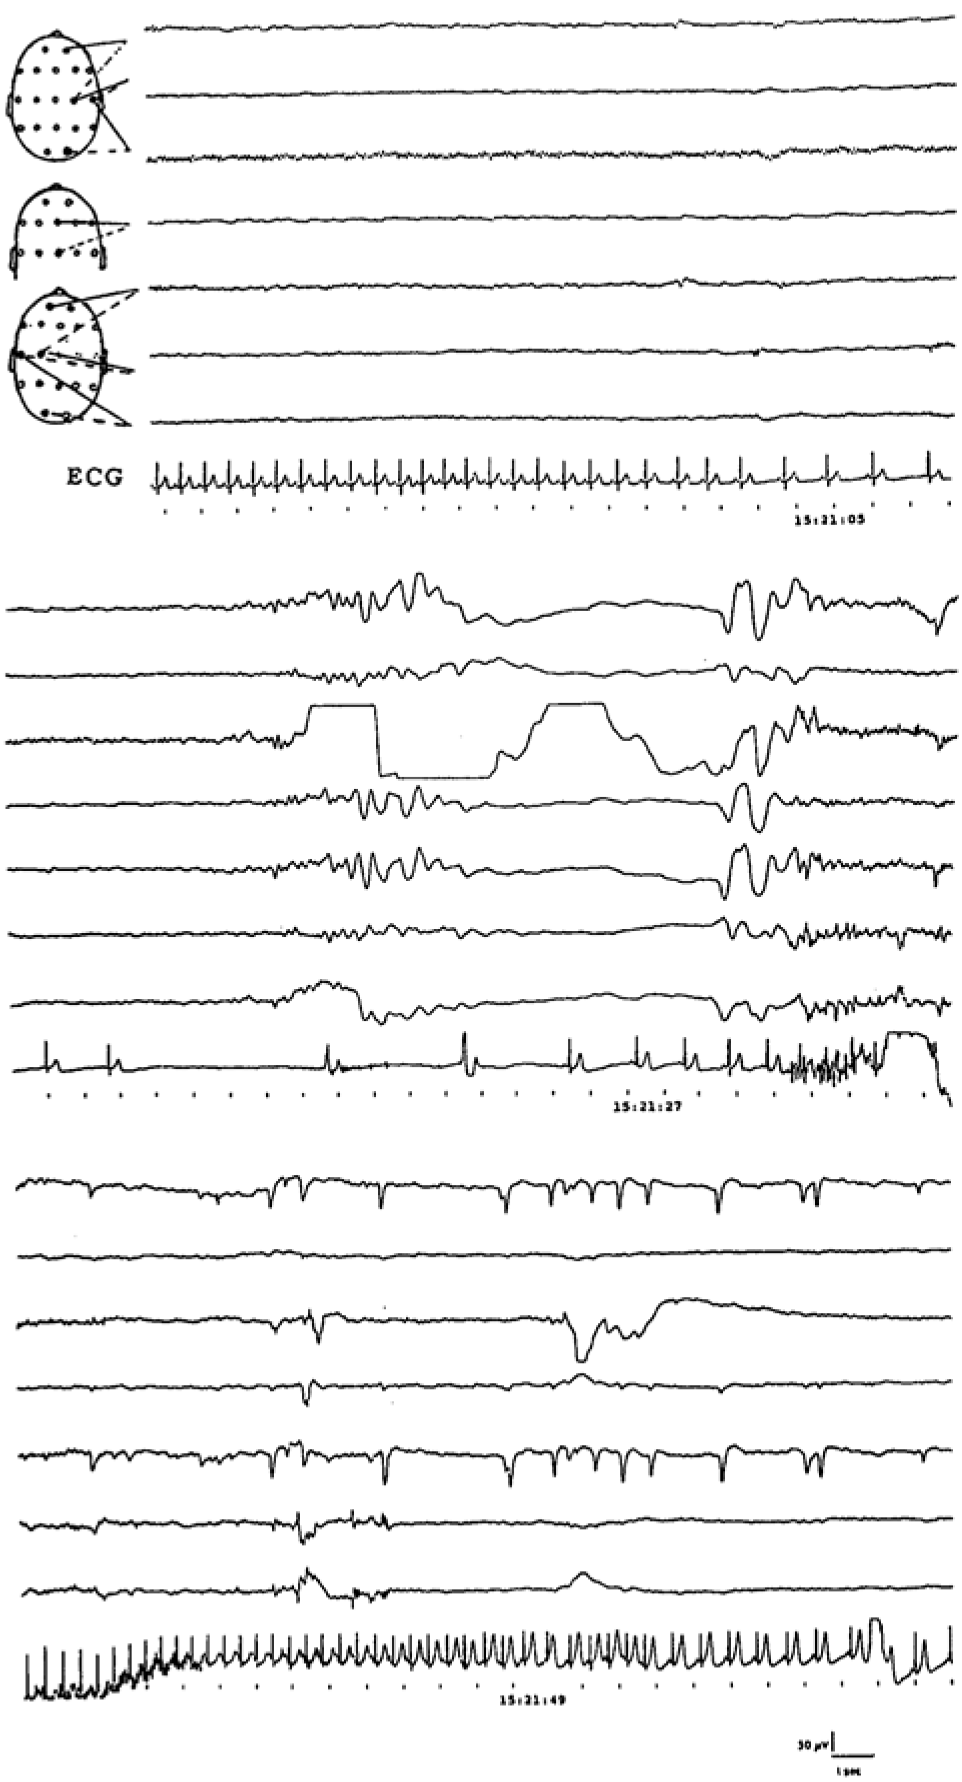

FIGURE 20. Ambulatory cassette electroencephalographic (EEG) /electrocardiographic (ECG) recording of a convulsive syncope during tilt test. **Upper:** A slowing of the heart rate begins (right). **Middle:** Heart

beats cease for a few seconds, followed by a flattening of the EEG activity and by movement artifacts due to massive jerks; then heart beats restart, and EEG alpha activity reappears. **Lower:** Tachycardia is evident a few seconds after resumption of cardiac activity.

Summary and Conclusions

Polygraphic recordings are essential tools in investigating physiologic parameters of epileptic phenomena and in providing relevant data for diagnostic and therapeutic purposes. Polygraphy is particularly useful in defining the various motor manifestations of different epileptic seizures and syndromes. Indeed, subtle motor phenomena—such as the diffuse myoclonia of Lafora disease that sometimes can be barely appreciable on clinical examination—can be detected only by polygraphy; their distribution can also be described. Complex motor patterns involving several muscular groups can be analyzed, and the existence of a stereotypic sequence of muscular activation can be investigated. It is possible, therefore, to describe not only "what moves first," but also "how it moves." In conditions such as epileptic negative myoclonus, polygraphy is essential to prove the effect of paroxysmal activity, demonstrating that an apparent "interictal" epileptic abnormality can actually be "ictal," depending on the state of the patient (relaxed or maintaining a muscular contraction) and on the methodology used to investigate the phenomenon (simultaneous EEG/EMG recording).

Rapid technologic progress will no doubt continue to provide new tools for collecting and processing different physiologic parameters, thereby increasing our ability to explore the relationships among distinct anatomic/functional systems during an epileptic event.

Acknowledgments

We thank Drs. Elena Gardella, Stefano Meletti, Roberto Michelucci, Franco Valzania, Lilia Volpi, for their help in collecting data.

Electroencephalographic and Magnetoencephalographic Source Modeling

John S. Ebersole

Hermann Stefan

Christoph Baumgartner

Introduction

Many patients who suffer from medically uncontrolled partial seizures are candidates for epilepsy surgery. A significant rate-limiting factor in delivering this care is the evaluation necessary to determine whether the epileptogenic focus is localized to a resectable brain region. Significant additional delay, expense, and some morbidity are incurred if intracranial electroencephalographic (EEG) monitoring is necessary. Accordingly, there has been great emphasis recently on improving noninvasive presurgical localization of focal epileptic activity and functionally important cortical areas. Although various imaging techniques are now playing a significant role, we continue to rely on the analysis of interictal spikes and ictal patterns recorded by scalp EEG for functional localization. However, the information obtained in this regard from traditional visual inspection of the EEG has not changed much over the last 20 years. Localization is often limited to defining the electrode with greatest spike amplitude or clearest seizure pattern. These data have, at best, an imperfect relationship to the underlying cerebral source. Visual inspection of the EEG is, in fact, mainly used to lateralize the most epileptogenic area rather than to localize it. If our understanding of the clinical neurophysiology of epilepsy is to advance, we must go beyond simple description of EEG waveforms and pursue the physiology and location of the underlying generators. Visual inspection and qualitative impressions should be replaced by quantitative characterization. Among the noninvasive approaches, source localization techniques applied to epileptiform EEG potentials and magnetoencephalographic (MEG) fields appear to be particularly promising. This chapter reviews the principles behind and the clinical applications of EEG and MEG dipole and other source models.

Electroencephalographic Dipole Source Modeling

Principles of Voltage Topography

Neuronal excitation and inhibition are accompanied by current flow across the membrane of and through affected cells. From these, secondary currents and a voltage potential field are generated in the extracellular space. The orientation of an EEG voltage field is orthogonal to the surface of the generating cortex because it is aligned with the pyramidal cells that are thought to produce it. Most epileptiform transients are initially negative when recorded from electrodes on or above the cortical surface. Electrodes on the opposite side of the generating cortical layer, whether in underlying white matter or even on the scalp at the other side of the head, would record a positive potential. The scalp voltage fields that we measure, therefore, have dipolar configurations, that is to say, two maxima—one negative and one positive (Figs. 1 and 2). Thus, what a given electrode records is very dependent on the orientation as well as the location of the source relative to the sensor. In general, it is the complete contour of the spike voltage field over the head that provides information about the location and orientation of its cerebral generator.

Cerebral sources that generate epileptiform potentials that can be recorded at the scalp are quite large, usually consider-ably larger than the 6 cm^2 often quoted in the literature.[29] Recent measurements of simultaneous intracranial and scalp EEG have shown that cortical spike sources commonly encompass 10 to 30 cm^2 (Figs. 3 and 4).[34,36,161] Voltage fields from opposing walls of individual sulci tend to cancel each other, leaving the major lobar outline of gyral crowns to predominate in producing the net voltage field. Spike sources may recruit adjacent cortex into discharging. The net geometry of activated cortex becomes different at different times during the course of this propagating spike, which, in turn, produces a change in field maxima position or shape. Thus, temporal evolution of the scalp voltage field provides information about changes in source geometry due to sequential cortical activation or propagation (Figs. 2 and 4).

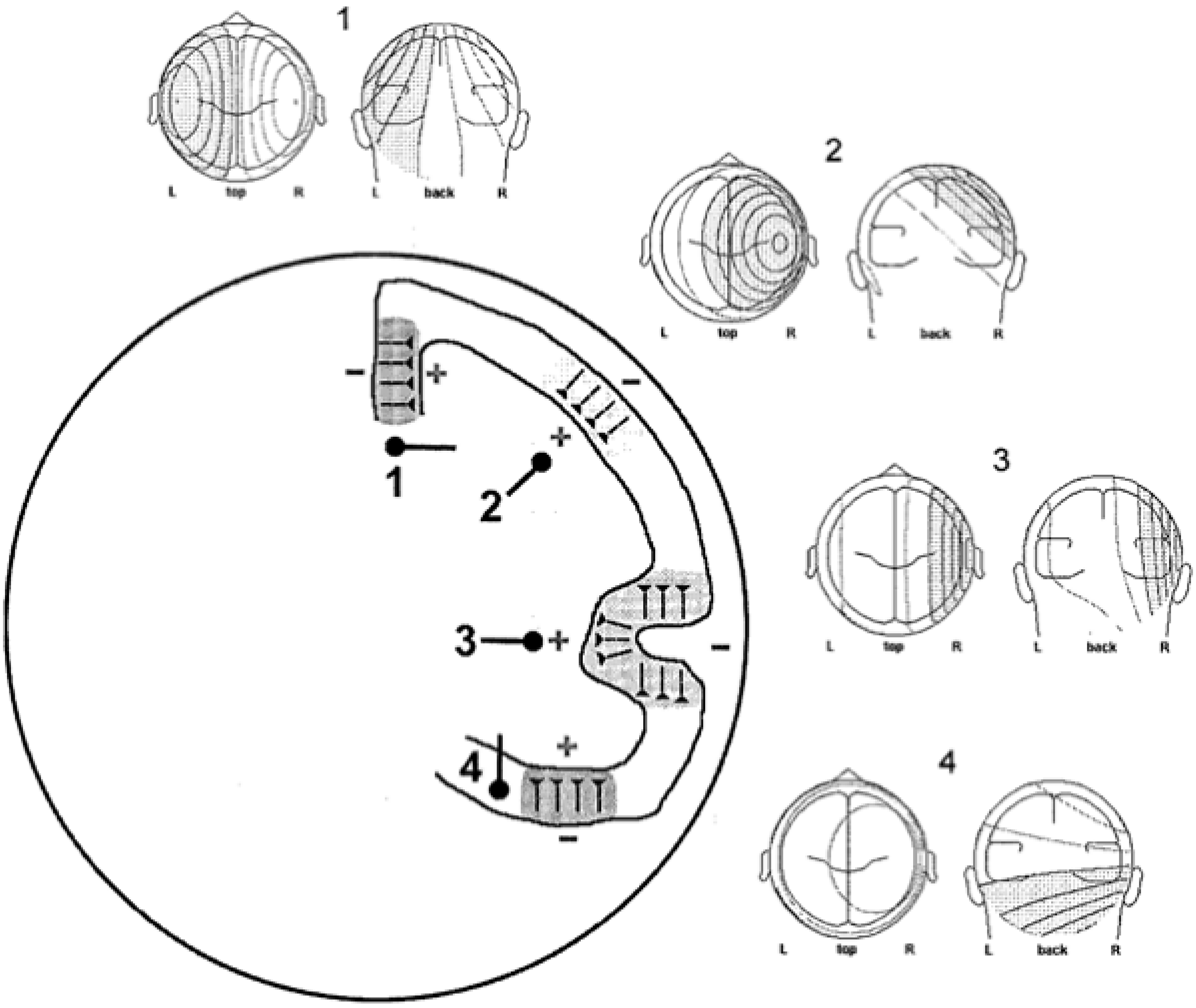

FIGURE 1. Example cortical sources 1–4 depicted in a schematic head/brain in coronal cross section. Typical pyramidal cell orientations are shown for each source. Resultant scalp voltage field topography for superficial laminar depolarization is displayed above each source as isopotential lines of field strength (*speckled*; negative; *clear*, positive). Typical dipoles modeling these sources are depicted beneath each source. Note that simple and more complex cortical convexity sources (1 and 2, respectively) produce radial fields with negative maxima directly above them and positive maxima contralaterally. Radial dipoles deep to the cortex model these sources. Interhemispheric source 3 and temporal base source 4 produce tangential fields with negative and positive maxima displaced on either side of the source and essentially no potential directly above them. Tangential dipoles deep to the cortex model these sources.

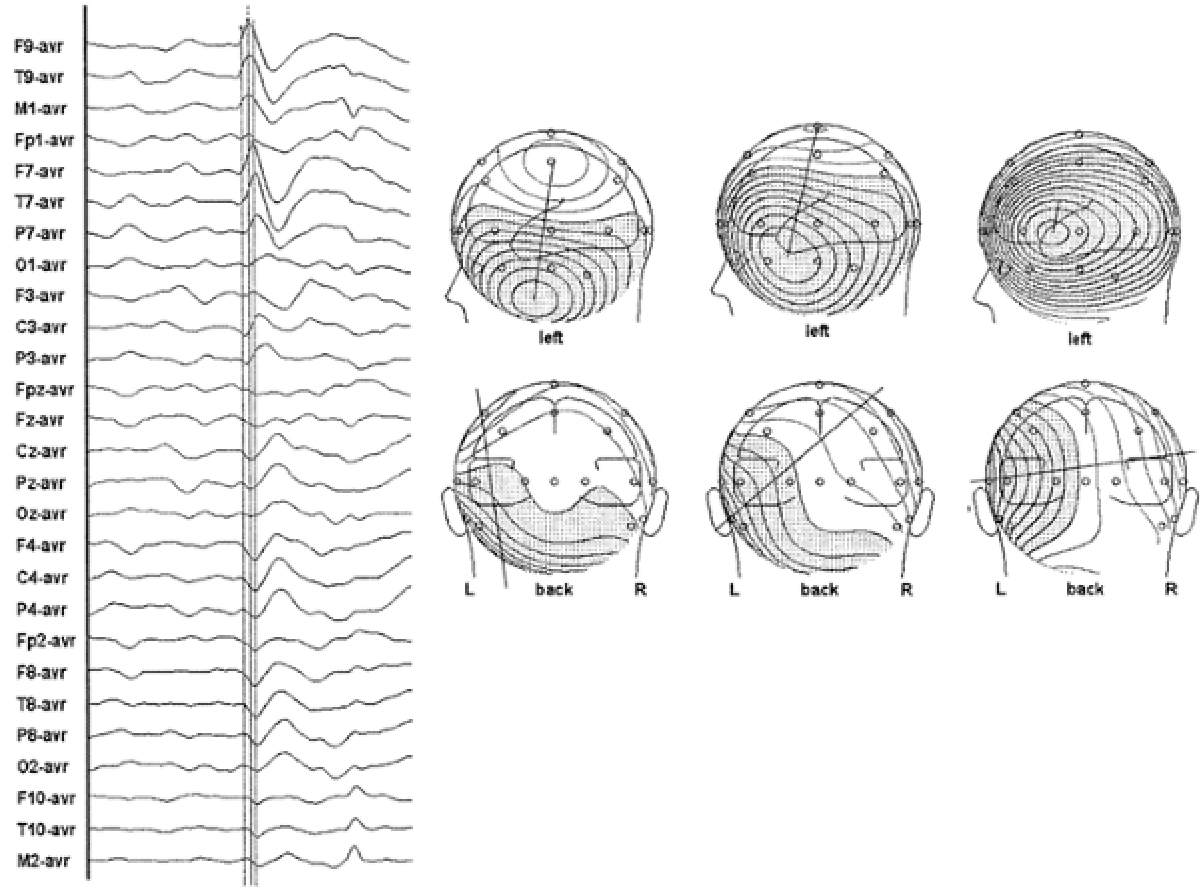

FIGURE 2. A scalp electroencephalogram (EEG) of a left temporal spike is shown at the left. In this and subsequent figures scalp EEG is illustrated in common average reference. Cursors mark three time points on the rising phase of this spike. Topographic maps depict the scalp voltage fields at these three points in isopotential lines. In this and subsequent figures voltage field negativity is shown as a speckled region and positivity as a clear region. A three-dimensional line defining field orientation connects the two maxima. Note that early in the spike the field is vertical and tangential. Later it is oblique, and at the spike peak the field is horizontal and radial. Such changes in the location of voltage field maxima and field orientation are the result of spike propagation across basal and into lateral temporal cortex.

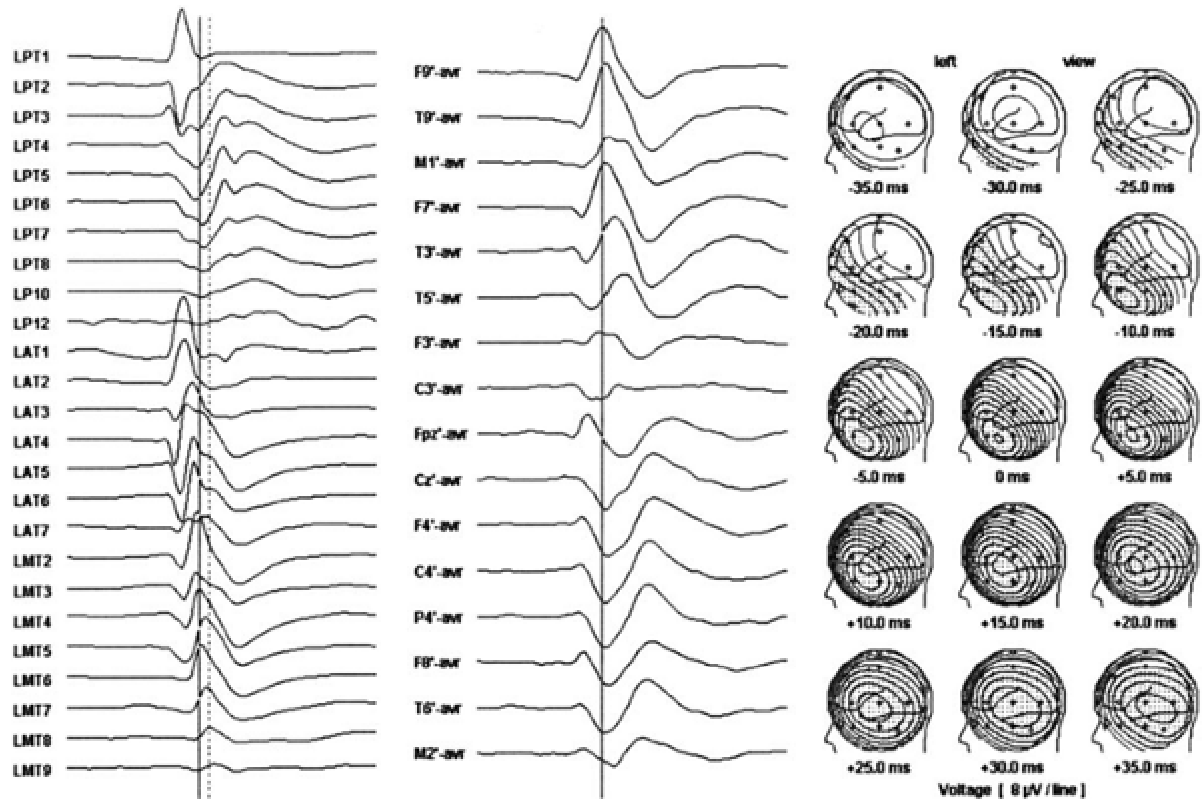

FIGURE 3. Simultaneous intracranial and scalp electroencephalogram of a left temporal spike. Topographic maps at the right show the evolution of the spike voltage field over 70 msec. Cursors denote the time point 0 msec. Note the progressive increase in spike potential latency across subdural strip electrodes LAT 1–7 and LMT 2–8 and across scalp electrodes F9 to T5. Note also the progressive movement of spike field maxima.

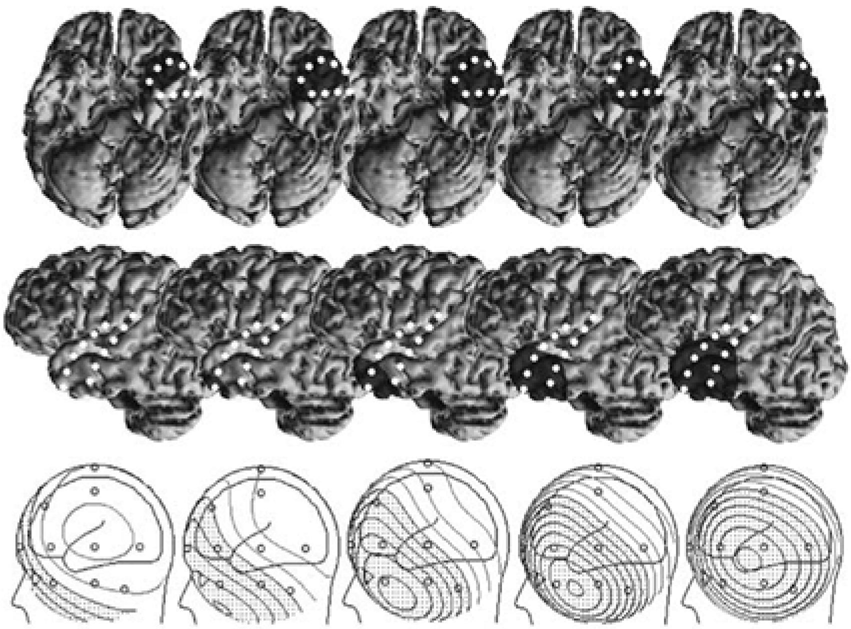

FIGURE 4. Subdural strip electrodes LAT (left anterior temporal) and LMT (left mid temporal) depicted on a three-dimensional reconstruction of the patient's brain. Voltage topography of the same temporal

spike as in FIGURE 3 at five time points is illustrated at the bottom. Location and area of the cortical spike source at each time point is shown as a shaded region. Sources were estimated from the subdural electrodes recording active spike depolarization at that time point. Note the progressive propagation of the source from the inferior temporal tip to the anterolateral temporal cortex and the associated movement of the negative spike field maximum. Note also the enlarging area of the cortical source.

Principles of Electroencephalographic Dipole Modeling

Dipole localization techniques are based on electric field theory applied to volume conduction that was developed by Helmholtz[66] in the mid-nineteenth century. Nearly 100 years later, electroencephalographers began to consider the physical relationship between electric fields on the scalp and their underlying sources within the brain.[20,60,148,151] At the same time, Wilson and Bayley[169] developed a method for calculating the voltage field generated on a spherical volume conductor by a known dipole. In simple terms, if the location, orientation, and strength of a dipolar source within a spherical and homogeneous conducting medium is known, one can predict the shape and magnitude of the potential field that is measurable on its surface. The answer to this type of problem has been called the "forward solution," and it is unique. There is only one field that can be generated by a given dipole. However, the usual clinical problem is the opposite, namely, trying to locate the intracerebral generator, having measured the topography of a

scalp potential. The answer to this is called the "inverse solution," and, unfortunately, for any given voltage field there is no unique answer. Rather, there are multiple possibilities because the fields of sources in a volume conductor sum linearly (the principle of superposition). Therefore, the field measured by a given electrode array may well be a composite from a number of different sources.

Certain assumptions are necessary to apply these principles to human EEG. First, the brain is usually modeled as a sphere of uniform conducting material,[25] and concentric shells are added around this to imitate the skull and scalp.[32,33,75,128,146] The brain and scalp are usually considered to be of equal resistivity, and the intervening skull is considered to have a resistivity that is 80 times greater. In addition, for ease of modeling, the source of the field is considered to be a point-like dipole. Obviously, the generators of scalp spikes are not point sources, but rather large aggregates of neurons that extend over 10 to 30 cm^2. However, the combined activity of such a generator region can be modeled effectively by a single dipole. That is, the field that would be produced by this "equivalent dipole" is very similar to that of the real source. As a first approximation, the equivalent dipole should reside close to the center of the real generator area and have a similar net orientation (Fig. 5).

Single Moving-dipole Model

The most common form of source localization is the instantaneous single-dipole inverse solution. This procedure takes the voltage values from all electrodes at a given instant in time and searches, using iterative minimization techniques, for an equivalent dipole within a spherical head that could generate such a field.[32,33,67,75,141,146] This method defines a single equivalent source for a voltage field at one point in time. Regardless of the complexity of the real cerebral sources, the resultant compound activity is simplified into that of a single-dipole generator.

Spike voltage fields evolve over time, but the instantaneous single-dipole technique models the field at only one instant. Temporal evolution of a voltage field can be described, however, by a series of sequential single dipoles that can move in position and orientation over time, and these can be displayed in

one image as a "moving" dipole.[35,36] For some spikes, repeated dipole solutions are very consistent during the course of the potential, varying only in magnitude and little in position or orientation (Fig. 6). A single-dipole model fits these types of data well and suggests a discrete cerebral generator or nearly synchronous activation of several generator regions. For other spikes, sequential solutions over the potential's time course show progressive drift in dipole location and rotation of vector orientation (Fig. 7). Such behavior of the dipole model is incompatible with a single generator region and suggests asynchronous activation of different cortical areas. The direction of dipole movement can convey useful information about likely spike propagation, as long as it is simple and unidirectional. Moving dipoles that spiral in a loop or make sudden turns in direction or position are usually the result of fields created by superposition of early source repolarization and later source depolarization or several different asynchronous sources. Therefore, one-dipole solutions can be misleading, particularly at later latencies when propagation is likely to have occurred, resulting in increased source complexity. Accordingly, several investigators recommend modeling the rising phase of the spike rather than the spike peak or later potentials.[72,88,89,139] However, a different technique is required to model successfully several simultaneously active sources.

Interpretation of Single-dipole Models

Unfortunately, solutions for an equivalent-dipole source seldom reflect precisely the location of actual cerebral generators. Clinical interpretation requires an appreciation for

the weaknesses in the modeling assumptions and the complexity of source geometry and physiology. Equivalent dipoles are usually located deep to the true source cortex. Dipole localization techniques are least accurate in depth determinations because this estimation depends on the size of the generator region. Single-dipole solutions provide a reasonable approximation for superficial cortical sources if their diameter is smaller than 2 cm, such as with somatosensory-evoked potentials.[50,132] Activation of a larger area of cortex, which is likely in the case of epileptiform spikes, produces a more diffuse scalp field that would be modeled as a deeper equivalent dipole. A large area of activated cortex also means that tangential fields from opposing sulcal walls will often cancel one another, allowing radial components to predominate. A reasonable simplification for interpreting spike dipole models is to consider only sources on the major outline of brain lobes. Accordingly, a tangentially oriented dipole is more likely to reflect an appropriately oriented major cortical surface or fissure, such as the temporal lobe base or sylvian fissure, rather than an individual sulcus. Dipole orientation is often more useful than is dipole location in determining which area of cortex in a given lobe is the likely generator.

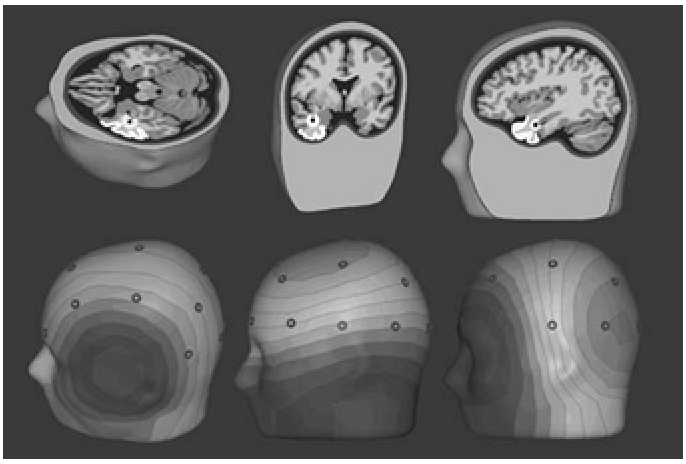

FIGURE 5. Shown as whitened cortex are the three most common types of temporal lobe spike sources, their resultant scalp voltage fields, and equivalent dipole models. Left to right: lateral temporal cortex, temporal base cortex, temporal tip cortex. Note that all the dipole models are located in temporal lobe white matter, but the dipole orientations differentiate the sources. Horizontal radial = lateral cortex source; vertical tangential = basal cortex source; horizontal anterior-posterior tangential = tip cortex source. Note also that dipole orientation is orthogonal to the net orientation of the source cortex.

Patients with complex partial seizures of temporal lobe origin have been found to have spike voltage fields that could be

categorized into one of two patterns, termed type 1 and type 2.[46,47] Type 2 spikes have a lateral temporal negative field maximum and a contralateral temporal positive field maximum. These spikes are well modeled by a single equivalent dipole located in the temporal lobe that has a radial and horizontal orientation (Figs. 6 and

8B).[35,36] Type 1 spikes possess an inferior temporal negative field maximum and a vertex positive field maximum. They are modeled by a similarly located single equivalent dipole that has instead a vertical tangential to oblique orientation (Figs. 7 and 8A).[35,36] In keeping with the foregoing interpretive guidelines, the horizontal, radial nature of type 2 spike dipoles suggests sources in lateral temporal cortex, whereas the more vertical and tangential orientation of type 1 spike dipoles suggests inferior and basal temporal cortex sources.

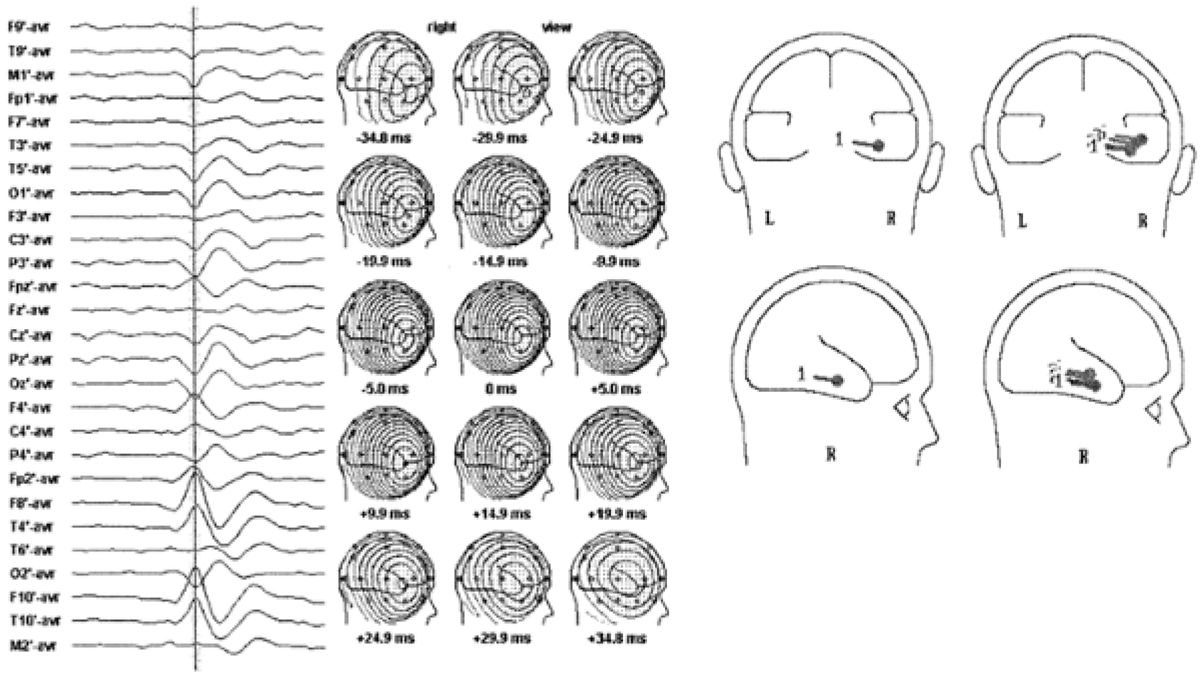

FIGURE 6. A scalp electroencephalogram of a right, type 2 temporal spike. Cursor denotes 0-msec latency. **Middle:** Sequential voltage topography of the spike. Note the stable shape of the fields over 70 msec. **Right:** Single- and moving-dipole models of the spike. Note that voltage field stability and the tight cluster of the moving dipole model suggest a simple source for which a single-dipole model is appropriate.

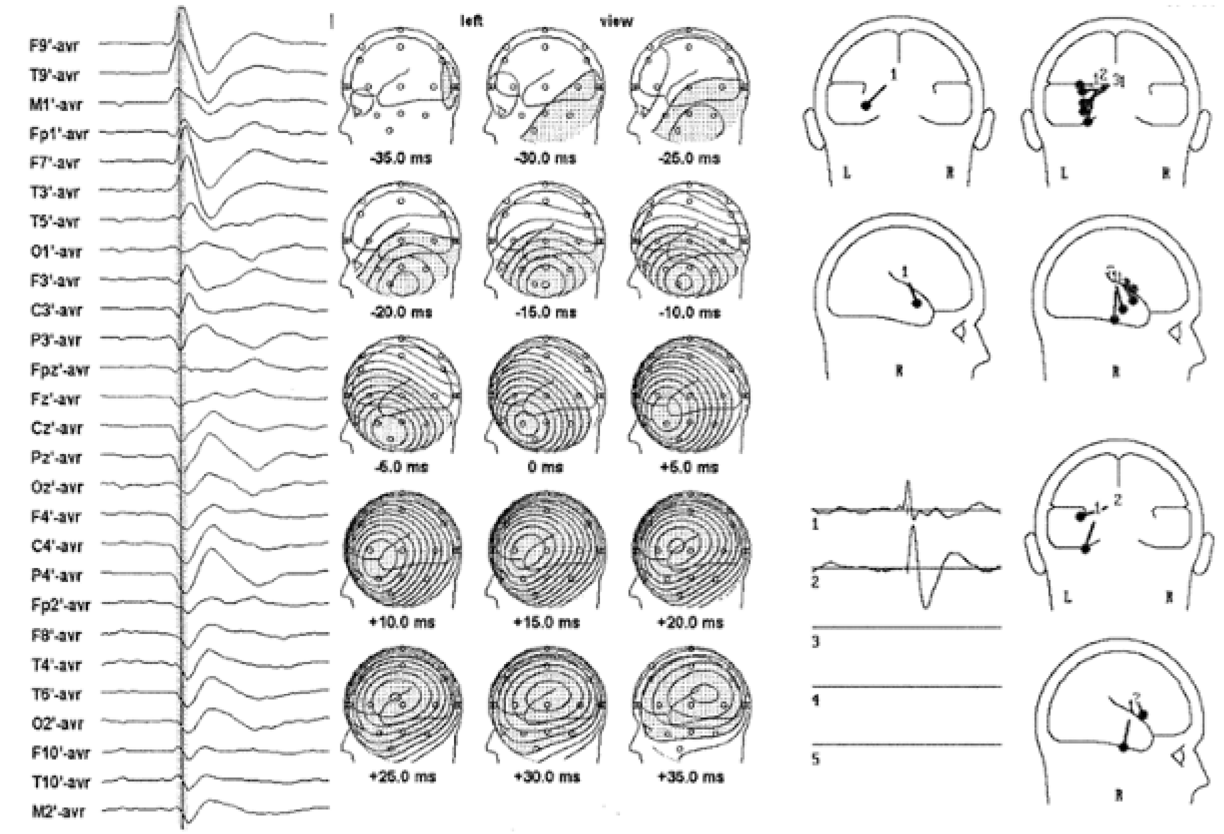

FIGURE 7. A scalp electroencephalogram of a left, type 1 temporal spike. The cursor denotes 0-msec latency. **Middle:** The progressive change in the sequential voltage topography of the spike is evident. **Right:** Single-dipole, moving-dipole, and spatiotemporal dipole models of the spike. The single dipole at the spike peak is oblique in orientation, whereas the moving-dipole model shows a progression in dipoles from the vertical tangential to the horizontal radial. The spatiotemporal model requires two dipoles to explain the field over time—the first vertical tangential and the later horizontal radial. Both the moving-dipole and the spatiotemporal dipole models suggest spike propagation.

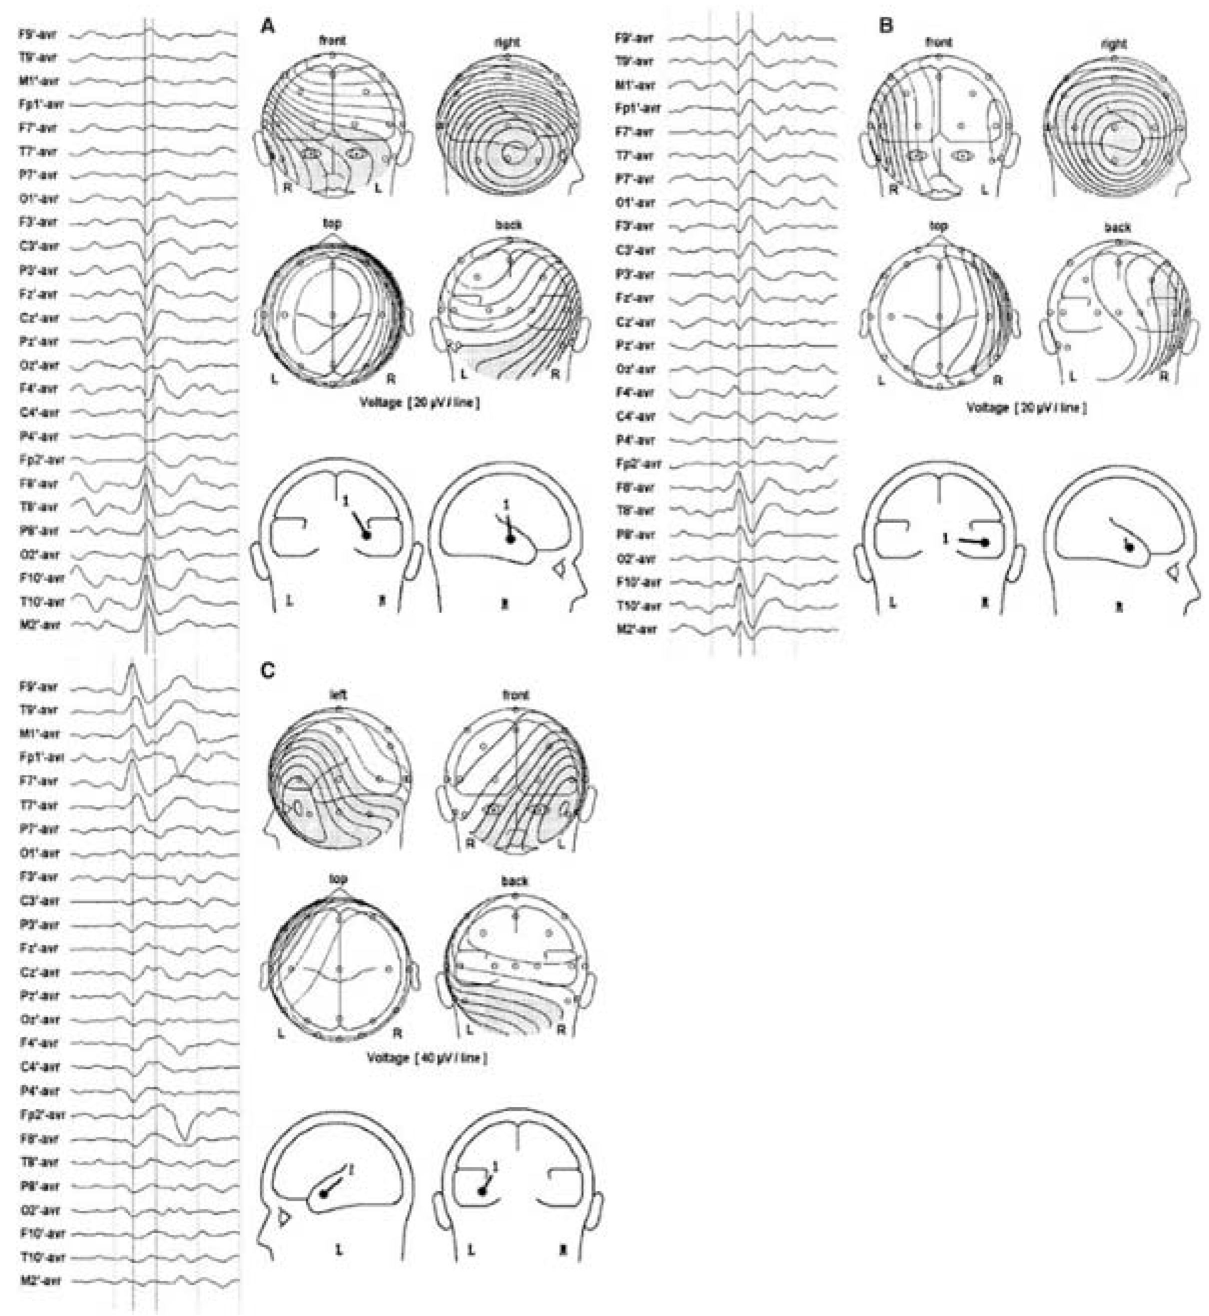

FIGURE 8. A scalp electroencephalogram, voltage fields, and single-dipole models of **(A)** type 1, **(B)** type 2, and **(C)** tip temporal spikes.

Spatiotemporal Multiple-dipole Model

It is overly simplistic to think that small brain regions are activated briefly in sequence when spikes propagate. It is more reasonable that adjacent cortical areas are activated for a longer period but not synchronously. Source modeling with single instantaneous dipoles cannot take into consideration such an overlap of activity of multiple generators, nor can it decompose the voltage fields produced by this superposition. Spatiotemporal source modeling is, however, an approach based on this rationale.[133,138,139] Dipoles are fixed in location and orientation but can vary over time in strength and polarity to explain the temporal evolution of a voltage field. Sufficient degrees of freedom are obtained to calculate multiple dipoles from this positional constraint and from modeling over several time points. The solution for a given data set reveals not only a best-fit location for the model, but also the putative activity of each dipole over time in the form of a source potential (Fig. 7).

Because there is no unique solution when trying to identify several sources that may underlie a voltage field that is a composite, it is necessary to use modeling strategies to constrain the solutions to those that are most realistic. Two major categories of strategies include those based on sequential temporal activation of adjacent generator areas and those based on the orientation of the cortical areas likely to be involved

P.900

in the process. Implicit in the "temporal" strategy is the idea that the earliest part of a spike waveform is more likely to be the product of a single source than are later segments. Accordingly, one should first attempt to model the early part of the field evolution as a single dipole rather than the spike peak, for example. Additional dipoles are used in sequence to model the residual field left unexplained by the preceding dipole(s). If the initial equivalent source explains, in spatiotemporal terms, the entire spike field evolution, the generator is rather discrete or simple in character. Commonly, however, two or sometimes three dipoles are necessary to explain "focal" spike data. The spatiotemporal technique attempts to find the fewest number of fixed equivalent sources that can explain field evolution by a temporal overlap of activity among them.

Several different patterns of multiple dipole models have emerged in applying this technique to the spikes of patients with presumed temporal lobe epilepsy.[17,19,35,36,37] Spikes with a type 1 topography usually require two or more dipoles to be modeled adequately (Fig. 7). One of these dipoles typically has an orientation that is vertical and tangential to the lateral skull convexity, whereas the other is horizontal and radial. The tangential dipole is usually deeper than the radial one. Type 1 spike topography is the result of the superposition of fields from both sources when their activity overlaps in time. Source analysis of type 1 spikes from different patients has shown tangential source activity leading, lagging, or being synchronous with radial source activity. The pattern of voltage field evolution for a particular spike thus depends on the temporal relationships of its various source components. Information about the direction of spike propagation is conveyed by the sequence in which dipole sources become active. Simultaneous intracranial and scalp EEG recordings have validated previous assumptions that the vertical tangential dipole models activity from basal temporal lobe cortex and the horizontal radial dipole models activity from lateral temporal cortex.[42,137] Spikes confined to the hippocampus produced no scalp-recognizable voltage field. However, when these spikes propagated to basal cortex, which was common, sufficient cortex was activated to result in a scalp potential. Basal to lateral cortex propagation and vice versa, suggested by timing differences in dipole source components, have also been confirmed.

The majority of spikes with type 2 topography require only one horizontal radial dipole to be modeled (Fig. 6); in approximately one third of patients, however, two or more dipoles are needed. In these cases, the dipoles usually differ in azimuth orientation and anteroposterior position yet continue to be predominantly radial. Differences in timing between these sources can suggest anterior to posterior or, less commonly, posterior to anterior propagation along the lateral temporal convexity.

P.901

More recently, dipole modeling has identified a third major cortical source contributing to typical temporal spike fields.[40,41,137] Synchronous activity of anterior temporal tip cortex results in a field with a negative maximum recorded from frontopolar and frontotemporal electrodes because of its net forward-facing orientation. Dipoles modeling this activity are horizontal but have a distinct anterior-posterior (AP) vector (Fig. 8C). Occasionally, spikes have just this dipole solution, but usually the tip component is present in combination with other temporal source components in more complex spikes that exhibit propagation.

Modeling strategies using anatomic constraints can also be useful. Unconstrained inverse-solution mathematics considers any position within the spherical head model and any orientation of dipole vector to be equally likely as a source. This is obviously not true biologically. Spikes arise from cortex that has limited and definable locations and orientations. Of the two, it is more useful to specify the orientation of possible

P.902

equivalent sources. As noted previously, it is reasonable to consider for purposes of modeling only the orientations of major lobar surfaces. For the temporal lobes, these orientations are horizontal radial for the lateral convexity cortex, vertical tangential for the basal cortex and superior temporal plane, and AP horizontal tangential for the temporal tip (Fig. 4). One approach in using this strategy for the temporal lobes is to create a priori a multiple spatiotemporal dipole model of major lobar surfaces based on specific orientations obtained from brain imaging studies and to note from the source potentials the extent to which each dipole can contribute to explaining spike voltage fields over time.[2,3,136,137]

Dipole Modeling in Clinical Investigations

By the mid 1990s several investigators began to apply EEG dipole modeling to the evaluation of epilepsy surgical candidates. In general they confirmed findings from earlier studies. In a series of investigations, Boon et al.[19,20,21,22,23] demonstrated that patients with medial temporal lesions had EEG spikes and early seizure rhythms that were modeled by dipoles having an elevated orientation above the horizontal (a combination of radial and tangential) similar to Ebersole's type 1 spike, whereas patients with lateral temporal or extratemporal lesions had EEG spike and early seizure rhythms that were modeled by dipoles having a radial orientation similar to Ebersole's type 2 spike. In a series of studies using simultaneous scalp and intracranial EEG recordings, Lantz et al. confirmed that dipole orientation was the major distinguishing factor in distinguishing spikes originating from basomesial temporal sources from those of lateral temporal origin.[86,90,92] Merlet and Gotman[99,100] in a pair of papers validated dipole models of spikes or seizures with a later combination of intracranial and scalp EEG. They concluded that only simple cortical sources could be well modeled by one dipole and that spike modeling yielded better and more frequent results than seizure modeling. Numerous other publications began appearing in the late 1990s that confirmed a good correlation between spike dipole models and other localization tools such as intracranial EEG,[69,106] positron emission tomography,[145] single photon emission tomography,[124,145] and magnetic resonance imaging (MRI) lesions in both adults and pediatric patients.[83]

Dipole Modeling of Seizures

Dipole modeling can also be applied to seizure rhythms with some modifications in the protocol used for spikes.[19,20,21,22,23,37,38,40,41,100] The earliest recognizable seizure potentials should be preferentially modeled because they are more likely to reflect the seizure origin than are later rhythms, which usually evolve only after significant propagation. In most instances, the EEG must be filtered with a narrow band pass covering those frequencies that represent the cerebral seizure activity and not the accompanying artifact. For partial seizures of the temporal lobes, this is approximately 2 to 10 Hz. For extratemporal seizures that commonly have a beta frequency component, this is a broader 2 to 20 Hz.

Because ictal onset rhythms are typically of low amplitude and are commonly confounded with movement and muscle artifacts, averaging successive potentials might be necessary to increase the signal-to-noise ratio. The key is to average seizure waveforms with similar voltage topographies (Fig. 9); only these reflect the same source configuration. These periods of stable fields might last only a few seconds. Alternatively, spatiotemporal modeling can be performed over this stable epoch. One or more fixed dipoles possessing cyclic variations in the magnitude and polarity of their source potentials can often explain the repeating evolution of an ictal voltage field. Temporal and orientation strategies are applicable in seizure modeling, just as in spike modeling. Modeling sequential epochs during the course of the seizure can provide insight about seizure propagation.

The orientation of dipole models of ictal waveforms carries the same significance as those of spikes, and it is most useful in identifying sublobar temporal lobe sources.[2,19,20,21,22,23,37,38,40,41] Temporal lobe seizures modeled by dipoles with dominant horizontal radial, vertical tangential, or horizontal tangential AP orientations are most likely associated with lateral temporal, hippocampal/basal, or temporal tip seizures, respectively (Fig. 10). In addition, many temporal lobe seizures are modeled best by dipoles having an anterior oblique orientation, that is, a combination of all three of the previous orientations (Fig. 10). In this case the ictally active cortical region includes inferior, tip, and lateral temporal cortex. Multiple fixed-dipole models can also be used to identify the contribution of various sublobar cortical areas to seizure potentials. This technique has recently been used to determine temporal lobe seizure origins and to predict surgical outcome following standard temporal lobectomy.[2,3]

Ictal EEG dipole models have been correlated with intracranial EEG and surgical outcome.[2,1923,37,38,40,41] The results are similar to those found with spike dipole modeling. Patients with seizures modeled by horizontal radial dipoles, which suggest a lateral cortex origin, do less well following a standard anteromesial resection and should be considered candidates for invasive monitoring and possibly tailored temporal lobe resections. Patients whose seizures are modeled best by dipoles with a vertical, horizontal AP, or anterior oblique orientation have seizures originating probably in baso-mesial, temporal tip, and anterior inferior temporal cortex, respectively. All of these patients do well following surgery because these cortices are customarily removed in the standard temporal lobe resection.

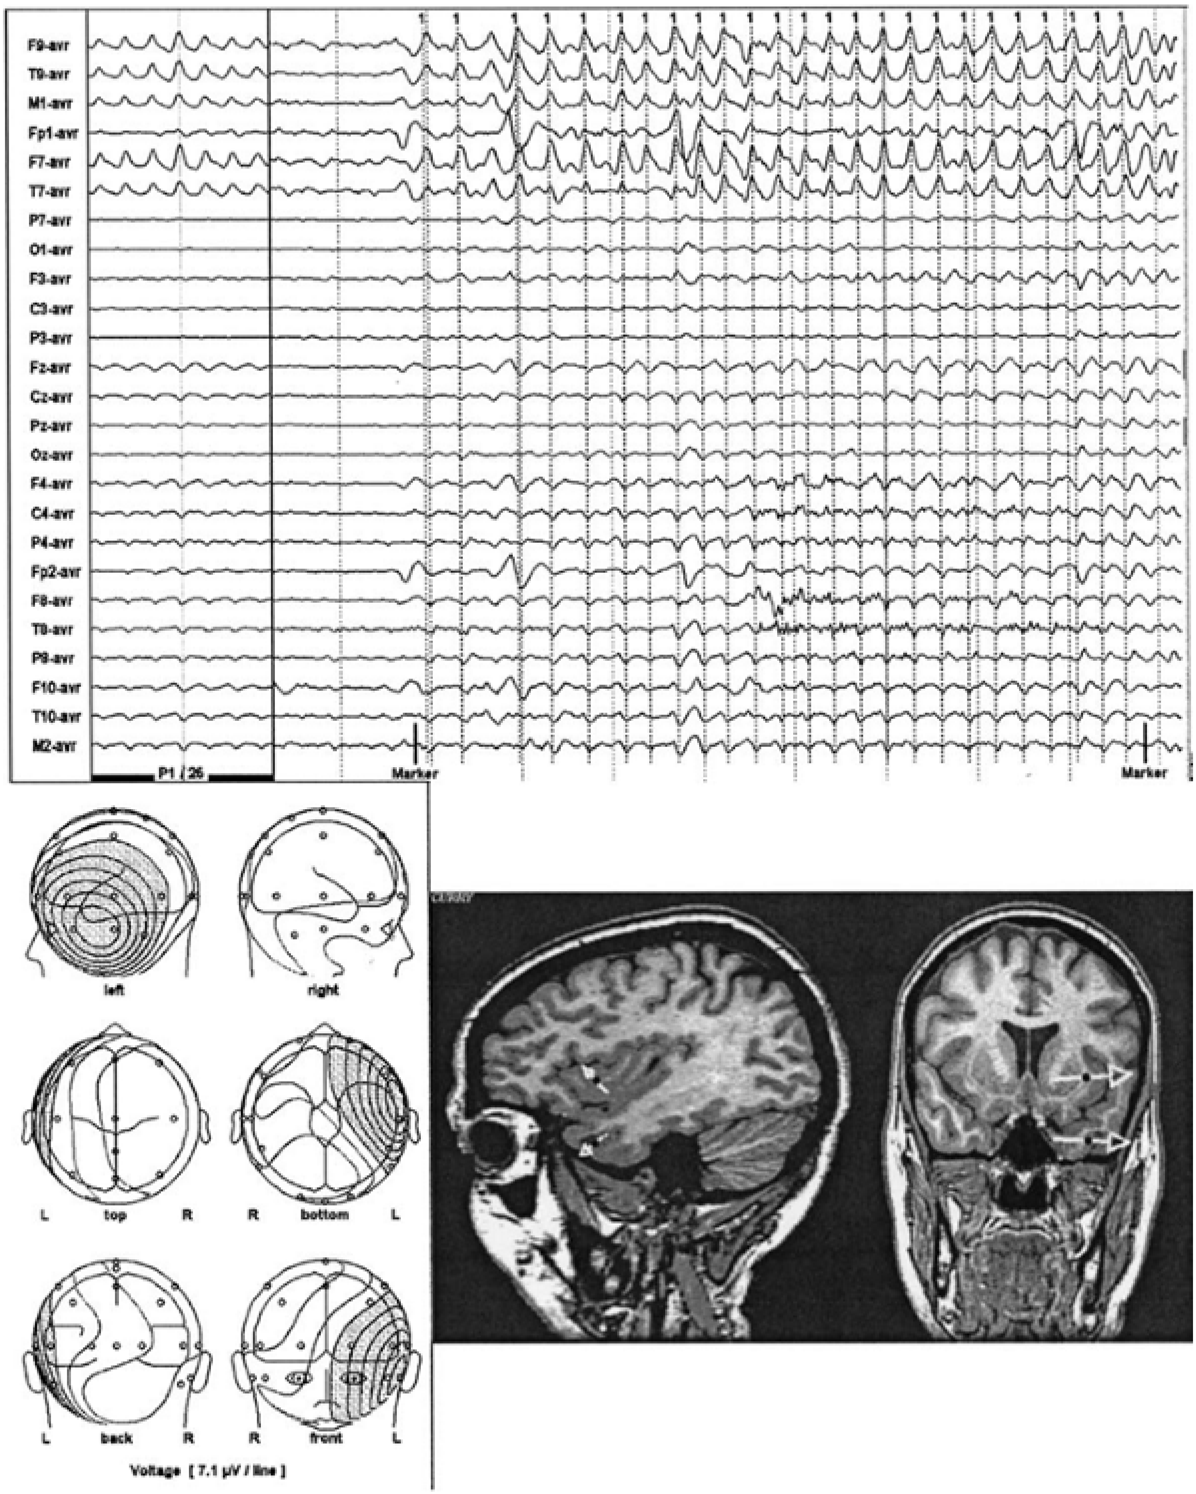

FIGURE 9. Scalp electroencephalogram of a left temporal seizure is illustrated at the *top right*. Cursors mark individual ictal potentials that are averaged to produce the ictal potential at the *top left*. Note the improved signal-to-noise ratio. The voltage field of the averaged ictal potential is shown at the *bottom left*. Single-dipole models of the ictal potential are coregistered with the patient's magnetic resonance image at the bottom right. Inverse solutions were obtained using a spherical head model (upper dipole) and a boundary element method (BEM) realistic head model (lower dipole).

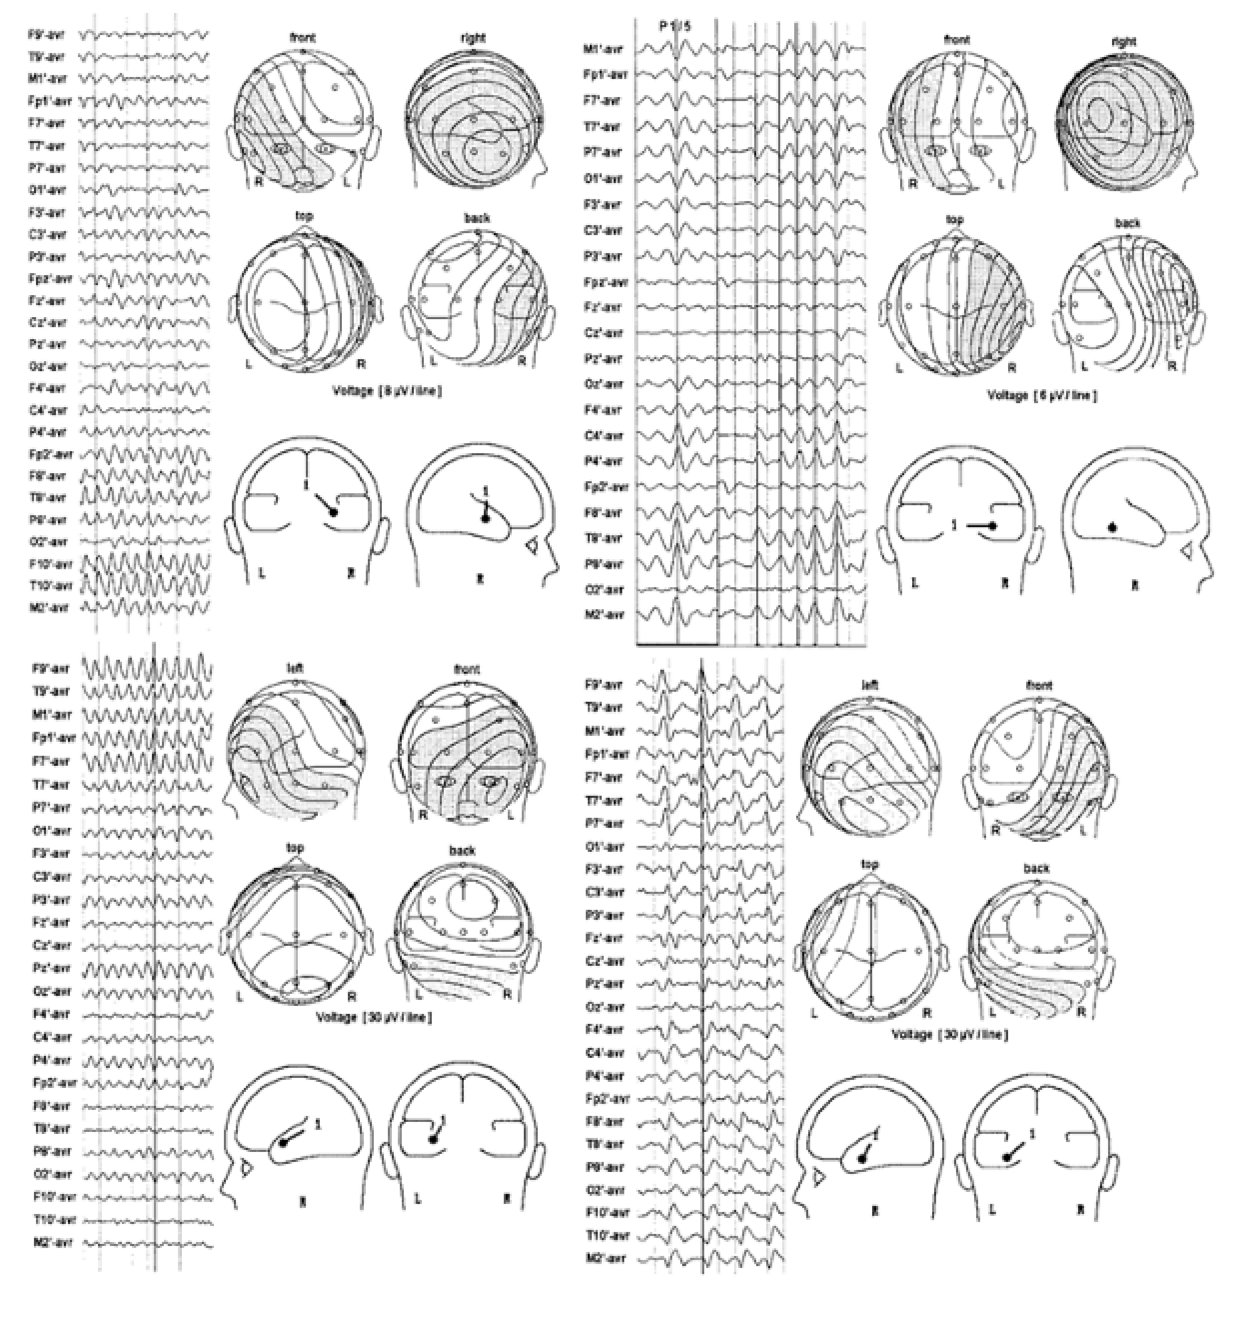

FIGURE 10. Scalp electroencephalogram, voltage fields, and single-dipole models of **(A)** type 1, **(B)** type 2, **(C)** tip, and **(D)** oblique temporal seizures.

Improvements in Recording and Modeling Techniques

With the advent of volumetric computed tomography (CT) and MRI, detailed anatomic information about an individual's head and brain has become readily available. However, only recently have these data been combined with EEG to provide “functional imaging” of the brain's electrical activity. Three-dimensional reconstructions of MRI have demonstrated the geometric relationship between standard scalp electrode positions and the underlying brain.[38,85] The standard International 10–20 temporal electrode chain passes across the superior aspect of the temporal lobe. Supplementary inferior temporal electrodes are necessary for properly recording the negative field of spikes and seizures from the basal cortex of frontal, temporal, and occipital lobes. Sphenoidal or the so-called anterior temporal electrodes, T1 and T2, are useful in this regard, but a broader spatial sampling of lower-head voltage fields is better for modeling purposes than simply one or two positions. Digitizing the scalp electrode locations and certain head fiducials, such as the nasion and preauricular points, in 3-space makes it possible for the topography of the scalp EEG fields to be coregistered with and superimposed on a three-dimensional (3D) MRI reconstruction of the patient's head or brain. In similar fashion, calculated dipole models can be coregistered with the same 3D brain image (Fig. 11).[38]

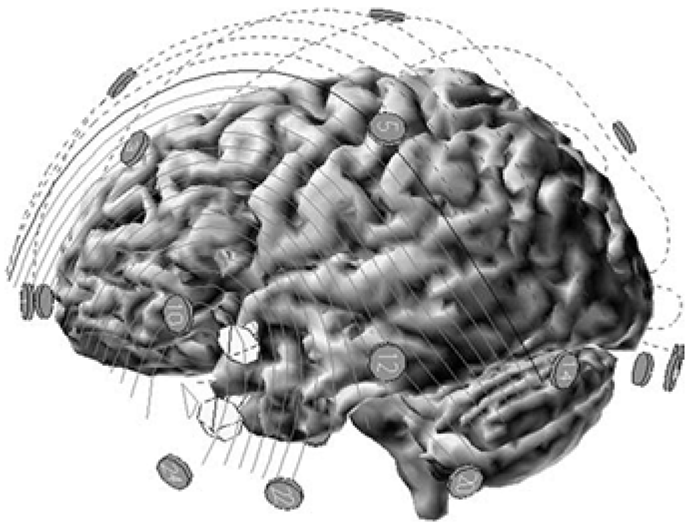

FIGURE 11. Three-dimensional coregistration of a patient's brain, scalp electrode positions, voltage field of a left temporal spike, and dipole models of that spike. Inverse solutions were obtained using a spherical head model (upper dipole) and a boundary element method (BEM) realistic head model (lower dipole).

Some have proposed on theoretical grounds that high-resolution EEG requires hundreds of electrodes,[63] whereas others have concluded that the gain beyond 40 to 64 electrodes is negligible.[84,176] This is particularly true for epileptogenic spike and seizure sources that tend to be large spatially and produce

P.903

P.904

voltage fields of low spatial frequency. Lantz et al.[87] recorded spikes from patients with epileptogenic lesions with 128 electrodes and performed source modeling with various downsampled arrays. An increase in electrode number from 31 to 63 resulted in significantly improved localization, whereas only minimal additional precision was achieved with an increase in electrode number to 128.

The spherical model commonly used to calculate EEG dipoles is a mathematically convenient approximation for the shape of a head. Although the superior convexity of the head is rather spherical, the base of the brain/skull is not. Realistic head models created by the boundary element method (BEM) are the most commonly used (Fig. 12). This type of model accounts for the individual, nonspherical shape of the main intertissue boundaries of the brain, skull, and scalp.[52,54,96,178] Each of these is discretized into triangular elements to form a mesh. The effects of conductivity inhomogeneities across the boundaries are modeled by so-called “secondary dipoles” that are placed in the center and perpendicular to each of the surface elements. The strength of these secondary dipoles is proportional to the conductivity difference and the electrical potentials, which are assumed to be constant over each surface element. BEM head

P.905

models have two shortcomings. Conductivity is assumed to be piecewise constant and isotropic, whereas cranial tissues are inhomogeneous and show anisotropy. Finite-element methods can overcome these problems but require considerably more computational effort.[26] In addition, the detailed conductivity information needed to construct such a model is not known. Accordingly, BEM realistic head models are a reasonable compromise. Recent investigations have also shown that the accuracy of source solutions can be further improved if an increase in the density of the triangulation mesh is made in the region of the source.[175,176]

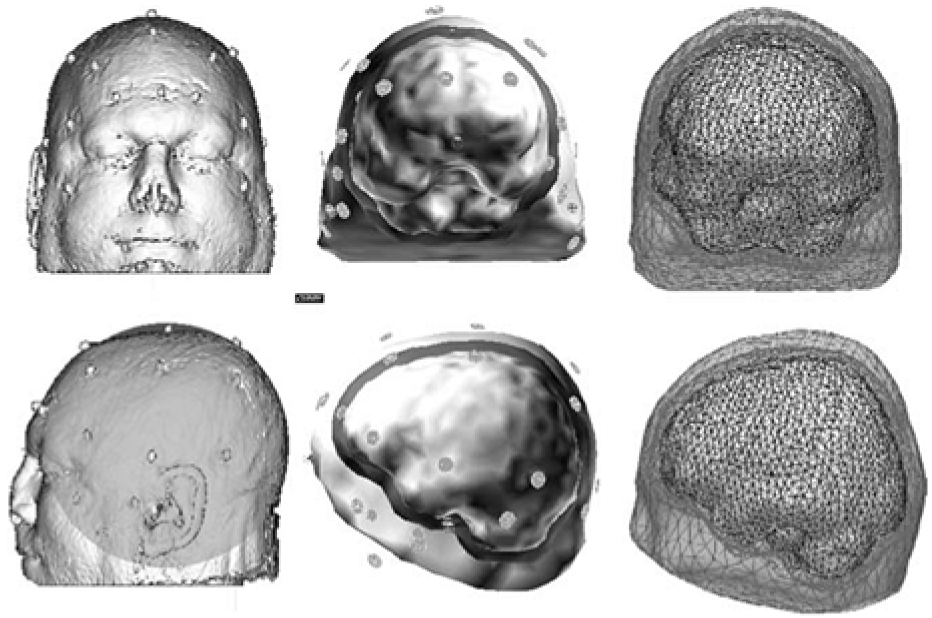

FIGURE 12. Middle: Realistic boundary element method (BEM) head model illustrating inner and outer surfaces of skull and scalp derived from three-dimensional magnetic resonance imaging reconstructions. **Right:** Tessellation of these surfaces into a triangular mesh. **Left:** The shaded circle on the patient's head depicts the typical shape of a spherical head model. Note the divergence of the brain and skull base from this spherical shape.

Systematic errors in dipole location introduced by spherical head models have been identified.[30,31,140] Roth and colleagues[126,127] first simulated and then studied real EEG sources in the temporal and frontal lobes to compare the effects of spherical versus realistic head models on dipole solutions. They noted location errors in the spherical models of 1 to 3 cm that were worse in the vertical or Z direction. Yvert et al.[175,176,177] and Fuchs et al.[52,54,56] simulated EEG dipole sources throughout the brain and found that spherical head modeling errors were worse for basal regions and in the Z direction. These results were also confirmed using temporal lobe spike and seizure foci as the source and validating the true location of these foci with intracranial EEG.[40]

Fig. 13 illustrates dipole solutions for a temporal lobe spike calculated with both spherical three-shell and BEM head models. Dipoles using a spherical model were misplaced on the average of 2 to 3 cm upward from those of a BEM model and their true temporal lobe source. In several patients, this gave the false impression that the spike/seizure sources were of superior temporal or frontal rather than anterior-inferior temporal lobe origin. Others have confirmed these observations.[68] It is apparent that realistic head models should be used whenever dipoles are coregistered with MRI for interpretation. This is particularly true for basal frontal, temporal, and occipital sources, where brain cortex and skull departs most from a spherical shape.

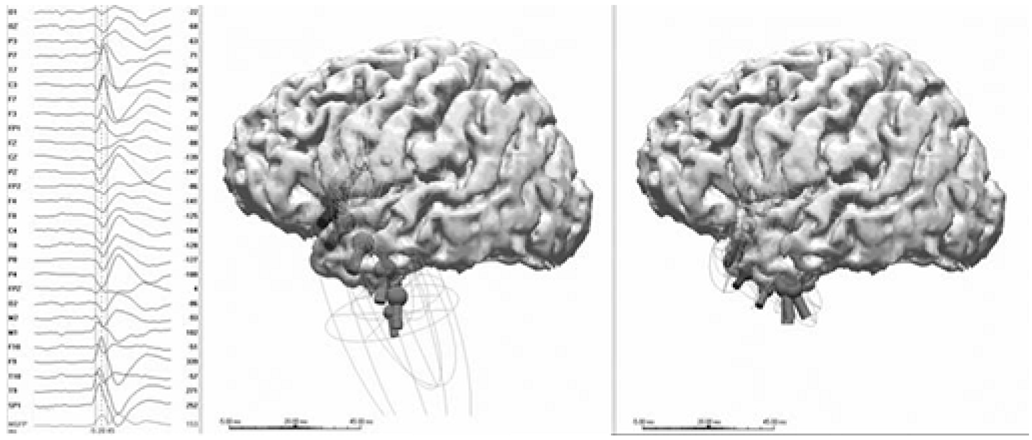

FIGURE 13. Moving-dipole model of a propagating left temporal spike calculated with a three-spherical-shell-head model **(left)** and a boundary element method (BEM) realistic head model **(right)**. Note that dipole solutions using a spherical model begin below the temporal lobe and end in the frontal operculum, whereas those using a realistic model all reside within the temporal lobe. Confidence volumes (displayed as ellipsoids) are largest with early and late dipoles and smallest with the best signal-to-noise ratio at the spike peak.

Fuchs et al.[53] described the use of a standardized BEM head model derived from an averaged MRI data set (Montreal Neurological Institute) to provide simple access to realistically shaped volume conductor models for source reconstruction. They compared dipole modeling accuracy using spherical head models, individually derived realistic head models, and the standardized realistic head model in both source simulations and epileptic spike data. Spherical head models resulted in dipole mislocation errors at the base of the brain, as previously noted. Standardized and individualized BEM head models resulted in more accurate and comparable dipole solutions. By using a standardized head for the BEM setup, an easier and faster access to the benefits of a realistically shaped volume conductor models can be achieved.

Recently, Kobayashi et al.[82] tested the accuracy of dipole models when applied to simulated EEG derived from cortical patches of different location and area. They demonstrated that dipole models of small sources (6 cm^2) or very large sources (>100 cm^2) were misleading, whereas dipole modeling sources between 18 and 36 cm^2 were consistent and accurate. Dipoles are thus a reasonable source model for focal spikes, given that Tao et al.[158] showed that epileptic potentials appreciated on scalp EEG commonly had source areas of 10 to 30 cm^2.

Other Electroencephalographic Source Models

Within the last 5 years there has been considerable development of new techniques for expanding the use of source modeling

P.906

in the evaluation of epilepsy patients. Many of these involve new mathematical approaches to the decomposition of the data or to the reconstruction of a source model. Because the number of cortical sources is not known when modeling spike or seizure potentials, some investigators feel that decomposing the data by a variety of techniques is worthwhile before attempting to model them. Several have chosen to use singular value decomposition[27] or independent-component analysis.[79,80,81] The likely number of component sources, or at minimum the dominant component, can be estimated and their contributions to the voltage field and waveform separated without prior knowledge. Others have devised techniques for systematically scanning the entire brain space for possible sources.[108,109]

Although the dipole is a useful concept from which practical diagnostic information can be obtained, it is anatomically not very realistic. Brain sources of spikes or seizures are extended cortical patches, not isolated points. Clinicians, in particular, are more comfortable seeing regions of cortical activation, such as displayed in positron emission tomography (PET), single photon emission computed tomography (SPECT), or functional MRI (fMRI) images, regardless of the physiologic soundness of these representations. There has been considerable effort recently to go beyond dipole source models to more realistic extended-source models. These take a variety of approaches; a common form of source reconstruction works on the hypothesis that brain currents are located only at specified locations. Using the cortical surface, for example, can afford a powerful reconstruction parameter because it restricts the search space to a surface that can be defined further by local orientation information.

Algorithms have been devised that can calculate discrete approximations of the current density distribution on a defined surface. This is an ill-posed problem, however, if many local sources are to be calculated from measurements at relatively few electrode locations. Regularization is necessary to proceed in these circumstances. This represents a compromise between the demands to explain the measured data and to meet certain source or boundary conditions. One such boundary condition is the minimum norm criterion, in which the source constellation of lowest electrical power is calculated. Variations include the L2 or L1 norms[54] and or the minimum spatial Laplacian, also called low-resolution tomography (LORETA).[101,121] Additional techniques for estimating multiple sources or a single extended source include LAURA and EPIFOCUS[64,103] and VARETA.[129] The usefulness of these techniques, however, needs to be proven with clinical data and further validated by intracranial EEG recording. One investigation demonstrated no advantage of current density reconstruction over source modeling with dipoles.[167] However, a recent study of 44 patients with partial epilepsy using 123 channels of EEG demonstrated that an extended-source model (EPIFOCUS) was capable of correct lobar localization in 90% of patients and correct sublobar localization in 79% when compared to the eventual surgical resection site that eliminated the patient's seizures.[102]

Another very recent approach to the problem of unrealistic point-like dipoles is the use of a “dipole patch” model. It is composed of many individual dipoles that are constrained to follow the surface of the patient's cortex, derived from 3D MRI reconstructions, in both position and orientation. This model, which has an adjustable spatial extent, was tested with data from eight surgical candidates with complex partial seizures.[65] Dipole patch solutions for EEG spikes and seizures were compared to single-dipole models and to the location and extent of cerebral sources recorded with intracranial electrodes. Physiologically reasonable dipole patch solutions were obtained for spikes or initial seizure rhythms in all patients. The location of dipole patches was accurate at a sublobar level when compared to underlying cerebral sources, as validated by intracranial EEG. Dipole patches with a diameter of 3 to 5 cm most accurately simulated the spatial extent of real cortical sources (Fig. 14). Single-dipole solutions usually fell within the boundary of the dipole patch or its underlying white matter, but often they did not lie at the geometric center of the patch. In this technique, the localization accuracy achieved with a dipole model using a realistic boundary element head model is enhanced by the spatial extent and realism of an extended generator area that is constrained to cortical anatomy. Other extended-source models, such as those employing current source density estimations, are not limited to realistic source areas, nor are they constrained to anatomically contiguous cortex. This EEG source model is probably this best one for comparisons with other functional imaging techniques, such as fMRI.

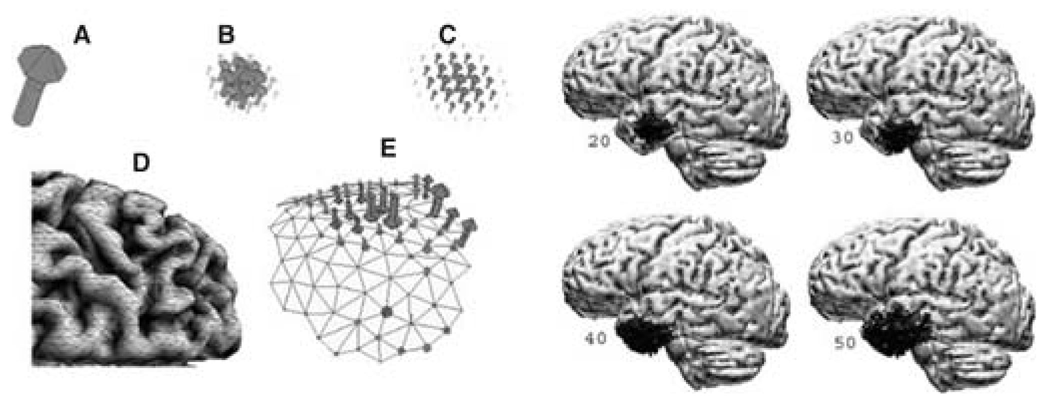

FIGURE 14. Source models of spikes or seizures do not have to be only single dipoles **(A)**; they also can

be arrays of dipoles **(B, C)**. Cortex can be tessellated into triangles **(D)** that have both location and orientation information. Dipole arrays or "patches" can follow the shape of tessellated cortex **(E)**. "Dipole patch" models have an adjustable extent that encompasses the physiologic range of sizes of cortical sources of scalp-recordable electroencephalogram potentials. Diameters of 20 to 50 mm are illustrated at right.

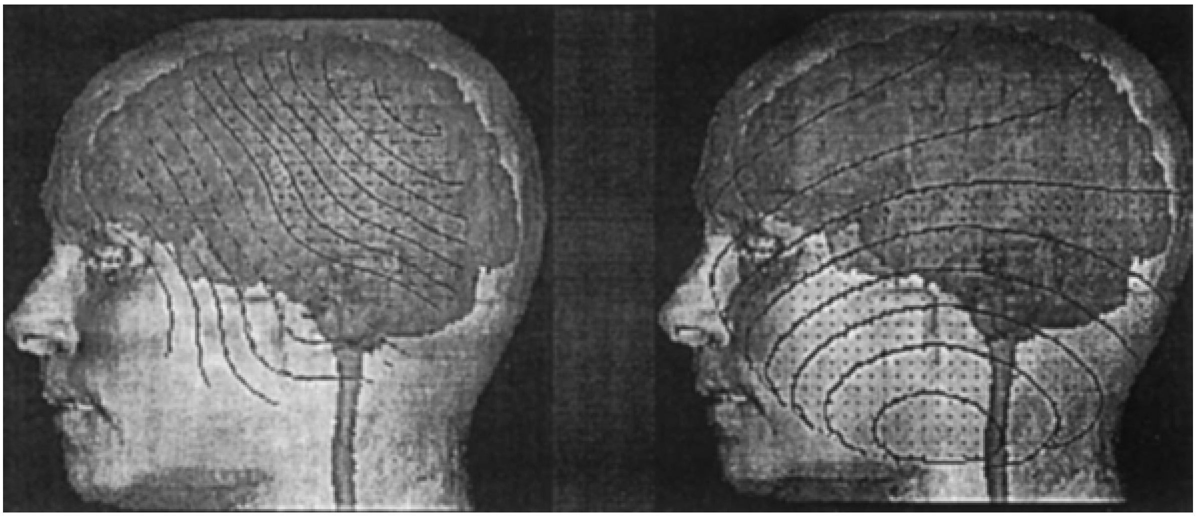

FIGURE 15. Isofield and isopotential contour lines of the magnetic field **(left)** and electrical field **(right)** of a type 1 spike projected onto a three-dimensional magnetic resonance imaging reconstruction of a patient's head to illustrate their spatial relationships. Dotted regions depict magnetic fields emerging from the head or electrical field negativity. Maps illustrate the fields at a time when source activity is principally from a vertical tangential dipole. Note that the magnetoencephalographic field is orthogonal to and more compact than the electroencephalographic field.

Magnetoencephalographic Dipole Source Modeling

Magnetoencephalography is the measurement of extracranial magnetic fields produced by electrical currents, mostly intracellular, within the brain. These magnetic fields are extremely weak, on the order of one-billionth that of Earth's, and can be measured only by superconducting quantum interference devices (SQUIDs). Current within the cell is called source current; the return current outside is called volume current. MEG, like EEG, is principally produced by aligned pyramidal cells oriented perpendicular to the surface of the cortex. The magnetic field associated with a neuronal current dipole encircles the cell at right angles to its direction. The SQUID gradiometer outside the head is usually oriented perpendicular to the head and is sensitive to the component of the magnetic field that is perpendicular to the head surface. Such a field is generated by tangentially oriented current dipoles. In contrast, EEG measures

P.907

principally volume currents associated with both radial and tangential dipoles.

Magnetoencephalography may be better for the localization of epileptogenic foci, or at least the source of epileptiform potentials, for several reasons relating to the physical properties of the signal. First, magnetic fields pass through the skull and scalp unperturbed, unlike EEG potentials, which are attenuated and smeared. Thus, the picture of underlying brain activity should be clearer, and a simple one-shell, rather than a three- or four-shell, head model can be used. In addition, because MEG represents nearly pure tangential source activity rather than an indeterminate mixture of radial and tangential components, as is the case for EEG, the modeling of MEG by inverse dipole methods should be easier and the results more accurate.

Principles of Magnetoencephalographic Dipole Modeling

If one assumes, as in EEG dipole modeling, that the cerebral generator of interest is reasonably discrete and can be modeled as a current dipole, the character of this source should be obtainable from the magnetic fields it produces. Magnetic fields from tangentially oriented brain sources exit the head at one location and reenter at another, producing two magnetic extrema of opposite sign at the surface. Once the magnetic field map is measured, three-dimensional characterization of the source can be done. Note that the MEG extrema should be and usually are orthogonal to EEG dipolar potential distribution on the head (if the EEG potential at that point is principally tangential and not a mixture). Note also that the magnetic extrema are approximately one-third closer together than are the EEG extrema, which are farther apart and smeared, due principally to the influence of the skull (Fig. 15).[28]

Because MEG signals are not perturbed by the skull and scalp, simpler modeling schemes have been used to localize ce- rebral sources. An infinite half-space model assumes that the source lies below the surface of the head, halfway between the two extrema and at a depth equal to their separation distance divided by two. More commonly, inverse solutions using iterative least squares methodology are now employed, in much the same way as with EEG dipole modeling. Research using implanted electrodes to produce artificial current dipoles has determined that volume currents may confound the magnetic field produced by cerebral source near the base of the brain and

lead to some inaccuracies.[7] Thus, even for MEG, in these instances more realistic head models may be useful in improving localization accuracy.

A serious limitation to successful clinical MEG recording is the magnitude of the signal. Epileptiform spikes and sharp waves typically have amplitudes of only one to several picoteslas (10^{-12} Tesla). In contrast, magnetic fields generated by wall power lines and room lighting, for example, are 10^5 to 10^6 times larger. These extraneous magnetic fields can be partially canceled by placing both patient and recording sensors in a magnetically shielded room and by using gradiometer detector designs. Such measures are expensive and limit patient studies to a fixed location where there is a shielded room.

Inadequate spatial sampling over the head was a serious limiting factor for MEG epilepsy studies until the introduction of the new large sensor arrays. The relative infrequency of interictal and, certainly, ictal events continues to be a major problem in MEG data collection. Patients have to lie or sit quietly and without motion under the MEG dewar for proper signal recording. Recording sessions of longer than several hours are impractical. Unlike long-term EEG monitoring, which may be continuous for several days or weeks to record spikes and seizures, MEG recording is restricted to one or more relatively shorter time periods. Consequently, recording ictal events is uncommon unless the patient is having very frequent seizures, and an adequate sampling of interictal spikes may require several recording sessions if they are infrequent.

Evolution of Clinical Magnetoencephalographic in the Evaluation of Epilepsy

Multiple early studies showed that dipole analysis of MEG spikes could estimate the character and location of the cerebral sources. Barth et al.[9,10,11] and Sutherling et al.[155,156] demonstrated that MEG localization agreed well with lesions, depth electrode data, electrocorticographic (ECoG) findings, PET, and postoperative follow-up. Magnetoencephalographic spikes were recorded in the absence of scalp EEG spikes and vice versa. They concluded that MEG and EEG data are complementary because the techniques are sensitive to spikes of different source orientation. However, magnetoencephalography may be less sensitive to deep spikes, according to their data. Modena et al.[107] and Ricci et al.[123] concluded that MEG was a better localizer of spike foci than was EEG. They too reported that some MEG spikes were without a scalp EEG transient. Sato and Smith[130] showed that the phase relationships between MEG and EEG and the timing of spikes recorded simultaneously from both were not always constant. Ricci et al.[123] correlated MEG with lesions and found better localization for centro-parietal-occipital foci than for frontal and, particularly, for temporal foci. It appears that both EEG and MEG modeling suffer in the basal frontal and temporal regions. Nonspherical, nonconcentric changes in conductivity in this region can produce secondary sources, and volume currents can add to the MEG field.

Sutherling and Barth[154] (154) as well as Stefan et al.[152] later studied spike propagation using MEG and demonstrated lateral to mesial spread in the temporal lobe. Barth et al.[9] applied multiple-source modeling to more complex MEG spikes, which probably involved several generator areas of cortex. Later, Nakasato et al.[110] compared the source localization provided by simultaneous MEG and EEG dipole modeling of spikes from patients with neocortical seizures, using ECoG as the “gold standard.” They concluded that MEG localization was consistently more accurate.

Further steps in the development of MEG concerned the use of increasing numbers of channels and its coregistration with MRI.[151] The development of large-array biomagnetometer systems capable of simultaneously sampling the magnetic field pattern over a large region of the head has greatly reduced the previous equipment-related limitations of MEG in epilepsy. Several groups demonstrated that with such instruments it is possible to record enough of the magnetic field of individual epileptiform spikes[58,112,117,118,119,151,152,159,164,174] or slow waves[59,165] to model single events without moving the sensors. Most of these studies were performed with a 37-channel, one-hemisphere, flat or concave sensor array.[112,152,153,174] With such systems, recordings are necessary from only two or three sensor positions over each hemisphere. Routine studies typically require 2 to 3 hours, depending on the frequency of spike activity.

In a series of reports Stefan et al.[151,152,153] observed a close correlation between MEG spike localizations and regions of functional abnormality noted by both PET and SPECT, temporal/hippocampal atrophy, or lesions. They concluded that MEG could help to reduce the need for invasive monitoring in partial epilepsy. In a group of 50 surgical candidates, Smith and et al.[147] found MEG to be most helpful in patients with nonlesional, cerebral convexity foci of temporal, frontal, parietal, and occipital lobes. Eliashiv et al.[49] compared MEG spike source locations with irritative and ictal onset zones in nine patients determined from depth and subdural electrodes. The lateralization and localization of MEG sources were most concordant with invasive EEG findings in patients with extratemporal seizure onset. By comparison, Ebersole et al.[43] studied 30 epilepsy surgery candidates with a bihemispheric 74-channel MEG system and found focal MEG spikes, which were localized to sublobar areas of temporal or frontal lobes. Nearly half of these patients had MRI/CT studies without focal abnormalities, including no hippocampal atrophy.

Interpretation of Magnetoencephalographic Dipole Models

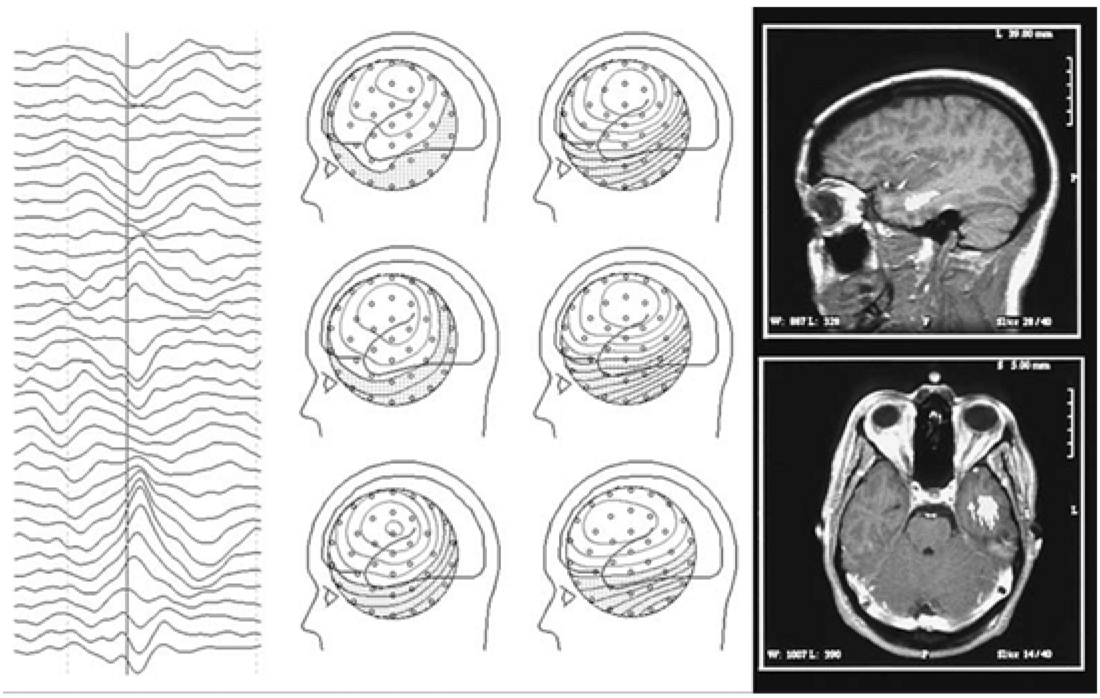

FIGURE 16. Left temporal spike recorded with 37-sensor magnetoencephalography. Note that the magnetic field is relatively stable in location and shape during the course of the spike. Dipole models of several such spikes are depicted at right and are of the anterior temporal anterior-posterior horizontal

type.

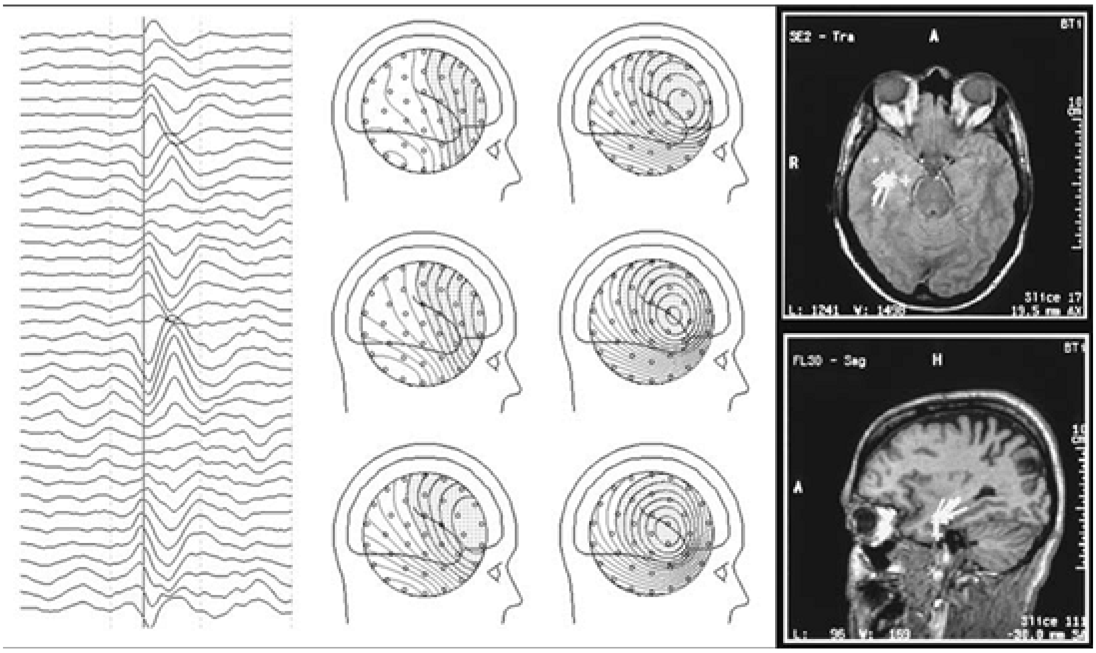

FIGURE 17. Right temporal spike recorded with 37-sensor magnetoencephalography. Note that the magnetic field maxima change considerably in location and shape during the course of the spike. A moving-dipole model of this spike has solutions that progress from vertical to horizontal in orientation. This suggests propagation from the base to the tip of the temporal lobe.

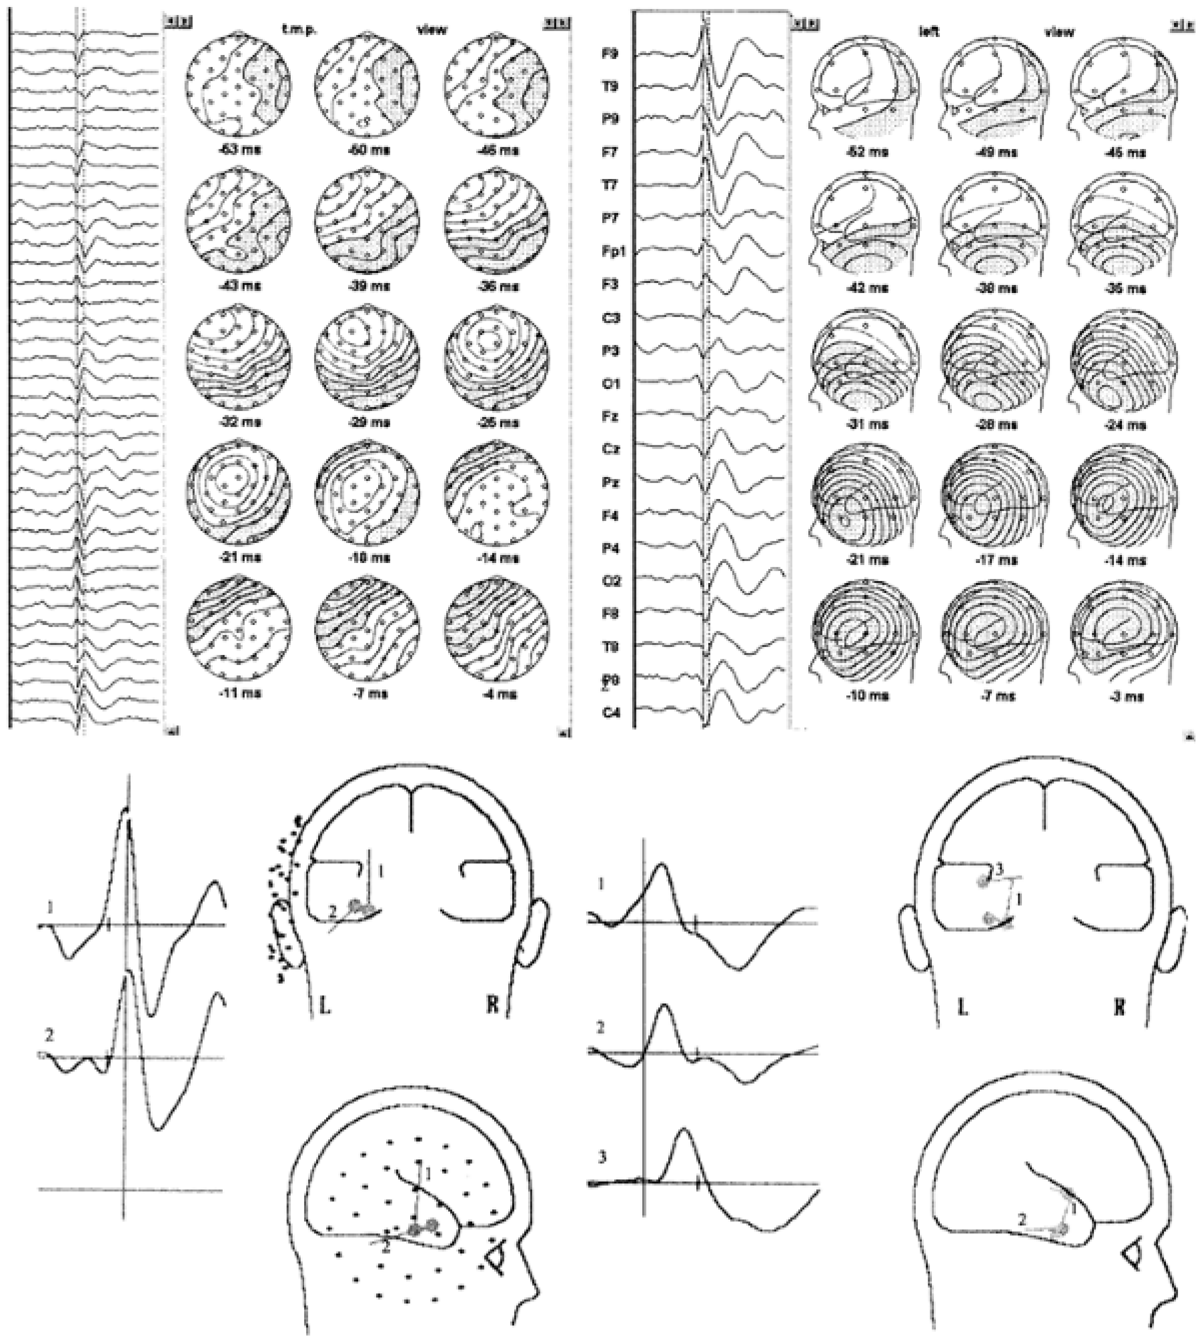

FIGURE 18. Simultaneously recorded magnetoencephalographic (MEG) **(left)** and electroencephalographic (EEG) **(right)** spike from the left temporal lobe. Maps of both MEG and EEG show movement of field maxima during the spike. A spatiotemporal model of the MEG spike reveals two component dipoles, an initial vertical tangential (1) followed by an anterior-posterior (AP) horizontal tangential (2). A spatiotemporal model of the EEG spike shows the same initial two component dipoles (1, 2) plus a later horizontal radial dipole (3). These source models suggest propagation from temporal lobe base to tip to lateral surface. MEG could not identify the last source because its orientation was radial.

In a series of 32 patients with complex partial epilepsy, Ebersole et al.[44] recorded simultaneously 37-channel MEG and 21-channel EEG to make direct comparisons between their respective dipole models for the same interictal spike. As in the case of EEG, they found that patients can have multiple types of MEG spikes when parameters of dipole orientation and evolution over time are taken into consideration along with location. Sorting spikes by these additional criteria led to tighter clusters of spike dipoles that were more likely modeling the same source. Many of the earlier MEG epilepsy studies calculated only equivalent dipole location, possibly resulting in a more heterogeneous sample.

When investigating MEG fields over the duration of the spike, Ebersole et al.[44] found that the majority were relatively stable in contour, reflecting a simple source character (Fig. 16). However, as more commonly noted in EEG, as many as 30% of spikes in a given patient possessed magnetic fields that changed over their time course (Fig. 17). This means that generator geometry is changing, probably from spike propagation. In these cases, instantaneous single-dipole modeling is not adequate, as explained earlier, and spatiotemporal multiple MEG dipole modeling is appropriate (Fig. 18). This type of analysis has provided good explanations for evolving MEG fields. Usually, two or, at most, three sources with temporally overlapping activity result from the modeling. Propagation within the temporal lobe from basal to anterolateral cortex and vice versa has been demonstrated in such modeling. It is important, therefore, to assess dipole stability before

P.909

attributing a spike to a single source. The earliest active source contributing to a spike is more important clinically than is a later source activated by propagation. Modeling just the peak of a spike or a single time point when the field is maximally dipolar may result in erroneous localization of spike origin.

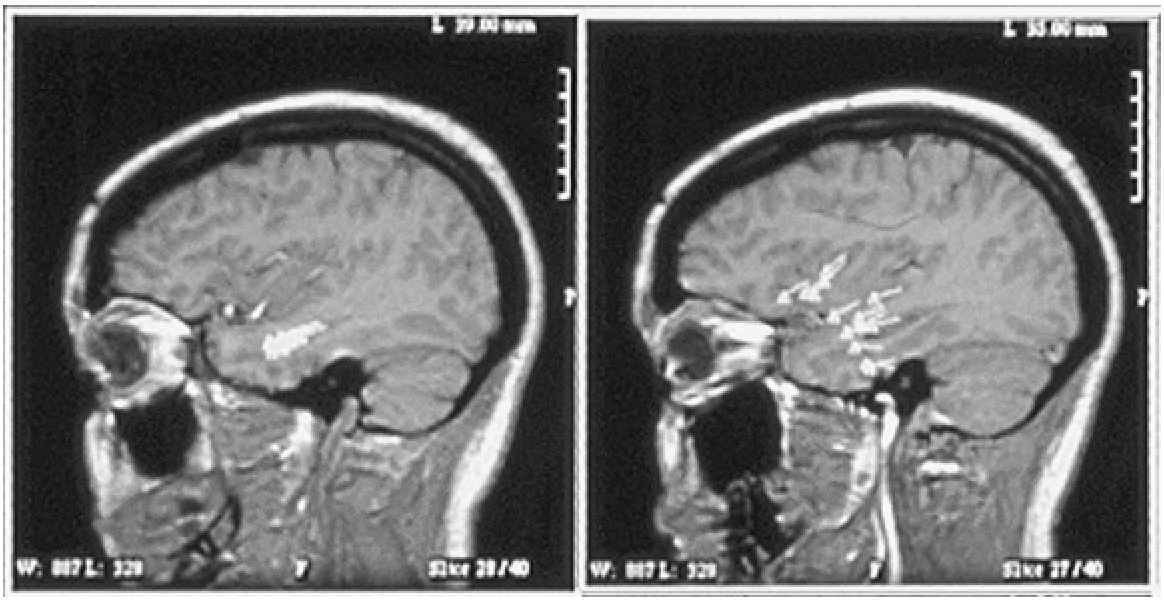

FIGURE 19. Left: A tight cluster of dipoles (anterior-posterior horizontal) modeling a series of magnetoencephalographic (MEG) spikes is coregistered with the magnetic resonance imaging of a patient with temporal lobe epilepsy. **Right:** electroencephalographic (EEG) dipole models of the same spikes. Note that the EEG dipole scatter is greater and that several of the dipoles fall outside of the temporal lobe.

When MEG and EEG dipole models of the same spike population were compared, several trends emerged across all patients. First, the MEG dipoles formed tighter, anatomically more restricted clusters than did counterpart EEG dipoles. Second, the EEG dipole clusters were usually higher and somewhat deeper in the head. When projected into the patients' MRIs, the MEG dipole clusters were confined to localized regions of the temporal lobe, whereas the more diffuse EEG dipoles were commonly scattered among temporal, frontal, and parietal lobes (Fig. 19). These patients were all presumed or later proven to have temporal lobe epilepsy by intracranial EEG monitoring. Ebersole et al.[44] concluded that MEG spike dipole localization was more accurate and anatomically reasonable

P.910

P.911

than that of EEG. Factors that probably contributed to the poorer performance of EEG dipole modeling included the smaller number of recording channels and the spherical head model, which was vulnerable to error in the temporal area. Scheler et al.[131] also showed, in data collected from 100 patients, that EEG results scattered significantly more than MEG results.

Detection Sensitivity of Magnetoencephalography

Baumgartner found that synchronized epileptic activity of about 4 cm^2 restricted to the most mesial temporal electrodes covering the parahippocampal gyrus did not produce a detectable MEG spike, whereas activity of about 8 cm^2 involving mesial plus more lateral electrodes overlying the fusiform gyrus could clearly be identified on MEG.[15] Other investigations with simultaneous subdural EEG and MEG recordings validated that temporal basal sources must be >4 cm^2 in area to be detected by MEG.[104] In the case of lateral neocortex, however, only 3 to 4 cm^2 of synchronized epileptic activity involving the lateral neocortex was necessary to produce a detectable MEG signal at the scalp,[15,104,113] which is smaller than the 10 cm^2 of spiking cortex found by Tao et al. to be necessary to generate a measurable scalp-EEG spike.[158] Thus, MEG appears be more sensitive than scalp-EEG for the detection and delineation of the irritative zone in neocortical epilepsy involving superficial cortex.

Diagnostic Yield of Magnetoencephalography

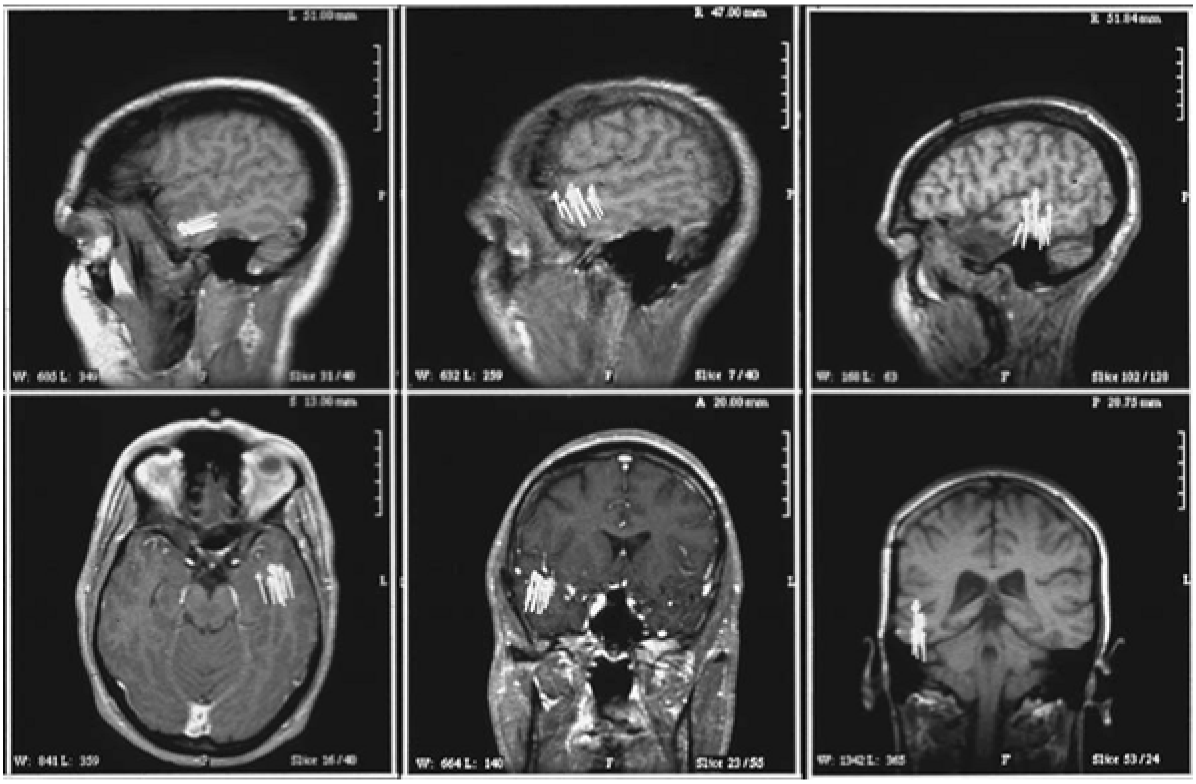

FIGURE 20. Three patterns of magnetoencephalographic (MEG) spike dipoles noted in patients with temporal lobe epilepsy. **Left:** Anterior temporal anterior-posterior horizontal. **Middle:** Anterior temporal vertical tangential. **Right:** Posterior temporal vertical tangential.

In many early MEG studies patients were selected because they had frequent spiking on prior EEGs. When randomized patients were evaluated, the yield for MEG spikes suitable for modeling using a single 2- to 3-hour study varied from 73% of cases[77] to 53.1% in patients with temporal lobe epilepsy.[18] Iwasaki et al.[74] blindly reviewed simultaneous MEG and EEG data from 43 consecutive patients with temporal lobe epilepsy. They found spikes in MEG alone in 8 and in EEG alone in 1. The remaining patients had spikes in both, with an overall agreement in 25 of 43 patients between the two modalities. They found that MEG was slightly more sensitive than EEG by 55.8% to 49.7%.

Interictal MEG spikes are more readily recorded from patients with neocortical seizures as compared to mesial temporal lobe seizures. Thus, the diagnostic yield was 92% for neocortical epilepsy versus 50% for mesial temporal lobe epilepsy in one study[77] and 73.3% for neocortical versus 42.3% for mesial temporal lobe epilepsy in another.[18] Park et al.[120] blindly reviewed simultaneous MEG and EEG data from 12 consecutive patients with neocortical epilepsy. All patients had spikes seen by both modalities; however, MEG spikes without an associated EEG potential represented from 5.9% to 97.9% of the total spikes in a particular patient, whereas spikes unique to EEG were seen in only 0% to 35% of spikes.

Intracranial Validation of Magnetoencephalographic Source Models

As in the case of EEG dipole analysis, validation of postulated source character and location requires either direct invasive measures, such as intracranial EEG, or a large controlled study of indirect measures, such as other noninvasive tests or surgical outcome. In numerous studies, MEG dipole localizations showed good agreement with the results obtained from subsequent invasive EEG recordings.[76,77,78,105,110,115,117,125,147,152,155,156] However, the problem with many attempts at validation has been a lack of confirmation that the activity recorded from the brain was the same as that recorded by MEG. It is well known that most interictal spikes recorded from invasive electrodes are not recordable with scalp EEG and probably not with MEG. Therefore, it is not adequate simply to show that there are interictal spikes arising from a brain region identified by a dipole model; rather, it must be shown that the spikes arising from this region are of sufficient size and extent to produce the EEG and MEG signals that were recorded at the scalp. Such proof requires at least simultaneous intracranial

and scalp EEG recording, if not simultaneous intracranial EEG and extracranial MEG recording.[44] This has been performed simultaneously in only in a limited number of patients.[15,77,104,113,150]

Magnetoencephalographic Dipole Modeling in Temporal Lobe Epilepsy

Several studies investigated the use of MEG in distinct subtypes of temporal lobe epilepsy (TLE)—mesial, nonlesional, and lesional TLE.

In classic mesial TLE, two patient subgroups could be identified. One group possessed spikes modeled by anterior temporal vertical (ATV) dipoles and the other had spikes modeled by anterior temporal horizontal (ATH) dipoles.[18,122] Whereas ATV dipoles indicate epileptic activity in the medial basal temporal, ATH dipoles are compatible with epileptic activity in the temporal pole and adjacent parts of the lateral temporal lobe. In patients with ATV dipoles, interictal and ictal EEG changes recorded during prolonged video-EEG monitoring were localized consistently to the ipsilateral temporal lobe. On the contrary, up to 50% of patients with ATH dipoles showed bitemporal spikes and/or seizure onsets.[122] Surgical outcome after selective amygdala-hippocampectomy was slightly better in patients with ATV dipoles than in those with ATH dipoles, which could serve as an argument for performing larger resections in the latter patient group, whereas a selective amygdala-hippocampectomy should be sufficient in the former.

In nonlesional TLE, MEG dipole localizations agreed reasonably well with invasive EEG recordings. One pattern of spike source localization and orientation (anterior temporal AP horizontal) correlated well with mesial temporal lobe seizure onset. Another pattern (anterior temporal vertical) was correlated with anterior, and perhaps mesial, temporal lobe onset. A third (posterior temporal vertical) correlated well with lateral or nonlocalized onset (Fig. 20).[18,39] MEG therefore may be helpful to noninvasively differentiate mesial from lateral neocortical epileptogenic zones in patients with nonlesional temporal lobe epilepsy.

In lesional TLE, MEG helped to resolve the relationship between structural lesions and the seizure-onset zone. In a study on patients with neocortical temporal lesions, lesionectomy produced a seizure-free outcome in patients in whom MEG spike dipole localizations corresponded to the lesion.[73] In patients with diffuse MEG spike dipole localizations, on the contrary, invasive EEG recordings documented a mesial temporal seizure onset distant from the lesion.

Magnetoencephalographic Dipole Modeling in Extratemporal Epilepsy

Patients with medically refractory extratemporal epilepsies pose major problems for presurgical evaluation and surgical treatment because lesions frequently cannot be identified on MRI scans and surgical outcome is worse than in temporal lobe epilepsy. MEG provided useful information during the evaluation of patients with extratemporal epilepsies in several recent studies, which found excellent agreement between MEG spike dipole localizations and the results of invasive recordings.[115,142,148,149] MEG helped to localize the irritative zone in patients with normal MRI scans, to define the relationship of epileptic activity with respect to large lesions and eloquent cortex, and to decide which of multiple lesions was the epileptogenic one.[148] With this information the correct placement of invasive electrodes could be improved significantly.[148] MEG also provided unique information during a second presurgical evaluation leading to a successful second resective surgery.[148] Finally, resection of the MEG-defined irritative spike

zone had prognostic implications for postoperative seizure control.[62,115]

Ictal Magnetoencephalography

Consistent regional interictal epileptiform discharges can add confirmatory evidence for identifying the area of seizure onset; however, regional ictal epileptiform discharges preceding or simultaneous with the patient's habitual seizures are considered the most reliable localizing sign in presurgical evaluation. Recently several studies presenting data on ictal MEG recordings in patient series were published.[4,8,48,157,160] Whereas some studies showed good concordance between interictal and ictal MEG localizations in most patients,[4,157,160] one study found ictal MEG clearly superior to interictal MEG.[48] Ictal MEG localizations could be confirmed by subsequent intracranial recordings in selected cases.[4,8,48] Nevertheless, ictal MEG recordings are impractical in a routine clinical setting for several reasons. First, the patient must have frequent seizures for an event to be captured during the restricted time of the MEG recording session. Second, the patient is required to stay in a fixed position in relation to the magnetometer over a prolonged time period, which is stressful and uncomfortable and can be achieved only with very cooperative patients. Third, seizures usually are accompanied by movement and associated artifacts, which make MEG data difficult to interpret. Finally, several seizures have to be recorded to localize the seizure onset zone reliably. Barkley et al.[8] reported one patient who had one seizure during MEG that colocalized to one of three zones of interictal MEG spikes. When this patient later had invasive EEG monitoring, all three zones of interictal MEG spiking were found to be zones of ictal onset. Thus, further technological improvements are necessary to facilitate long-term MEG recordings.

Clinical Utility of Magnetoencephalography in Presurgical Evaluations

A number of investigations have attempted to quantify the usefulness of MEG in the evaluation of patients who are being evaluated for epilepsy surgery as compared to other diagnostic studies. MEG was second only to invasive video-EEG in correctly localizing the epileptogenic focus in the patient series studied by Wheless et al.[170] Later Stefan et al. demonstrated that interictal MEG localized to the lobe where the resection was performed in 71% of seizure-free patients, as compared to 43% using ictal scalp EEG.[149] In a study of temporal lobe epilepsy patients, those with anterior temporal (AT) MEG spike localization (defined as >70% of spike dipoles located in the anterior temporal lobe) had a different surgical outcome from patients with non-AT localizations.[73] All AT-localized patients became seizure and spike free after anterior temporal lobectomy with amygdala-hippocampectomy, whereas patients with non-AT MEG spike localizations faired less well, indicating either non–medial temporal lobe epilepsy or spike propagation to the posterior and extratemporal neocortex. In another study on 26 patients with TLE, MEG dipole locations and orientations provided useful localizing information about the seizure onset zone.[5] Twenty-three patients with ATV and ATH dipoles became seizure free after anterior-medial temporal lobectomy or selective amygdala-hippocampectomy; however, the remaining 3 patients with lateral vertical dipoles became seizure free after restricted neocortical temporal resections. In lesional frontal lobe epilepsy, complete resection of the MEG-defined irritative zone correlated with a favorable surgical outcome.[62] Finally in a study of 33 patients, successful surgical outcome was correlated with (a) MEG dipole ellipsoids being in the surgical resection volume, (b) a small distance separating the center of the MEG dipole ellipsoid and the center of the resection volume, and (c) a homogeneous distribution of MEG dipole localizations, thus supporting the prognostic implications of MEG in epilepsy surgery.[51]

Simultaneous Magnetoencephalographic and Electroencephalographic Dipole Modeling

There are few studies in the medical literature that compare dipole models of both MEG spike fields and EEG spike potentials that were simultaneously recorded. Early investigations with small sensor arrays showed that both MEG and EEG dipole modeling gave good results relative to ECoG findings, but most researchers felt that

MEG was superior.[34,78,110] Recent investigations with whole-head systems have emphasized that in individual cases spike localization may be better with one or the other technique.[12,13,94,122,173] All concluded that using data from both MEG and EEG is better than using either alone. This is easily understandable, given the complimentary strengths of each type of recording.

Future of Magnetoencephalographic/Electroencephalographic Dipole Modeling

As noted, investigators have concluded that future successes of source modeling in epilepsy evaluations may lie in combining the strengths of MEG and EEG. Several researchers have developed methods for combining EEG and MEG data in one source model.[6,76] They too claim that these combined-source models are superior to either MEG or EEG model alone and can provide information not present in either. Directions of highest sensitivity for MEG and EEG are orthogonal to each other—tangential and radial, respectively. MEG data are simpler, less ambiguous, and easier to model, but they are incomplete. Electroencephalographic data are more complete, but they are more complex and less clear. Combining MEG and EEG makes great theoretical sense, but exactly how to do this is an incompletely solved question, particularly given the considerable influence of the volume conductor on the EEG. Significant advances in the EEG component will come with further implementation of high-density sampling and realistic head models. Magnetoencephalography has been enhanced by whole-head systems. Technological advances in the future may dramatically reduce the cost of MEG equipment. This includes the elimination of shielded rooms and the development of sensors based on high-temperature superconductivity. Both techniques will benefit from a more complete understanding of brain/head anatomy, conductivity, and anisotropy. These will enhance both data display and provide parameters/constraints that can be used to improve source modeling. Certainly it is likely that there will be continued development of cortex-constrained extended-source models. These will probably replace simpler dipole models in the near future.

Summary and Conclusions

Spatiotemporal analysis of EEG and MEG by means of voltage and magnetic field topography and dipole and extended-source modeling can reveal a wealth of information beyond that routinely obtained from scalp EEG. Pattern recognition, as the foremost form of EEG analysis, will soon be supplanted by a more sophisticated appreciation for EEG and MEG source characterization that is now available with modern computer-analysis techniques. It is likely that these sensitive measures will

P.914

also allow us better to understand the relationships between brain function and dysfunction. Improved noninvasive characterization of the epileptogenic focus and of functionally important cortical areas in surgical candidates will likely be the first beneficiary of these diagnostic developments.

Chapter 79

Structural Neuroimaging

Graeme D. Jackson

Ruben I. Kuzniecky

Introduction

The magnetic resonance imaging (MRI) study has become part of the basic assessment of patients with epilepsy and is of equal importance to the electroencephalogram (EEG). The assessment of the problem of seizures requires knowledge of the clinical details and features of the seizures, the functional abnormality in the brain as shown on the EEG, and the structural assessment of the brain with an MRI study optimized for epilepsy.

Several commissions of the International League Against Epilepsy have considered which patients with epilepsy should have an MRI study. It is becoming increasingly clear that a basic MRI study now has a similar status to the EEG as part of the basic assessment of epilepsy (Table 1).

Because there is the option of a surgical excision of the â€œseizure focus,â€ which may cure the patient, the detection of a focal abnormality of the brain is important for the formulation of the reason for the seizures and the options available for treatment. Knowledge of the brain abnormalities early in the course of treating the patient greatly helps the management of each individual. Magnetic resonance imaging is indispensable in many areas of neurology. The challenge to epileptologists is that the problem of epilepsy is a special one, which requires optimized protocols dedicated to it. In this chapter, we explain the essential elements of this issue and give a broad overview of what imaging options are available for the investigation of the patient with epilepsy from the perspective of the practicing epileptologist.

MRI studies should fit into the overall assessment of the patient. To understand the basis of the epileptic disorder, we first need to define and understand the epileptic events (clinical and EEG, ictal single photon emission computed tomography [SPECT]), the structural abnormalities in the brain, and the clinical context in which seizures occur.

In this chapter, we first deal with the need to define and understand the structural brain abnormalities by acquiring appropriate epilepsy-focused MRI of high quality and diagnosing the important lesions with high sensitivity and specificity. The clinical context, seizure features, and interpretation of the imaging, with full knowledge of the hypothesized basis of each individual's epilepsy, are the keys to proper use of imaging. MRI interpretation is different when used in a screening way and when viewed in the context of other investigations. This is particularly important when the patient has partial seizures and may be considered for surgical treatment.

In Epilepsy, â€œNormalâ€ and â€œAbnormalâ€ are Diagnoses That Require Certainty: â€œSuspiciousâ€ is Equally Important and Different

It is important to identify suspicious as well as definitely abnormal areas. In the interpretation of the MRI in epilepsy, it is not enough to evaluate the images as â€œabnormalâ€ or, by default, â€œnormal.â€ The diagnosis of â€œnormalâ€ should be an active and positive one. If there is any change that is suspicious but not definitely abnormal, the diagnosis of normal is not appropriate. This â€œin-betweenâ€ assessment can be very important in deciding how further investigations progress.

Most centers that deal with epilepsy spend a great deal of time in ensuring the quality of their EEG and EEG interpretation. However, unless there is a radiologist with an interest in epilepsy or an epileptologist who spends time with radiologic colleagues, it can be difficult to establish good epilepsy-focused MRI with appropriate sequences, radiography, and interpretation (Table 2).

Technical Issues

An â€œEpilepsy Protocolâ€ Is Essential

An epilepsy MRI is not just a â€œroutine MRI.â€ This is because the lesion of hippocampal sclerosis (HS) is hard to diagnose without using a dedicated epilepsy protocol, and it is essential to be confident about this in the basic assessment of the patient with epilepsy.

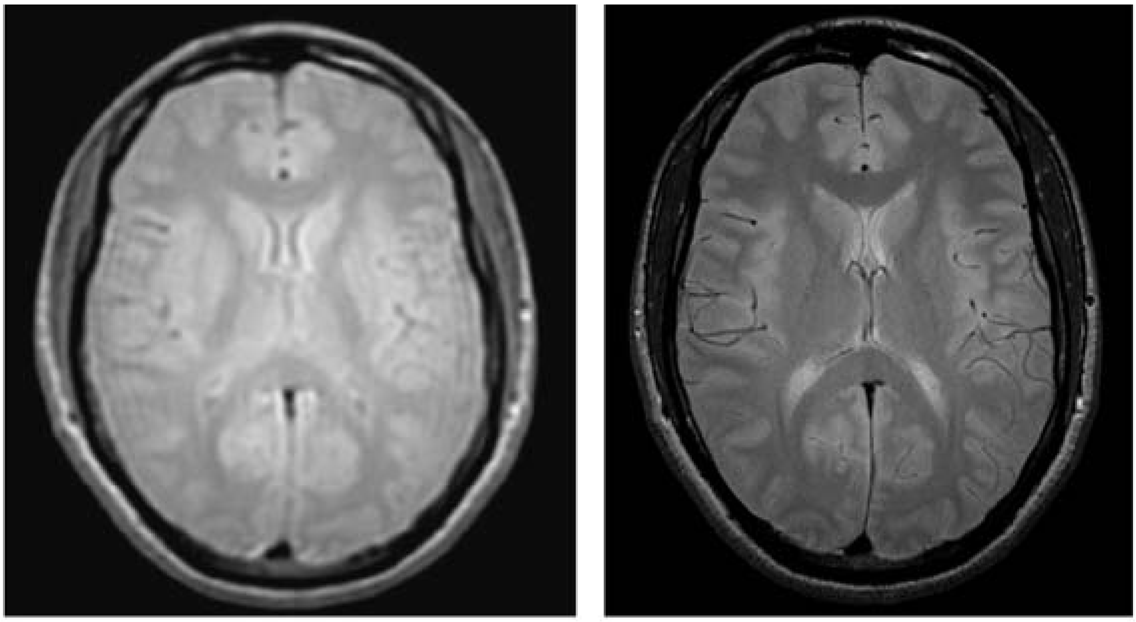

FIGURE 1. Spatial resolution. An optimal magnetic resonance study needs to optimize spatial resolution contrast and imaging time. Low spatial resolution is shown on the left and high resolution with longer scan time is shown on the right. All other imaging parameters are identical between these images.

MRI acquisition and interpretation need to be focused on the problem of epilepsy (Table 2). An optimal MR study needs to deal with the issues of partial volume, which can blur the edges of a structure such as the hippocampus, as well as have good spatial resolution, good signal-to-noise ratio, good contrast, and short imaging time. To deal with this issue of partial volume effects, often very thin images are acquired. This can lead to increased noise in the images, which can defeat the purpose of having these thin slices. This interplay between spatial resolution and signal-to-noise ratio is illustrated in Figures 1 and 2. (For a review of the physical principles of imaging see Jackson et al.[8] and references therein.)

P.918

T1-Weighted Images

T1-weighted images are usually presented so that cerebrospinal fluid (CSF) is black, gray matter is gray, and white matter is bright. Generally these images are used to assess brain morphology. Different sequences give different types of T1-weighted images. FIGURE 3A shows an inversion-prepared, gradient-echo, echoplanar image. Sequences like this are fast, give good brain coverage, and often allow reasonably thin slices to avoid â€œpartial volumeâ€ effects. FIGURE 3B shows a true inversion recovery image. This gives better grayâ€“white matter contrast, improved contrast for gliosis, and also better delineation of the internal features or architecture of the hippocampus. These images take longer and have thicker slices and often incomplete brain coverage, but they can be extremely helpful in difficult cases.

Table 1 The three most important tests in assessing the patient with epilepsy

A good clinical history
A good electroencephalogram
Epilepsy-protocol magnetic resonance imaging

T2-Weighted Images

T2-weighted images usually show the CSF as white and the gray matter of higher signal (brighter) than the white matter. These images typically show pathology as areas of increased signal and are used to assess whether the tissue is abnormal (Fig. 4). As with T1-weighted images, there are many choices of sequence that one can use. Fast spin echo is a sequence that allows high-resolution images with good contrast in a short time (Fig. 5).

Fluid-Attenuated Inversion Recovery Images

Table 2 Epilepsy magnetic resonance imaging involves a team

The epileptologist must be involved in imaging
The radiologist must understand clinical needs
The radiographer must deliver high-quality epilepsy-focused images
Training and development must be ongoing between radiology and neurology
The members of the team all need to understand some of the technical issues

Fluid-attenuated inversion recovery (FLAIR) images can be thought of as T2-weighted images in which the CSF, through clever tricks applied during imaging, has been made to look dark. Pathology still looks high in signal (bright, Fig. 6). It is often much easier to see the pathology in these images, largely because there is no concern that the signal change can be attributed to partial voluming of the CSF and also because it is visually easier to identify. Some lesions that with a practiced eye can be seen on T2-weighted images become obvious on FLAIR images because of this issue of CSF partial voluming (Fig. 7). FLAIR images are not good for looking at morphology and may produce some artifactual signal increases in some areas. In the case of epilepsy, the issue of most concern relates to subtle signal changes in the mesial temporal regions on coronal images, in which these artifacts need to be interpreted with an experienced eye.

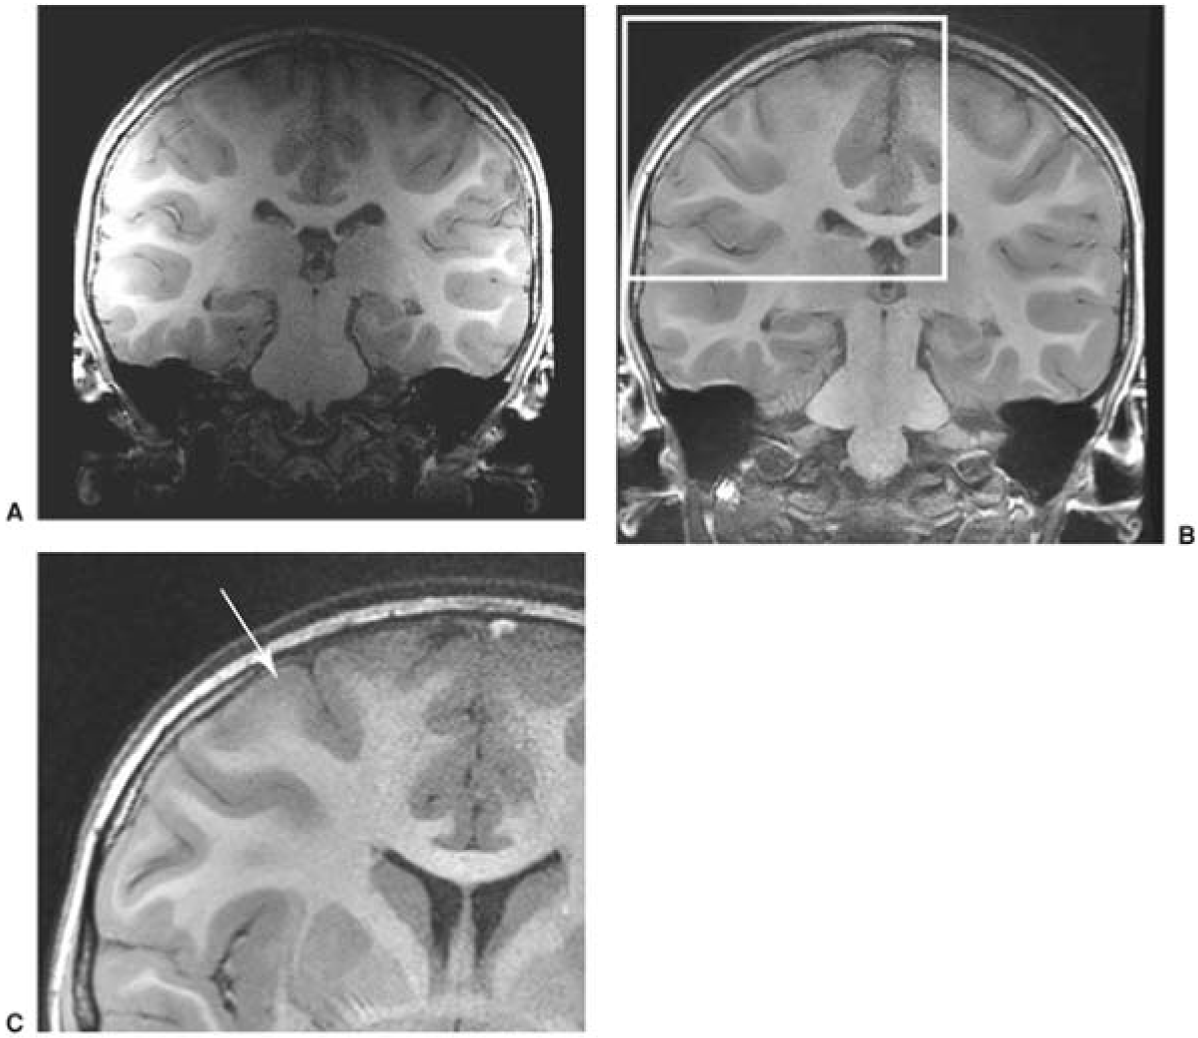

FIGURE 2. Signal-to-noise ratio. The issue of signal-to-noise ratio is well illustrated by this image, which was obtained using temporal surface coils. There is high signal-to-noise ratio close to the surface coils (bright in panel A). The image intensity is corrected in panel B and expanded in panel C. The consequences of low signal-to-noise ratio are easily seen here. Laterally, the grayâ€“white matter junction is crisp and well defined. In the medial frontal region the image appears â€œspeckledâ€ and the grayâ€“white matter junction is harder to define. An optimal signal-to-noise ratio may be somewhere in the area shown by the arrow.

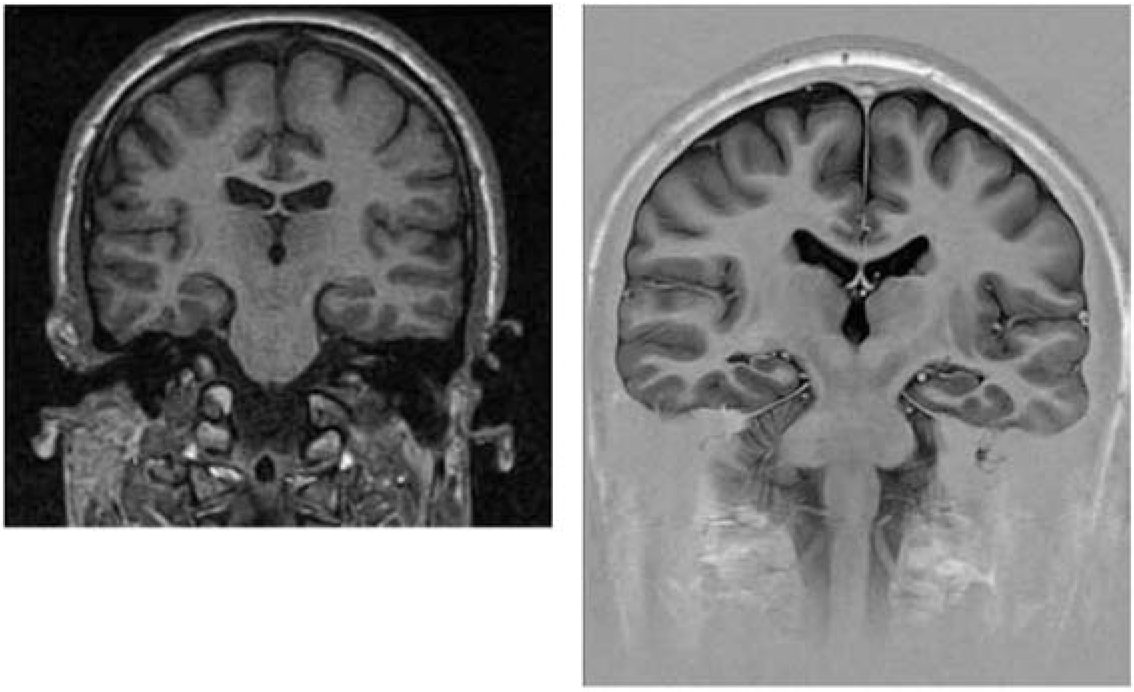

A

B

FIGURE 3. Different sequences give different types of T1-weighted images. **A:** An inversion-prepared, gradient-echo echoplanar image. **B:** A true inversion recovery image. The image in panel B shows right hippocampal sclerosis with a small right hippocampus and loss of the normal internal architecture (CA1 is not seen).

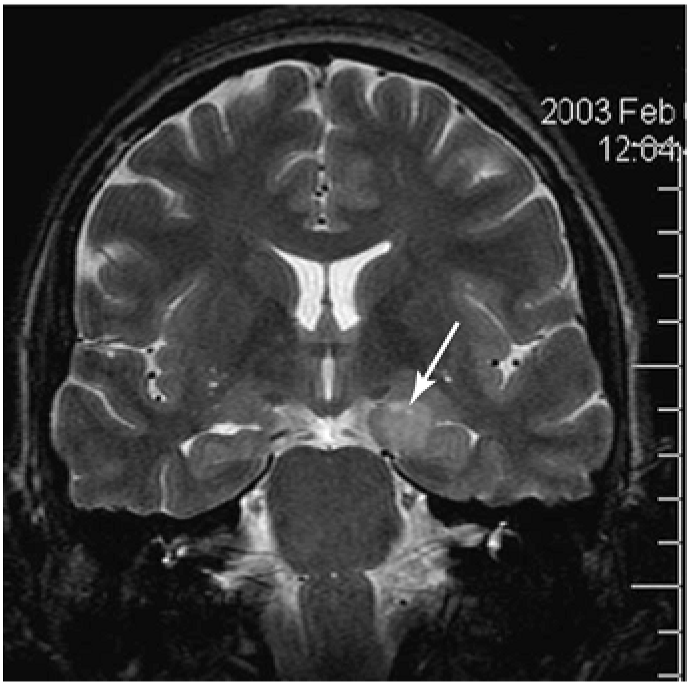

FIGURE 4. This T2-weighted image shows a dysembryoplastic neuroepithelial tumor in the mesial temporal region, involving the amygdala and the hippocampus on the left side (*arrow*).

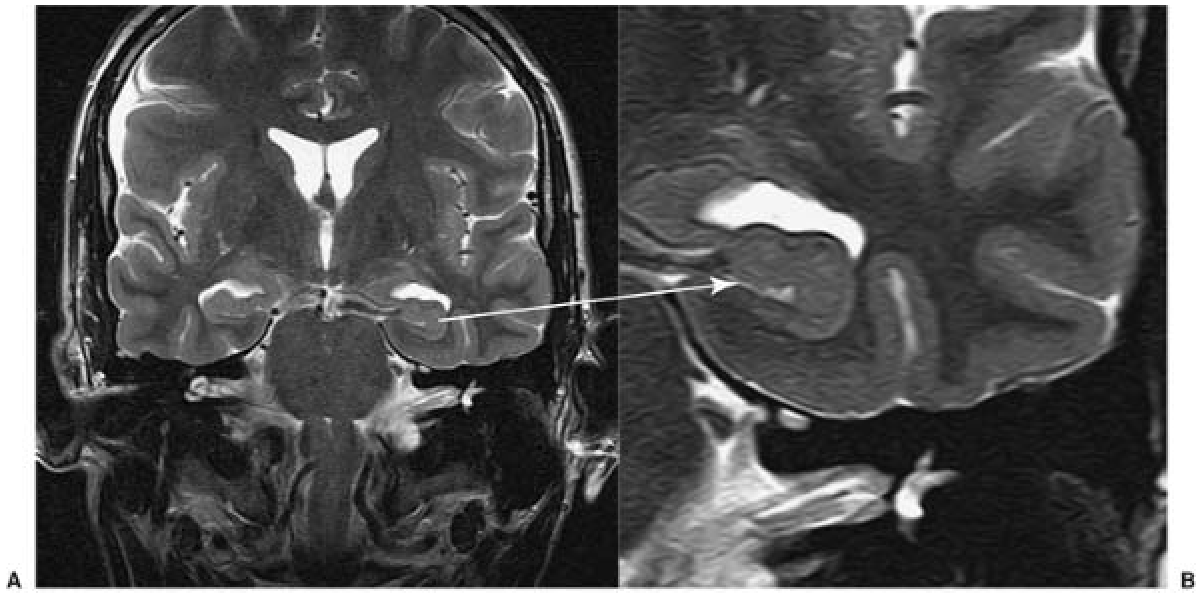

FIGURE 5. Fast spin echo = faster or higher resolution. The internal structure of the hippocampal head can be seen in these fast spin echo images.

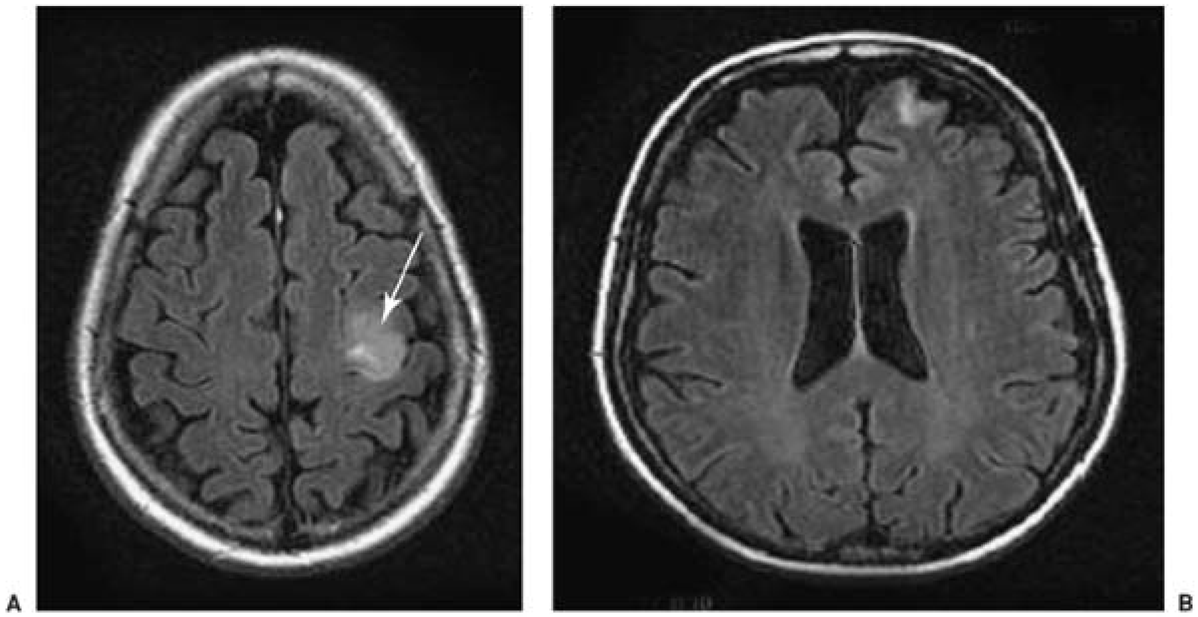

FIGURE 6. Fluid-attenuated inversion recovery (FLAIR) images can sometimes make lesions easier to see. This image shows a focal lesion in the middle frontal gyrus (*arrow*, panel A). This would be seen easily on a

routine T2-weighted sequence, but note the additional abnormality in the left frontal pole (*unmarked,* panel B). When signal change from pathology is close to a cerebrospinal fluid (CSF) boundary, it can sometimes be hard to identify. FLAIR images are not good for looking at morphology and may produce some artifactual signal increases in some areas, but they are excellent for identifying non-partial-volume signal changes that cannot be due to CSF.

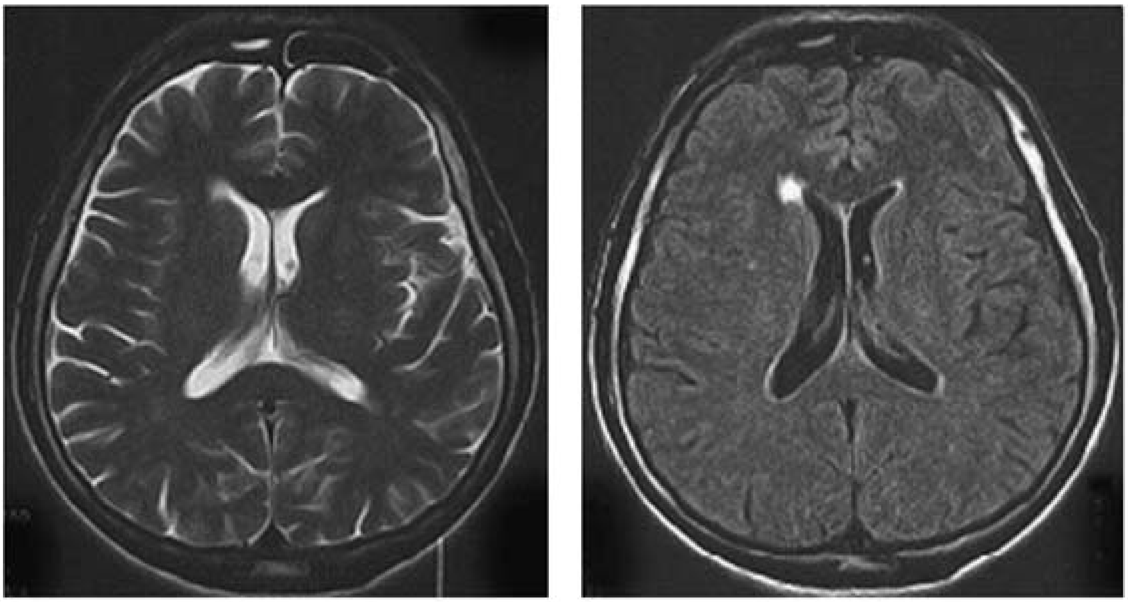

FIGURE 7. The same lesion on T2-weighted **(A)** and fluid-attenuated inversion recovery (FLAIR) **(B)** images. To the experienced eye, the lesion is easily seen on the T2-weighted images, but it is much more apparent, more easily noticed, and more confidently diagnosed with the FLAIR sequence.

Figure 8 shows the practical importance of this. This patient had severe intractable frontal lobe epilepsy, and the MRI had been reported as normal over a long period of time. A repeat imaging study using these principles revealed a focal cortical dysplasia in the right frontal lobe that led to a clearly defined surgical option. Recognition of these subtle lesions is the fundamental skill toward which the optimization of epilepsy imaging and interpretation is directed.

Radiography

For epilepsy protocol images, the orientation of the imaging plane must be according to â€œin-brainâ€ landmarks. This means that the radiographer must understand the hippocampal axis and ensure that all imaging is in this plane (Fig. 9). Some centers still acquire images in the â€œmachine axis,â€ which is in terms of the x, y, and z directions of the bore of the MRI system. Because patients lie in the MR system at different angles, this gives images of inconsistent orientation. This is most important to keep in mind if one is to interpret the pathology of the hippocampus. Because one will need to compare structures on the left and the right, the angulation of the imaging in the coronal plane must also be symmetric, based on in-brain landmarks. In older MRI systems, this angulation caused some problems or was not possible. With new MR systems, this is easily done, but old habits may carry over from previous practice. Images can also be reconstructed in this appropriate axis from three-dimensional (3D) data sets. It is important that the epileptologist review and be satisfied with the quality of the imaging.

Figure 9 shows the basic orientation for an epilepsy protocol.[6] The image sequence in this case gives axial and coronal images as shown. This is possibly the most important message of this chapter. Without understanding of the importance of this, the rest does not follow. The whole of the hippocampus is seen in a single slice (top right image), and there is little partial voluming of the hippocampus (lower left image). Because the diagnosis of abnormalities in the mesial temporal region is fundamental to the assessment of any patient with epilepsy, this imaging plane must be part of any effective epilepsy protocol imaging.

Interpretation

Even when imaging is excellent, the correct interpretation of subtle changes needs to be based on a clear understanding of the

features of the abnormality that has been looked for. In the case of epilepsy, the major difficulty that confronts the radiologist, and one with which the epileptologist must also be confident, is the reliable diagnosis of HS and subtle malformations of cortical development (MCDs).

The features of HS are altered signal in a small hippocampus and loss of the normal internal architecture (Table 3, and Figs. 10 and 11).[6] Not all asymmetry is HS, and abnormal signal in a large hippocampus is usually hippocampal dysplasia rather than sclerosis. If one only looks for atrophy or asymmetry, the wrong hippocampus may be diagnosed as abnormal.

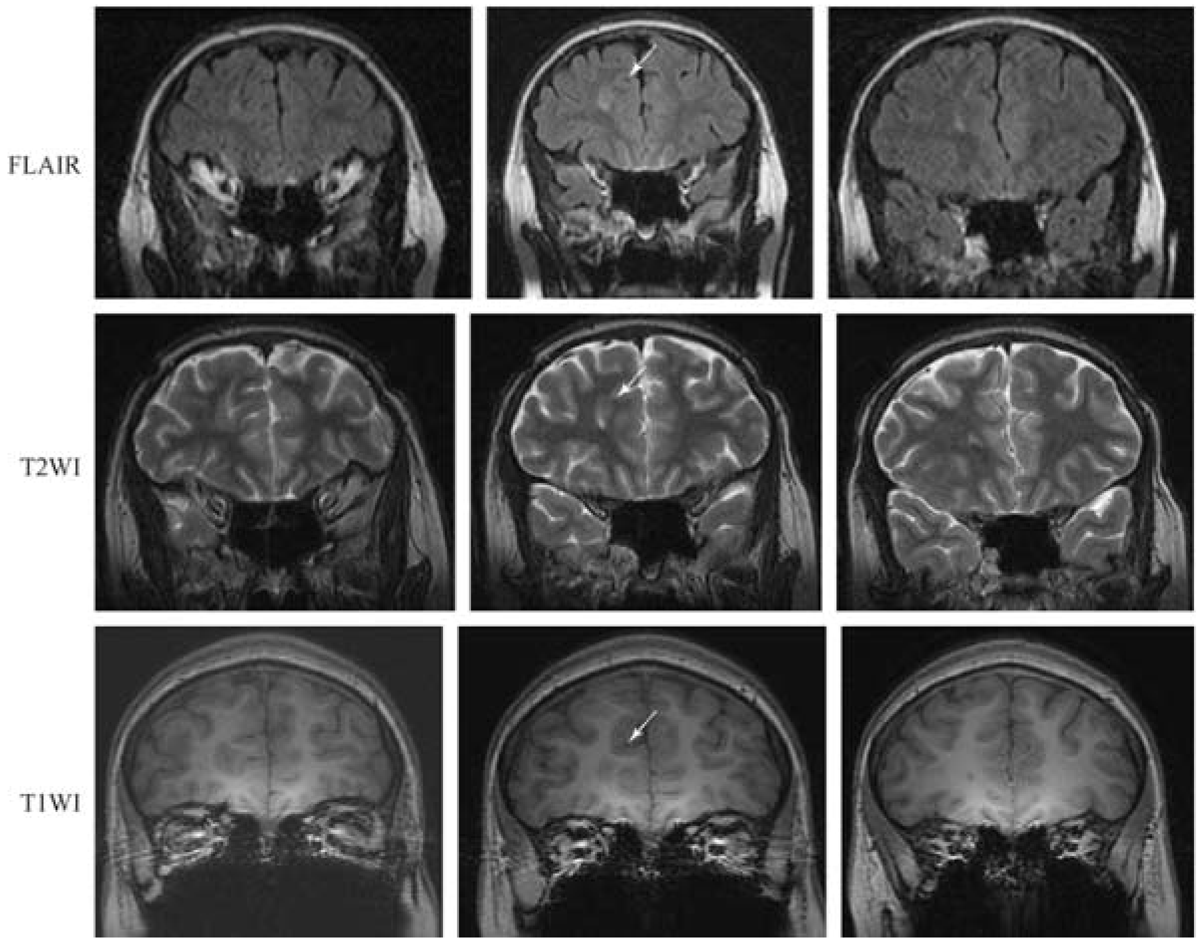

FIGURE 8. A typical imaging sequence (*arrow*). Note that the focal cortical dysplasia is visible in all sequences but is much easier to identify in the fluid-attenuated inversion recovery (FLAIR) sequence because of the easily seen abnormal and focal signal. T1WI, T1-weighted image; T2WI, T2-weighted image.

Requests

MRI is like the EEG in terms of requirements for basic study, sleep-deprived study, extra electrodes, or video-monitored

study. One can acquire many different bits of information using MRI that give different degrees of assessment of the brain (Table 4). This also involves having the patient potentially in the scanner for a long time. Although basic MRI is needed in nearly all patients, further studies need to be clinically driven and aimed at solving a specific problem. The epileptologist needs clearly to understand what information is needed and what can be obtained. The more focused the question that is asked of the radiologist, the better focused will be the assessment of the images. This is often the weak link in otherwise excellent MR imaging. Effort to focus the request is well rewarded.

There are many levels of information that can be acquired using MRI. In many ways this is similar to the EEG: It is familiar practice to order a routine EEG, a sleep-deprived EEG, or prolonged video monitoring studies. In addition, it is understood that a routine EEG may be associated with activations such as hyperventilation and photic stimulation.

The indication and interpretation of an MR depend on the electroclinical findings and are assessed along with other examinations, such as video-EEG telemetry, positron emission tomography (PET), and SPECT. The correct application and interpretation of MR imaging also depend on knowledge of the brain anatomy (see Kuzniecky and Jackson[10] for detailed review and further discussion of these issues).

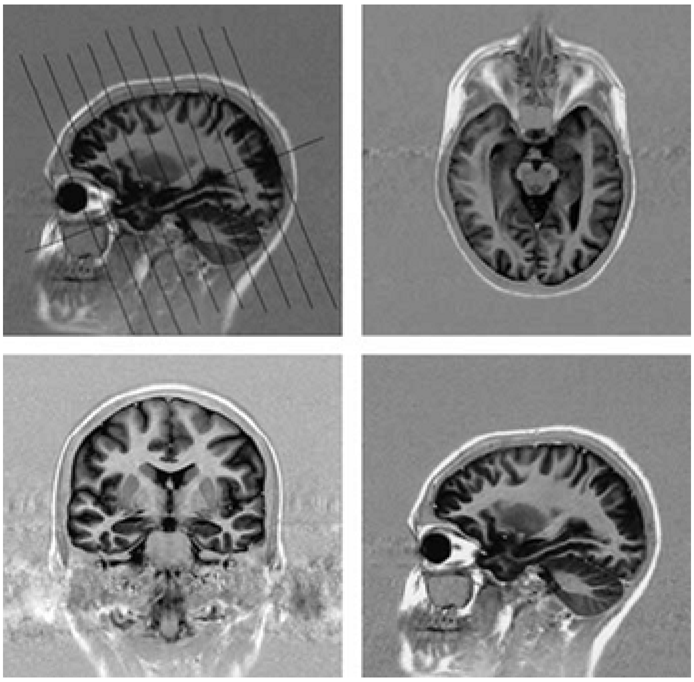

FIGURE 9. Epilepsy magnetic resonance imaging basics â€”the â€œhippocampal axis.â€ This image shows the basic orientation for an â€œepilepsy protocol.â€ The image sequence in this case gives axial and coronal images as shown. The whole of the hippocampus is seen in a single slice **(top right)**, and there is little partial voluming of the hippocampus **(lower left)**. Because the diagnosis of abnormalities in the mesial temporal region is fundamental to the assessment of any patient with epilepsy, this imaging plane must be part of any effective epilepsy protocol imaging.

Typical Imaging Sequences for an Optimized Epilepsy Protocol

A typical clinical scanning protocol for a patient with refractory epilepsy may include T1-weighted imaging, T2-weighted imaging, FLAIR imaging, and 3D volume acquisition sequences. T1-weighted imaging (short repetition time [TR] and echo time [TE]) is commonly used to initially define the brain anatomy. In T2-weighted images (long TR, long TE), many types of brain pathology are discernible. On FLAIR images, the CSF appears dark, which helps to identify lesions with long T2-relaxation times. A high-resolution 3D volume acquisition provides a useful degree of T1-weighted contrast between gray and white matter and helps greatly in the identification of subtle abnormalities, such as those associated with malformations of cortical development. The 3D data are made up of contiguous slices and allow characterization of the spatial extent of anatomic structures. Common 3D acquisition sequences include magnetization-prepared rapid acquisition gradient echo (MPRAGE) and 3D fast spoiled GRASS (3D-SPGR) imaging, where GRASS stands for gradient recalled echo acquisition at steady state. These sequences use a combination of short TR and TE to improve the time efficiency of the acquisition.

Table 3 Magnetic resonance imaging features of hippocampal sclerosis

Altered morphology (structure): Atrophy
Altered abnormal signal (tissue property)
High T2
Low T1
Abnormal internal structure with loss of CA1 microarchitecture

Based on multiple acquisitions with a variety of these pulse sequences acquired in optimized imaging planes, it is possible to detect low-grade tumors, vascular malformations, infarction, inflammation, or trauma as sources of seizures. The application of contrast agents is indicated if there is suspicion of a primary or metastatic tumor, infection, or inflammatory lesion.

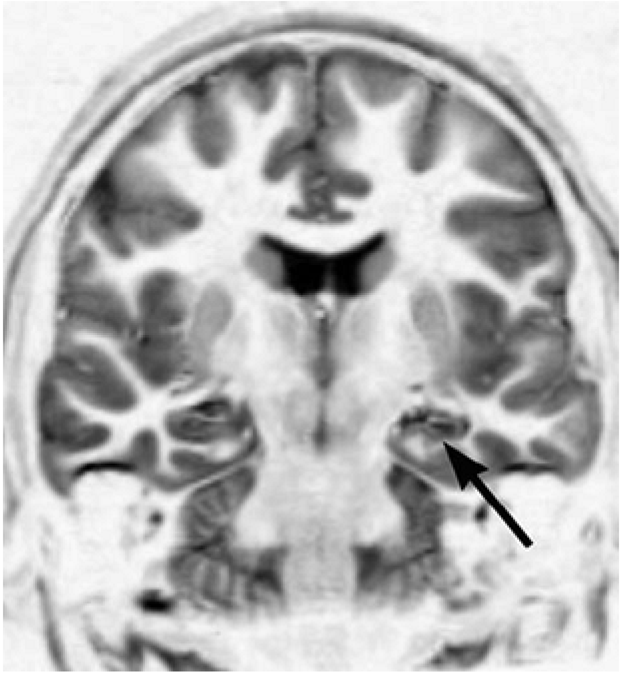

FIGURE 10. Classic hippocampal sclerosis (HS). Note the small hippocampus, with abnormal T1-weighted signal (*dark*) and no normal internal features (*arrow*). The hippocampus on the other, contralateral, side shows clearly demonstrated internal features. In this case the CA1 and dentate show decreased signal. This is also the case in heavily T1-weighted images in normal controls, suggesting that these neuronal parts have special imaging properties. In this case, this is more than is usual, suggesting that there may be minor changes in the contralateral hippocampus in these areas. This patient had a prolonged febrile convulsion at the age of 9 months and now has temporal lobe epilepsy.

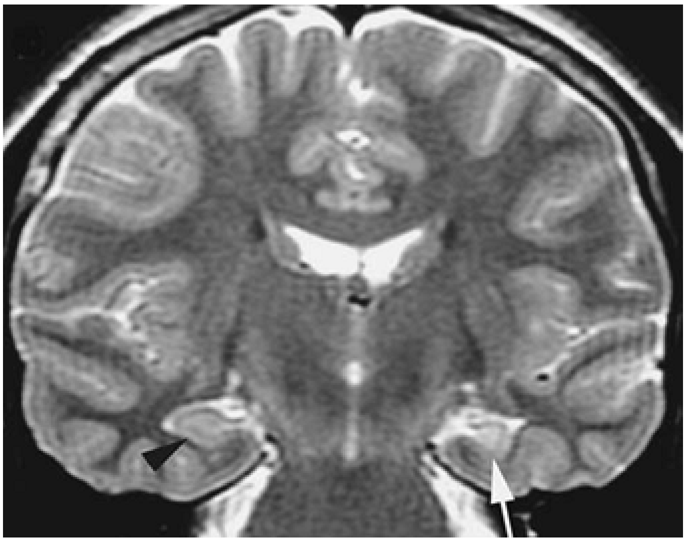

FIGURE 11. This 24-year-old woman had left temporal lobe epilepsy. The coronal T2-weighted images show increased signal and reduced volume (*white arrow*). The contralateral hippocampus is normal

(*black arrow*).

One should think good â€œepilepsy MRIâ€ not â€œMRI.â€ To achieve this, knowledge of MRI is needed not only by the radiologist, but also by the neurologist and epileptologist. It is this continuing interaction that enables optimized imaging to be obtained (Table 5).

Table 4 Types of magnetic resonance imaging studies and information acquired

Type of study	Information	Aim
Basic screening study	Structural information with good morphology and signal data	Detect all obvious lesions, evaluate hippocampal sclerosis and suggestive areas of gyral abnormality
Further assessment	Special studies, e.g., volumes, T2 relaxometry, further analysis of images, magnetic resonance spectroscopy, diffusion-weighted imaging, diffusion tensor imaging, quantitative methods, reconstructions	Support other investigations, detect subtle structural changes not easily seen on visual inspection
Intensive investigation	Functional studies, e.g., language and memory, functional magnetic resonance imaging (fMRI) MR physiology Simultaneous electroencephalogram/fMRI	
	MR physiology	
	Simultaneous electroencephalogram/fMRI	

Table 5 Dedicated imaging protocol for epilepsy

Imaging must be in the â€œhippocampal axisâ€
There must be a high-quality T1 and T2 sequence
Fluid-attenuated inversion recovery (FLAIR) images must be part of the protocol
Good signal-to-noise ratio is as important as thin slices

In epilepsy centers, it must be possible to diagnose hippocampal sclerosis with high sensitivity and specificity with visual analysis.

Quantification of Volumes and T2 Relaxometry in Epilepsy

High-resolution T1-weighted 3D volume sequences can be used quantitatively to measure the volume of any particular regions of interest. In the case of epilepsy this is usually the hippocampus.[7] Volumetric measurements require a significant investment in learning the hippocampal boundaries and depend on a large number of variables that need to be understood and controlled for in image analysis and acquisition. Volumetric assessment can be done manually or with half- or fully-automated software (Fig. 12), and increasingly advanced methods of anatomic analysis are being developed and

implemented. Longitudinal studies are possible, and this makes it possible to assess the progression of volumetric changes and may begin to help unravel the effects of the primary disease from the secondary effects of seizures.

T2 relaxometry is the quantitative determination of the T2 relaxation time. To achieve this, several T2-weighted images are acquired at different echo times, and in each voxel the resultant values are fit with an exponential decay curve to estimate the T2 decay rate of the imaged tissue. T2 relaxometry has been established as a reliable tool that is stable over time. In contrast to elaborate volumetric assessment, the T2 relaxometry is a quick technique with small variance and can be implemented in large-scale studies (Fig. 13).[7]

In epilepsy patients with HS, signal increase on T2-weighted images is typically observed in the hippocampus. The measured values of the hippocampal volume and the T2 time are correlated with each other, indicating that a marked volume loss is associated with a significant increase in T2 relaxation, reflecting the complex pathology that is HS.

Diffusion-Weighted Imaging

A diffusion-weighted signal reflects the molecular motion of water in the extra- and intracellular environments. The extent of this motion depends on the microscopic environment, and is therefore tissue dependent. In tissues with a linear arrangement of myelinated fibers, such as white matter tracts, the molecular motion is restricted to the axis along the white matter tracts. This is known as anisotropic diffusion. In other tissue components, such as CSF, molecular motion is not restricted in any direction, and this is known as isotropic diffusion. Diffusion-weighted MR techniques are frequently used to assess early signs of cerebral ischemia. Diffusion changes similar to those observed in ischemia may also be present in tumors or infection. Diffusion imaging requires postprocessing, which allows the measurement of summary parameters such as diffusivity and fractional anisotropy. It is also possible to visualize the path of the white matter tracts using tractography techniques. This is a computationally intensive technique and is in the process of being refined.[5]

Advanced Analysis Techniques

There are a number of methods for analysis of images. Voxel-based methods such as voxel-based morphometry (VBM), voxel-based relaxometry (VBR), and voxel-based diffusivity (VBD) can use statistical methods to demonstrate the areas of the brain that differ from control values. This approach is particularly powerful when examining the effects between groups (such as patients with temporal lobe epilepsy [TLE] and controls) (Fig. 14).[2]

Major Findings on Magnetic Resonance Imaging

The major findings on MRI can be thought of in a fairly simple way as being the obvious lesions, HS, malformations of cortical development, or, at least after the initial epilepsy protocol imaging, normal (Table 6).

Obvious Lesions

In several series, detailed analysis of MRI images has revealed a high percentage of abnormalities that can be detected in the brains of patients with intractable partial epilepsy (see Kuzniecky and Jackson[10] for review and more details).

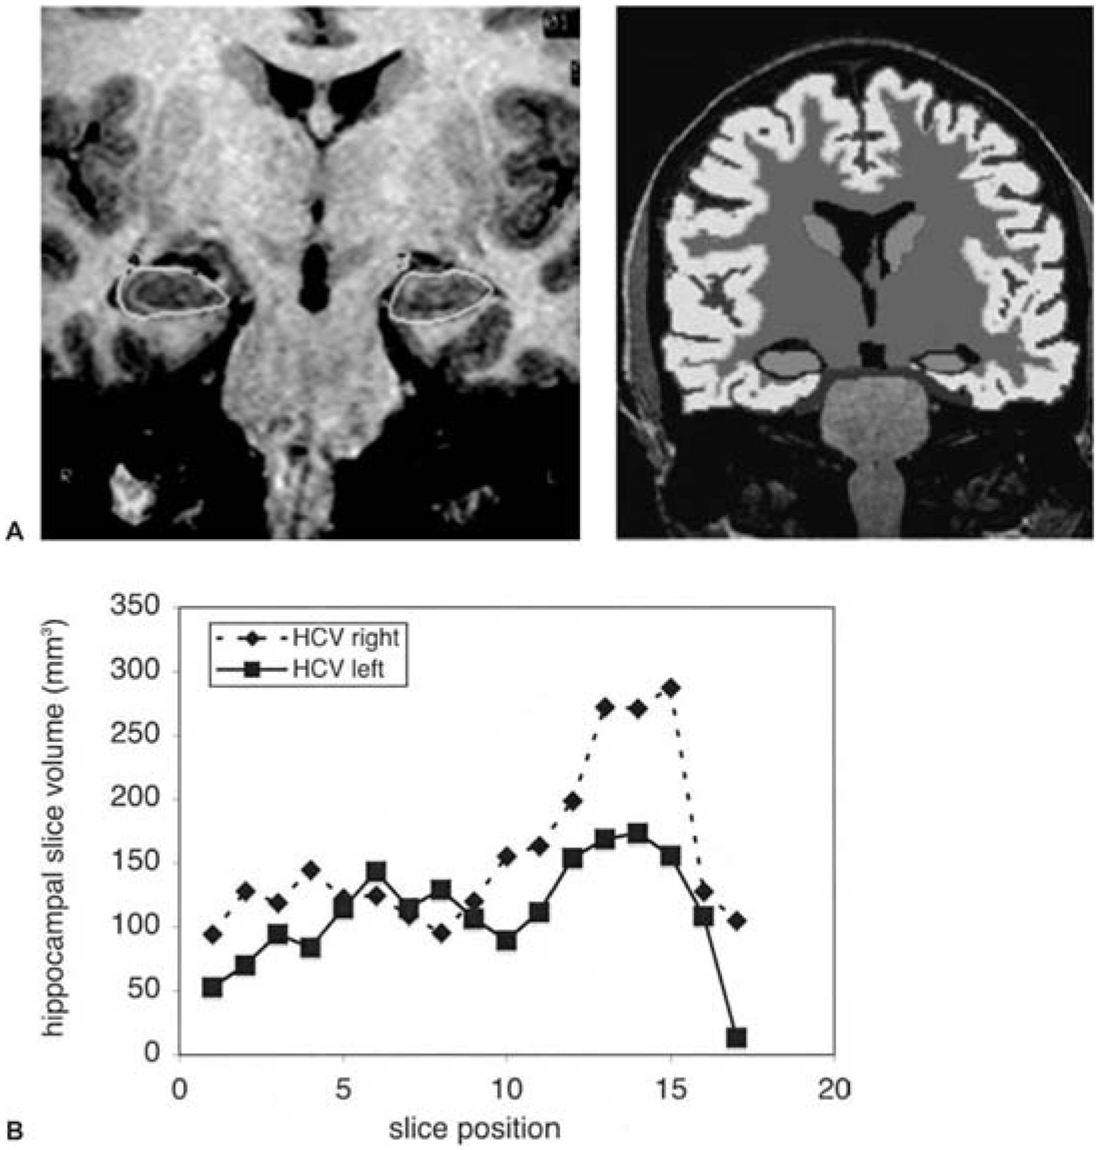

FIGURE 12. Hippocampal volumes can be measured, and this quantification can be useful for distinguishing subtle abnormalities that may not be visually apparent. This can be done by drawing the boundaries of the hippocampus manually **(left, A)** or semiautomatically **(right, A)**. The cross-sectional area of each slice measured can be plotted to give a shape curve **(B)**. In this case, atrophy of the left hippocampal head is easily appreciated.

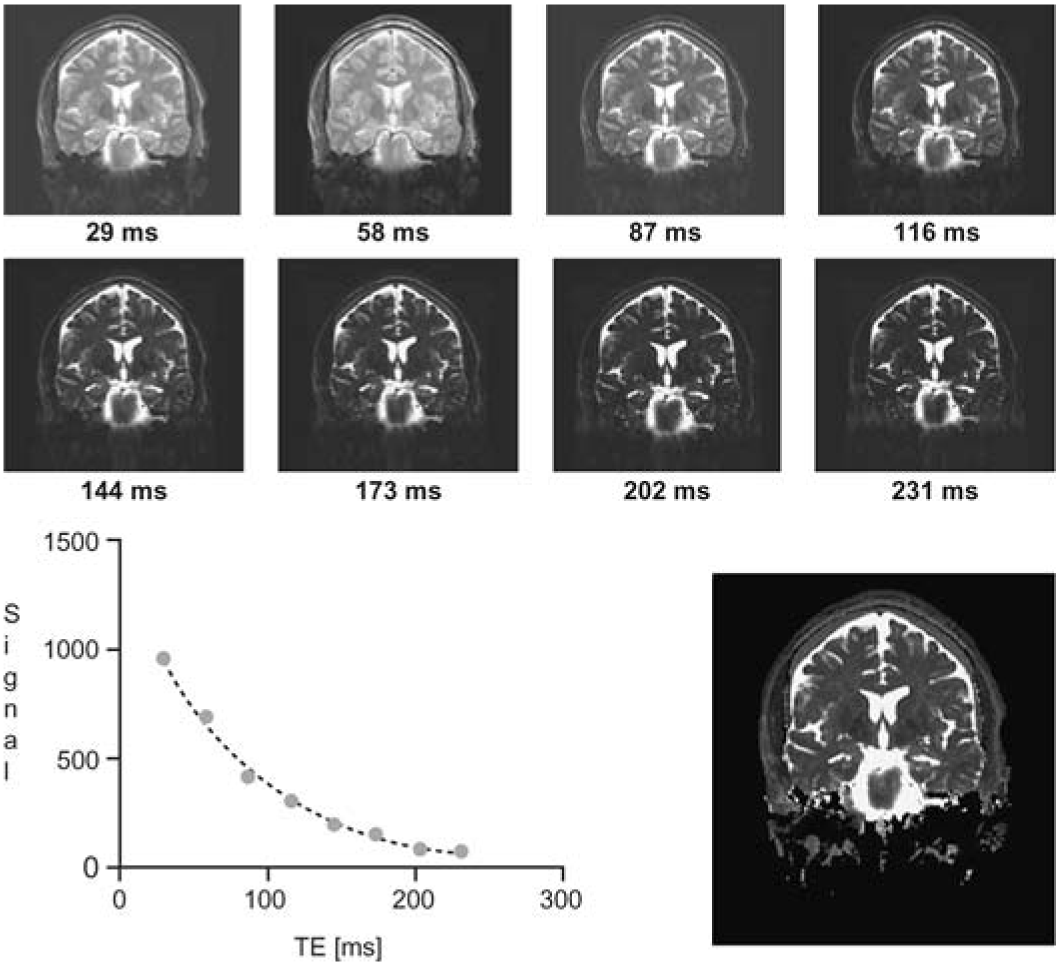

FIGURE 13. T2 relaxometry is a quantitative way of measuring the signal changes in tissue. The upper sequence of images shows how the T2 characteristics of the magnetic resonance image changes as a function of echo time. If one plots the signal change in a voxel or region of interest, the T2 decay curve is seen **(bottom left)** as the reduction of signal intensity as a function of echo time. The measured values can then be presented as a T2 map **(bottom right)**. The T2 time of any region of interest can be determined from this map. This information can also be used in a voxel-based way with statistical analysis of signal changes compared to a control group, in a similar way to voxel-based morphometry.

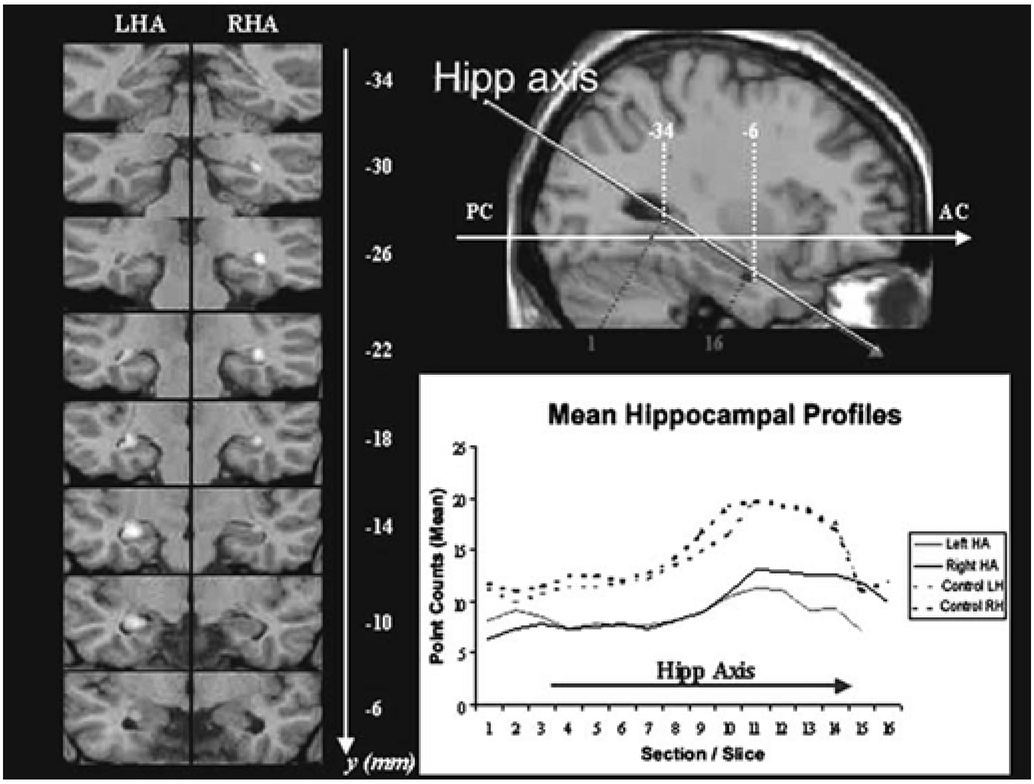

FIGURE 14. Quantitative measurement of the hippocampus. The volume can be measured in the cross-sectional coronal images obtained in the hippocampal axis. This can be extracted to give a shape analysis. The left panel shows this data in a statistical way by using voxel-based morphometry to show how the patient groups differ from a control group. LHA, left hippocampal axis; RHA, right hippocampal axis. (Figure courtesy of Gaby Pell, Brain Research Institute, Australia.)

Table 6 Findings on visual assessment of magnetic resonance images

Type of finding	Comments
â€œObviousâ€ lesions	Basic magnetic resonance imaging is appropriate and will demonstrate these; tumors, vascular lesions, and obvious malformations of cortical development will be seen on any MR imaging protocol
Hippocampal sclerosis	Must have a dedicated epilepsy protocol
Malformations of cortical development	Images must have optimal signal-to-noise ratio and spatial resolution; advanced analysis may be appropriate; need good imaging and interpretation skills

Nothing	Advanced methods of imaging and analysis might be considered for further investigation; quantitative analysis can reveal subtle abnormalities

Besides from mesial temporal sclerosis, other epileptogenic lesions commonly seen in the temporal lobes of patients with epilepsy include tumors, vascular malformations, and traumatic and developmental lesions. In general, these lesions constitute approximately 10% to 15% of the focal abnormalities found in partial epilepsy.

P.925

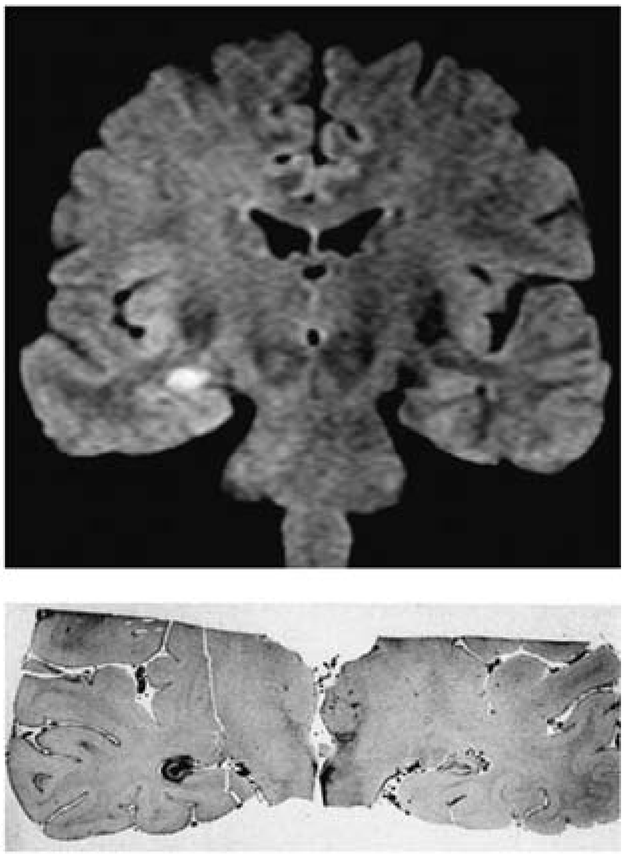
Neoplasms

Astrocytic Tumors.

Astrocytic tumors constitute about 20% of those epilepsy patients with â€œalienâ€ or â€œforeign tissueâ€ lesions and often involve the parahippocampal gyrus and the amygdala. Fibrillary astrocytomas are most common. MRI typically demonstrates homogeneous masses, with calcifications present in up to 20% of cases. The location is variable, with cortical lesions having extension into the white matter, and they are poorly demarcated. MRI features are not specific. Anaplastic tumors or glioblastomas are the most frequent astrocytic tumors; they do not constitute a significant number of patients referred with intractable epilepsy because they usually present as a primary tumor problem. Pilocystic astrocytomas are more frequent in children. On MRI these lesions are sharply demarcated and often lobular. Contrast enhancement is typically present due to prominent vascularity. Edema is rare, and calcifications are not seen.

Xanthoastrocytomas usually occur in the first decade of life and have a good prognosis. Cystic components are common in this tumor, which usually occurs in the temporal or parietal region.

Oligodendrogliomas.



A

B

FIGURE 15. A: Fluid-attenuated inversion recovery (FLAIR) image in a patient with hippocampal sclerosis (HS). **B:** A pathologic specimen from a different patient reported by Meencke and Veith. It is a histologic specimen with Nissl stain. In both cases the degree of hippocampal atrophy was symmetric. (From Meencke HJ, Veith G. Hippocampal sclerosis in epilepsy. In Luders H, ed. *Epilepsy Surgery*. New York: Raven Press; 1991:705â€"715; with permission.)

Oligodendrogliomas are histologically characterized by the presence of compact groups of large, rounded cells with empty cytoplasm, often also with mixed glial components. These tumors are less frequent than astrocytomas and uncommon in patients referred for intractable epilepsy, but, when present, they are located within the temporal lobe and tend to involve the amygdala and the uncus and parahippocampal gyrus, with sparing of the middle and inferior temporal convolutions. The underlying white matter often shows tumor infiltration.

Mixed Glial Lesions

Mixed glial lesions are a common tumor type in epilepsy (about 5% of foreign tissue lesions). Calcifications are often present. Seizures begin typically in childhood. These tumors are predominantly seen in young patients (younger than age 14 years). Gangliogliomas tend to spare the lateral temporal neocortex and primarily involve the mesial structures.

Dysembryoplastic Neuroepithelial Tumors

Dysembryoplastic neuroepithelial tumors (DNETs) are a common tumor type in patients with intractable partial seizures. These tumors are usually located in the temporal region or, less commonly, the frontal region. These represent about 10% of all tumors removed in patients with intractable epilepsy. Cysts are uncommon. DNETs involve both gray and white matter. Imaging findings are quite characteristic. They commonly involve the temporal lobes (Fig. 4). The MR characteristics, although not pathognomonic of this condition, should strongly suggest the underlying abnormality.

Metastatic Disease

Metastatic spread of tumor to the brain is common and comprises approximately 20% of brain neoplasms. Seizures are the presenting symptom in about 30% of patients with cerebral metastasis. Metastases have fairly stereotyped localization (grayâ€"white matter junction) and often have peripheral edema.

Vascular Malformations

Although seizures and epilepsy are frequent presentations of vascular malformations of the brain, these lesions are less common (1%â€"2%) among the alien lesions in patients with intractable epilepsy referred to epilepsy surgery. These abnormalities are less frequent in the temporal lobes than in other regions and can be divided into arteriovenous malformations, cavernous angiomas, capillary telangiectasia, and venous angiomas. Capillary telangiectasias and venous angiomas are rarely associated with chronic seizure disorders.

Cavernous angiomas constitute a distinct vascular malformation. In the majority of patients with intractable seizures, cavernous angiomas constitute the most common vascular abnormality, particularly with multiple lesions. The MRI features of cavernous angiomas are fairly characteristic. The lesions have a central core with mixed signals indicating blood byproducts of different stages. Within the core, methemoglobin appears as high signals often intermixed with lower signals. Typically, a complete rim of hypointensity surrounds the central core. This rim is usually hypointense on both long and short echoes, with marked hypointensity in the longer echo. These lesions are void of mass effect or surrounding edema, and they should be easily recognized. Venous angiomas are probably the most common vascular malformation, but they are rarely the cause of chronic epilepsy.

Posttraumatic Lesions and Stroke

Trauma to the brain can cause epilepsy. This includes injuries of all sorts, including percussive injuries and those due to vascular disease (stroke). In general the presence of blood products is highly epileptogenic. Reorganization of damaged tissue after injury of any kind can also lead to epilepsy. The imaging of these disorders is primarily a radiologic issue rather than an epileptologic one, and these are included here for the sake of completeness. It is worth noting that contusions commonly affect the temporal lobes, and the brain injury is often bilateral and multilobar, even if the abnormalities seem very focal on MRI.

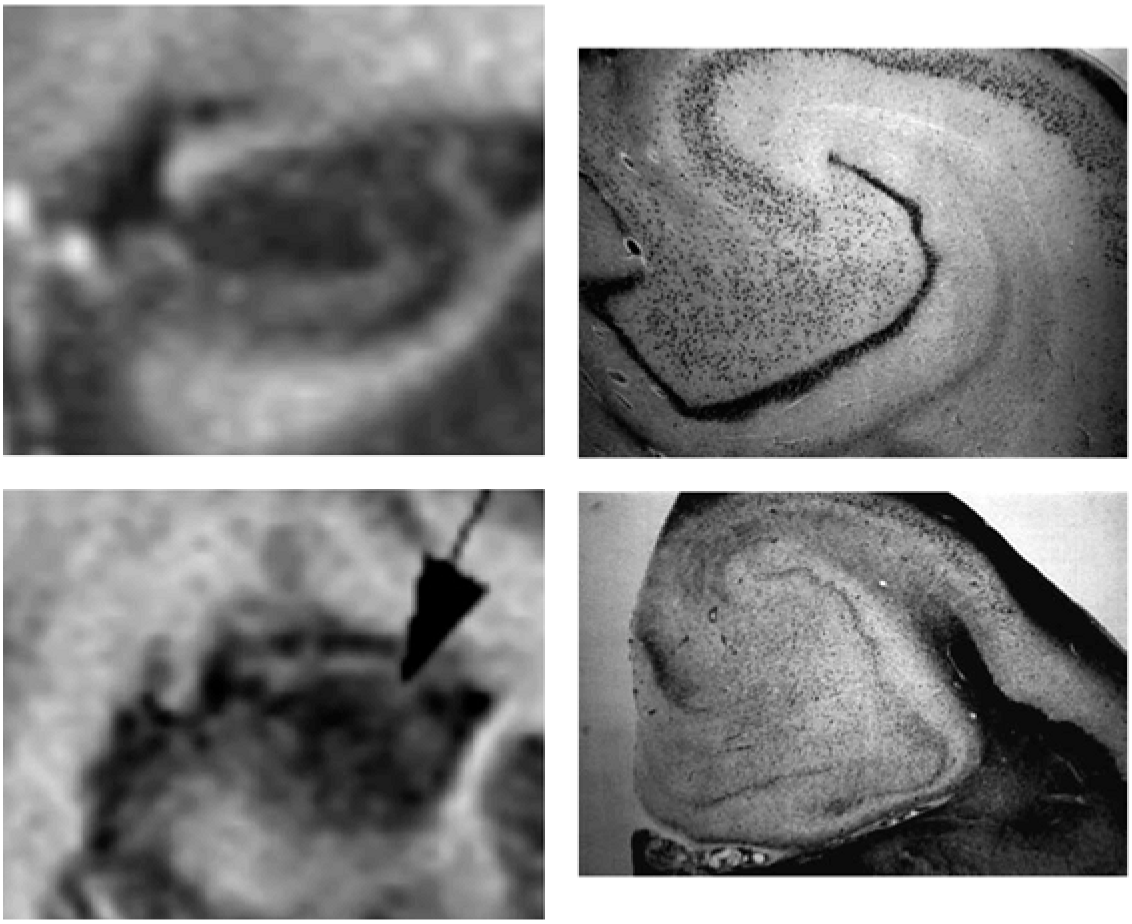


FIGURE 16. Magnetic resonance and pathology images of a normal hippocampus **(top row)** and hippocampal sclerosis **(bottom row)**. Different sequences show these features to varying degrees, but a heavily T1-weighted sequence, such as an inversion recovery sequence, seems to reveal contrast in the CA1 and dentate gyrus that parallels the distribution of the pyramidal cells. The basis of this magnetic resonance image contrast is not known. (From Kuzniecky RI, Jackson GD. *Magnetic Resonance in Epilepsy: Neuroimaging Techniques*, 2nd ed. London: Elsevier; 2005; with permission.)

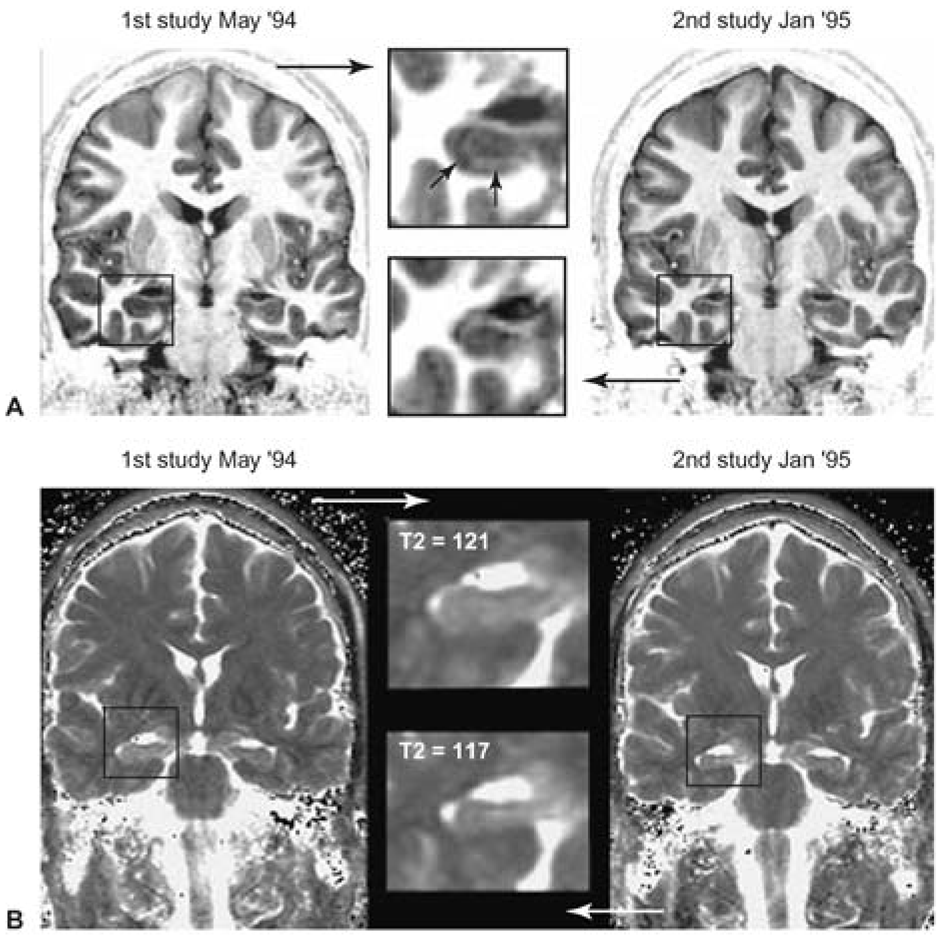

FIGURE 17. Progressions of hippocampal sclerosis. This 25-year-old man presented with three tonicâ€"clonic seizures. Note that the internal architecture of the hippocampus (*arrows* in panel A) is clearly seen in the first study but is absent in the second study. There is atrophy of the hippocampus in the second study in the areas that showed abnormal signal in the first study. In panel B, the right hippocampus shows high signal in both the first and the second study. This was confirmed on T2 relaxometry studies (numbers).

Hippocampal Sclerosis

Methods of Detecting Pathology Using Magnetic Resonance

As described earlier, the detection of pathology by MRI in general, and of mesial sclerosis in particular, can be performed in three ways:

P.928

P.929

P.930

1. The visual detection of abnormal tissue quality by *contrast* between normal and abnormal tissue. Tissue characteristics that reflect the pathology of abnormal tissue composition can be identified by alterations in signal intensity, T1 or T2 relaxation times, magnetic resonance spectroscopy (MRS), diffusion-weighted imaging, or other methods.

2. The visual detection of *morphologic changes* of a structure that can demonstrate changes in size or appearance that correlates with underlying pathology.

3. Advanced quantitative and statistical image analysis methods.

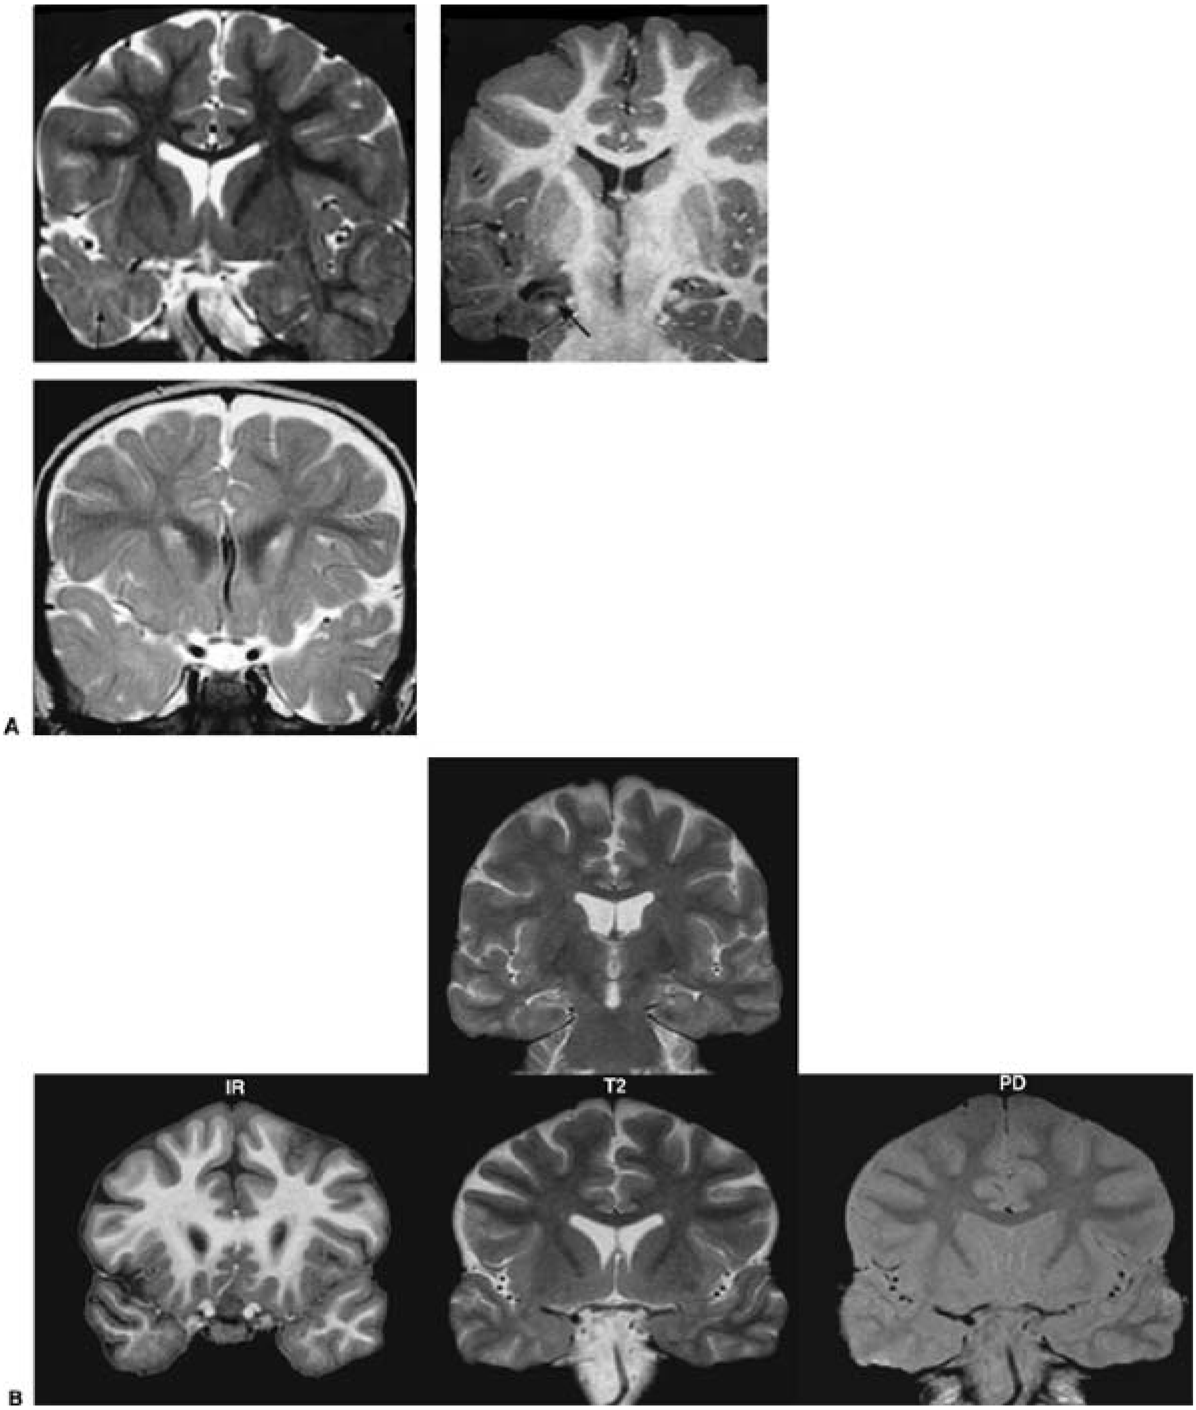

FIGURE 18. A: Magnetic resonance findings in a 10-year-old boy with intractable temporal lobe epilepsy emanating from the right. He suffered a very prolonged febrile convulsion at 12 months of age. The features of hippocampal sclerosis (HS) and mesial temporal sclerosis are clearly seen. The hippocampus is small, with abnormal signal and absence of normal internal architecture (*arrow*). There are also changes in signal in the white matter of the temporal lobe, seen on both T2- and T1-weighted images. The whole temporal lobe is small. The temporal lobe essentially shows the features of an arrest in development at the 12-month stage. For comparison, the lower left panel shows the findings in a normal 12-month-old without epilepsy. (From Mitchell LA, Harvey AS, Coleman LT, et al. Anterior temporal changes on MR images of children with

hippocampal sclerosis: an effect of seizures on the immature brain? *Am J Neuroradiol*. 2003;24:1670â€"1677; with permission.) **B:** Hippocampal sclerosis and anterior temporal lobe changes. HS is often associated with changes in the anterior temporal lobe. These images show the typical constellation of features associated with HS. HS is present on the right, and there is increased signal in the anterior temporal pole white matter. In some cases the gray matter also seems to show some change in signal. In this case no pathologic cause for these changes was apparent on careful assessment. It has been suggested that this is due to abnormalities in myelin or an arrest of development in the immature temporal lobe. For a review of this issue, see Ryvlin et al.[12] and references therein. It is clear that these changes are different than and can be distinguished from focal cortical dysplasia. IR, inversion recovery; PD, proton density-weighted; T2, T2-weighted.

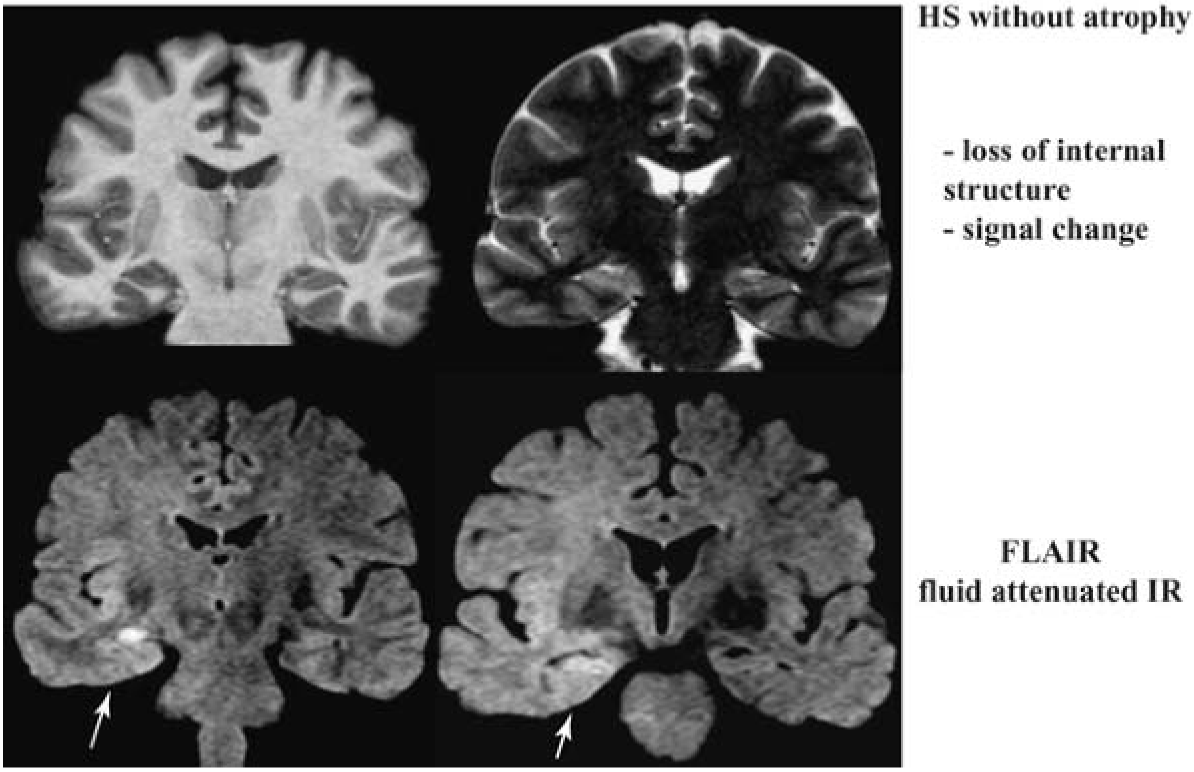

FIGURE 19. Atrophy of the hippocampus is not apparent in this case of hippocampal sclerosis (HS). There is signal change in the hippocampus that may be considered to be subtle. When assessed with fluid-attenuated inversion recovery (FLAIR) imaging, the signal change is dramatic, and there is a suggestion of changed signal more extensively throughout the hemisphere. The latter subtle change should be interpreted with care because FLAIR imaging can give a variety of artifacts. In this case this was confirmed on T2 relaxometry studies. (See also Fig. 18.)

Optimized imaging of the hippocampus and temporal lobe structures depends on image orientation and image sequences optimized to display the anatomy and signal abnormality of hippocampal sclerosis and temporal pathology (Fig. 9).[6]

Abnormal Signal in the Hippocampus

Using optimized T2-weighted sequences (orientation and sequence), including CSF nulled sequences such as the FLAIR sequence, one can easily detect the presence of increased signal from the hippocampal body. The high signal is localized to the hippocampal gray matter and usually can be seen in the middle of the structure if one uses the corresponding T1-weighted image for definition of anatomic detail (Figs. 10,11,12,13,14).

Although the abnormal T2 signal is a reliable finding for hippocampal sclerosis, one needs to be aware of a number of common problems. A problem may arise from the presence of normal dilation of the hippocampal fissure. Although this may be incorrectly diagnosed as a high signal from the hippocampus, it should rarely be mistaken for hippocampal sclerosis. Bilateral hippocampal T2 signal abnormalities may be present, which may create difficulties. These and other problems are usually resolved by using clearly defined criteria for the diagnosis of hippocampal sclerosis in optimized images or by using more advanced methods of analysis or quantitation when doubt exists. These criteria have proven to be very reliable and sensitive for the detection of hippocampal sclerosis in experienced hands. The quantification of T2 relaxation times has also confirmed that T2 signal abnormality is almost invariably present with hippocampal sclerosis even when this cannot be seen by visual analysis.

The use of a heavily T1-weighted sequence is, in our experience, a valuable approach to studying hippocampal sclerosis. Currently, despite the time and coverage issues, we still routinely use IR as part of our epilepsy protocol because we believe that it provides information not seen on our 3D or other T1-weighted sequences. It would be reasonable, however, to only run this sequence if the hippocampus looks normal or equivocal on other sequences in the context of a diagnosis of TLE. The atrophic hippocampus more often demonstrates decreased signal with a dark appearance (Fig. 10).

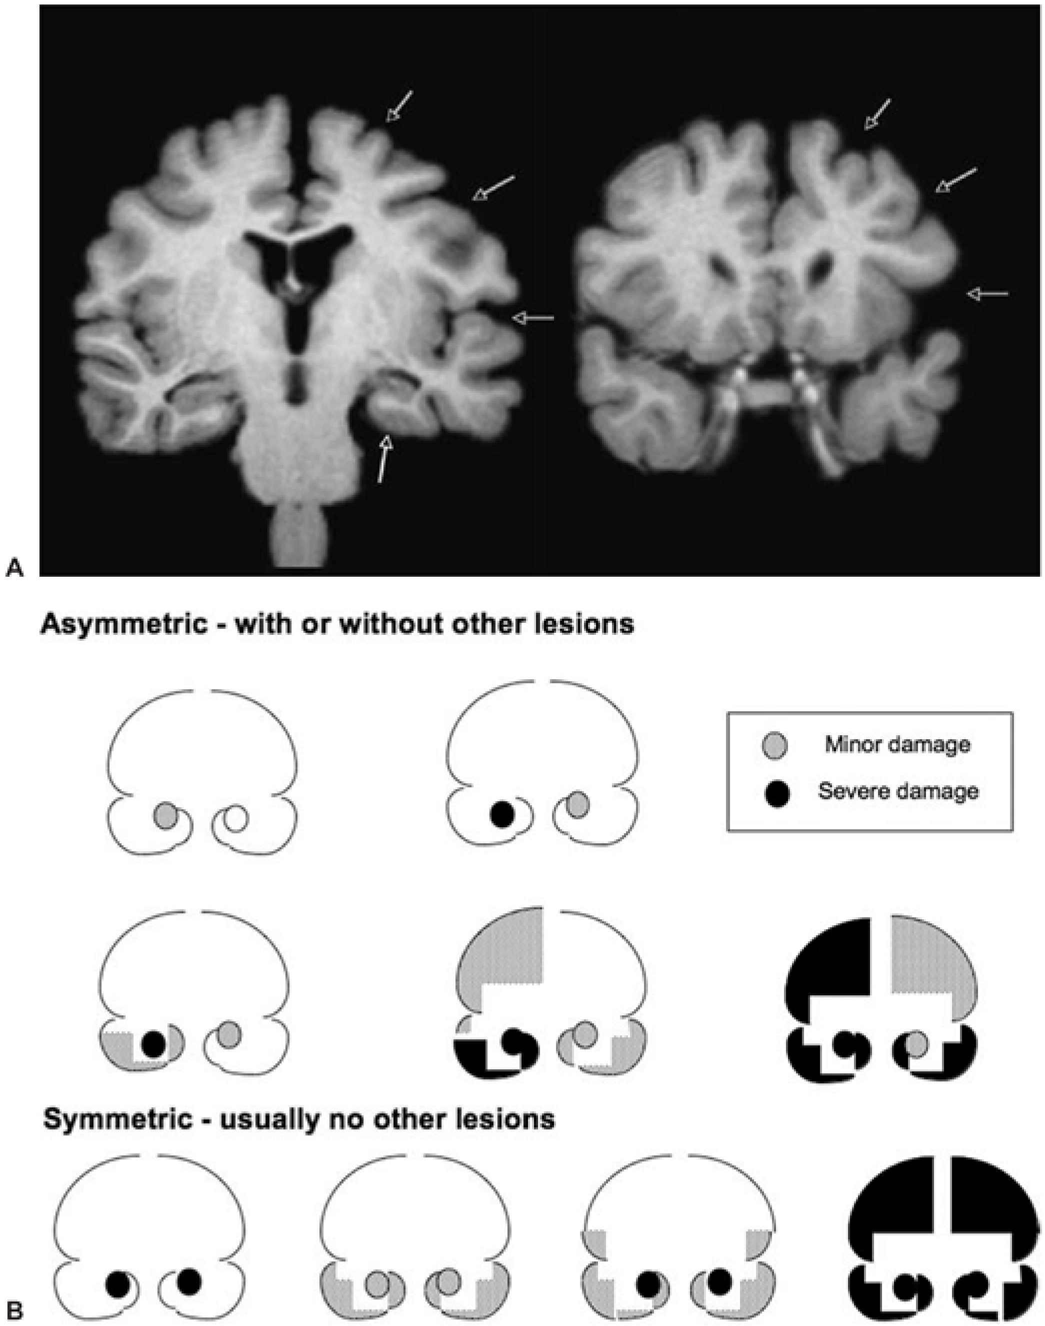

FIGURE 20. A: Hippocampal sclerosis and hemiatrophy. Hippocampal sclerosis can be associated with more extensive changes, usually throughout the ipsilateral hemisphere. This case shows hippocampal atrophy in the context of hemispheric atrophy. **B:** The types of hippocampal sclerosis seen on magnetic resonance studies. These patterns can be conceived of as being caused by seizure or other damage that is either lateralized **(upper rows)** or generalized **(lower row)**. (From Kuzniecky RI, Jackson GD. *Magnetic Resonance in Epilepsy: Neuroimaging Techniques*, 2nd ed. London: Elsevier; 2005; with permission.)

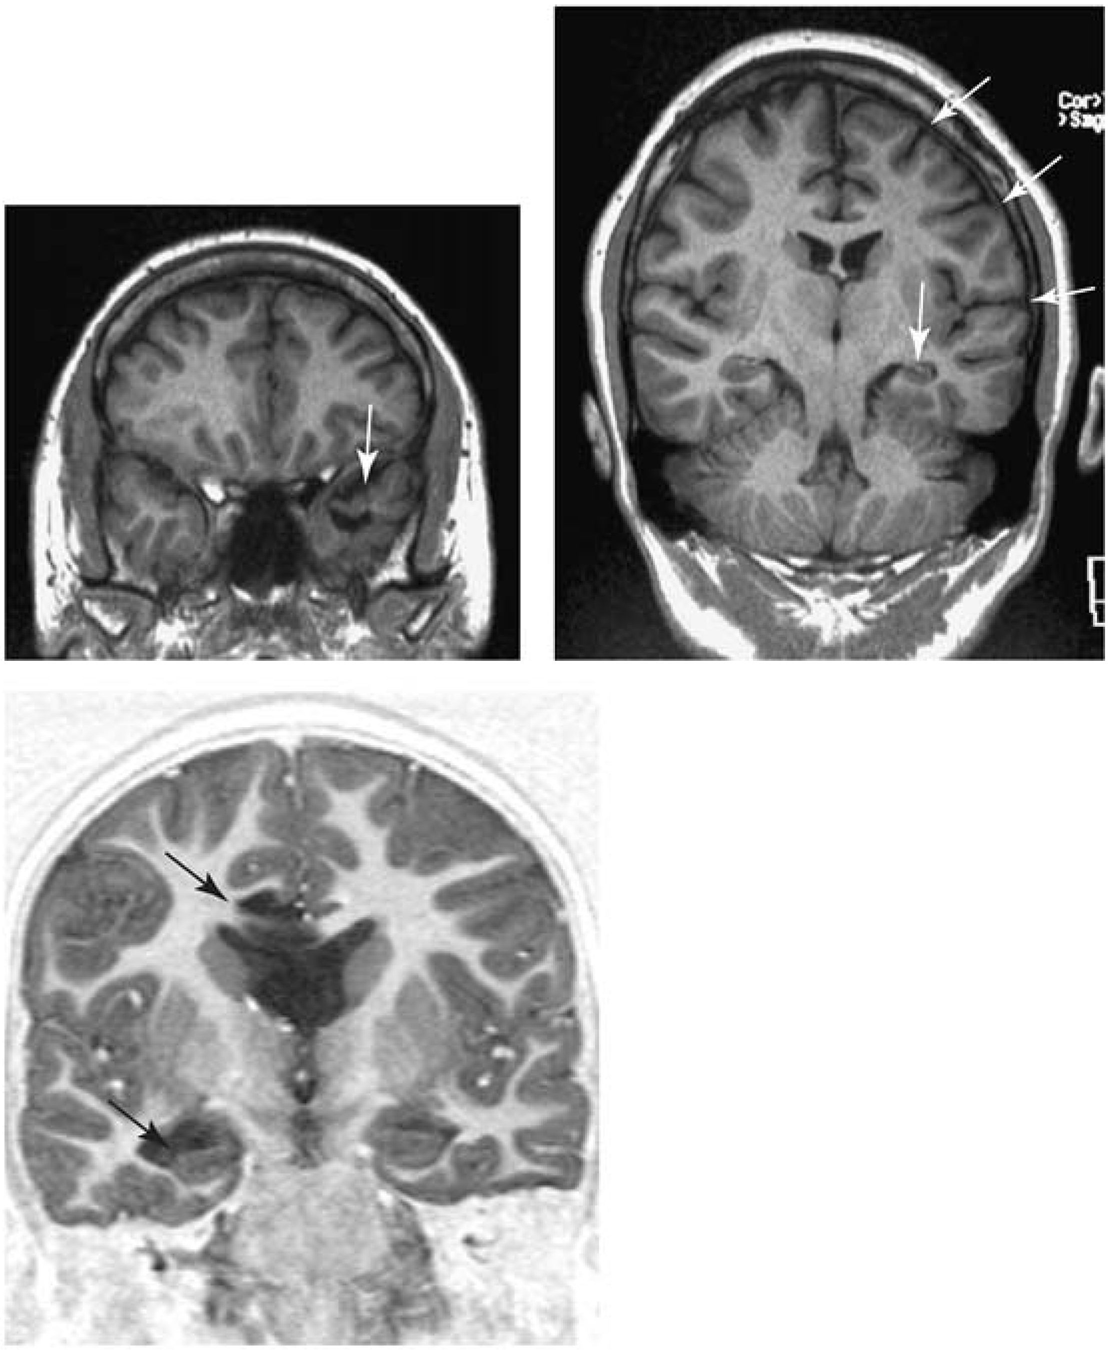

A

B

FIGURE 21. A: This 49-year-old patient has temporal lobe epilepsy, with no childhood antecedents and onset of epilepsy at age 11 years. She has an abnormality in the anterior temporal pole, with a deep sulcus and abnormal gyral pattern, suggesting a malformation of cortical development (MCD) (left panel). She has an atrophic hippocampus on the ipsilateral side, and the whole hemisphere is small (*small arrows*, right panel). A proposed sequence of events is that the MCD initiated the first seizure and the changes in the hippocampus are secondary to this. The hippocampus can then become the primary epileptogenic lesion. **B:** Dual pathology. Hippocampal sclerosis (HS) is present on the right, and a lesion is seen in the right cingulate gyrus. Dual pathology is usually ipsilateral to the HS and is likely to be pathogenically important in the genesis of unilateral HS.

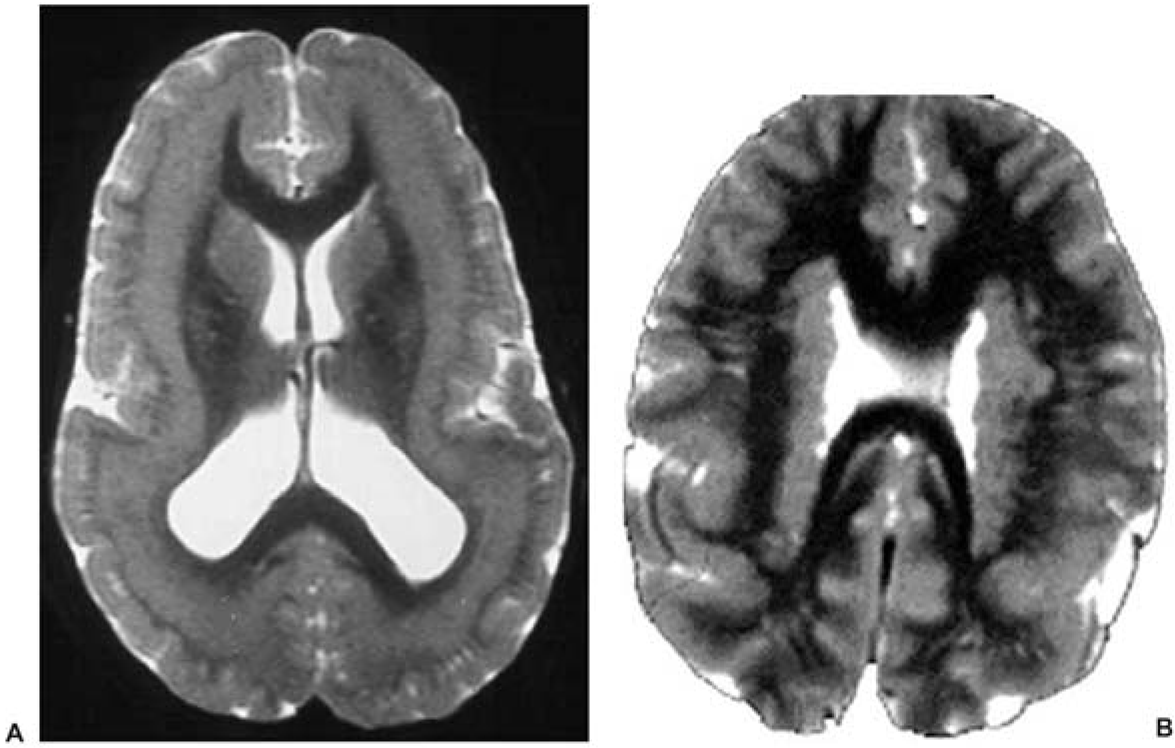

FIGURE 22. Malformations of cortical development can be dramatic. The heterotopia may be subcortical **(A)** or periventricular **(B)**. The overlying cortex is abnormal.

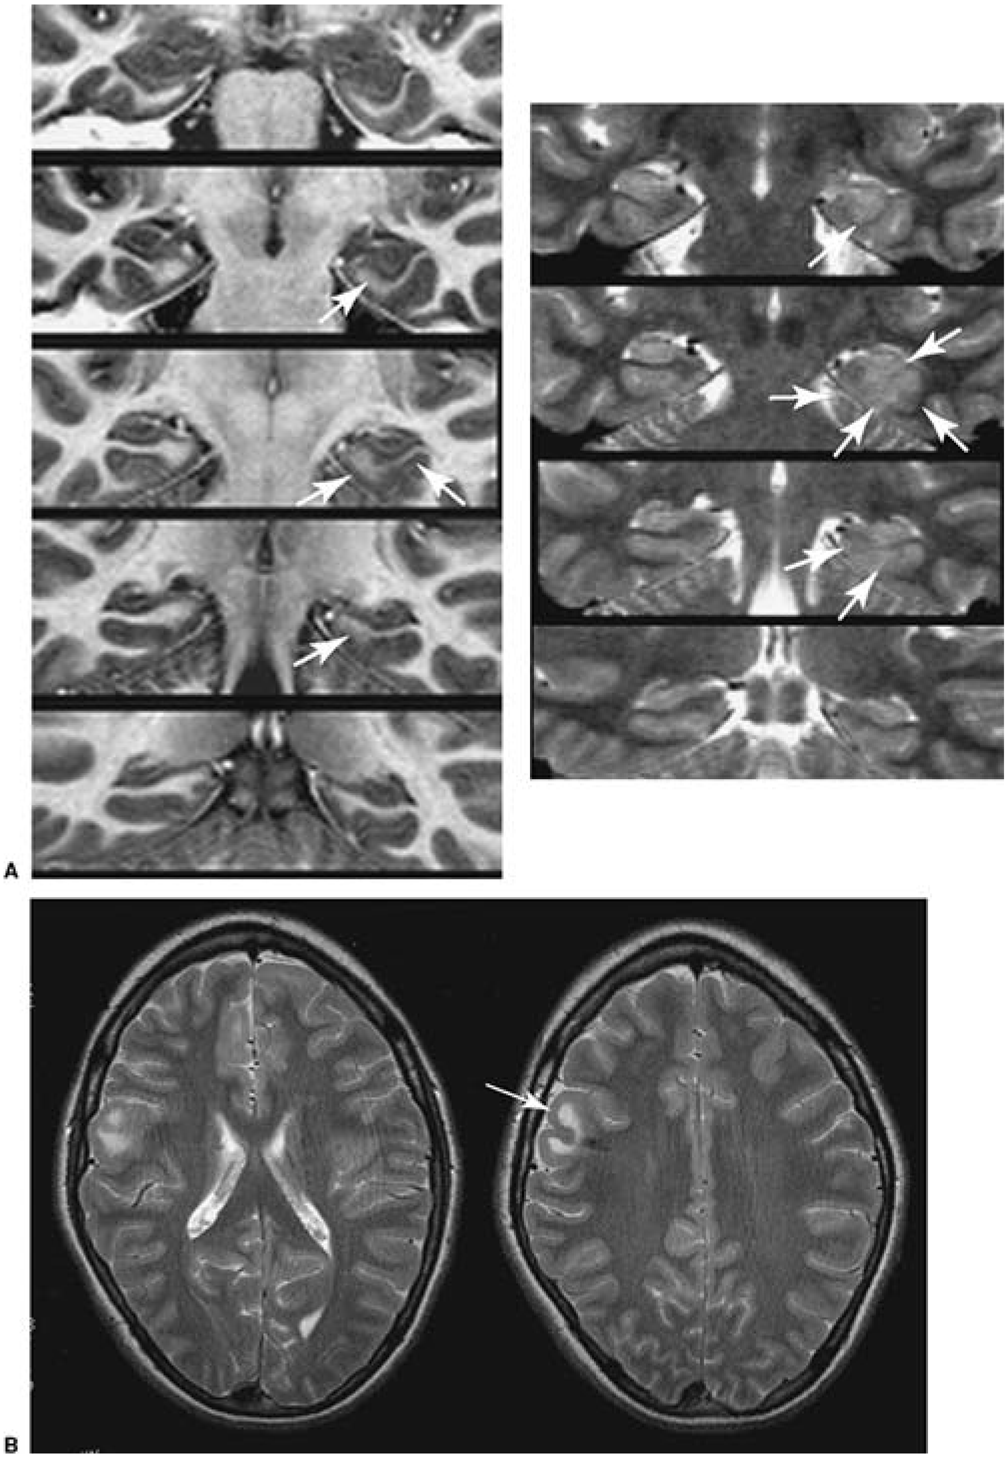

FIGURE 23. A: This 31-year-old woman with epilepsy demonstrates one of the problems of seizure localization in the mesial temporal lobes, particularly in the parahippocampal gyrus. This woman had confusing lateralization of her temporal lobe seizures. Depth electrodes were implanted in the mesial temporal region anteriorly, and these showed independent bilateral seizures more from the right. The ictal single photon emission computed tomography also showed bilateral seizures more from the right. Eventually a resection of this lesion was performed, and she became seizure free with persisting auras. In general, when there is disparity of the electroencephalographic data and an apparently epileptogenic lesion, we believe that seizure freedom is rarely achieved without resection of the lesion. The obvious and difficult issue is to recognize when lesions are truly incidental and irrelevant to the epilepsy. **B:**

Tuberous sclerosis. Tuberous sclerosis is often best appreciated by the changes in the white matter. Although the gray matter may appear to be normal in these magnetic resonance images, the pathology is of dysplasia. Just because the lesion appears to be in the white matter does not mean that is not epileptogenic. (Image courtesy of Simon Harvey, Royal Children's Hospital, Melbourne, Australia.)

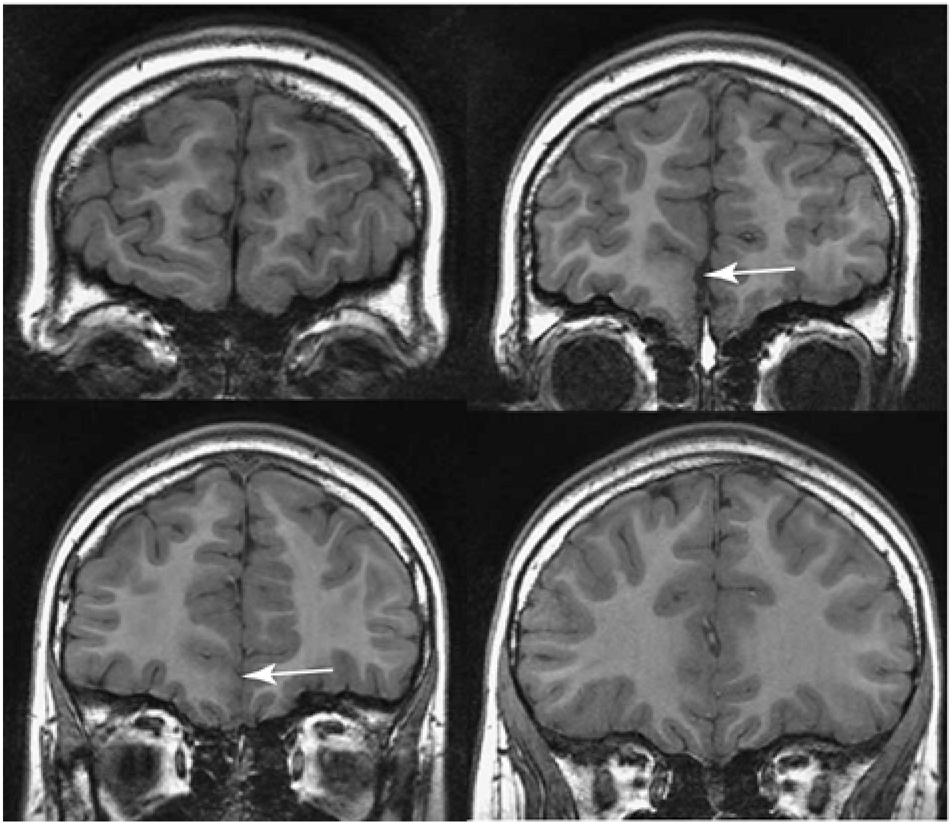

FIGURE 24. Subtle lesions require reliable boundaries between gray and white matter. These images show a focal cortical dysplasia in the medial and inferior aspect of the frontal lobe. The patient had frontal lobe epilepsy with lateralization to the right on ictal electroencephalogram. The identification of this lesion with concordant ictal single photon emission computed tomography led to focal resection of the lesion with good outcome without the need for implantation of subdural electrodes. The key to the recognition of this subtle lesion is the good signal-to-noise ratio of the imaging, which gives a clear grayâ€"white matter demarcation.

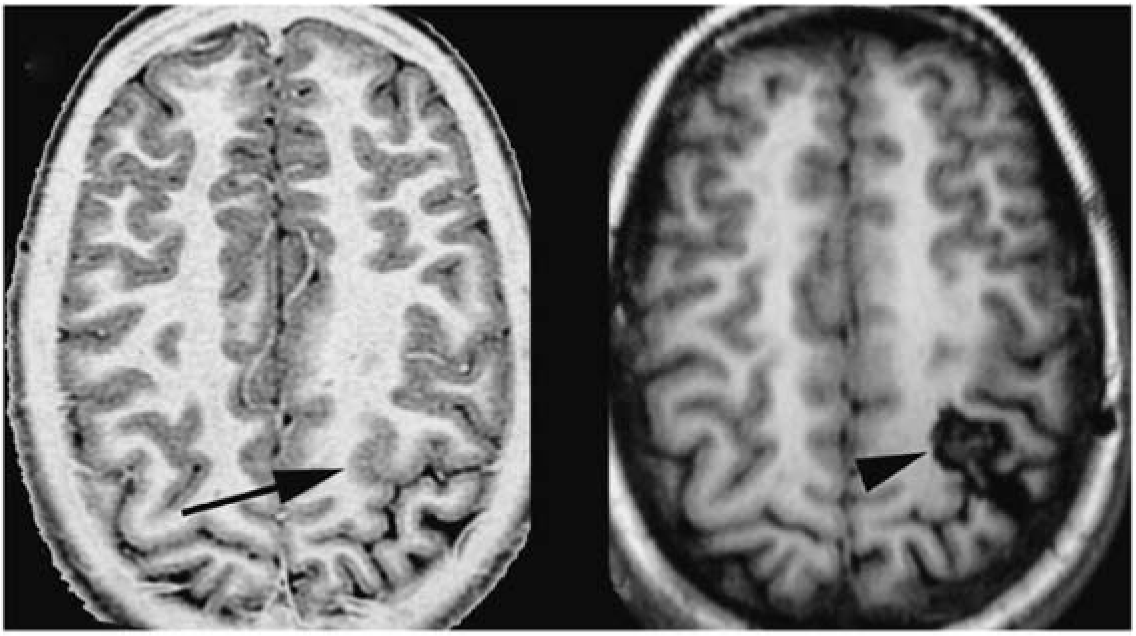

A B

FIGURE 25. â€œBottom of the sulcusâ€ dysplasia. This 30-year-old man had very intractable epilepsy, and a large right frontal resection was proposed because the precise onset was hard to determine. A small abnormal gyrus extending from the hand area of the central sulcus was identified **(A)** that had subtle blurring of the grayâ€“white matter junction. A focal resection was performed **(B)**, and the patient has now been completely seizure free for >5 years. Finding and correctly identifying subtle abnormalities such as this may make a large difference to treatment options.

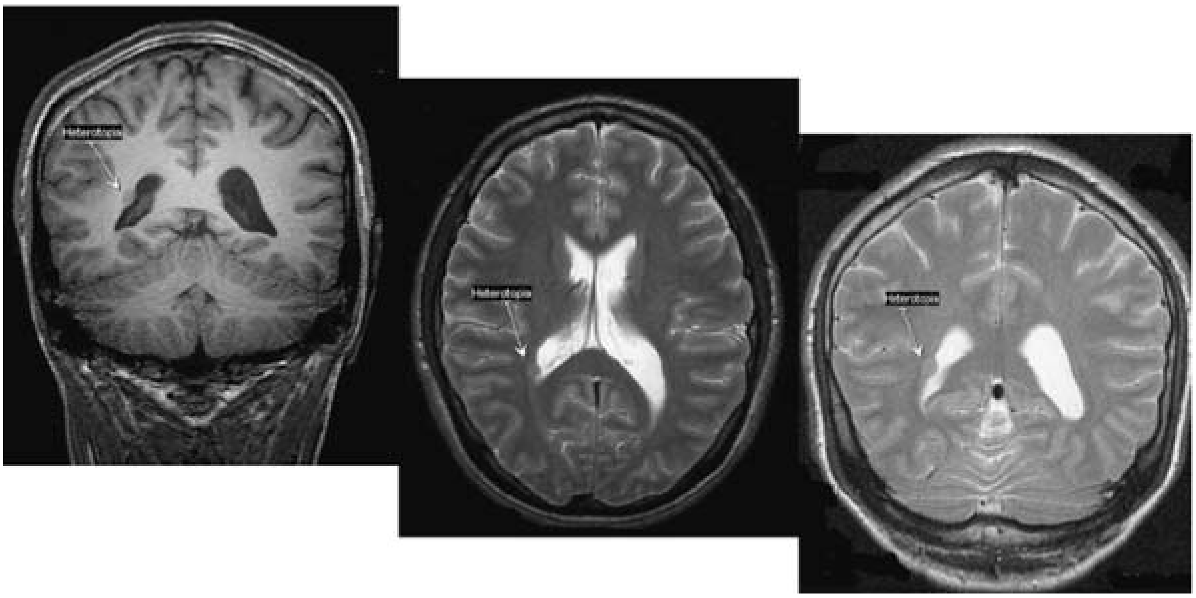

FIGURE 26. Periventricular nodular heterotopia can easily be missed. It is important because it is a poor prognostic feature for focal resections in localized epilepsy. (Images courtesy of Simon Harvey, Royal Children's Hospital, Melbourne, Australia.)

The signal change can sometimes be best seen on FLAIR images. There can sometimes be artifacts in the mesial temporal region, and interpretation of subtle changes without confirmation on the T2 sequences can be problematic, but real signal change can sometimes be dramatically emphasized with this imaging contrast (Fig. 15).

P.931

Hippocampal Atrophy

Hippocampal atrophy remains the best-known feature of HS in radiologic assessment. It is important that this be seen only as part of the complex of findings that give the correct diagnosis and avoid errors. Nonetheless, when severe, this is the most dramatic feature of HS, and often where visual screening starts. It is essential to use the appropriate imaging planes to correctly visualize these structures. It must be remembered that the hippocampus is indeed like a sea horse in shape, curving around the mesencephalon with a superior rostrocaudal angulation of approximately 30 to 35 degrees (Fig. 9). Using MRI, the assessment of the cross-sectional size of the hippocampus must be made in images obtained in the coronal axis that transects the hippocampus at right angles, often now known as the â€œhippocampal axis.â€ Using this angulation largely avoids partial volume effects, in particular in the posterior sections of the body and tail of the hippocampus. Although assessment of epilepsy has adopted this coronal plane in most centers, axial imaging is usually ignored. Axial images or reconstructions should also follow the long axis of the hippocampus, thus avoiding similar problems.

Visual assessment of hippocampal atrophy is reliable in experienced hands and with optimal imaging sequences. Hippocampal volume measurements and T2 relaxometry objectively and quantitatively confirms that these features are present in specific cases (Figs. 12 and 13) and can be useful in helping to train the epileptologist and radiologist in the degree of abnormality in the visually assessed images that can be confidently diagnosed. It must be remembered that these abnormalities might be considered to be subtle to the radiologist used to looking at â€œobviousâ€ pathology. In addition, the mesial temporal region is an area where signal change from flow artifacts in the adjacent major intracranial vessels can generate doubt in the mind of the reporting specialist. The key is the anatomic â€œexactnessâ€ of where the changes are. This means

P.932

that good knowledge of the mesial temporal anatomy is the most important skill in diagnosis.

Table 7 Malformations of Cortical Development

Malformations due to abnormal neuronal *proliferation*
Malformations due to abnormal neuronal *migration*
Malformations due to abnormal neuronal *organization*

Loss of Definition of Internal Microarchitecture of the Hippocampus (Loss of the Normal Internal Structure)

Normal internal morphologic structure of the hippocampus is produced by the alveus, the molecular cell layer of the dentate gyrus, and the pyramidal cell layer of the cornu ammonis, and can be seen on optimized coronal MR images. In hippocampal sclerosis, the loss of this normal internal structure is a consequence of neuronal cell loss and replacement of normal anatomic layers with gliotic tissue. It is difficult to describe precisely this feature because, even in severe cases, the alveus can give the appearance of structure in the hippocampus. Once recognized, it is important for confidence of diagnosis in cases in which other features are only mildly abnormal. As imaging is becoming better, this is a more important feature. The degree of T1 weighting is important here, however, and inversion recovery images demonstrate this better than other T1-weighted sequences (Figs. 16 and 17).

Anterior Temporal Lobe Changesâ€"The Temporal Pole

Hippocampal sclerosis is often associated with changes in the anterior temporal lobe (Fig. 18). The typical constellation of features associated with HS can be considered to

include changes in other parts of the brain. This includes hemisphere atrophy (see Figs. 20A and 21A), and white matter changes in the anterior temporal lobe. When HS is present there also can be increased signal in the anterior temporal pole white matter. In some cases the gray matter may also show some change in signal, suggesting that this is not simply a myelin effect. In careful studies no pathologic cause for these changes has been found. Meiners[10a] suggested that this is due to abnormalities in myelin and Mitchell and Blumke[3a,10b] that it is an arrest of development in the immature temporal lobe, which includes immaturity of the myelin as well as persistence of immature cells and the overall structure of the temporal lobe into adult life. It is clear that these changes are different than and can be distinguished from focal cortical dysplasia.

Anterior temporal lobe white matter changes are probably due to delayed development and early insult. They are rarely due to â€œdysplasia.â€ This issue and its associated controversies are well reviewed by Ryvlin et al.[12]).

Hippocampal Sclerosis With Minimal Atrophy

Sometimes HS can exist without significant atrophy. Usually when there is high signal in a large hippocampus, this reflects hippocampal dysplasia, and this is one of the key reasons why asymmetry between hippocampi should not be accepted as HS on the side that may be interpreted as being small, in the absence of assessment of the signal in that hippocampus (Fig. 19). It is always important to assess the signal and the internal structure as well as the size of the hippocampus.[7]

Not Just Damage to the Hippocampus in Hippocampal Sclerosis

There are various degrees of asymmetric damage that has the hippocampus as the most obvious part. The presence of hemisphere atrophy is common and perhaps underappreciated in many of these cases (Figs. 20 and 21A). As the ipsilateral damage becomes more severe, it is more likely that one finds regional and contralateral damage of lesser degrees. In the case of the symmetric hippocampal sclerosis, the degree of damage equally involves regional structures on both sides. These patients are not the same as the unilateral cases that have well-lateralized HS and unilateral TLE and are seen in adult surgical series. Often the seizure disorder is severe, or this is associated with devastating loss of function in children who show impairment after a bout of uncontrolled seizures. This suggests that there might be two fundamentally different mechanisms that cause the full spectrum of hippocampal damage. It may be that a severe insult or some property that causes sensitivity of the subject to the effects of seizures might determine the final outcome.

In the case of predominantly unilateral HS, one can conceive of a mechanism by which seizures are sustained and maximal unilaterally.

The range of imaging findings that can be seen in association with MRI is shown in FIGURE 20. Note the concept that there are bilateral and symmetric changes associated with HS, as well as the more usual lateralized cases that are more commonly associated with intractable seizures in epilepsy surgery centers.[7]

FIGURE 27. Mesial temporal dysplasia. This 15-year-old female had â€œdÃ©ja-vuâ€ events. There is a periventricular dysplasia in the left mesial temporal region (*arrow*). (Image courtesy Simon Harvey, Royal Children's Hospital, Melbourne, Australia.)

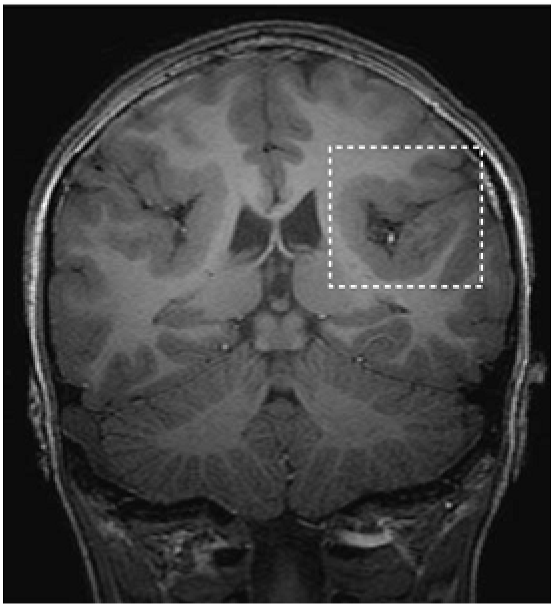

FIGURE 28. Bilateral perisylvian polymicrogyria. Perisylvian polymicrogyria can be easily missed if the thickened gray matter is not appreciated. These lesions may be better appreciated in the parasagittal images, and these need to be reviewed in all cases in which no other lesion is identified.

Dual Pathology

The incidence of dual pathology in TLE with HS is common. It is nearly always ipsilateral (Figs. 21A and 21B). Dual pathology is present in at least half of all cases of HS. There are two sorts of dual pathology. In the obvious case, there is a lesion, clearly unrelated to the HS, and it is usually on the same side as the HS. It is easy to imagine that this may be causally related to the existence of HS by causing predominantly unilateral seizures. The other sort of dual pathology occurs when the MRI shows changes in other parts of the brain that might be related to a

common injury that caused both the HS and changes such as unilateral atrophy or anterior temporal lobe changes.

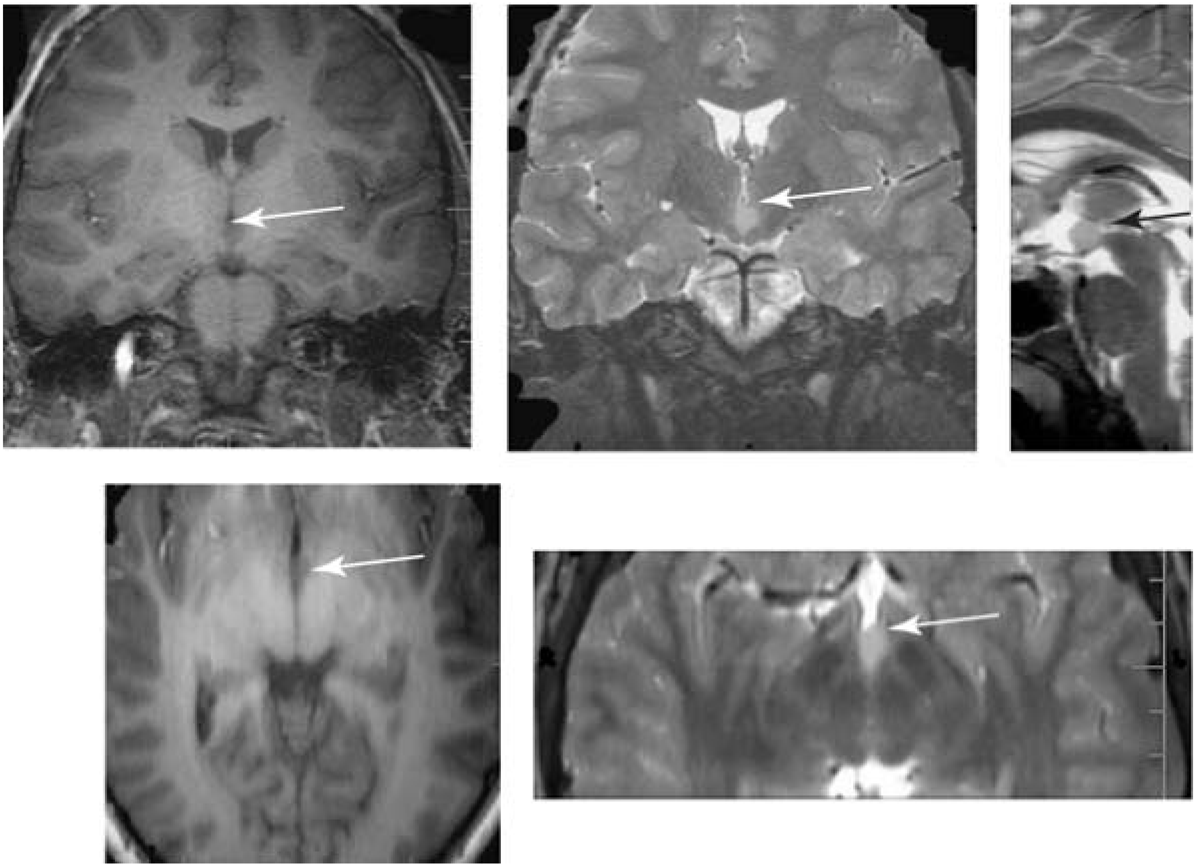

FIGURE 29. Hypothalamic hamartomas can be seen in the third ventricle. They are small and can easily be missed. They should be specifically looked for in all cases of temporal lobe epilepsy or partial epilepsy in which the magnetic resonance imaging is otherwise considered to be normal. (Image courtesy of Simon Harvey, Royal Children's Hospital, Melbourne, Australia.)

Malformations of Cortical Development

Under this term we include a number of pathologic entities that result from derangements of normal cortical development (Table 7).[1] These malformations are usually manifest in childhood. They can sometimes be dramatic, and knowledge of these abnormalities can greatly assist in understanding the patient (Fig. 22). Here we briefly address some particular forms of focal developmental lesions. These lesions are not exclusive to the temporal lobes, but in our opinion they merit separate discussion because of some distinctive clinical and imaging features.

Cortical dysplasia has been classified into what is now known as Taylor-type dysplasia characterized by the presence of balloon cells, and often the abnormality extends from the ventricle to the cortex. Focal cortical dysplasia (FCD) is a disorder of cortical organization and does not contain such bizarre cell types and hamartomas of the temporal lobe. Clinically, patients with cortical dysplasia of either type and temporal lobe epilepsy do not have striking clinical differences when compared to those with mesial temporal sclerosis. The frequency of childhood febrile convulsions is lower (20%â€"30%) in this population. Sometimes these can be subtle, and the abnormality appears to be predominantly in the white matter on MRI (Figs. 8 and 23). Tuberous sclerosis has imaging features that are similar to those of Taylor-type dysplasia (Fig. 23B).

Although MRI findings are abnormal in many patients with focal dysplasia, often the findings are subtle, and sometimes they are not seen on MRI, even with ideal imaging (Figs. 24 and 25). The MRI features range from abnormal signal changes to subtle abnormalities.

In contrast to cortical dysplasia, hamartomas are defined as abnormal proliferation of neuronal, meningeal, glial, or any combination of these cell types without evidence of neoplastic changes.

P.935

Periventricular nodular heterotopia is another important finding that can be easily missed (Fig. 26). When this is present, focal resections usually do not lead to a good outcome, regardless of how localized the cortical EEG activity is. The basis of the epileptogenicity is still controversial. It has been argued that the overlying cortex must be the source of the epileptogenic focus, but recently, epileptogenicity within the hamartoma has been demonstrated in at least a few cases. It is not clear whether resection of these lesions will lead to seizure freedom in an analogous way to the situation with regard to hypothalamic hamartomas.

Dysplasia in the mesial temporal region can also give seizures indistinguishable from mesial TLE from HS. In some cases these lesions can be subtle, and sometimes they are associated with ipsilateral HS (Fig. 27).

Bilateral perisylvian polymicrogyria can be easily missed if the thickened gray matter is not appreciated. These lesions are often better appreciated in the parasagittal images, and these

P.936

need to be reviewed in all cases in which no other lesion is identified (Fig. 28).

Hypothalamic hamartomas are highly epileptogenic. The seizures are typically partial, and they may appear to originate from the temporal lobe. Temporal lobe resections do not lead to seizure freedom. These lesions need to be looked for in all cases of cryptogenic TLE. Resection of the hamartoma can lead to seizure freedom (Fig. 29).

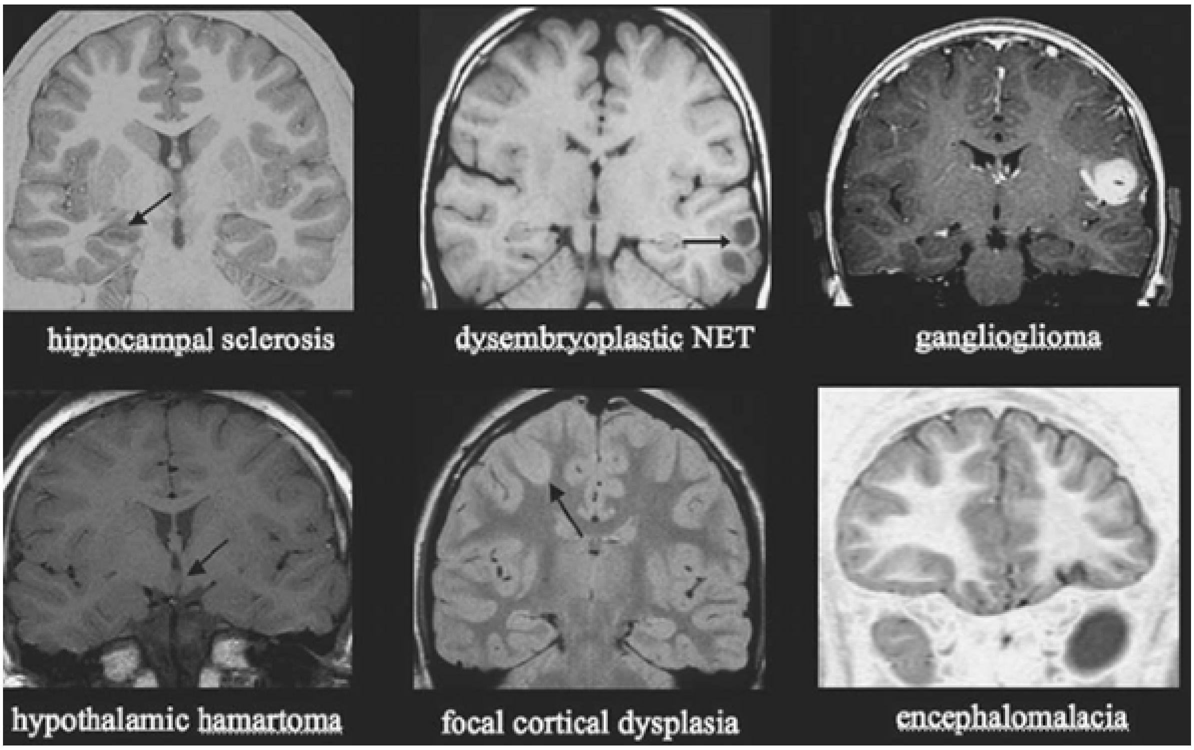

FIGURE 30. A range of the common causes of focal epilepsy that are essential to diagnose. NET, neuroepithelial tumor. (Courtesy of Simon Harvey, Royal Children's Hospital, Melbourne, Australia.)

There are a number of abnormalities that can be easily missed if not specifically looked for (Table 8 and Fig. 30). Conversely, some lesions can be overdiagnosed in inexperienced hands (Table 9).

A number of lesions that are highly significant for epilepsy are found at the â€œbottom of the sulcus.â€ In some cases there is a fine tract from the ventricle to the sulcus. These lesions are often the hardest to see on MRI, but small resections

P.937

(Fig. 30) can render the patient seizure free. We propose that the mechanism of the development of these lesions may be a small injury or MCD on the surface of the brain that ends up at the bottom of the sulcus because of the continuing growth of the brain (Table 10) and the formation of gyri (after 20 weeks of gestation). The brain grows a great deal even after birth (Table 10).[13] This may be an explanation of the â€œabnormal gyriâ€ or â€œstrange-looking gyral patternâ€ that is

P.938

nonspecific but with which all who deal with epilepsy are familiar (Fig. 31).

There is a range of abnormalities that give rise to diffuse pathology in the hemisphere. These are usually readily identified (Fig. 32).

Table 8 Subtle lesions that can be missed on magnetic resonance imaging

Focal cortical dysplasia

Mild or bilateral hippocampal sclerosis
Small hypothalamic hamartoma
Polymicrogyria
Subcortical band and periventricular nodular heterotopia
Mild tuberous sclerosis

Curvilinear surfaces can be of great help in visualizing abnormalities of gyral pattern and understanding the anatomic location of an abnormality that may be hard to appreciate in standard imaging planes (Fig. 33). The curvilinear surface maintains information about the gray and white matter and can be more useful than a simple surface-reconstructed image. There are a number of nonstandard investigations that can be requested that might help in particular cases (Table 11).

Other Imaging Techniques in The Context of The Anatomic Magnetic Resonance Imaging Study

Although it might be desired to perform all studies in all patients, the proliferation of imaging technologies means that we have entered an era in which appropriate selection of imaging is required. This is partly a cost-effectiveness problem as well as an issue of how much imaging is reasonable for a patient to undergo.

Electroencephalogram Simultaneous With Functional Magnetic Resonance Imaging

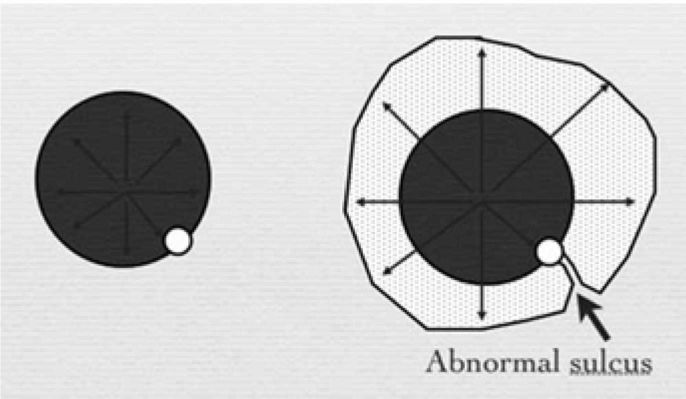

FIGURE 31. Why small focal dysplasias may be at the â€œbottom of the sulcus.â€ The brain grows a great deal after birth, and any abnormality that is on the cortical surface may not grow as much, leading to folding of the cortex in a slightly unusual way and leaving the abnormality at the bottom of the folded sulcus.

Idiopathic generalized epilepsies (IGEs) have been believed to have normal imaging. With advanced methods, one can now find structural and functional abnormalities in these cases using MRI methods. In childhood absence epilepsy, simultaneous EEG and functional MRI (fMRI) can show that electrographic bursts of spike and wave are associated with intense blood oxygenation levelâ€“dependent (BOLD) â€œactivationâ€ of the thalamus bilaterally (Fig. 34).

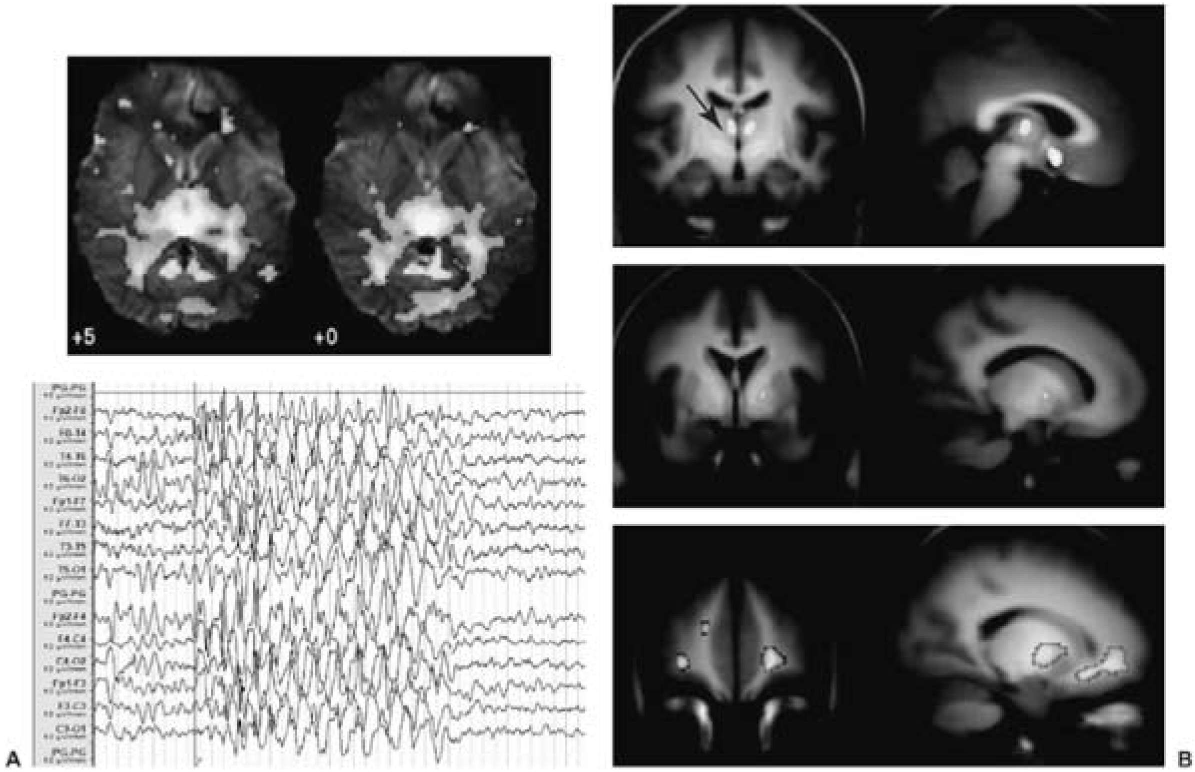

FIGURE 34. In childhood absence epilepsy, simultaneous electroencephalography and functional magnetic resonance imaging can show that electrographic bursts of spike and wave are associated with intense blood oxygenation levelâ€“dependent â€œactivationâ€ of the thalamus bilaterally **(A)**. In a group study, there is atrophy of the thalamus in these patients when compared to controls **(B)**. These advanced methods give insight into the structural and functional changes that occur in these epilepsies.

Focal activation low in the rolandic region can be seen in benign epilepsy with centrotemporal spikes (BECTS) with quite specific localization on the EEG/fMRI study (Fig. 35).

Structure can be correlated with function using a range of techniques in absence epilepsy (Fig. 36). Diffusion imaging and tractography can also reveal important aspects of the microarchitecture of the brain that is important in understanding the networks of the brain that may be altered in epilepsy (Fig. 37).

In addition to defining the structural basis of epilepsy, important aspects of brain function can also be identified with MRI. Functional MRI and EEG/fMRI can reveal remarkable aspects of brain function. Language fMRI using BOLD is a robust technique for the lateralization of language, and this is in common use in epilepsy centers. For the issue of lateralization of language function, in our center we have the opinion that fMRI provides better and more robust information than the Wada test. The combined use of these techniques can suggest hypotheses about the nature of the pathophysiology of brain function in epilepsy and its consequences that no other data can provide (Fig. 38).[3,14]

Positron Emission Tomography

The typical finding that can be very helpful in the localization of focal epilepsy is an area of hypometabolism that raises the question of whether this might be related to the seizure focus. This role in extratemporal epilepsy is very important. This then can direct further investigations if it is supported by the clinical context and seizure semiology. In the case of temporal lobe epilepsy, positron emission tomography (PET) study usually confirms the other imaging finding, and although it might make a useful contribution to assessing outcome, the decision for surgery is only occasionally affected by fluorodeoxyglucose (FDG) PET findings (Fig. 39) in centers such as ours.

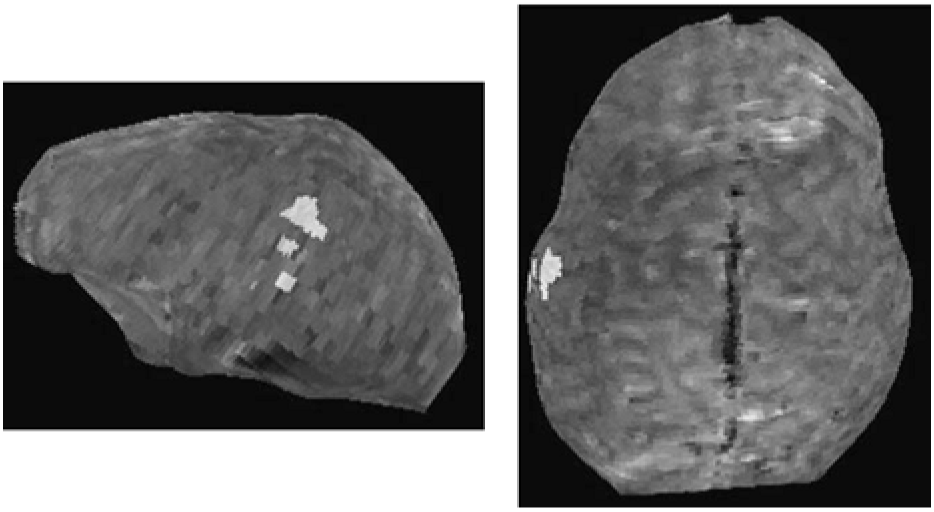

FIGURE 35. Blood oxygenation levelâ€"dependent functional magnetic resonance imaging (fMRI) activation in a child with classical benign epilepsy with centrotemporal spikes (BECTS), electrographically coming from the left. The fMRI study uses the â€œspikesâ€ as events. The activation is focal and in the postcentral gyrus, mostly in the anterior bank from the level of the inferior frontal gyrus, extending into the sylvian fissure and contiguously including the opercular bank of the postcentral gyrus on the left. The activations are shown on curvilinear reconstructions in Brainsight.

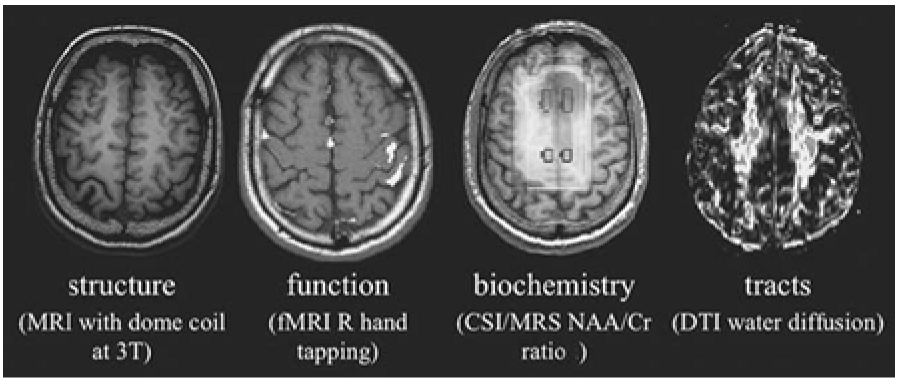

FIGURE 36. Advanced magnetic resonance imaging (MRI) in epilepsy. A range of advanced methods is

available. Functional MRI (fMRI) can reveal the localization of functions such as language or, in this case, hand function, biochemistry (using chemical shift imaging [CSI]), and aspects of the microstructure of the brain such as white matter with diffusion imaging. Cr, creatine; DTI, diffusion tensor imaging; MRS, magnetic resonance spectroscopy; NAA, *N*-acetyl aspartate; R, right.

FIGURE 37. White matter tracts delineated using diffusion-weighted magnetic resonance imaging (MRI) fiber tracking, superimposed on a T1-weighted coronal MR image. The tracks were generated from a seed point in the body of the corpus callosum, using a probabilistic streamlines tracking algorithm. To allow tracking through crossing fiber regions, the directional information was obtained from the diffusion-weighted images using constrained spherical deconvolution (CSD). (Image courtesy of J-Donald Tournier, Brain Research Institute, Melbourne, Australia.)

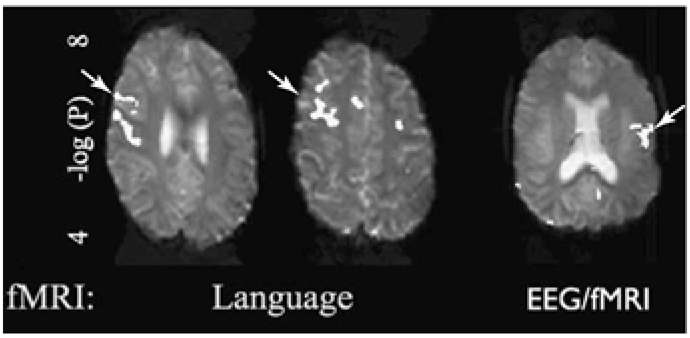

FIGURE 38. Physiologic and pathologic function. In the case shown here, there is right-sided language lateralization in a right-handed individual with no family history of sinistrality. The magnetic resonance imaging (MRI) was structurally normal, and seizures were partial and left hemispheric. Language functional MRI (fMRI) shows right-sided function in inferior and middle frontal gyri, suggesting atypical lateralization of language. The electroencephalographic/fMRI study localized the blood oxygenation levelâ€“dependent response from the interictal events to the left inferior frontal gyrus. We propose that this is likely to be the reason that language function is on the right, away from an area of epileptic activity. This patient's seizure onset was in early childhood.

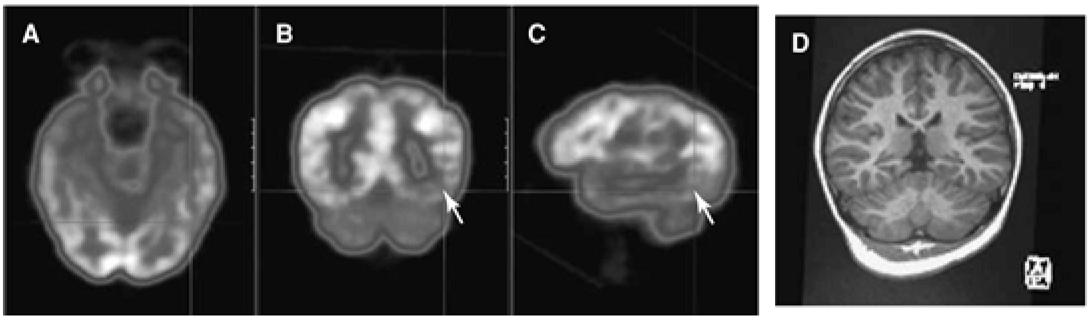

FIGURE 39. An area of decreased glucose uptake in the floor of the left temporal lobe (*arrows*) in a patient with photosensitive epilepsy and complex partial seizures **(Aâ€“C)**. In this case the magnetic resonance imaging was normal **(D)**. (Image courtesy of Sam Berlangieri, Austin Health, Melbourne, Australia.)

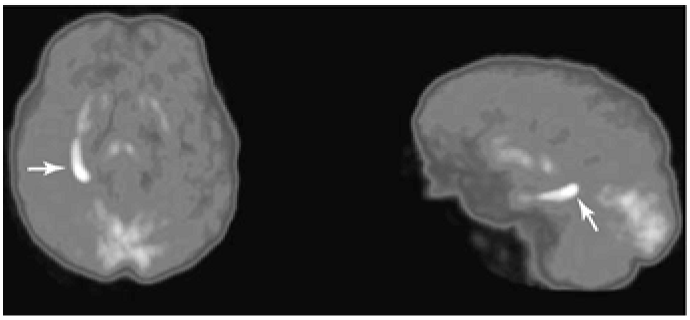

FIGURE 40. The positron emission tomography images show increased glucose uptake in the left hippocampus, consistent with limbic encephalitis. No obvious cause was identified despite extensive investigations.

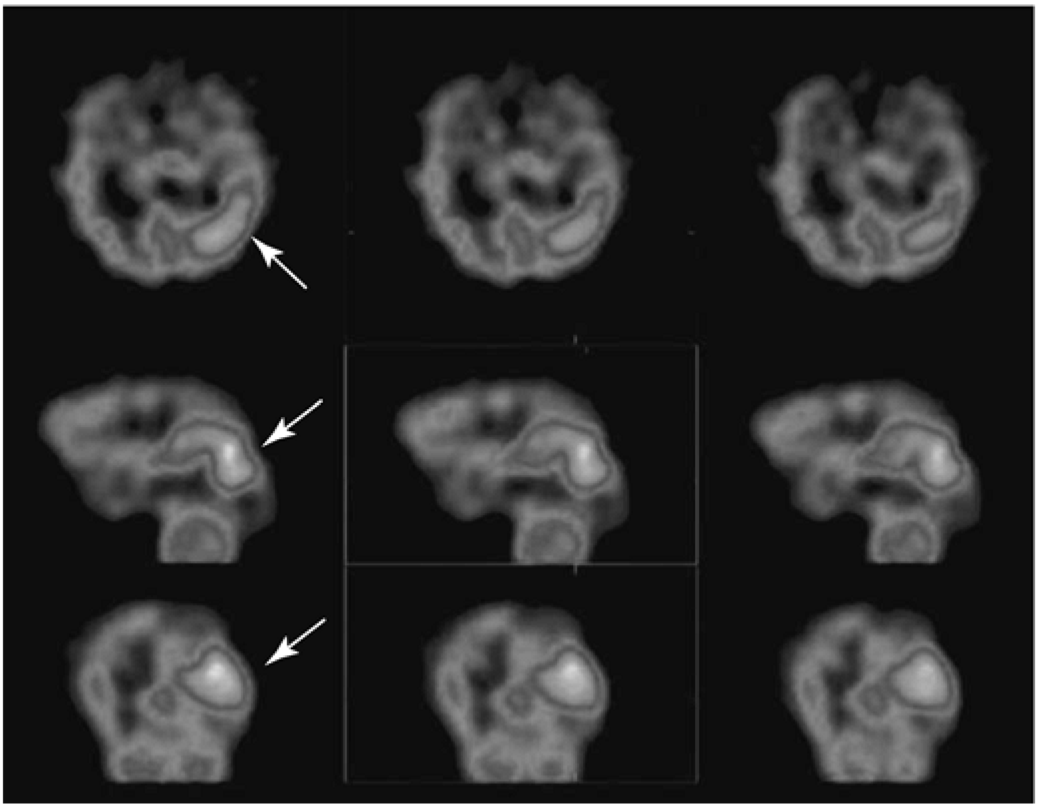

FIGURE 41. Injection of a single photon emission computed tomography radioligand during a seizure can show dramatic focal increase in perfusion in the posterior temporal region, suggesting seizure origin in this area.

In many such cases there is also some hypometabolism in the temporal lobes (first image). The presence of temporal hypometabolism in this clinical context is nonlocalizing, and the concept that the temporal lobe is a â€œsinkâ€ that is affected secondarily by lateralized partial seizures may be important.

P.941

P.942

P.943

P.944

PET images can give remarkable insights into epilepsy in some cases. When MRI is normal, it can give localizing information that will inform a more detailed review of the structural images. In some cases it suggests processes that could not have been determined from other information. For example, there are cases in which the structural images are normal, and yet there can be dramatic regional or hemispheric hypometabolism. Rarely, focal status or other dramatic findings may give unique insight into the epilepsy problem (Fig. 40).

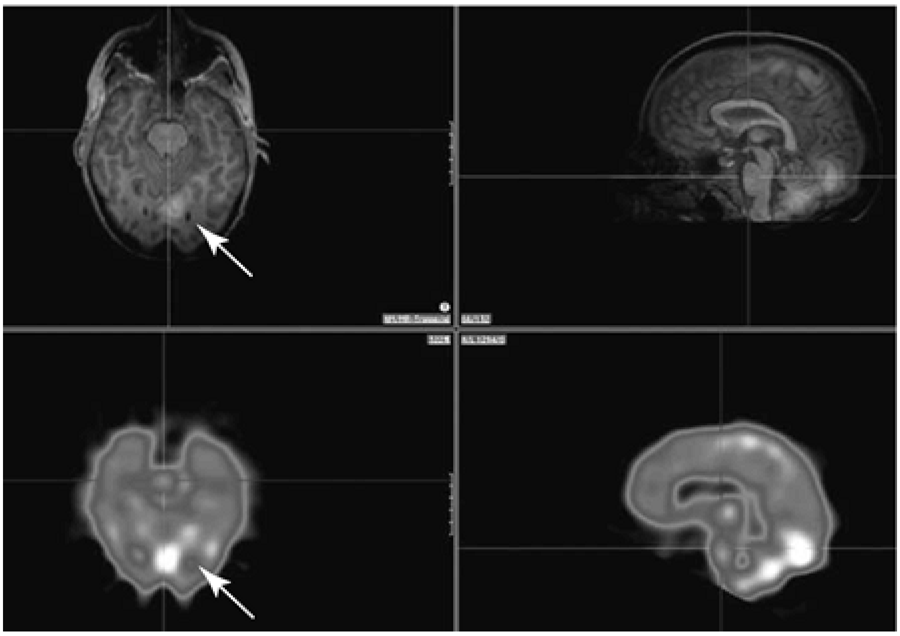

FIGURE 42. Early injection can suggest areas that should be further investigated. An early injection in a patient with apparent temporal lobe epilepsy suggests that there is early activity in the mesial occipital region. The top panels show the activation coregistered and superimposed over the magnetic resonance imaging anatomy, the lower panels show the single photon emission computed tomography image only.

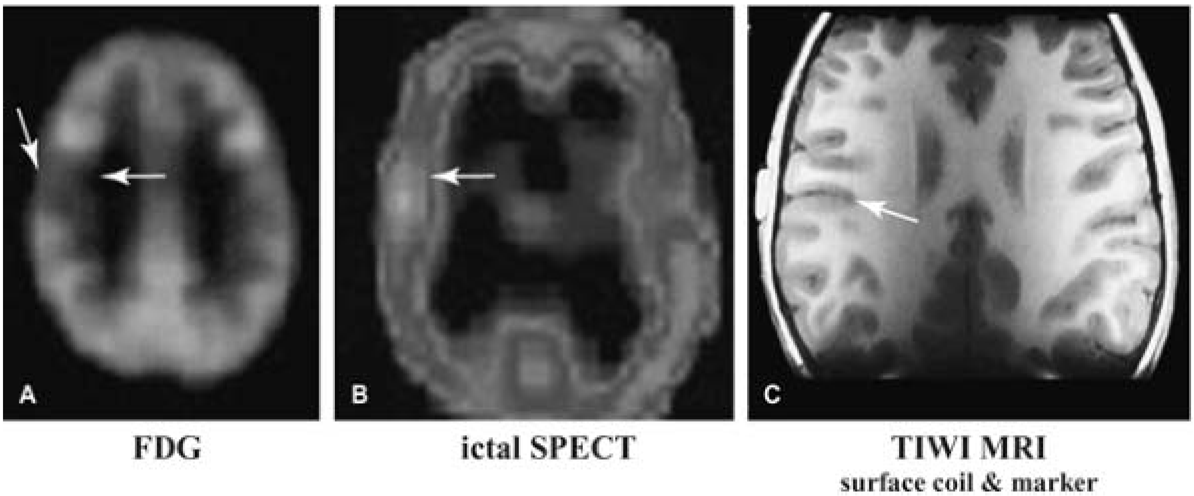

FIGURE 43. Simple partial seizures with right face sensation and jerking. In many cases of partial epilepsy the initial magnetic resonance imaging shows no abnormality. The patient had simple partial seizures with a sensation in the right face and jerking of the face. Fluorodeoxyglucose (FDG) positron emission tomography (PET) **(A)** showed a clear focal abnormality that accords with the increased perfusion on ictal single photon emission computed tomography (SPECT) **(B)**. Careful analysis of the magnetic resonance imaging (MRI) and a further surface coil study with a fiducial marker **(C)** revealed a focal abnormality. In this case a small â€œbottom of the sulcus dysplasiaâ€ was identified. Surgery of this small focal area led to seizure freedom. T1WI, T1-weighted imaging. (Case courtesy of Simon Harvey, Royal Children's Hospital, Melbourne, Australia.)

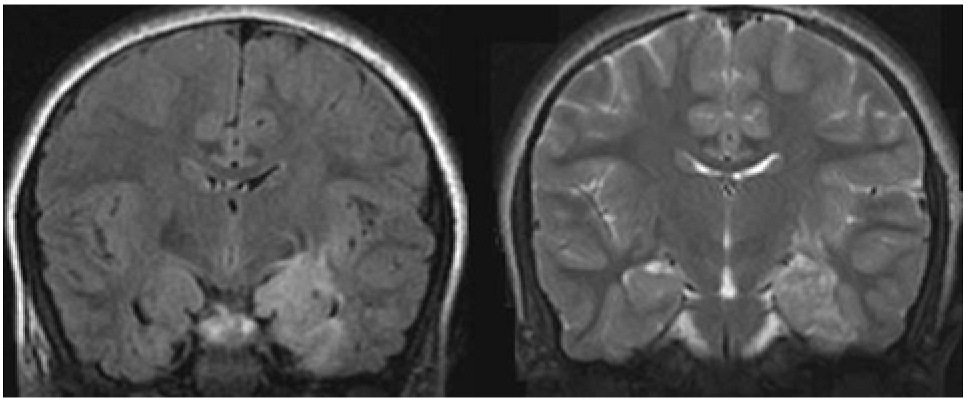

FIGURE 44. Dysembryoplastic neuroepithelial tumors in the temporal lobe are an important cause of epilepsy. Lesions such as these are â€œobviousâ€ on most imaging, regardless of epilepsy optimization. The relationship of the lesion to other mesial temporal structures is most easily seen in images acquired in the hippocampal axis.

Probably the most exciting use of PET is the development of techniques for the evaluation of receptor-specific aspects of epilepsy such as the role of serotonin in tuberous sclerosis.[9]

Single Photon Emission Computed Tomography

Ictal single photon emission computed tomography is technically very demanding and requires a high degree of organization within the epilepsy monitoring unit and good collaboration with the nuclear medicine department. The effort is certainly of benefit, and in some cases this is an essential investigation that allows understanding of the epilepsy origins or the ability to offer surgery without the need for intracranial implantation (Fig. 41). Early injection and comparison to the interictal study are the keys to using this method. It is essential to interpret these studies with knowledge of the timing of the injection relative to the clinical and electrographic events of the seizure, and this must be done with video monitoring. Early injection can be revealing (Fig. 42).

Ictal SPECT is a very important tool in understanding the localization of epileptic seizures.[11] It is important for two reasons. First, it can identify a region that gives focus to more detailed assessment with structural imaging studies. The best outcome in epilepsy surgery occurs when the functional studies showing seizure origin are concordant with a focal lesion. In the absence of an identified focal structural lesion, outcome is worse. Second, ictal SPECT shows information that is primarily about the paroxysmal events that are the basic complaint of the patient with epilepsy. Conceptually, structural imaging, and even PET, shows abnormalities that are present in the brain all of the time. Although they might be the basis of the paroxysmal seizure events, ictal SPECT is a way of actually imaging these events. Therefore it provides data that are of a different nature than those from other imaging methods and adds to the understanding of the cause of an individual patient's epilepsy.

Ictal SPECT must be interpreted in conjunction with an interictal study. This can be done visually by comparison of the two studies or with advanced processing methods such as subtraction ictal SPECT coregistered to MRI (SISCOM). When these findings suggest a focal area, the MRI and structural studies should be reviewed, and further imaging might be indicated to specifically interrogate these areas. Finding a focal area of abnormality gives great confidence that focal resection will be associated with a good outcome from surgery (Fig. 43).

Summary and Conclusions

MRI studies are an essential component of the overall assessment of why a patient has epilepsy. This requires us to define and understand the epileptic events, the structural abnormalities in the brain, and the clinical context in which seizures occur. Unless high-quality information is obtained in all three of these domains, the basis of the epilepsy in any individual has not been fully assessed.[4]

In this chapter, we have dealt with the need to define and understand the structural brain abnormalities by acquiring appropriate epilepsy-focused MRI of high quality and diagnosing the important lesions with high sensitivity and specificity because this is fundamental to good epileptology, albeit often difficult to implement in practice. The clinical context, seizure features, and interpretation of the imaging, with full knowledge of the hypothesized basis of each individual's epilepsy and the other investigations, are the key to the proper use of imaging.

Chapter 80

Positron Emission Tomography

Thomas R. Henry

Harry T. Chugani

Introduction

Positron emission tomography (PET) generates physiologic images that are complementary to brain structural magnetic resonance images (MRI) in numerous epilepsy research applications and also in a major clinical application (planning epilepsy surgery). Epilepsy research with PET has used various radiopharmaceutical tracers to measure cerebral blood flow, glucose metabolism, neurotransmitter synthesis, receptor density, kinetics of antiepileptic drugs, and effects of antiepileptic drugs and therapeutic neural electrostimulation (Table 1). Cerebral glucose metabolic mapping, using PET and 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG), has been extensively studied in the epilepsies. Regions of interictal glucose hypometabolism are highly associated with cerebral sites of seizure generationâ€"propagation in partial epilepsies and in West syndrome. Localization of interictal hypometabolism in planning epilepsy surgery is widely accepted as a clinical application of PET. This chapter reviews essential principles of PET (Table 2) methodology and emphasizes epilepsy research and presurgical epilepsy evaluations using clinical PET.

Methodology

Interictal [^{18}F]FDG PET is readily available in clinical PET centers, whereas research centers typically provide [^{18}F]FDG and multiple other radiopharmaceutical agents. Clinical PET centers are financially supported mainly by whole-body [^{18}F]FDG PET, which is used to screen for metastases of solid tumors. The relatively long half-life of ^{18}F (about 2 hours), the common use of highly standardized protocols for synthesizing [^{18}F]FDG, and the availability of high-resolution tomographic cameras all serve to make [^{18}F]FDG imaging practical and affordable in an advanced oncology center. Epileptologists can easily arrange for brain [^{18}F]FDG imaging in a clinical PET center, which provides the multidisciplinary expertise required for safe and accurate PET imaging. Clinical epileptologists need to understand essentials of PET methodology and [^{18}F]FDG physiology to apply [^{18}F]FDG images in presurgical epilepsy evaluations. Following intravenous injection of radiolabeled [^{18}F]FDG, patients are observed for 30 to 45 minutes, and then scanning is performed. During the observation period after [^{18}F]FDG injection, the labeled [^{18}F]FDG circulates through cerebral arterioles and capillaries, with diffusion into brain tissue; [^{18}F]FDG is taken up by neurons and other cells and is phosphorylated, as is glucose; unlike glucose, [^{18}F]FDG does not enter the rest of the Krebs cycle and remains in place as ^{18}F decays and emits positrons.[146] The tomograph detects oppositely directed high-energy photons produced in positron decay. Image data usually are reconstructed into a set of axial [^{18}F]FDG activity images, which are viewed and interpreted by a nuclear medicine physician.

Research studies with PET also use the sophisticated physics (for generation of positron-emitting radionuclides), neurochemistry (for radiopharmaceutical preparation), and computing (for image reconstruction and analysis) widely available in nuclear medicine facilities. Clinical cyclotrons can produce positron-emitting isotopes of fluorine (^{18}F, half-life of 110 minutes), carbon (^{11}C, half-life of 20 minutes), nitrogen (^{13}N, half-life of 10 minutes), and oxygen (^{15}O, half-life of 2 minutes). Radiochemists have perfected reaction sequences rapidly to incorporate these radionuclides into a wide variety of labeled organic molecules, which can be administered intravenously in high purity to image many neurochemical sites and brain processes of interest to epileptologists. The accuracy of PET measurement and anatomic display is determined by the biochemical and physical properties of the selected radiopharmaceutical tracer (Table 1) and its mathematical model, performance characteristics of the tomographic instrument, scanning procedure, and other factors. Several reviews have covered general and epilepsy-related aspects of PET methodology in detail.[49,50,71,219,220]

Table 1 Positron-emitting radiopharmaceuticals used in Positron emission tomography studies of epilepsy

Function	Radiopharmaceuticals
Glucose metabolism	2-[^{18}F]fluoro-2-deoxyglucose (FDG)
Oxygen metabolism and oxygen extraction ratio	[^{15}O]O_2
Cerebral blood flow	[^{15}O]O_2, [^{15}O]H_2O, [^{15}O]CO_2, [^{13}N]NH_3
Central benzodiazepine receptor distribution	[^{11}C]flumazenil (formerly [^{11}C]RO15-1788)
Muscarinic cholinergic receptor distribution	[^{11}C]*N*-methyl piperidyl benzilate
Opiate receptor distribution	[^{11}C]Carfentanil (Âµ-receptors)
	[^{18}F]Cyclofoxy (Âµ-/Îº-receptors)
	[^{11}C]Diprenorphine (Âµ-/Îº-/Î´-receptors)
Serotonin synthesis	[^{11}C]Î±-methyl tryptophan
Serotonin-1 Aâ€“receptor distribution	[^{11}C]WAY100635, [^{18}F]FCWAY, [^{18}F]MPPF
Drug distribution	[^{11}C]Phenytoin
	[^{11}C]Valproate
Monoamine oxidase B distribution (glial density)	[^{11}C]Deuterium-deprenyl

[^{11}C]WAY100635, [*O-methyl*-^{11}C]-*N*-(2(4(2-methoxyphenyl)-1-piperazinyl)ethyl)*N*-(2-pyridinyl) cyclohexanecarboxamide trihydrochloride; [^{18}F]FCWAY,

[18F]*trans*-4-fluoro-*N*-2[4-(2-methoxyphenyl)piperazin-1-yl]ethyl]-*N*-(2-pyridyl)cyclohexanecarboxamide; [18F]MPPF, 2â€²-methoxyphenyl-(*N*-2â€²-pyridinyl)-*p*-[18F]fluoro-benzamidoethylpiperazine.

Table 2 Indications for FDG PET in presurgical evaluation of epilepsy

Indications	Temporal lobe epilepsy	Extratemporal partial epilepsy	Infantile spasms and Sturge-Weber syndrome
Lateralization and regionalization of interictal hypometabolism for possible resection without prior intracranial electrophysiologic ictal monitoring	Requires PET concordance with scalp-sphenoidal EEG ictal onsets, with any cortical abnormalities on MRI, and with any other localized epilepsy-associated cerebral dysfunction	No established role for PET	Requires PET concordance with any lateralized or focal features on ictal scalp EEG recordings, with any cortical abnormalities on MRI, and with absence of significant cerebral dysfunction beyond the intended margins of resection
Regionalization of interictal temporal or extratemporal hypometabolism for direction of intracranial electrode placement	Requires correlation of PET with semiologic, interictal, and ictal extracranial EEG, MRI, and other noninvasively acquired data	Requires correlation of PET with semiologic, interictal, and ictal extracranial EEG, MRI, and other noninvasively acquired data	No established role for PET
Prognostication of surgical outcome with regard to seizure control	Presence of temporal hypometabolism and absence of extratemporal cortical hypometabolism predict best outcome	No established role for PET	No established role for PET

EEG, electroencephalogram; FDG, 2-[^{18}F]fluoro-2-deoxyglucose; MRI, magnetic resonance imaging; PET, positron emission tomography.

The performance of each PET tracer and PET scanning system must be considered in four dimensions of physiologic imaging: (a) process, (b) temporal, (c) contrast, and (d) spatial resolutions. *Process* resolution is the accuracy of a tracer kinetic method in measuring the intended biochemical process. *Temporal* resolution is the duration of brain function represented in any PET data set. *Contrast* resolution (â€œsignal-to-noise ratioâ€) is determined by the ability of a PET system accurately to measure the activity of positron-emitting tracer within the object scanned. *Spatial* resolution is determined by the ability of an imaging system to detect subdivisions of the object scanned to support image reconstruction that renders the subdivisions in accurate position and shape. Each dimension of a volume of tissue must be at least twice the linear resolution of the imaging system if the volume is to be accurately resolved in space and functional intensity on the image.[126] Structures smaller than this will have their functional activity averaged with those of adjacent structures (the partial volume effect). The higher spatial resolution of current PET tomographs compared with those reported in earlier [^{18}F]FDG imaging research has been shown to generate more sensitive and accurate detection of hypometabolism, with greater ability to correlate [^{18}F]FDG image coordinates with brain MRI locations.[72] Epileptologists who use MRI in research are accustomed to spatial resolution and signal-to-noise ratio in determining which reported findings are supported by the imaging techniques. Results of PET-based epilepsy research must be critically analyzed with respect to all four dimensions of resolution in physiologic imaging.

Evaluation of [^{18}F]FDG images is complex with respect to temporal resolution, but otherwise it is fairly straightforward. The [^{18}F]FDG kinetics generates a nonlinear temporal resolution, in that glucose metabolism is averaged over about

P.946

40 minutes, with earlier periods during scanning weighted more heavily in this average. The tracer kinetic model of [^{18}F]FDG requires steady-state conditions for absolute measurements of glucose metabolic rate, and so only relative comparison of metabolism within different regions of the image set can be made if a single seizure occurs during [^{18}F]FDG imaging.[146] Ictal [^{18}F]FDG PET studies cannot be quantified because glucose metabolism is not at steady-state.[146] Dynamic [^{15}O]H_2O PET imaging of cerebral blood flow (CBF) is in theory superior for ictal scanning of single seizures to either

P.947

[^{18}F]FDG PET or single photon emission computed tomography (SPECT) techniques due to its superior temporal resolution and the possibility of fully quantifying CBF (without requirement of correction for nonlinear activityâ€“CBF relationships, as occur with SPECT agents). In practice, the short half-life of ^{15}O and the usually unpredictable timing of seizure onsets render ictal [^{15}O]H_2O PET impossible except for the study of reflex seizures. Relative increases and decreases in ictal regional metabolism have been observed with [^{18}F]FDG PET.[127] Ictal [^{18}F]FDG studies are most useful when the duration of continuous seizure activity approximates the duration of [^{18}F]FDG uptake and phosphorylation following bolus [^{18}F]FDG injection, that is, when seizures last 10 minutes or longer. Epilepsia partialis continua is required for â€œpurelyâ€ ictal [^{18}F]FDG scanning.[59] Occurrence of a brief complex partial seizure shortly after [^{18}F]FDG injection may actually be associated with false normalization of apparent [^{18}F]FDG activity, presumably due to averaging of interictal hypometabolism and ictal hypermetabolism in the same region.[71]

Many centers perform continuous scalp electroencephalographic (EEG) monitoring immediately prior to and following [^{18}F]FDG administration, including for outpatient PET. Continuous EEG is useful in determining wakeâ€“sleep state, frequency of interictal epileptiform discharges, and occurrence of electrographic seizures. Scalp electrodes do not significantly attenuate or scatter the high-energy (511 keV) photons that are produced by positron annihilation. Some centers do not routinely perform EEG monitoring because this slightly increases the cost of [^{18}F]FDG scanning and because some believe that subclinical or unreported seizures rarely occur in the imaging suite and that single seizures do not alter [^{18}F]FDG images.[6] The latter point has been disproved (see, e.g., the case presented by Henry et al.[71]). Nonetheless, the costâ€“benefit ratio of continuous EEG during clinical [^{18}F]FDG studies has not been established. Continuous EEG monitoring is standard in PET research protocols, not only for [^{18}F]FDG, but also for other radiopharmaceuticals; focal seizures cause marked focal increases on cerebral blood flow and therefore cause marked increases in delivery of any PET ligand to areas of maximal seizure involvement, resulting in altered physiologic images.

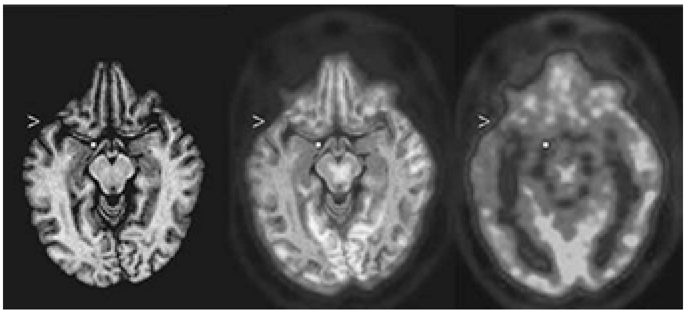

FIGURE 1. Coregistered axial image plane of magnetic resonance imaging (MRI) and interictal 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a limbic temporal lobe epilepsy (TLE) patient. The gray-scale MR image **(left)** and the color PET image **(right)** are coregistered in the center image. The MRI and PET data were reoriented parallel to a line through the anterior and posterior commissures. A widespread area of reduced [^{18}F]FDG activity is evident on the left side of the PET image; inspection of the PET image alone does not clarify whether the reduction extends from mesial structures (at the dot internal to the brain FDG image) of the temporal lobe into the basal frontal lobe, nor whether the lateral temporal hypometabolism (at the arrowhead) extends above the sylvian fissure. The dot and arrowhead appear at the same coordinates in the MRI and the coregistered MRIâ€“PET images as in the PET image, clarifying that all sites with severe hypometabolism are confined to the temporal lobe. (See the color insert.)

Structural imaging data should guide anatomic analysis of PET images. An individual's MRI and PET images can be coregistered and then viewed side by side or with superimposition of the functional and structural images (Fig. 1). Accurate PETâ€“MRI coregistration permits comparison of anatomically specific metabolic measurements of the individual with normal subjects' means and variances of regional metabolism.[34] Statistical parametric imaging detects some abnormalities that cannot be appreciated with qualitative interpretation. For example, unilateral temporal lobe epilepsy often causes bilateral temporal hypometabolism with marked asymmetry of temporal metabolism (with lower [^{18}F]FDG activity on the epileptogenic side). Bilateral but asymmetric temporal lobe hypometabolism can be detected readily with statistical parametric imaging techniques, but it usually appears only as unilateral temporal hypometabolism on visual interpretation. Quantitative analyses that determine an asymmetry index also will fail to detect bilateral temporal hypometabolism, although the temporal lobe with relatively greater metabolic decrease will be accurately noted as the more hypometabolic. Issues regarding the construction of regions of interest for regional sampling of [^{18}F]FDG activity have been previously discussed.[71] Despite the advantages of statistical parametric imaging techniques, visual interpretation and quantification of asymmetry remain useful in current clinical applications because unilateral TLE often has asymmetric, bilateral temporal hypometabolism interictally.

Research Findings in the Epilepsies

Mesial Temporal Lobe Epilepsy: Glucose Metabolism and Cerebral Blood Flow Studies

Interictal [^{18}F]FDG PET usually demonstrates hypometabolism of one temporal lobe (Figs. 2,3,4) or bilateral temporal hypometabolism with more severe hypometabolism of one temporal lobe (Fig. 5) in adults and children with refractory mesial temporal lobe epilepsy (TLE).[1,3,10,11,39,40,41,42,60,61,67,71,72,74,75,98,106,108,118,137,151,164,165,167,168,186,187,189,197,204,208,210,212,215] Qualitative visual analysis of [^{18}F]FDG scans obtained with high-performance tomographs detects unilateral (or bilateral, but asymmetric) temporal lobe hypometabolism in >70% of refractory TLE patients. Higher-resolution tomographic systems support a higher detection rate for hypometabolism, and greater concordance among readers, in qualitative interpretation of [^{18}F]FDG imaging in localization-related epilepsies.[72] With quantitative analysis, detection of significant temporal lobe hypometabolism may exceed 90% in this group.[92,98,216]

Temporal lobe hypometabolism usually extends over mesial and lateral portions of an interictally dysfunctional temporal lobe on [^{18}F]FDG scans in mesial TLE.[72,74,167,215] Regional hypometabolism in mesial TLE typically is diffuse, with graded demarcations from adjacent areas of normal metabolism and a relatively large area of hypometabolism. Even in the presence of a temporal lobe foreign-tissue lesion, patients with refractory mesial temporal seizures usually have widespread temporal lobe hypometabolism rather than focal hypometabolism restricted to the site of the lesion. When using older tomographs with lower spatial resolution, the lateral temporal hypometabolism often appeared more severe than the mesial temporal hypometabolism of an affected temporal lobe on qualitative scan interpretation and even with quantification.[72,167] Using an ultra-high-resolution tomograph, however, one study of mesial TLE found that small volumes of anterior mesial

P.949

temporal structures were more severely hypometabolic than were any other temporal or extratemporal areas in many mesial TLE patients.[215] As shown in FIGURE 3, current tomographs more often provide [^{18}F]FDG scans that show mesial temporal greater than lateral temporal hypometabolism of the affected temporal lobe. This suggests that partial-volume averaging of severe hypometabolism in the epileptogenic amygdala-hippocampus together with less depressed metabolism of adjacent basal temporal areas may cause the mesial temporal areas to appear less severely hypometabolic than they actually are when older clinical PET systems are used. In contrast to lateralized temporal lobe predominance of metabolic dysfunction most often observed in refractory TLE, some TLE patients have symmetric hypometabolism of both temporal lobes (Fig. 6).[10,93] Normal interictal metabolism also occurs in refractory mesial TLE, but normal [^{18}F]FDG scans are more common in nonrefractory than in refractory mesial TLE.[55,124]

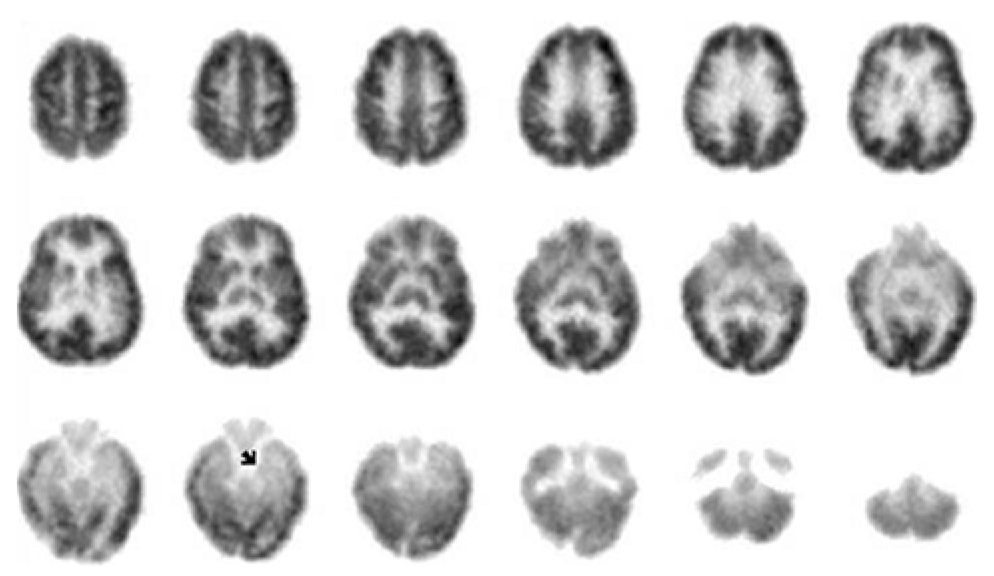

FIGURE 2. Interictal 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a limbic temporal lobe epilepsy (TLE) patient. These transaxially oriented images show anterior hippocampal hypometabolism (*arrow*), which is more severe than reduction in [^{18}F]FDG activity in the adjacent inferior-lateral temporal regions. No extratemporal abnormalities are evident. The patient's brain magnetic resonance imaging (MRI) was normal. Mild hippocampal sclerosis was present in tissue resected on the side of hypometabolism and of extracranially recorded electroencephalographic (EEG) ictal onsets. Seizures ceased after resection.

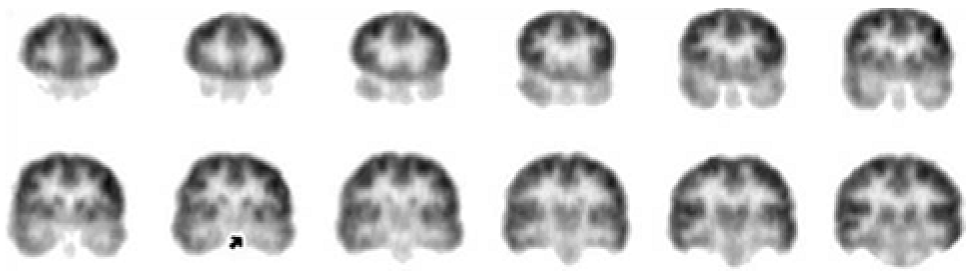

FIGURE 3. Interictal 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a limbic temporal lobe epilepsy (TLE) patient. These coronally oriented images were reconstructed from the same [^{18}F]FDG data as shown in FIGURE 2. It is evident that mesial is greater than lateral temporal hypometabolism (at arrow and on adjacent planes). On each row, the coronal images are arranged with the most anterior plane to the left and 4 mm spacing. Subject left is displayed on image right.

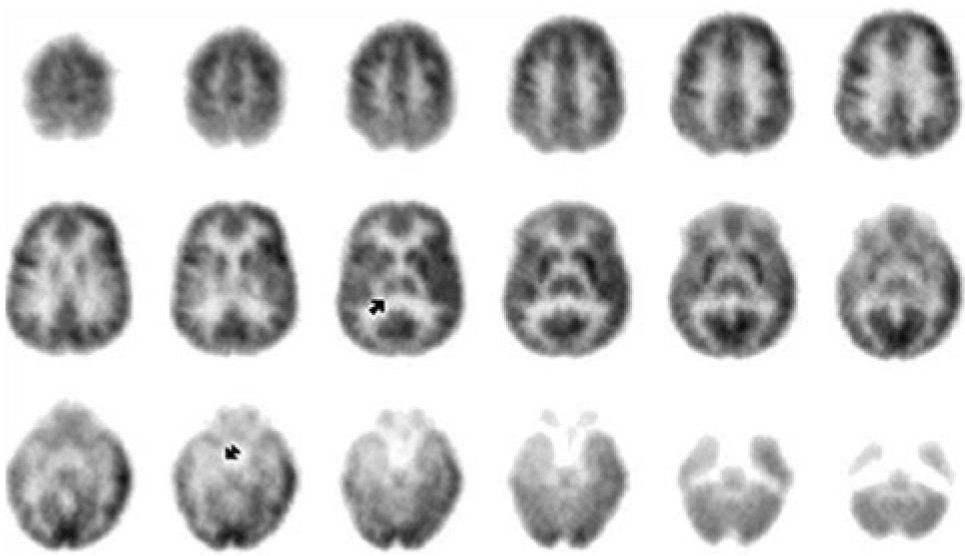

FIGURE 4. Interictal 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a limbic temporal lobe epilepsy (TLE) patient. These images show severe hypometabolism of the anterior hippocampus (*arrow*) and moderate hypometabolism of the ipsilateral temporal neocortex and thalamus (*arrow*). Mild hypometabolism is seen diffusely over the dorsolateral frontal and parietal cortex ipsilaterally. The patient's brain magnetic resonance imaging (MRI) showed mild bilateral hippocampal atrophy. Moderate hippocampal sclerosis was present in tissue resected on the side of hypometabolism and of intracranially recorded electroencephalographic (EEG) ictal onsets. Seizures ceased after resection.

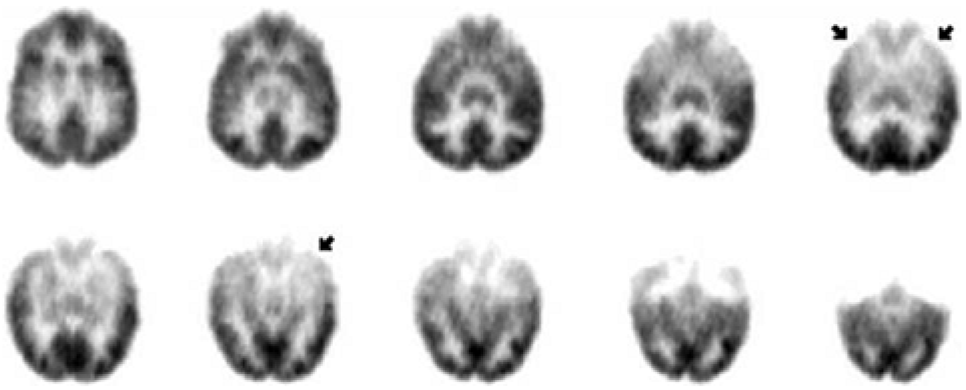

FIGURE 5. Interictal 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a limbic temporal lobe epilepsy (TLE) patient. These images show bilateral mesial temporal hypometabolism (arrows on image at upper right), which is more severe on the left (arrow on image in lower row). The patient's brain magnetic resonance imaging (MRI) showed mild left hippocampal atrophy. Moderate hippocampal sclerosis was present in tissue resected on the side of hypometabolism and of intracranially recorded electroencephalographic (EEG) ictal onsets. Seizures ceased after resection.

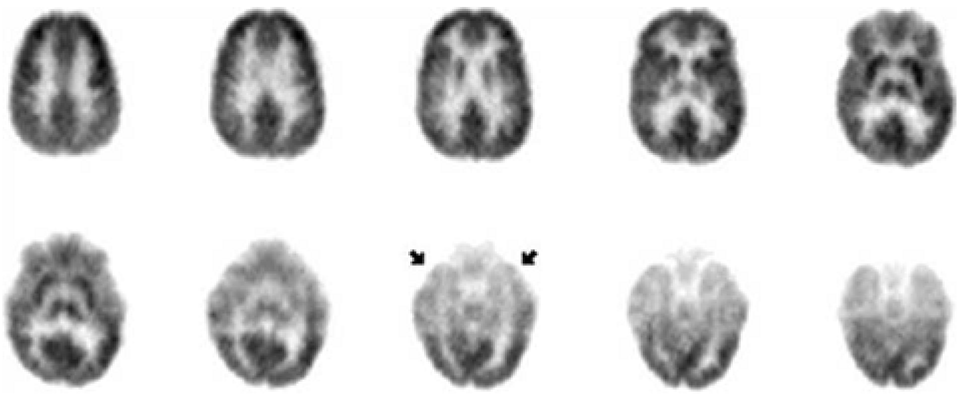

FIGURE 6. Interictal 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a limbic temporal lobe epilepsy (TLE) patient. These images show bilateral mesial temporal hypometabolism (arrows on image at upper right), which is symmetric. The patient's brain magnetic resonance imaging (MRI) was normal. Extracranially recorded electroencephalographic (EEG) ictal onsets were artifactually obscured, in some instances with prolonged right temporal ictal discharges seen in later periods during complex partial seizures. Intracranially recorded EEG ictal onsets occurred independently over each hippocampus in approximately equal numbers. Resective surgery was not performed.

Many TLE patients have unilateral frontal, parietal, thalamic, or basal ganglial hypometabolism ipsilateral to temporal hypometabolism, but occipital hypometabolism is rare in mesial TLE.[3,11,72,74,161,168,186] The temporal hypometabolism is nearly always more severe than is any extratemporal hypometabolism. The thalamus ipsilateral to the affected temporal lobe is the extratemporal site most likely to demonstrate hypometabolism in limbic TLE.[72,74] Thalamic asymmetries in [^{18}F]FDG activity are mainly dorsal (Fig. 4), and in some cases are associated with dorsal thalamic hypovolemia on structural MRI. The ipsilateral putamen is significantly more likely to be interictally hypometabolic in patients whose complex partial seizures involve dystonic posturing than in patients without ictal hemidystonia.[161] The cortical hypometabolic area typically is contiguous across its entire temporal and extratemporal extent (Fig. 4). In particular, the insular and inferior frontal regions are most often the portions of the ipsilateral frontal lobe that are hypometabolic in association with temporal lobe hypometabolism.[3,11,72,137] Bilateral cerebellar hypometabolism is common.[203] Thus, interictal [^{18}F]FDG PET in refractory mesial TLE usually reveals unilateral diffuse regional hypometabolism of one mesial-lateral temporal area, with or without ipsilateral extratemporal cortical hypometabolism or contralateral temporal hypometabolism; ipsilateral extratemporal hypometabolism almost always appears to be less severe than does the temporal lobe hypometabolism.

The pathophysiologic basis of regional hypometabolism imaged with [^{18}F]FDG interictally in TLE is unclear. Ablative structural lesions must contribute to localized decreases in glucose metabolism. Nonetheless, it has been recognized for some time that the volume of hypometabolism is greater than the volume of associated structural lesions in localization-related epilepsies.[39] Acute-subacute cerebral infarction is associated with hypometabolism at the site of neuronal loss, and additional extra-infarctional sites of hypometabolism are considered to represent â€œdiaschisisâ€ as passive and usually impersistent effects of a focal insult on remote brain regions that receive projections from the insulted area. Neuronal loss and diaschisis were considered the causes of the anatomically

P.950

distributed interictal hypometabolism in TLE patients with hippocampal sclerosis. This hypothesis was refuted, however, by a study of quantified preoperative [^{18}F]FDG PET in patients whose resected temporal tissue underwent quantitative neuronal volumetric densitometry.[67] Subsequent studies, using different methodologies, confirmed this observation.[15,33,47,112] Similarly, several studies of MRI volumetry and interictal [^{18}F]FDG PET found that hippocampal atrophy and temporal lobe hypometabolism are not highly correlated in mesial TLE.[53,99,139,205] Furthermore, MR spectroscopic determination of the neuron-specific peaks of *N*-acetylaspartate (NAA) also found limited association of mesial temporal glucose hypometabolism and NAA decreases.[2,97] Although neuronal loss and diaschisis probably cause some of the disseminated glucose metabolic depression in mesial TLE, other factors must also influence regional metabolism interictally. Indeed, surgical ablation of epileptogenic temporal lobe tissue might be expected to increase diaschisis effects on extratemporal glucose metabolism. Instead, comparisons of preoperative and postoperative [^{18}F]FDG scans have shown postoperative increases in [^{18}F]FDG activity of the contralateral temporal lobe and of ipsilateral thalamus and frontal sites.[37,61,183] Several pathophysiologic processes other than diaschisis have been proposed, including reduced transmembrane glucose transport rates and reduced mitochondrial glucose oxidation of viable neurons in sites of ictal onset and habitual propagation.[155,217] On comparing the anatomic distributions of ictal hyperperfusion (using SPECT) and interictal glucose hypometabolism (using [^{18}F]FDG PET) within individual TLE patients, it is evident that many TLE patients have an identical or highly similar distribution of ictal hyperperfusionâ€"interictal hypometabolism that predominates in the temporal lobe and thalamus ipsilateral to the epileptogenic site (including but extending beyond the electrographic ictal onset zone), often with less severe involvement of ipsilateral frontoparietal and basal ganglial sites and of contralateral temporal cortex[76]; one exception is the occipital hyperperfusion often observed in the absence of occipital hypometabolism in TLE. Possibly long-duration postictal dysfunctions may underlie some of the reduction in [^{18}F]FDG activity, as suggested by differential associations of specific distributions of extrahippocampal hypometabolism with specific patterns of electrographic seizure propagation in groups with unilateral hippocampal sclerosis, for example, patients with bitemporal hypometabolism having earlier spread of ictal discharges from one hippocampus to the other.[16,171] Altered energy use in neurotransmitter metabolism might mediate such spatial relationships between ictal dysfunctions and postictal dysfunctions, as suggested by a study using MR spectroscopic determination of the glutamate-glutamine peaks in which localized interictal decreases and ictal increases of [^{18}F]FDG activity and glutamate-glutamine peaks were coupled.[144] Dual pathology undetectable with MRIâ€"specifically, microscopic cortical dysplasia accompanying some but not all cases of hippocampal sclerosisâ€"might generate some of the heterogeneity of [^{18}F]FDG topography in TLE.[32] The diagnostically robust patterns of interictal glucose hypometabolism in TLE are not fully explained by macrostructural, microstructural, and biochemical alterations.

Peri-ictal [^{18}F]FDG PET studies have shown a complex time course of changes in regional cerebral metabolic rate of glucose utilization (CMRGlc) following seizures. In a group of patients with complex partial seizures who had PET at different intervals following the most recent seizure, quantified regional metabolic changes evolved for >48 hours after a single complex partial seizure.[116] The most severe regional hypometabolism occurred >48 hours after the seizure, the least severe hypometabolism occurred at 24 to 48 hours postictally, and metabolism was intermediate in the first 24 hours postictally. In a study in which [^{18}F]FDG studies were performed on average <60 hours after the most recent seizure, the type of seizures that preceded the scan had a strong influence on the regional distribution of hypometabolism.[171] In general, the most localized ictal discharges preceded scans with the smallest volumes of hypometabolism, and secondarily generalized seizures preceded scans with the most widespread patterns of unilateral hypometabolism. In both lesional and nonlesional partial epilepsies, the volume of hypometabolism expands with increasing numbers of seizures over the course of the epilepsy, even with nonprogressive lesions,[88,124] and in limbic TLE, the severity of mesial temporal hypometabolism increases with increasing duration of epilepsy.[209]

Focal mesial temporal *hyper*metabolism sometimes occurs interictally in children with mesial TLE, but it rarely occurs in adults with localization-related epilepsies.[23,41,210] Continuous or repetitive focal mesial temporal seizures, which are subclinical and not detectable with scalp electrodes, may cause â€œinterictalâ€ deep temporal hypermetabolism.[185] Alternatively, there may be interictal epileptogenic processes that are peculiar to childhood and that generate greater glucose metabolism interictally. The latter speculation is encouraged by the presence of interictal regional hypermetabolism in some young children with Sturge-Weber syndrome or with infantile spasms, which does not occur in older children with Sturge-Weber syndrome or with Lennox-Gastaut syndrome (a common â€œendpointâ€ for patients with infantile spasms earlier in life), the older children having exclusively hypometabolism or normal metabolism interictally.

Ictal or peri-ictal (representing mixed ictalâ€"postictalâ€"interictal states during the [^{18}F]FDG uptake period) [^{18}F]FDG scans are difficult to obtain and interpret. True ictal imaging with [^{18}F]FDG is restricted to status epilepticus due to the relatively poor temporal resolution of the [^{18}F]FDG method. Occurrence of a single complex partial seizure during the [^{18}F]FDG uptake period may be associated with the usual interictal findings of unilateral temporal hypometabolism. In one reported case, a partial seizure occurred about 2 minutes after [^{18}F]FDG injection and the scan appeared normal; the same patient later had marked hypometabolism of the epileptogenic temporal lobe on an interictal [^{18}F]FDG scan.[71] Presumably, ictal hypermetabolism was averaged with interictalâ€"postictal hypometabolism over the temporal lobe to cause â€œnormalizationâ€ of [^{18}F]FDG activity on the peri-ictal scan. In another case, a TLE patient had repeated complex partial seizures following [^{18}F]FDG injection, and the scan showed hypermetabolism over the epileptogenic temporal lobe, with ipsilateral frontal and thalamic metabolic increases.[44] Alterations on ictal and peri-ictal [^{18}F]FDG images likely reflect ictal dysfunction at the site of ictal onset, but they also reflect dysfunctions in areas of ictal propagation and interictal and postictal dysfunction in these areas. It is difficult or impossible to sort out the relative contributions of these various dysfunctions to a single set of $[^{18}F]$FDG images.

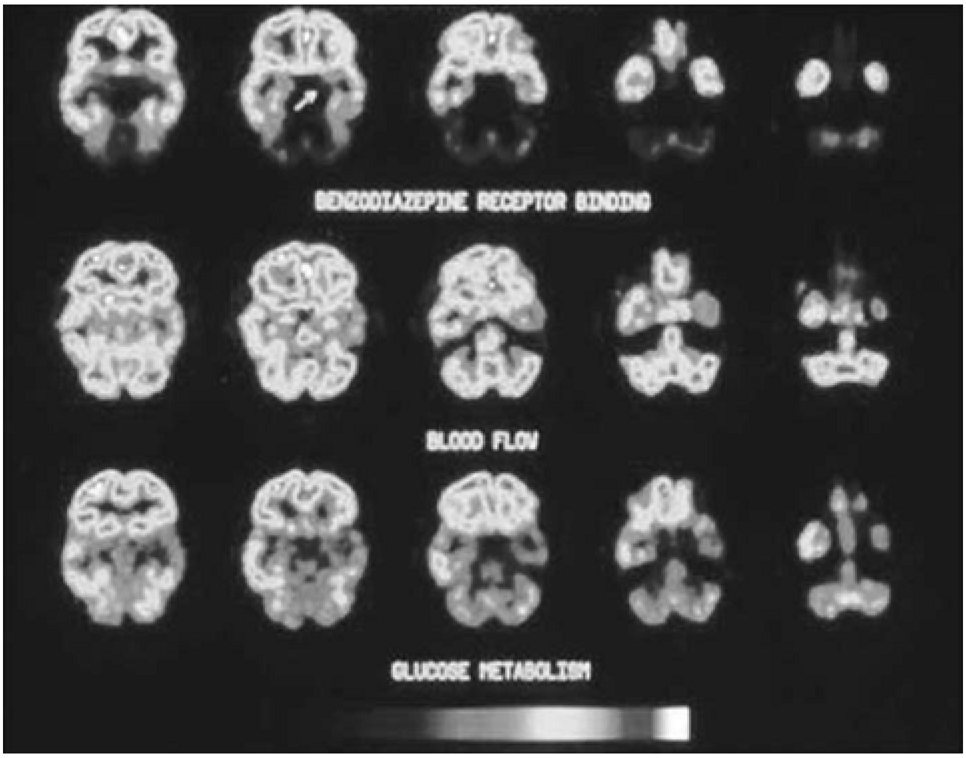

FIGURE 7. Coregistered interictal $[^{11}C]$flumazenil and 2-deoxy-2-$[^{18}F]$fluoro-D-glucose ($[^{18}F]$FDG) positron emission tomography (PET) images of a mesial temporal lobe epilepsy (TLE) patient. Flumazenil transport rate is determined predominantly by regional cerebral blood flow. Flumazenil distribution volume is determined by the regional density of central benzodiazepine receptors. Five adjacent image planes are displayed for each modality. The more superior image plane is to the left of each row. The subject's left is on the right of each image. Images of glucose metabolism and flumazenil transport rate show a widespread left mesial and lateral temporal decrease. Images of flumazenil distribution volume show a highly localized left anterior mesial temporal decrease (*arrow*). The specimen at efficacious temporal lobectomy demonstrated sclerosis of the left anterior hippocampus. (From Henry et al. with permission.) (See the color insert.)

Cerebral glucose metabolism and CBF normally are â€œcoupledâ€ (increasing and decreasing in parallel with changes in synaptic activity within each region of cortex), but interictal PET measurements show uncoupling of CBF and $[^{18}F]$FDG activity in TLE.[53,114] Interictal CBF imaging with PET often shows â€œdiffuseâ€ regional hypoperfusion, consisting of a relatively large area of hypoperfusion with indistinct boundaries from adjacent areas of normal CBF and with inhomogeneous severity of hypoperfusion.[9,48,108,118] Interictal regional CBF decreases often occur predominantly contralateral to the ictal onset zone in mesial TLE.[118,206] Ictal CBF imaging of complex partial seizures with $[^{15}O]H_2O$ is nearly impossible to obtain, given the 2-minute half-life of $[^{15}O]$, except with seizure induction by proconvulsant drugs or during complex partial status epilepticus.[196] For these reasons, ictal imaging and resting

P.951

interictal imaging with $[^{15}O]H_2O$ have no clinical role in presurgical evaluation. It has been suggested, however, that detection of regional glucose metabolicâ€“CBF uncoupling might be more sensitive in detecting epileptogenic tissue than is $[^{18}F]$FDG mapping alone.[226]

Mesial Temporal Lobe Epilepsy: Neuroreceptor and Other Ligand

Studies

Imaging of the GABAergic Inhibitory System in Temporal Lobe Epilepsy

The Î³-aminobutyric acid A ($GABA_A$) receptors in temporal lobe epilepsy have been examined using [^{11}C]flumazenil ([^{11}C]FMZ), a high-affinity, highly selective ligand of central benzodiazepine receptors (BZRs) that are consistently present in the $GABA_A$-receptor complex.[28,62,63,73,90,91,101,102,103,105,162,163,172,173,176,177,178,193,194] The doses of [^{11}C]FMZ required for PET receptor studies do not have detectable pharmacologic effects. The first study in TLE reported averaged imaging data of six patients; it showed unilateral temporal lobe decreases in receptor density that were significantly different from averaged normal control values, whereas calculated receptor affinity was normal.[176] Subsequently, individually quantified [^{11}C]FMZ scans showed that in mesial TLE patients, highly focal decreases in BZR density were usually limited to the anterior mesial temporal lobe.[73,75] Cerebral MRI studies in some of these patients showed significant decrease in hippocampal volume. Quantitative analysis of coregistered [^{11}C]FMZ PET and MRI showed that hippocampal atrophy did not account for the decreased hippocampal BZR density.[73,105,113,193]

Decreased hippocampal BZR density is evident on autoradiography of resected hippocampi in mesial TLE,[14,87] including that resected from patients who had anterior mesial temporal decreases in [^{11}C]FMZ activity on preoperative PET.[102] These autoradiographic observations support the assertion that focally decreased anterior mesial temporal activity on [^{11}C]FMZ PET, in fact, represents a decrease in anterior hippocampal BZR density. Nonetheless, it appears that [^{11}C]FMZ binding on PET studies can be altered by recent or increased seizures shortly before PET data acquisition.[13,177] Such seizure-related temporal changes may not only alter the quantitative measurement of [^{11}C]FMZ PET, but it may also rarely even cause false lateralization of [^{11}C]FMZ PET abnormalities in refractory TLE.[163] Furthermore, developmental changes in the composition and regional density of $GABA_A$ receptor complexes are detectable with [^{11}C]FMZ PET.[18] Many patients who have focal anterior mesial temporal BZR decreases on [^{11}C]FMZ PET are shown on [^{18}F]FDG PET to have widespread temporal and extratemporal hypometabolism (Fig. 7), but TLE patients with mesial temporal [^{11}C]FMZ reductions sometimes have more restricted mesial temporal hypometabolism or normal metabolism interictally.[73,173] In addition to unilateral mesial temporal [^{11}C]FMZ reductions, ipsilateral thalamic, insular, and neocortical regions sometimes show reduced [^{11}C]FMZ binding in mesial TLE.[63,73,91] Although extratemporal [^{11}C]FMZ reductions appear to be less common and less widespread than are [^{18}F]FDG reductions, on comparing these PET modalities in refractory TLE, all of these factors pose complexities in possible clinical application of [^{11}C]FMZ PET.

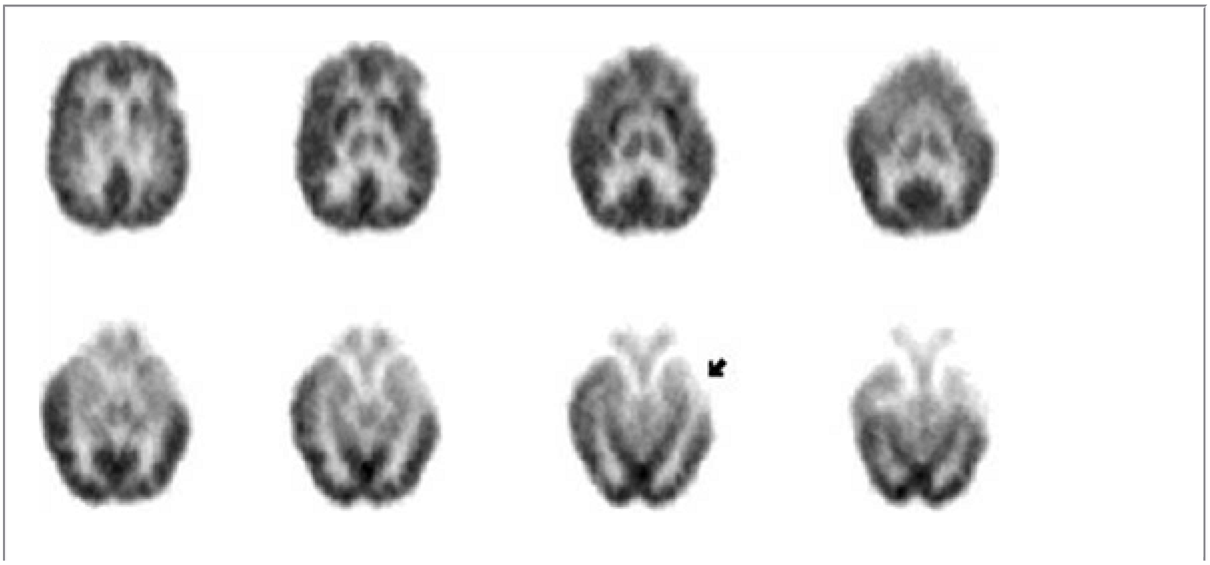

FIGURE 8. Interictal 2-deoxy-2-[^{18}F]fluo-ro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a neocortical temporal lobe epilepsy (TLE patient). These images show severe hypometabolism of the lateral and inferior temporal neocortex (*arrow*), and moderate hypometabolism of the ipsilateral mesial temporal structures. The patient's brain magnetic resonance imaging (MRI) was normal. Focal cortical dysplasia was present in tissue resected at the site of severe hypometabolism and of intracranially recorded electroencephalographic (EEG) ictal onsets. Seizures were reduced by >90% after resection.

Focal BZR decreases in mesial TLE show a high rate of concordance with the ictal onset zone determined by intracranial ictal EEG monitoring and other studies in unilateral TLE, despite the complexities in pathophysiologic interpretation of [^{11}C]FMZ decreases.[28,162] It is important to note that focal mesial temporal [^{11}C]FMZ decreases are detectable and are highly associated with the ictal onset zone in patients whose brain MRI is normal.[101] Although some consider the evidence of clinical utility of [^{11}C]FMZ PET in presurgical evaluation of refractory TLE to be adequately established, widespread clinical application of [^{11}C]FMZ PET in presurgical evaluation has not occurred. Possibly the difficulty in preparing and administering [^{11}C]FMZ with ^{11}C labeling will remain excessive with respect to clinical utility. An exciting possibility is that an ^{18}F analogue of [^{11}C]FMZ such as [^{18}F]fluoroethylflumazenil[119] will have similar accuracy in central BZR imaging to that of

P.952

[^{11}C]FMZ and will be less expensive to use in clinical settings. This compound is biochemically distinct from [^{11}C]FMZ, however, and so full safety and other validation studies will be required before large-scale clinical trials can be planned.

Imaging of the Excitatory Amino Acid System in Temporal Lobe Epilepsy

Glutamatergic excitation may be expected to increase during partial-onset seizures, but one PET study suggested that TLE patients might have decreased *N*-methyl-D-aspartate (NMDA) receptor density at the ictal onset zone. Binding at the NMDA receptor was reduced in the epileptogenic temporal lobe of patients studied with [^{11}C]ketamine and PET.[110] This study did not determine, however, whether this regional reduction in [^{11}C]ketamine retention was due to reduced receptor density, reduced receptor affinity for ketamine, or higher regional endogenous ligand concentration. Furthermore, the kinetic modeling did not determine the tracer input function, and so reduced regional blood flow might account for the observed local reduction in [^{11}C]ketamine binding. At this time, it cannot be stated with certainty that [^{11}C]ketamine PET has fully established the existence of decreased NMDA receptor density in epileptogenic hippocampus.

Imaging of the Opiate System in Temporal Lobe Epilepsy

Opiate receptors have been imaged in TLE with several ligands selective for different receptor subtypes. Mu-opiate receptor activity, measured with [^{11}C]carfentanil PET, frequently demonstrates marked increases in [^{11}C]carfentanil binding over the lateral temporal neocortex.[52] Amygdalar and hippocampal [^{11}C]carfentanil binding shows a smaller increase.[125] Lateral temporal glucose metabolism and [^{11}C]carfentanil binding have a significant inverse relationship.[52] Combined Âµ- and Îº-opiate receptor binding, measured with [^{18}F]cyclofoxy PET, also has shown greater mesial and lateral temporal binding on the epileptogenic side.[200] Combined Âµ-, Îº-, and Î´-opiate receptor binding, measured with [^{11}C]diprenorphine PET, shows no asymmetry among various temporal regions in unilateral TLE.[125] Thus, different opiate receptor subtypes appear to have differentially distributed binding alterations in TLE. The relevance of these complex findings to epileptogenesis and the interictal behavioral disturbances of TLE have not been clarified.

Imaging of Other Neurochemical Systems in Temporal Lobe Epilepsy

Serotonin synthetic capacity has been imaged in TLE patients, using [^{11}C]Î±-methyl-L-tryptophan and PET.[135] Serotonin-1Aâ€“receptor binding has been imaged in TLE patients, using PET with

2â€²-methoxyphenyl-[(*N*-2â€²-pirydynyl)-*p*-[^{18}F]fluorobenza-midoethylpiperazine ([^{18}F]MP-PF),[128,129] with [^{18}F]*trans*-4-fluoro-*N*-2-[4-(2-methoxyphenyl)piperazin-1-yl]ethyl]-*N*-(2-pyridyl)cyclohexanecarboxamide ([^{18}F]FCWAY),[214] and [*O-methyl*-^{11}C]-*N*-(2-(4-(2-methoxyphenyl)-1-piperazinyl) ethyl)- *N*- (2-pyridinyl) cyclohexanecarboxamide trihydrochloride **(**[^{11}C]WAY100635).[174]

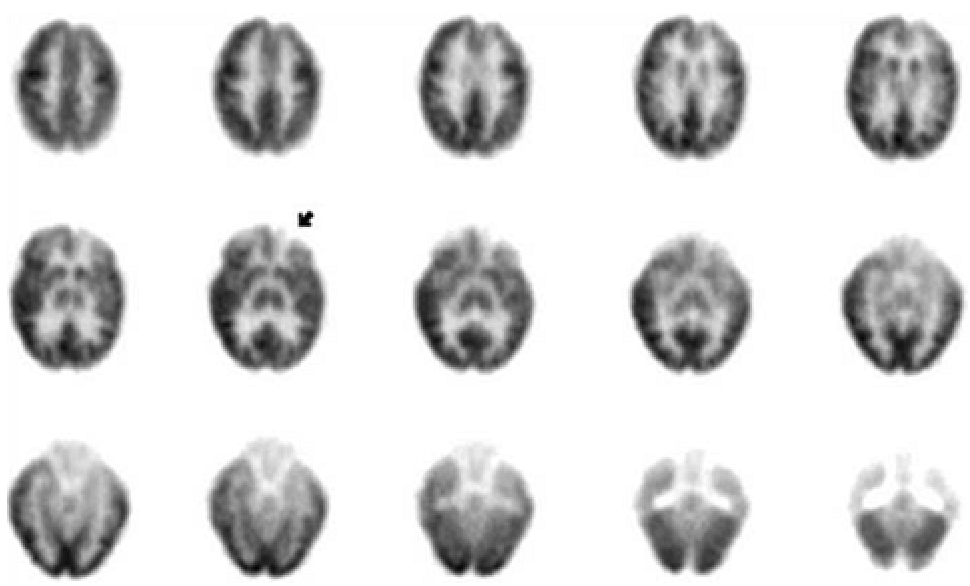

FIGURE 9. Interictal 2-deoxy-2-[^{18}F]fluo-ro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a lesional frontal lobe epilepsy patient. These images show a left frontopolar FDG defect (*arrow*) and left anterior temporal hypometabolism. The patient's brain magnetic resonance imaging (MRI) was normal within the anterior temporal lobes but showed an apparent cavernous malformation of the left frontal pole. Extracranially recorded electroencephalographic (EEG) ictal onsets showed left temporal maxima. Intracranially recorded EEG ictal onsets showed earliest changes near the MRI lesion, with rapid propagation to the ipsilateral temporal lobe and delayed spread contralaterally. Seizures ceased after resection of a histopathologically confirmed cavernoma.

Muscarinic cholinergic receptor density has been imaged in TLE patients, using [^{11}C]*N*-methyl piperidyl benzilate and PET.[143] Muscarinic receptors were reduced predominantly over the anterior mesial temporal lobe, in a distribution similar to that of BZR decreases imaged with [^{11}C]flumazenil PET.[143]

Hippocampal sclerosis causes increased local deprenyl binding (at the monoamine oxidase B sites on glia), which can be detected with [^{11}C]deuterium-deprenyl and PET.[109]

Other Localization-related Epilepsies

Interictal [^{18}F]FDG PET often demonstrates a region of pathologic hypometabolism in adults and children with refractory partial seizures of extratemporal origin or of neocortical (extralimbic) temporal origin.[60,61,71,78,151,186,189,202] In patients with a single neocortical site of ictal onset, interictal [^{18}F]FDG PET usually demonstrates a single region of hypometabolism (Fig. 8), but normal metabolism also is frequently observed. Compared with nonlesional limbic TLE, nonlesional neocortical epilepsies are much more likely to have normal interictal [^{18}F]FDG PET studies.[78,152] Interictal focal neocortical areas of *hyper*metabolism may occur in early childhood epilepsies[23] but have not been reported in adults. In many lesional neocortical epilepsies, the hypometabolic region is small, sharply circumscribed, and colocalized with a focal structural lesion detected with MRI (Fig. 9); a similar relationship of â€œmatchingâ€ focal PET hypometabolism and focal MRI lesion rarely is observed in limbic TLE.[78] Many individuals with lesional or nonlesional neocortical localization-related epilepsies have a more widespread hypometabolic zone, which has graded transitions from areas of severe hypometabolism to areas of normal metabolism, similar to patterns of hypometabolism in limbic TLE. When associated with a lesion, a diffuse hypometabolic area of neocortex often is much larger than any associated

structural imaging abnormality and than any histopathologic lesion (Fig. 8), as also is observed in limbic TLE. In the absence of a structural lesion on MRI, the volume of diffuse regional hypometabolism sometimes is fairly small in neocortical epilepsies. Larger areas of hypometabolism often include mesial temporal, thalamic, and basal ganglial hypometabolism ipsilateral to the neocortical site of hypometabolism. Hypometabolism over an entire hemisphere is rare, as is symmetric bilateral hypometabolism, in unilateral neocortical epilepsies. The degree of hypometabolism usually varies across a region of diffuse hypometabolism. The zone of most severe hypometabolism, excluding the site of a foreign-tissue lesion, usually contains the electrophysiologically defined ictal onset zone.[71]

Children with frontal lobe epilepsies may demonstrate interictal frontal hypometabolism more often than do adults with frontal lobe epilepsies. When onset of frontal lobe seizures is in the neonatal period or in infancy, an underlying structural lesion is almost always present, even when the MRI is normal. Under these circumstances, [^{18}F]FDG PET can be quite useful in defining an area of hypometabolism that correlates both with the extent of microdysgenesis[24] and with the area of epileptogenicity.[141]

Ictal and peri-ictal [^{18}F]FDG imaging during simple partial seizures of neocortical frontal origin demonstrate patterns of increased and decreased (or normal) [^{18}F]FDG uptake, which likely reflect neuronal activity at the site of ictal onset, in areas of ictal spread, and in regions involved in postictal depression. Epilepsia partialis continua can be associated with a small volume of cortical hypermetabolism or hypometabolism when the ictal discharge remains limited, or more diffuse unilateral cortical and thalamic hypermetabolism or hypometabolism when intrahemispheric spread occurs.[43,44,48,59] In one patient with epilepsia partialis continua manifested as left arm and leg clonus, right frontal hypermetabolism and other bilateral regions of hypermetabolism were present.[43,44] In other cases of epilepsia partialis continua, [^{18}F]FDG scans have revealed focal frontal hypermetabolism with ipsilateral thalamic or contralateral cerebellar hypermetabolism or widespread hypometabolism without detectable areas of hypermetabolism. In several patients with epilepsia partialis continua, [^{15}O]O_2 scans showed increased blood flow, increased oxygen metabolism, and decreased oxygen extraction fraction in widespread areas of one cerebral hemisphere, which was contralateral to the focal motor seizure; frontal lobe abnormalities were quantitatively more severe than those of other regions.[48]

Partial epilepsy of motor cortex origin was studied with [^{11}C]flumazenil PET interictally.[176] The activity of the likely epileptogenic zones, averaged over sets of images in three subjects in this early study, was interpreted as showing decreased central benzodiazepine receptor density but normal receptor affinity. The contralateral frontal areas and extrafrontal areas on either side showed apparently normal receptor density and affinity. In a more recent report of [^{11}C]flumazenil PET, each of six patients who had intracranial EEG localization to the frontal lobe were reported to have focal BZR decreases in the ictal onset zone.[179] A patient with occipital seizures had decreased benzodiazepine receptor density limited to the epileptogenic occipital lobe.[176] Lesional and nonlesional partial epilepsies of extralimbic origin consistently demonstrate FMZ abnormalities as reductions in FMZ activity except for malformations of cortical development, which may demonstrate either increased or decreased FMZ binding.[64,88,133,156,157,158,159]

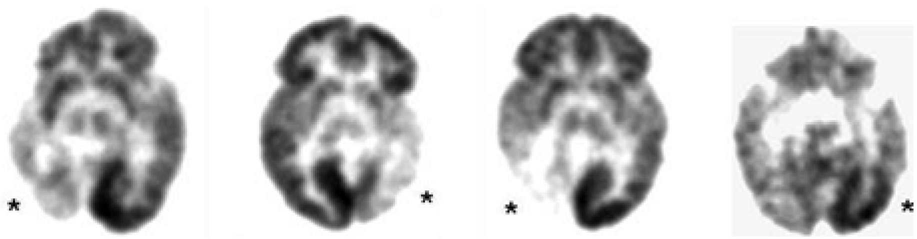

FIGURE 10. Interictal 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of four patients with Sturge-Weber syndrome. These transaxially oriented images show considerable variability in extent and severity of hypometabolism of cortex underlying the vascular malformation in three patients (*single asterisks*). A fourth patient had paradoxical hypermetabolism interictally in cortex underlying the malformation (*double asterisks*).

Sturge-Weber Syndrome

The Sturge-Weber syndrome of unilateral encephalotrigeminal angiomatosis is highly associated with partial epilepsy, although some have secondary generalized epilepsy or no seizures. In children and adults with advanced Sturge-Weber syndrome, PET typically reveals unilateral diffuse regional hypometabolism ipsilateral to the facial nevus (Fig. 10) in a distribution that extends beyond the abnormalities depicted on computed tomography (CT) or MRI. As the cerebral injury progresses during childhood in this condition, early periods of unilaterally increased [^{18}F]FDG activity give way to profound and extensive unilateral hypometabolism.[115,145] In contrast, infants with Sturge-Weber syndrome and recent seizure onset show a paradoxical pattern of increased glucose utilization in the cerebral cortex of the anatomically affected hemisphere on interictal PET.[22] Metabolism appears to correlate with the course of progressive cerebral dysfunction in some Sturge-Weber patients (Fig. 11). In Sturge-Weber syndrome patients with refractory epilepsy, PET has been useful both in guiding the extent of focal cortical resection (i.e., correlating better with intraoperative

P.954

electrocorticography than with CT or MRI) and in assessing candidacy for early hemispherectomy.[22] Children with cutaneous anomalies similar to those of Sturge-Weber syndrome but without intracranial angiomas have normal cerebral [^{18}F]FDG PET.[22] Thus, PET provides a sensitive measure of the extent of early cerebral involvement in Sturge-Weber syndrome patients, a means of monitoring disease progression, and information useful in guiding resective surgery.

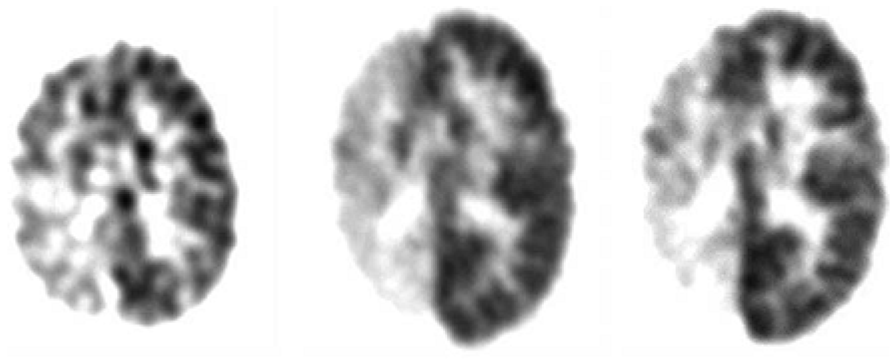

FIGURE 11. Serial 2-deoxy-2-[^{18}F]fluoro-D-glu- cose ([^{18}F]FDG) positron emission tomography (PET) images of a patient with Sturge-Weber syndrome. These transaxially oriented images, which were acquired interictally at the indicated ages, demonstrate progression from mild to severe hypometabolism diffusely over the involved hemisphere. Despite severe right hemispheric metabolic dysfunction, the cognitive outcome was good.

Idiopathic Generalized Epilepsies

Presurgical evaluations with PET have not been used to exclude primary generalized epilepsy patients from consideration of surgery because clinical histories and interictal and ictal scalp EEG recordings usually have established the diagnosis. Even when history and EEG might not entirely distinguish atypical primary generalized epilepsy from secondary generalized epilepsy, interictal [^{18}F]FDG imaging would not be helpful. Interictal [^{18}F]FDG studies are normal in primary generalized epilepsies.[45,140,199] Some patients with symptomatic generalized epilepsies and some with localization-related epilepsies also have normal interictal [^{18}F]FDG imaging,[21,75,211] and so the finding of normal interictal cerebral glucose metabolism is not useful in syndromic classification.

On the other hand, thalamic CBF is increased to a greater extent than is cortical CBF during absence seizures studied with [^{15}O]H_2O and PET.[148]

Interictal [^{11}C]flumazenil PET detected significantly decreased central benzodiazepine receptor densities within the thalami and significantly increased receptor densities within deep cerebellar nuclei bilaterally but normal receptor densities in cerebral cortex, cerebellar cortex, and basal ganglia in eight primary generalized epilepsy patients.[104,149,150,175,180]

Combined Âµ-, Îº-, and Î´-opiate receptor density was normal in all brain regions interictally in eight childhood and juvenile absence epilepsy patients who had [^{11}C]diprenorphine PET.[147] During absence seizures, endogenous opiate release was shown to be increased, based on displacement of [^{11}C]diprenorphine, but the increase was limited to frontoparietotemporal association cortex and did not involve visual or sensorimotor cortex or the thalamus.[7] Serotonin-1Aâ€"receptor binding has been imaged in juvenile myoclonic epilepsy patients, using PET with [^{11}C]WAY100635.[130]

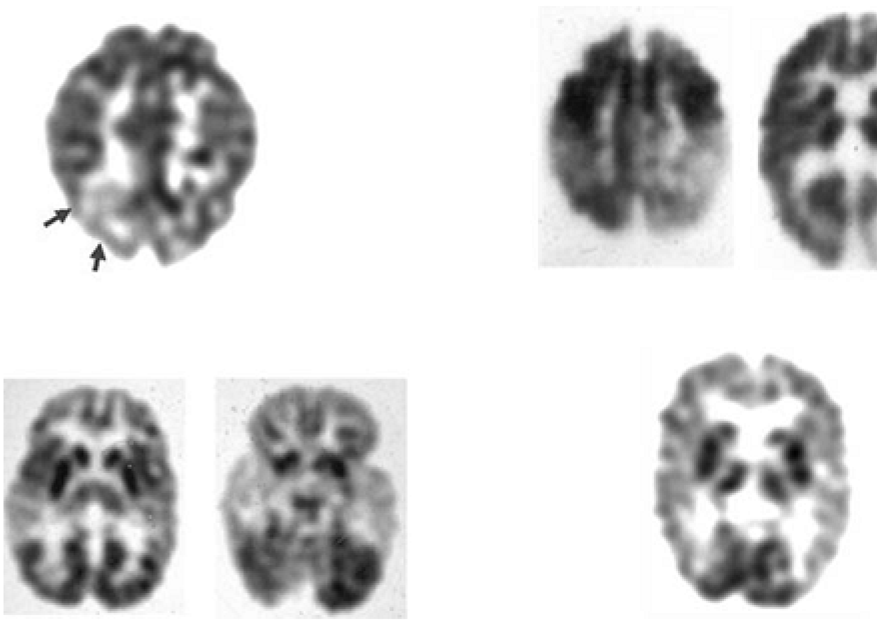

FIGURE 12. Interictal 2-deoxy-2-[^{18}F]fluo-ro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of West syndrome patients. These fours sets of transaxially oriented images, acquired in four different patients, demonstrate the most common spatial distributions of interictal metabolic dysfunction in patients with refractory infantile spasms. The unifocal pattern occurs in about 20% of patients and is the only pattern associated with consistently good epilepsy and developmental responses to surgical intervention. The multifocal, bitemporal, and generalized patterns occur in approximately 65%, 10%, and 5% of patients, respectively. The bitemporal pattern is more strongly associated with autism, whereas the generalized pattern is more associated with neurogenetic syndromes, than are the other patterns.

Lennox-Gastaut Syndrome

Patients with the Lennox-Gastaut syndrome usually have multiple regions of bilateral cortical hypometabolism interictally on [^{18}F]FDG scans, but they sometimes have predominantly unilateral hypometabolism (Fig. 10) when pati-ents with structural lesions are included.[21,58,85] When only Lennox-Gastaut patients with no lateralizing findings on neurologic examination and with normal cranial x-ray CT scans were imaged with [^{18}F]FDG interictally, most patients had symmetric generalized cortical and thalamic hypometabolism, although a few had symmetric generalized cortical hypermetabolism.[211]

A series of 32 children with â€œcryptogenic epileptic encephalopathies,â€ which presumably included mainly children with symptomatic generalized epilepsies, demonstrated generalized metabolic dysfunction in most cases (usually hypometabolism, but hypermetabolism in some), regional metabolic dysfunction in some cases, and normal metabolism in only 2 cases.[46] The [^{18}F]FDG scans in this series detected thalamic hypometabolism in 90% of cases, which was usually bilateral, but thalamic metabolism was lower on the side of more severe cortical hypometabolism.

P.955

Mutations causing deficiency of the glucose transporter Glut1 result in epilepsy and developmental delay. In these patients, the cortex and thalami show generalized reduction in [^{18}F]FDG activity on PET but relatively high [^{18}F]FDG activity in the basal ganglia.[142] In the presence of normal brain MRI, this peculiar [^{18}F]FDG pattern should lead to genetic studies in early symptomatic epilepsy.

Unilateral focal or multifocal sites of hypermetabolism during sleep, with more nearly normal cerebral glucose metabolism during waking, are typical of electrical status of slow wave sleep.[123] The sites of metabolic dysfunction mainly were found in association cortex. This childhood syndrome of continuous generalized spike-and-wave discharges during slow wave sleep, usually with dementia or progressive aphasia, and with clinically evident epileptic seizures, thus provides another example of a symptomatic generalized epilepsy in which generalized EEG phenomena are associated with focal or multifocal cortical metabolic dysfunction.

Infantile Spasms

Patients with infantile spasms have been extensively studied with [^{18}F]FDG imaging in both research applications and presurgical evaluation. Unilateral cortical metabolic dysfunctions (hypo- or hypermetabolism) are relatively common in West syndrome[19,20,25,27] (Fig. 12). Bitemporal hypometabolism is less common, occurring in approximately 15% of infants with spasms in Chugani's series. In this series, bitemporal hypometabolism was never associated with a single predominant zone of structural imaging or electrophysiologic abnormality, and so surgery was never performed; most of these infants later developed autism.[20] (Bitemporal hypometabolism also has been reported in autistic children who had partial status epilepticus early in life,[31] but these children had evidence of hippocampal sclerosis on MRI.) By contrast, approximately 20% of infants with refractory spasms had [^{18}F]FDG studies showing unilateral cortical regions of metabolic dysfunction; those who underwent unilateral cortical resection, which usually included large volumes of cortex, often had cessation of seizures and normal or near-normal cognitive development.[26] In a recent study, [^{18}F]FDG PET showed prognostic value following initial therapy of West syndrome, in that patients who had normalization of earlier cerebral [^{18}F]FDG abnormalities on initiation of medical therapy were later observed to have better seizure control and less developmental delay than were those with persisting cerebral [^{18}F]FDG abnormalities.[86]

Many infants with West syndrome have both unilateral cortical metabolic dysfunction, and bilateral lenticular and brainstem metabolic dysfunction.[25] Chugani hypothesized that infantile spasms begin with a focal cortical abnormality, which induces brainstem activities that are projected symmetrically to the basal ganglia and spinal cord.[25] This theory is consistent with the observations that infantile spasms are generalized from onset and that unilateral cortical resection can result in cessation of the spasms.[27] Such patients often have cortical dysplasias in resected tissue, and in some of these cases, brain MRI did not detect the malformation.[26]

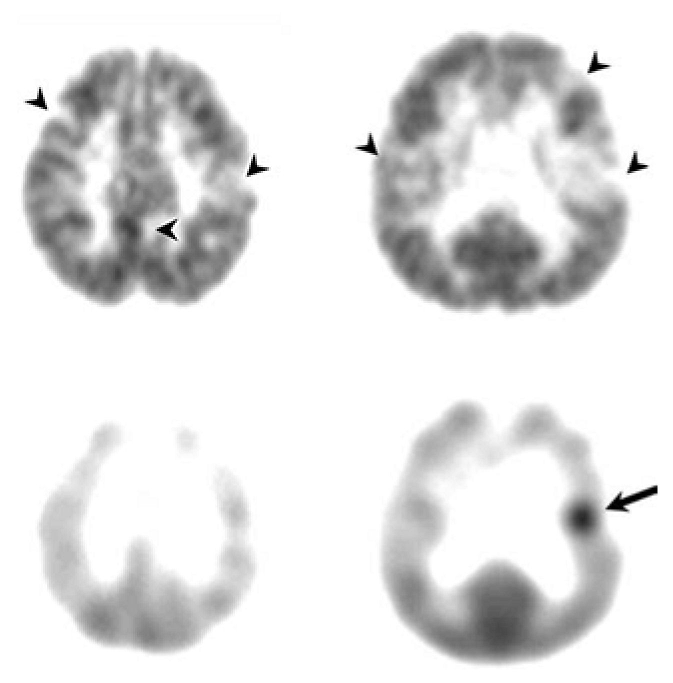

FIGURE 13. Interictal 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) and [^{11}C]Î±-methyl tryptophan ([^{11}C]AMT) PET images of a patient with tuberous sclerosis. These transaxially oriented images show multiple foci of glucose hypometabolism (*arrowheads*) and a single site of increased [^{11}C]AMT activity (*arrow*) in a patient with refractory seizures. The image planes are coregistered at higher **(left)** and lower levels **(right)**. Resection of cortex at the site of increased AMT uptake resulted in improved seizure control.

High-resolution PET tomographs permit detection of focal cortical regions of decreased or increased glucose utilization in many infants who previously were diagnosed as having idiopathic West syndrome. Chugani reported a series of 140 cases of infantile spasms, including 7 who had neurogenetic syndromes and 29 who had lesions on structural imaging; among the patients without lesions or neurogenetic syndromes, [^{18}F]FDG imaging detected regional metabolic dysfunction at one cortical site in 30 cases and at multiple cortical sites in 62 cases.[19] The patients in this study were biased by referral pattern toward infants with refractory spasms and without a structural lesion on MRI. Nonetheless, one might logically conclude that infantile spasmâ€"associated malformations of cortical development are more likely to be detected as metabolic dysfunction than as structural lesions during infancy. Chugani suggested that in infants the normal absence of myelination of subcortical white matter may render MRI less sensitive in detecting subtle neuronal heterotopia and other dysplastic features compared with the high MRI sensitivity to dysplasias in children and adults with completed myelination.

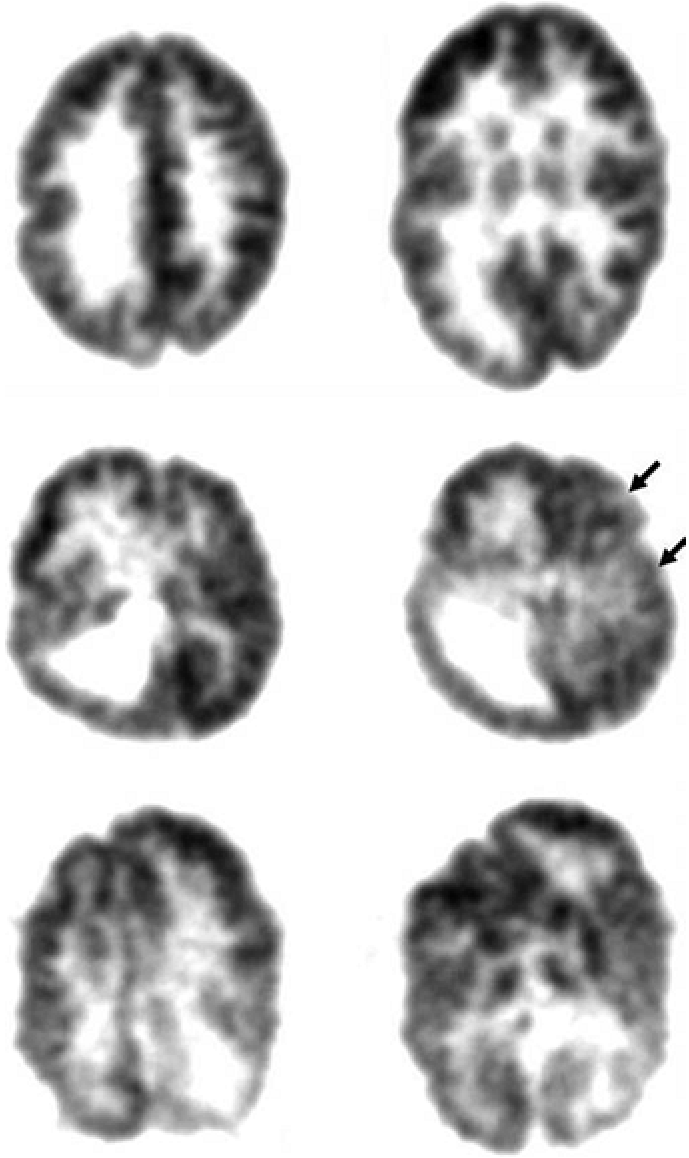

FIGURE 14. Interictal 2-deoxy-2-[[18]F]fluoro-D-glucose ([[18]F]FDG) positron emission tomography (PET) images of three patients with hemimegalencephaly. These transaxially oriented images show marked variability in extent and severity of hypometabolism within the malformed hemisphere (the right hemisphere in the first two cases, shown as a pair of images for each patient, on the upper and middle rows, and on the left hemisphere for the third patient, on the lower row). The second patient (middle row) also has mild hypometabolism of the frontotemporal opercular area (*arrows*). The third patient (lower row) also has marked hypometabolism diffusely over the contralateral hemisphere. The subject's left is on the right of each image.

Tuberous Sclerosis

Cortical tubers in tuberous sclerosis appear as hypometabolic areas (Fig. 13) on the interictal PET scan,[191] presumably due to the simplified dendritic arborization within tubers. When the PET study is performed ictally, the tuber is seen as a hypermetabolic zone. Some hypometabolic regions on PET do

not correspond to abnormalities on CT and MRI scans and may either represent small tubers or be related to epileptogenic mechanisms.

Î±-Methyl tryptophan with ^{11}C labeling often demonstrates one tuber that has increased serotonin synthetic function among other tubers with decreased serotonin synthesis.[17,89]

Other Childhood Epilepsy Syndromes

Hemimegalencephaly is a rare developmental brain malfor-mation characterized by congenital hypertrophy of one cerebral hemisphere and ipsilateral ventriculomegaly. The distribution of glucose metabolic dysfunction on [^{18}F]FDG PET is quite variable across different patients with hemimegalencephaly (Fig. 14). When the epilepsy is medically uncontrolled, cerebral hemispherectomy is recommended. Irrespective of seizure control postoperatively, however, hemimegalencephalic children, as a group, have a worse developmental outcome than children who have been hemispherectomized for Sturge-Weber syndrome or chronic focal encephalitis of Rasmussen. PET studies of cerebral glucose metabolism have indicated that the worse developmental outcome in hemimegalencephaly is related to the presence of focal areas of cortical dysfunction in the remaining hemisphere and that preoperative assessment of the integrity of the less affected hemisphere with PET may provide important prognostic information with regard to cognitive outcome, despite seizure control.[160]

An [^{18}F]FDG PET study during sleep in three children with acquired epileptic aphasia (Landau-Kleffner syndrome) confirmed the general notion that this condition is heterogeneous. Metabolic disturbances consisting of hypermetabolism or hypometabolism were seen during sleep in the temporal lobes and were right-sided, left-sided, or bilateral.[122]

Research in Therapeutic Mechanisms

Antiepileptic drug (AED) research using PET techniques has mainly focused on mechanisms of AED toxicity and to a lesser extent on AED kinetics and AED effects on specific neurochemical systems.[65] Several PET investigations also have examined effects of vagus nerve stimulation and of resective epilepsy therapy on CBF or glucose metabolism.

Mechanisms of adverse or unintended effects of specific therapies have been studied with PET in healthy and epileptic individuals. Barbiturates, benzodiazepines, phenyt-oin, carbamazepine, and valproate globally depress absolute values of cerebral metabolic rate for glucose without significant regional variability in reduction of [^{18}F]FDG

P.957

activity.[117,197,198,201,204,218,222] Phenobarbital depresses cerebral glucose metabolism to a greater degree than does valproate, and carbamazepine and phenytoin have lower effects on cerebral glucose metabolism when these AEDs were in chronic steady state at serum levels commonly used in clinical practice. The severity of thalamic hypometabolism induced by lorazepam has been shown to correlate significantly with the degree of drowsiness induced by the drug.[218] Valproate causes global cerebral decrease in CBF, but thalamic CBF is decreased to a greater degree than is cortical CBF.[56] The basis of relatively greater thalamic (than cortical) hypoperfusion due to valproate effect is unclear, as is the question as to whether other AEDs would show a similar pattern. Another [^{18}F]FDG PET study suggested that severe AED intoxication might cause enduring ataxia and cerebellar hypometabolism, although groups of patients with and without histories of AED intoxication were studied with PET only many years after the episodes of intoxication.[181]

Cerebral kinetics of phenytoin and of valproate were mapped using ^{11}C-labeled AED and PET. Following intravenous administration, [^{11}C]phenytoin rapidly entered cerebral gray matter and equilibrated within 20 minutes on dynamic PET imaging.[4] The early kinetics of [^{11}C]phenytoin did not differ between the epileptogenic region and its contralateral homologue. No other AEDs have been similarly studied. Intravenously administered [^{11}C]valproate was distributed equally to gray and white matter in a flow-dependent fashion in primate PET studies, but kinetic modeling did not fully determine the radiotracer input function, and therefore valproate-specific distribution parameters could not be calculated.[153]

The effects of AEDs on GABAergic and serotonergic systems have been reported. Chronic valproate therapy was associated with generalized cerebral decreases in [^{11}C]flumazenil binding, but interictal [^{11}C]flumazenil activity was normal in patients with absence seizures who were receiving AEDs other than valproate.[149] This observation suggests that valproate may act to increase cerebral endozepine concentration, which would reduce the availability of central benzodiazepine receptors to bind flumazenil at the $GABA_A$â€“chloride ionophore complex; reduced affinity of the receptor for flumazenil or reduced neuronal expression of the receptor (or of the entire $GABA_A$ complex) is less likely to explain the association of valproate use and [^{11}C]flumazenil activity reduction. Chronic phenytoin, carbamazepine, valproate, lamotrigine, oxcarbazepine, and levetiracetam use did not appear to be associated with altered serotonin-1Aâ€" receptor affinity for [^{18}F]FCWAY or of the cerebral density of serotonin-1A receptors[207]; however, several AED exposures significantly altered the free serum fraction of [^{18}F]FCWAY to an extent that PET measures of cerebral serotonin-1Aâ€“receptor binding would be rendered inaccurate in the absence of mathematical modeling to correct for this effect.

Mechanistic studies of therapeutic vagus nerve stimulation (VNS) have used [^{18}F]FDG PET in rodent studies[29] and CBF PET in humans to map sites of VNS-induced activation and deactivation of synaptic activity.[68,69,79,100] Acute VNS-activation PET studies (performed within the first 24 hours after VNS therapy began) found synaptic activations in the dorsal medullary complex of the vagus, the central pons and midbrain, inferior cerebellum, hypothalami, and thalami, and also showed a combination of activations and deactivations in amygdalae, hippocampi, insulae, and other neocortical sites bilaterally.[69] Somatosensory system responses to VNS were unilateral, as might be expected in patients experiencing exclusively left-sided cervical paresthesias during VNS. Chronic VNS-activation PET studies (performed after 3 months of ongoing VNS therapy) showed synaptic activations in the same brainstem, cerebellar, and diencephalic sites as were observed acutely, but cortical effects were markedly reduced on chronic as compared with acute CBF imaging.[68] Acute VNS-activation PET findings were compared with response to seizures during 3 months of VNS without AED changes.[79] Patients who had greater bilateral thalamic activation went on to experience significantly greater seizure reduction during VNS than those who had little or no thalamic activation. In this study other sites of acute VNS-induced CBF changes also tended to occur more often in VNS responders, but these trends did not achieve statistical significance. Chronic VNS-activation PET studies also showed that bilateral thalamic activation was significantly associated with greater seizure reduction.[68] The metabolic mapping in rodent studies produced rather different findings than observed in human CBF mapping of VNS effects, although numerous differences in the study conditions are apparent.[29] Two functional MRI (fMRI)-based studies found greater seizure reduction in patients who had greater thalamic CBF activation during VNS.[120,134] The PET and fMRI studies suggest that VNS acutely and chronically alters thalamic processing in some way so as to antagonize partial-onset seizures.

Effects of epilepsy surgery on cerebral function have been studied by comparing preoperative and postoperative [^{18}F]FDG PET imaging within individuals. Among patients who become seizure free following anterior temporal lobectomy, [^{18}F]FDG activity increases in the contralateral (unresected) temporal lobe and in the ipsilateral thalamus and frontal cortex.[37,61,183] Similarly, after efficacious temporal resection in several patients who had preoperative FMZ PET, relative increases in FMZ binding at sites of earlier seizure propagation were found.[172] These observations are highly relevant to understanding the pathophysiology of hypometabolism and altered GABAergic physiology interictally in TLE, as discussed earlier, but have yet to be adequately explored in relevance to postoperative improvements in cognition and other cerebral functions.

Presurgical Evaluation

Planning Surgery of Localization-related Epilepsies

Single regions of interictal hypometabolism on [^{18}F]FDG PET are highly associated with the region that can be resected to control seizures in localization-related epilepsies. In the syndrome of medically refractory limbic TLE, strong support for anterior temporal resection *without* prior intracranial EEG monitoring is provided by the presence of most severe dysfunction in one temporal lobe on interictal [^{18}F]FDG PET if other noninvasively acquired data support this localization. Specifically, unilaterally predominant hypometabolism supports temporal resection in the absence of intracranial EEG recordings when (a) extracranial EEG recordings show temporal ictal onsets exclusively on the side of functional imaging abnormality, (b) MRI is normal, or nonspecifically abnormal, as in the case of puncta of subcortical white matter abnormalities, or MRI shows hippocampal atrophy, malformation of cortical development, or foreign-tissue lesion or encephalomalacia in the same temporal lobe, and (c) other noninvasively acquired data are not discordant with this localization.[40] When brain MRI is normal in the syndrome of refractory mesial TLE, interictal [^{18}F]FDG PET can detect temporal lobe hypometabolism.[15,72,98] In the syndrome of limbic TLE, when interictal [^{18}F]FDG PET shows most severe abnormality in one temporal lobe, this does not alone establish that all seizures are arising from that temporal lobe (as discussed later). Thus, intracranial EEG is necessary when [^{18}F]FDG or ictal CBF abnormalities are not supported by ictal extracranial EEG localization and when [^{18}F]FDG or ictal CBF abnormalities contradict other localizing abnormalities.

In extratemporal epilepsies and in localization-related epilepsies that cannot be fully characterized by electroclinical manifestations, ictal CBF and interictal [^{18}F]FDG abnormalities cannot be used to determine the margin of cortical resection but can be used with other data to determine sites that should be monitored with intracranial electrodes.[78,182] Current evidence demonstrates that PET and SPECT data are not redundant with electrophysiologic data nor with structural imaging data. These functional imaging modalities sometimes provide evidence of falsely localized extracranial ictal EEG data or evidence that EEG and MRI falsely suggested unifocal ictal onsets in patients who actually have two independent ictal onset zones.[77] The cost effectiveness of performing one of these functional imaging modalities in all patients before resective epilepsy therapy is unknown. Based on the available information, it is reasonable to perform either interictal [^{18}F]FDG PET or ictal/interictal SPECT in all patients with localization-related epilepsies before resective surgery, in addition to ictal recordings with extracranial EEG, MRI, and neuropsychometric studies.

Unilateral temporal lobe hypometabolism is â€œfalsely lateralizedâ€ (located contralateral to the intracranially recorded site of ictal onset in patients with single ictal onset zone) in approximately 1% to 2% of patients in series in which potential sources of imaging artifact and unreliable forms of quantitative analysis were excluded. Prior intracranial surgery, including depth electrode placement, can produce temporal hypometabolism that is falsely lateralized with respect to intracranially recorded temporal lobe ictal onsets and to the side of subsequent, efficacious resection.[40] Imaging artifacts also can be produced by unrecognized errors in cranial positioning, errors of improperly aligned images in attenuation correction, and other aspects of imaging; visual image analysis should be used to exclude these artifacts prior to any automated quantitative image analysis. Volume-of-interestâ€“based quantitative analysis should sample regions whose volumes are in the range of the usual volume of the interictally hypometabolic area of TLE, and techniques that do not use predefined volumes of interest, such as statistical parametric mapping, should use a volume threshold to avoid detection of potentially misleading, tiny foci of statistically significant hypometabolism, at least for application in presurgical evaluation. Continuous EEG monitoring can be performed during [^{18}F]FDG scanning and sometimes can exclude unintentional ictal scanning that could lead to misinterpretation of [^{18}F]FDG images.[71] Sperling et al.[185] reported a patient who did not have subjective or objective clinical changes or scalp EEG changes during â€œinterictalâ€ [^{18}F]FDG scanning, which appeared to show falsely lateralized temporal hypometabolism. In fact, the scan probably showed correctly lateralized ictal hypermetabolism. Subsequent intracerebral recordings showed frequently recurrent seizures confined to one hippocampus (without subjective or objective behavioral change and without scalp EEG change). Visual interpretation relies on detecting asymmetry, and so hypermetabolism on one side may appear to represent hypometabolism on the other side. Sperling suggested that relative quantification of temporal lobe and occipital lobe metabolism might support distinction of temporal hypermetabolism on one side from temporal hypometabolism on the other side. As is true of all noninvasive means of localizing the epileptogenic zone, presurgical application of interictal [^{18}F]FDG PET in partial epilepsies should be limited to correlation with other studies used to regionalize the ictal onset zone.

Cerebral MRI is essential in detection of hippocampal sclerosis, neoplasia, vascular malformations, other foreign-tissue lesions, ablative lesions, and malformations of cortical development.[36,111] Cerebral structural abnormalities are highly but not completely correlated with the epileptogenic zone. In some cases, a small foreign-tissue lesion may be located distant from the ictal onset zone, although most cerebral lesions are located near ictal onset zones, and this topographic relationship is especially strong in the case of cavernomas. In cases of a large area of encephalomalacia, porencephaly, or cerebral maldevelopment, the ictal onset zone may be much smaller than the lesion; even when extracranial EEG recordings suggest that the ictal onset zone is near the lesion, it often is not desirable or necessary to resect the entire lesion when the exact location of the ictal onset zone is unclear; sometimes such lesions are distant from the region of ictal onset. In groups of patients with tuberous sclerosis and other conditions with longstanding multifocal lesions, individual patients can have a single ictal onset zone, multiple independent ictal onset zones, or even generalized-onset seizures. Optimal choice of intracranial electrode placements is necessary for successful localization of the electrophysiologic ictal onset zone when noninvasive data do not suffice. Interictal metabolic and ictal perfusion information may be combined with other data to direct intracranial electrode placement to sites of possible ictal onset.[131] Regional hypometabolism or ictal hyperperfusion can suggest otherwise unsuspected possible sites of ictal onset to avoid intracranial monitoring procedures that record ictal propagation patterns but fail to record earliest ictal onset patterns (evidenced by absence of ictal discharges recorded during earliest behavioral manifestations). The absence of any hypometabolism obviously does not rule out localization-related epilepsy. Similarly, regional hypometabolism strongly suggests that seizures may begin somewhere within the region of hypometabolism, but it does not rule out multiple areas of ictal onset both within and beyond the hypometabolic cortex. Many epilepsy surgery programs offer temporal resection to a patient who has refractory complex partial seizures with semiology characteristic of mesial TLE, without prior physiologic imaging or intracranial EEG monitoring, if the patient has unilateral temporal lobe spikes interictally and ictal onsets on extracranial EEG and has hippocampal atrophy or specific mesial temporal lesions ipsilaterally on MRI, in the absence of contradictory information on neuropsychometric or other standard studies. In some programs, confirmatory information is sought with interictal [^{18}F]FDG PET or ictal SPECT in such a patient, although no detailed costâ€“benefit analysis of this additional physiologic imaging has been reported.

Unilateral temporal hypometabolism has been reported in patients who have bilateral independent hippocampal ictal onsets recorded with intracranial electrodes during habitual complex partial seizures, and most of these patients also had exclusively unilateral MRI abnormality.[48,77] Furthermore, ictal scalp-sphenoidal EEG recordings are much more likely than are MRI or PET images to show evidence of bilateral TLE among patients who subsequently have intracranial recording of bilateral independent hippocampal ictal onsets during complex partial seizures.[77] Alternatively, some patients who had bilateral independent temporal ictal onsets on extracranial EEG with unilateral temporal abnormalities on MRI and PET or on PET only have been shown to have exclusively unilateral hippocampal intracranial EEG onsets that were on the side of the imaging abnormality (and of efficacious temporal lobectomy). On the other hand, bilateral hippocampal atrophy on MRI sometimes is observed in patients who have unilateral temporal hypometabolism interictally, unilateral hippocampal ictal onsets, and good surgical outcome.[98] All focal ictal onset patterns on extracranial EEG, all focal cerebral gray matter lesions on MRI, and all regions of cortical hypometabolism on PET should be considered when planning intracranial electrode placements.

Imaging of ictal CBF with SPECT and imaging of interictal CMRGlc with PET have similar roles in evaluations for epilepsy surgery. Both ictal CBF SPECT and interictal [^{18}F]FDG

P.959

PET can detect definite abnormalities when structural ima-ging is normal or nonspecifically altered.[80,81,94,164,166,184,188,223] Overall sensitivity and specificity of ictal SPECT and interictal [^{18}F]FDG PET are similar in large series of partial epilepsies; studies of the two techniques in the same sets of patients report sensitivity to functional abnormality of >70% (and usually â‰«70%), with specificity to the ictal onset zone >90%.[12,80,84] In fact, a relatively greater sensitivity of ictal SPECT (over [^{18}F]FDG PET) in detecting extratemporal epileptogenic zones may be obscured in series that include all forms of partial epilepsy, due to the predominance of temporal lobe epilepsy over other partial epilepsies and to the profound glucose metabolic dysfunctions of temporal lobe epilepsy. Quantitative statistical image analysis may significantly increase the sensitivity and specificity of [^{18}F]FDG PET in detecting evidence of neocortical (lateral) temporal and extratemporal ictal onset zones compared with standard clinical interpretation.[95,96]

Interictal regional hypometabolism also is useful in predicting the outcome of temporal resection with respect to seizures. Greater severity of preoperative hypometabolism of the resected temporal lobe is associated with significantly better postoperative seizure control, using either qualitative or quantitative definitions of severity of hypometabolism.[30,38,121,138,151,169,212,213,224] The high correlation of temporal hypometabolism and seizure outcome is independent of the pathologic diagnosis. Uncal or temporal pole metabolism, analyzed quantitatively, may provide the most accurate correlation with seizure outcome.[38,121] Qualitatively severe *extra*temporal cortical or thalamic hypometabolism, however, is associated with a higher incidence of postoperative seizures.[136,190] Symmetric, severe, bilateral temporal hypometabolism also is associated with a higher incidence of postoperative seizures, even when other data suggest that all seizures originate in one temporal lobe.[10] A site of reduced [^{18}F]FDG activity that is distinct and noncontiguous with a cavernous angioma is highly associated with recurrent seizures after lesionectomy.[107,165] Temporal lobe hypometabolism contralateral to intracranially recorded ictal onsets also is reportedly associated with recurrent seizures after resections of the electrophysiologically defined focus,[8] although individual cases with good outcome of resection contralateral to temporal lobe hypometabolism have been reported.[132] Interictal CBF imaging with [^{15}O]H_2O PET is not useful in predicting seizure outcome.[206]

Cognitive activation CBF PET or [^{18}F]FDG PET studies might be useful in predicting the outcome of temporal resection with respect to language and memory function, although fMRI has the potential to do so without exposure to ionizing radiation. Both activation PET and fMRI appear likely to be able to lateralize hemispheric language specialization.[51,69,221] Specific deficits of delayed recall may be associated with severity and distribution of glucose hypometabolism interictally in TLE.[82,154,170] These [^{18}F]FDG PET abnormalities, however, have not been used to provide the presurgical memory prognostication afforded by the Wada test.[57,81,170] Full application of activation PET or fMRI in presurgical evaluation will require many studies to determine the answers to many areas of uncertainty, including the following issues: (a) whether fMRI techniques can be developed to permit speech-related cranial motion during imaging, and whether it is essential to assess patient effort with analysis of verbal responses (given that patients may not comply with instructions during silent cognitive task performance, as apparently do paid, healthy volunteers in studies of normal cognitive activation), (b) how results of activation PET and fMRI compare with current clinical tools such as the Wada test and direct cortical electrical stimulation mapping, and (c) whether modification of resection based on functional imaging results actually improves functional outcome of surgery.

In the future [^{11}C]flumazenil PET and, in patients with tuberous sclerosis, [^{11}C]Î±-methyl tryptophan (AMT) PET, may prove useful for noninvasive determination of the epileptogenic zone when concordant with other data. The more focal distribution of the [^{11}C]flumazenil PET abnormality than the [^{18}F]FDG PET abnormality and the specificity of increased [^{11}C]AMT activity for epileptogenic tubers are particularly attractive in these potential applications. Randomized clinical trials have not been completed to evaluate these potential applications.

Planning Surgery of Symptomatic Generalized Epilepsies

Single regions of interictal hypometabolism on [^{18}F]FDG PET are highly associated with the region that can be resected to control seizures in West syndrome, Sturge-Weber syndrome with generalized-onset seizures, and other secondary generalized epilepsies of early childhood.[24,25,26,27] In addition to the generalized interictal and ictal EEG phenomena, these early childhood secondary generalized epilepsies frequently have focal scalp EEG abnormalities,[26] which often correspond to the PET focus in patients with infantile spasms. When a single region of abnormal glucose utilization is apparent on PET corresponding to the EEG focus and the seizures are intractable, surgical removal of the PET focus results not only in seizure control, but also in complete or partial reversal of the associated developmental arrest. This is in contrast to the expectation of moderate to severe retardation based on preoperative developmental decline.

Neuropathologic examination of the resected tissue in West syndrome in patients who underwent surgery reveals that the epileptogenic zone is typically a previously unsuspected area of cortical dysplasia.[26,27] It is recommended that any patient considered to have cryptogenic medically refractory infantile spasms following extensive evaluation, including metabolic studies and structural neuroimaging, should have a PET study of glucose metabolism. About 20% of these refractory cases will show a single focal lesion and be candidates for cortical resection. The remainder will show multifocal abnormalities on PET, usually corresponding to bihemispheric epileptogenicity on the EEG.

In Sturge-Weber syndrome patients with refractory epilepsy, PET has been useful both in guiding the extent of focal cortical resection (i.e., correlating better with intraoperative electrocorticography than CT or MRI) and in assessing candidacy for early hemispherectomy.[22] Children with cutaneous anomalies similar to those of Sturge-Weber syndrome but without intracranial angiomata have normal cerebral [^{18}F]FDG PET. Thus, PET provides a sensitive measure of the extent of early cerebral involvement in Sturge-Weber syndrome patients, a means of monitoring disease progression, and information useful in guiding resective surgery.

Normal metabolism or complex regional metabolism bilaterally on [^{18}F]FDG PET might be proposed as indirect support for corpus callosotomy. Further investigation will be required to establish a specific role for PET in precallosotomy evaluation.

Summary and Conclusions

Positron emission tomography permits in vivo measurement and whole-brain anatomic mapping of a wide variety of brain functions in healthy and epileptic individuals. Glucose metabolic imaging has revealed unexpected patterns of interictal cerebral dysfunction in most forms of epilepsy. In localization-related epilepsies, the zone of interictal metabolic

dysfunction is often more lateralized than is interictal electrophysiologic dysfunction, but it is typically much larger than the electrophysiologically determined ictal onset zone and larger than any associated structural lesion. Mesial temporal reductions in central benzodiazepine receptors exceed the degree of hippocampal atrophy and only rarely extend beyond the anterior mesial temporal regions in mesial TLE. Mu-opiate receptor density is increased over the entire temporal lobe in mesial TLE. In patients with infantile spasms, focal cortical dysplasias are often associated with unilateral cerebral metabolic dysfunction and with bilateral lenticular nuclear and brainstem dysfunction. This suggests that the cortical dysfunction influences the brainstem and lenticular nuclei symmetrically to account for the generalized spasms and hypsarrhythmic EEG. In absence epilepsies, cerebral metabolism and opiate receptor density are normal interictally. During absence seizures, metabolic increases are generalized, but increased endogenous opiate release is limited to frontoparietotemporal association cortex. In tuberous sclerosis with partial-onset seizures, epileptogenic tubers often demonstrate significantly greater serotonin synthesis than is present in nonepileptogenic tubers. Cerebral blood flow PET imaging revealed that bilateral thalamic activation was associated with antiseizure effects of vagus nerve stimulation. These and other PET findings have expanded our understanding of neurochemical alterations and interictal disturbances in human epilepsies and to some extent have elucidated therapeutic mechanisms.

Interictal metabolic imaging with [^{18}F]FDG PET has been extensively applied in presurgical evaluations of refractory seizures. Primary clinical applications have been correlative with ictal electrophysiologic and structural magnetic resonance findings for the following purposes:

1. Increasing certainty that the ictal onset zone has been accurately determined by noninvasive studies prior to anterior temporal lobectomy, hemispherectomy, or multilobar resection.
2. Optimizing selection of intracranial electrode placement sites for ictal monitoring.
3. Prognostication with regard to seizure control.

With further clinical trials, PET imaging and other functions may support future applications in planning epilepsy surgery.

Introduction

One of the primary goals of neuroimaging in epilepsy is to identify the epileptogenic zone. The epileptogenic zone is the focus of the brain that is necessary and sufficient to generate seizures, and the focus that, when resected, would render the patient seizure free. The phenomenon of increased blood flow at the time and location of seizure activity has long been observed and studied.[13] Single photon emission computed tomography (SPECT) is a functional imaging test that can provide a semiquantitative map of cerebral blood flow changes associated with the epileptogenic zone. The SPECT radiotracer is rapidly taken up by the brain within 40 to 60 seconds after its injection.[25] When the radiotracer is injected during seizure activity (ictal SPECT), it can provide a â€œsnap shotâ€ of the transient hyperperfusion at the region of the focal seizure activity. This is the major advantage of ictal SPECT because it can image the dynamic ictal state, unlike other imaging modalities, such as positron emission tomography (PET) and magnetoencephalography (MEG), which give information about the static interictal state. If the seizure had ended by the time the radiotracer is injected (postictal SPECT), blood flow SPECT can image the pattern of intensely reduced perfusion that is frequently present for a few minutes at the seizure.[28] Furthermore, the radiotracer can also be administered during the interictal nonseizure state (interictal SPECT) to image the pattern of persistent but low-grade hypoperfusion that is detectable at some seizure foci.

An additional advantage of SPECT is that it is widely available and relatively inexpensive to perform. A cyclotron is not required for the production of SPECT radiotracers. Therefore, blood flow SPECT has been an important tool for localizing the seizure focus for epilepsy surgery. It has also been used to detect seizure spread patterns in different forms of epilepsy. This chapter discusses the principles, techniques, and clinical applications of blood flow SPECT studies and interpretation in epilepsy evaluation.

Radiotracers for Blood Flow Single Photon Emission Computed Tomography

The acquisition of images by the SPECT camera is based on the detection and localization of an internal source of Î³-energy rays emitted by the radiotracer that has been administered to the patient.[25] The basic images acquired by the camera when it is stationary in one position are termed planar images. Modern SPECT technique uses computer-aided mathematical reconstruction of multiple planar images taken at different rotational angles to produce a series of thin cross-sectional two-dimensional images of a three-dimensional object.

The properties of a radiotracer that is ideal for SPECT imaging in epilepsy are as follows:

1. Stability for at least several hours in vitro, without need for further reconstitution, so that it can be ready near the patient for immediate intravenous injection as soon as seizure activity is detected.

2. Rapid brain uptake that is linearly proportional to blood flow at all physiologic and pathologic blood flow rates and minimal backdiffusion after uptake. This ensures that the relative concentration of the radiotracer (and therefore the intensity of the Î³ radiation emitted) will closely reflect the relative regional cerebral blood flow.
3. Minimal extracerebral uptake and rapid blood clearance, thereby maximizing the contrast between cerebral and noncerebral structures.

Although no currently available radiotracer completely fulfils these criteria, modern blood flow SPECT radiotracers are compounds that have high first-pass brain extraction and are rapidly metabolized to hydrophilic compounds, so that back-diffusion is minimal. Therefore, the radiotracers become trapped in the brain in an amount that is closely proportional to the regional cerebral blood flow at the time of their uptake. Two technetium-based radiotracers have been in widespread clinical use in epilepsy studies: ^{99m}Tc-HMPAO (hexamethyl propylene-amine-oxime) and ^{99m}Tc-ECD (ethyl cysteinate dimer). The principal disadvantage of ^{99m}Tc-HMPAO is that it is chemically unstable in vitro and it has to be used within 30 minutes of preparation. Therefore, the radiotracer has to be reconstituted immediately prior to its injection. Preparing the radiotracer delays its injection when the onset of a seizure is recognized. Because ^{99m}Tc-HMPAO was the radiotracer used in most early SPECT studies in epilepsy, results of those studies are not comparable with those of more recent studies that used stabilized ^{99m}Tc-HMPAO or ^{99m}Tc-ECD, both of which do not require reconstitution immediately prior to their injection.[16] ^{99m}Tc-HMPAO has relatively high uptake in the extracerebral soft tissues (10%â€“30%) and a slow urinary clearance of 40% in 48 hours.[42] This results in poor cerebral-to-extracerebral contrast, which makes extraction of the brain surface for surface matching coregistration algorithms particularly difficult. ^{99m}Tc-ECD has been observed to have better brain-to-background contrast. There is controversy, however, regarding the superiority of one radiotracer over the other in sensitivity for detecting the seizure focus.[1,18,32]

Interictal Blood Flow Single Photon Emission Computed Tomography

Earlier SPECT studies in patients with intractable partial epilepsy were interictal studies. For interictal SPECT, the radiotracer should ideally be injected following a seizure-free

period of at least 24 hours and without immediate postinjection seizure activity, including that of auras. Concurrent electroencephalographic (EEG) recording during the radiotracer injection is ideal for ensuring that the SPECT study is truly interictal, although it is not routinely practiced. The injection should be performed in a quiet room with the lights dimmed and the patient calm, to minimize the activation of cerebral regions by environmental factors.

Results of interictal SPECT studies varied widely among different institutions, with reported sensitivity ranging from 36% to 96% and specificity from 36% to 94%.[14,30,50,53] Most studies have a small number of patients. Comparing the results of different series is difficult because of the wide variation in patient population, SPECT instrumentation, type of radiotracer used, concurrent EEG monitoring, and the criteria for determining the correct localization (i.e. EEG, magnetic resonance imaging [MRI], pathology, or surgical outcome). Spencer[50] combined the results of 23 series of interictal blood flow SPECT studies in 539 patients and found sensitivity of 66% and specificity of 68% for lateralizing temporal lobe seizures to the side localized by ictal scalp EEG. Devous et al.[6] performed a meta-analysis of 13 series of interictal SPECT studies in 247 patients and found a mean sensitivity of 44% and a false-positive rate of 7.4%. These results are lower than those for PET or volumetric MRI.[41]

Interictal SPECT is particularly disappointing in nonlesional epilepsy and extratemporal epilepsy patients. Interictal SPECT studies using ^{99m}Tc-HMPAO correctly localized the epileptogenic zone in only 20% to 47% of nonlesional temporal lobe epilepsy (TLE) patients.[41,44,50] Many studies of interictal SPECT in extratemporal epilepsy found poorly localizing results.[17,22,51] In a study that used ^{99m}Tc-HMPAO in pediatric frontal lobe epilepsy (FLE) patients, only 9% had focal hypoperfusion that corresponded to EEG or MRI abnormality.[9] Similarly, Ho et al.[11] found that interictal SPECT was localizing in only 4 of 14 parietal lobe epilepsy patients, compared with localizing ictal SPECT finding in all of the patients. It is now generally accepted that the main role of interictal SPECT images is as a baseline for comparison with ictal SPECT images.[6]

Peri-ictal Cerebral Blood Single Photon Emission Computed Tomography

Peri-ictal SPECT studies include both ictal and postictal SPECT studies. Attempts at ictal injection of the radiotracer might not always be successful, and the seizure might have ended by the time the radiotracer is injected. Earlier reports of peri-ictal SPECT in the literature consist mostly of postictal SPECT studies. Immediate injection of the radiotracer during seizure activity was impractical because of the need to reconstitute older radiotracers and the lack of continuous video-EEG monitoring for prompt recognition of seizure onset. The radiotracer injection technique has now been refined, however, to allow earlier injection times in the ictal or immediate postictal period, and video-EEG monitoring is now widely available. It is well known that earlier ictal injection time improves the sensitivity and the specificity of SPECT in localizing the seizure focus, particularly in extratemporal epilepsy, in which seizures are often brief in duration but rapid in their spread to other regions of the brain.[7,26]

Technique of Peri-ictal Single Photon Emission Computed Tomography Injection

It is essential that the peri-ictal SPECT injections be performed while the patient is undergoing video-EEG monitoring. Interpretation of the perfusion patterns on the SPECT images requires knowledge of the injection timing relative to the clinical and EEG seizure activity. The dose of ^{99m}Tc to be injected is typically 20 mCi for either HMPAO or ECD. Accurate calibration of the radioactive decay dose is needed to ensure that the correct dose is administered.[24] All persons who handle the radiotracer must have formal training on safe handling of radioactive materials. If the patient has childbearing potential, a pregnancy test must be performed. An intravenous indwelling catheter is inserted to provide ready access for injecting the radiotracer. The catheter must be checked regularly to ensure patency. Ideally, the person responsible for injecting the radiotracer must be experienced in recognizing on the video-EEG screen, the clinical and the EEG manifestations of seizure activity. The radiotracer is then injected immediately into the indwelling intravenous catheter. The person injecting the radiotracer must indicate the instant when the plunger of the syringe is completely depressed and the radiotracer has been completely injected. One way to indicate this time of injection is to say â€œinâ€ so that the timing of the injection relative to the time of the seizure onset can be determined accurately by reviewing the video-EEG recording. The catheter is then immediately flushed with intravenous normal saline, and the injected extremity is elevated to help clear the radiotracer from the injection site into the systemic circulation.

There are other factors that enhance the likelihood for successful ictal SPECT injection. The number of hours in a day when the injection could be performed is often determined by the availability of the radiotracer and the staff in the video-EEG, nursing, and nuclear medicine departments. Radioactivity half-life of SPECT radiotracers requires that the radiotracer be replenished every few hours. The chance of injecting during a seizure is hampered if the injection and subsequent scan can be done during only a limited of hours in the day. To increase the likelihood of seizure occurrence so that ictal SPECT can be accomplished, antiepileptic drugs (AEDs) are often withdrawn and the patient deprived of sleep. Triggers of seizures can be employed if the precipitants of habitual seizures are known.

SPECT injection is problematic in patients whose seizures occur usually during sleep at night when the SPECT procedure is typically not available. One strategy for addressing this situation is to have the patient stay up at night and sleep in the daytime or at a time when it is possible to do the SPECT study. If seizure frequency is high, as is the case of many FLE patients, arrangements can be made for the staff and the radiotracer to be at the patient's bedside for immediate SPECT injection when a seizure occurs. This arrangement is especially important when seizures are brief, as often is the case with FLE. It is also preferable to inject during a seizure without secondary generalization because the sensitivity of ictal SPECT is reduced by seizure generalization.[31,38] Because the likelihood of seizure generalization is increased by AED withdrawal, AEDs should be withdrawn more cautiously if the patient's history suggests that habitual seizures have a tendency to generalize.

Peri-ictal Single Photon Emission Computed Tomography Perfusion Patterns

To be able to recognize focal ictal or postictal perfusion changes that are attributable to the seizure activity, ictal or postictal SPECT images have to be compared with interictal SPECT images. Peri-ictal SPECT studies in TLE have shown a characteristic pattern of evolving blood flow changes at the site of seizure activity (Fig. 1). Ictal blood flow changes consist of focal hyperperfusion at the mesial and anterolateral regions

of the temporal lobe.[7,28] Within 1 to 5 minutes following the termination of seizure activity, the lateral temporal neocortical region becomes intensely hypoperfused while the mesial temporal region remains slightly hyperperfused. Over the next few minutes, the hypoperfusion becomes more diffuse in both the lateral and the mesial temporal areas. The pattern of conversion from ictal hyperperfusion to postictal hypoperfusion has been termed â€œpostical switch.â€[28] The degree of this focal hypoperfusion gradually lessens over the next 15 minutes or so until it reaches the interictal state of mild hypoperfusion.

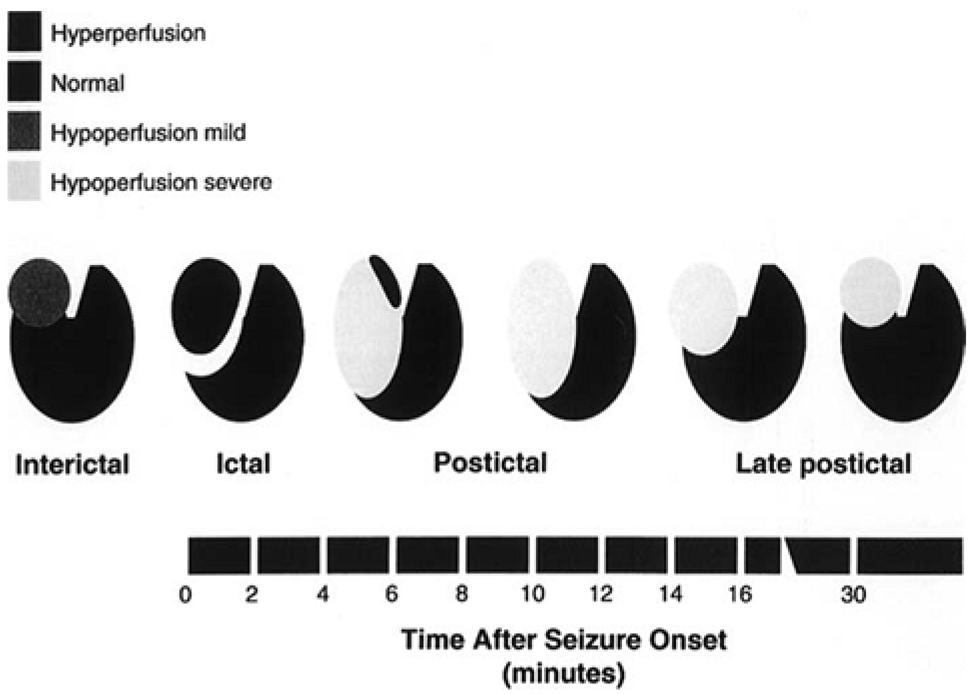

FIGURE 1. Single photon emission computed tomography of temporal lobe seizures according to timing of the radiotracer injection in relation to epileptic seizure activity. (From Rowe C, Berkovic S, Austin M, et al. Patterns of postictal cerebral blood flow in temporal lobe epilepsy: qualitative and quantitative analysis. *Neurology*. 1991;41:1096â€“1103, with permission.)

The timing of the postictal switch cannot be accurately predicted. Postictal switch of perfusion may occur earlier in extratemporal seizures that are short in duration, but SPECT studies are still useful for these seizures if seizure activity persists for 10 to 15 seconds after the injection. Therefore, it is prudent to look for both focal hyperperfusion and hypoperfusion abnormalities regardless of the timing of the radiotracer injection relative to the seizure onset.

Techniques in Single Photon Emission Computed Tomography Image Analysis and Interpretation

Clinical interpretation of peri-ictal SPECT studies typically requires comparison of the peri-ictal (ictal or postictal) SPECT images with the interictal SPECT images. The comparison has conventionally been made by side-by-side visual comparison of the images, but more modern methods use computer-aided techniques for image analysis, display, and interpretation. One method subtracts the interictal from the peri-ictal images and then registers the difference image on the MRI image (subtraction SPECT). Another method statistically compares the degree of peri-ictal perfusion changes in the patient with control values derived from aggregates of interictal studies or nonepileptic volunteer studies (statistical parametric mapping [SPM]).

Conventional Single Photon Emission Computed Tomography Analysis and Interpretation

Clinical Usefulness of Conventional Ictal Single Photon Emission Computed Tomography Studies

Several studies have demonstrated the superiority of ictal SPECT studies over interictal SPECT studies in lateralizing seizure onset in patients with known temporal lobe epilepsy. Sensitivity reported for ictal SPECT in these patients ranged from 75% to 97%, whereas specificity ranged from 71% to 100%.[10,50,53] Devous et al.[6] conducted a meta-analysis of series of peri-ictal SPECT studies that met the following criteria: (a) localization-related epilepsy with at least interictal EEG-documented epileptiform abnormality, (b) at least six adult patients in each series, and (c) a study population that is not highly selected. Only three series with total of 51 patients met the criteria, of whom 42 were from one institution.[22,27,51] The calculated sensitivity for ictal SPECT for TLE in these studies was 96% with a false-positive rate of 1.5%, but Devous et al. cautioned that the number of patients in each series is small.

Most older series of peri-ictal SPECT studies involved patients whose TLE focus had been well localized with interictal scalp EEG, ictal video-EEG, or MRI. The outcome of epilepsy surgery in these patients would be expected to be very good. For new diagnostic tests such as SPECT to have an important role in the presurgical evaluation of partial epilepsy patients, they must provide localizing information that is additional to that provided by current standard tests. This is particularly important in patients with extra-temporal lobe epilepsy, nonlesional epilepsy, or poorly localized seizures.[48,52,55] Surgical outcome in these patients is often poor. Ictal SPECT has been reported to have a sensitivity of 81% to 95% and specificity of about 93% in extratemporal epilepsy.[9,50] Ho et al.[11] found that ictal SPECT localized seizures in all 14 patients with parietal lobe epilepsy. Using ictal SPECT to guide intracranial EEG studies, Siegel et al.[45] obtained good postsurgical seizure outcome in 83% of patients with nonlesional epilepsy. In a

P.968

study by Markand et al.,[21] ictal SPECT correctly lateralized the EEG focus in 87% of MRI-negative patients, compared with 82% with PET. Therefore, ictal SPECT appears to have a useful role in identification of the nonlesional epileptogenic zone.

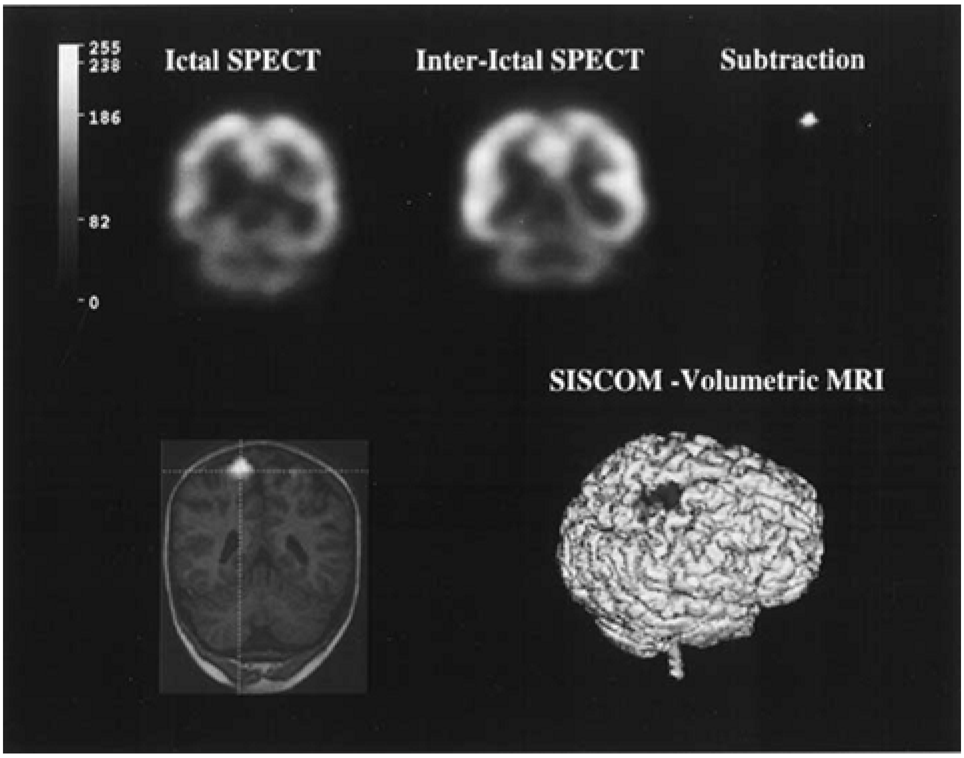

FIGURE 2. Steps to obtaining subtraction ictal SPECT (single photon emission computed tomography) coregistered to MRI (magnetic resonance imaging) (SISCOM) image. Ictal (*upper left*) and interictal (*upper middle*) SPECT images are obtained. After normalization of their mean intensities and coregistration with each other, subtraction is performed to obtain a â€œdifferenceâ€ image (*upper right*). The difference image is then coregistered with MRI at specific planes (*lower left*) or on the surface of a three-dimensional MRI (*lower right*). (From So E. Role of neuroimaging in the management of seizure disorders. *Mayo Clin Proc*. 2002;77:1251â€“1264, with permission.) (See the color insert.)

Clinical Usefulness of Conventional Post-ictal Single Photon Emission Computed Tomography Studies

Clinical interpretation of postictal SPECT is more difficult than that of ictal SPECT.[7,29,40] Most studies have reported a lower sensitivity and specificity for postictal SPECT in lateralizing TLE than for ictal SPECT, although the sensitivity and specificity are still better than those for interictal SPECT.[6,29,50] Meta-analysis involving four series of postictal SPECT studies in 69 patients showed sensitivity of 75% and false-positive rate of 1.5%, but most series had a small number of patients.[6]

Subtraction Single Photon Emission Computed Tomography With Magnetic Resonance Imaging Coregistration

The conventional method of SPECT interpretation by side-to-side visual comparison of peri-ictal and interictal SPECT images is beset with a number of technical limitations, including (a) image intensity differences, which depend on the radioisotope dose injected and the time between injection and scanning, (b) differences in slice level and orientation of the images, which depend on the position of the patient's head in the scanner when the images were acquired, and (c) the fact that the exact anatomic location of perfusion abnormalities can be difficult to determine because of poor spatial resolution and structural detail of SPECT images compared with MRI images. To overcome these limitations, a few investigators introduced computer-aided subtraction of peri-ictal SPECT data from interictal SPECT data and subsequent registration of the difference data as images on brain MRI.[8,56] At the Mayo Clinic, we have developed, validated, and applied a method of subtraction ictal

SPECT with coregistration on MRI (SISCOM) for epilepsy evaluation.[33]

SISCOM involves five steps that are semiautomated and can now be performed in <10 minutes (Fig. 2). First, the interictal SPECT is coregistered and transformed into the three-dimensional space of the ictal SPECT by either surface matching or a voxel-based method. Second, the intensities of both images are normalized to a standard value (most commonly the mean cerebral intensity). Third, the normalized and coregistered images are subtracted to derive a difference (activation) image of cerebral blood flow related to the partial seizure activity. Fourth, the difference image is threshold to display only pixels with intensities greater than two standard deviations above (for hyperperfusion) or below (for hypoperfusion) zero. Finally, the resulting image is coregistered onto the brain MRI. Each of these steps has been validated by using both phantom and patient studies.[33]

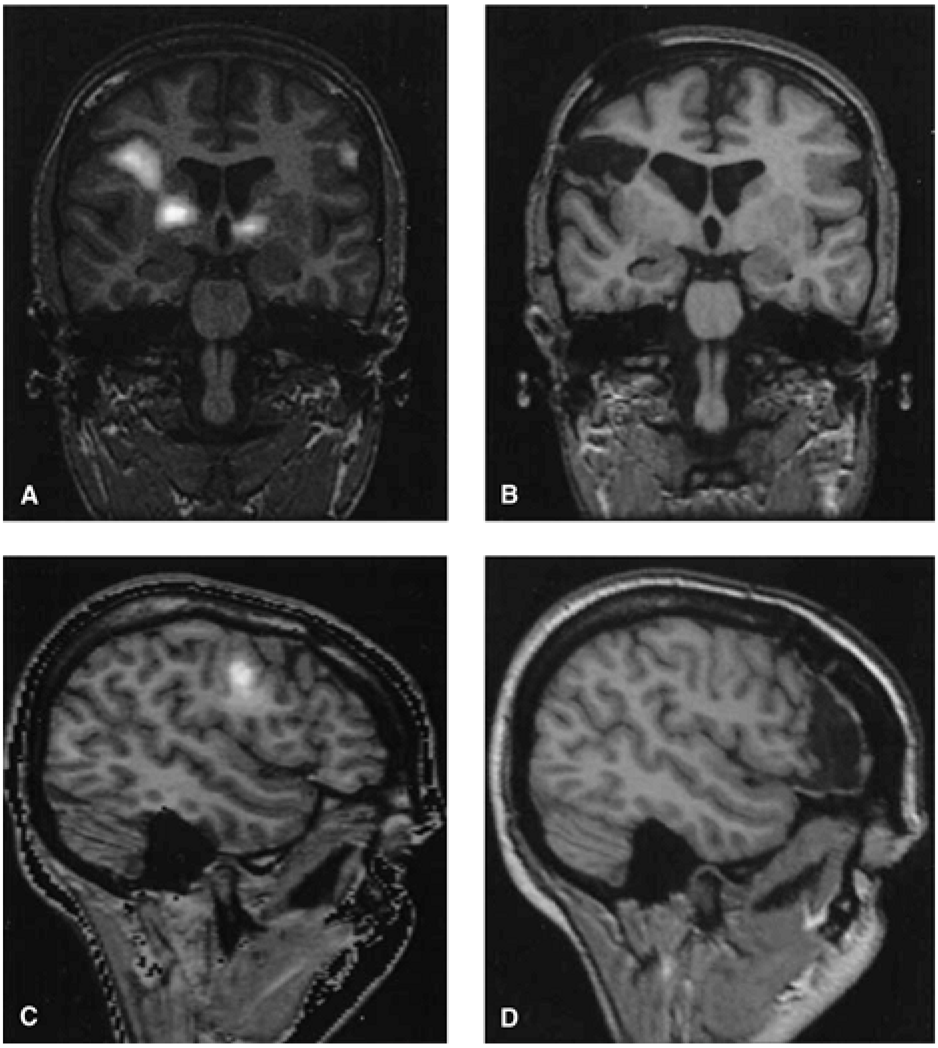

FIGURE 3. Preoperative subtraction ictal SPECT (single photon emission computed tomography) coregistered to MRI (magnetic resonance imaging) (SISCOM) images (A and C) and postoperative MRI (B and D). **A, B:** Complete resection of neocortical region underlying SISCOM focus. **C, D:** Nonresection of neocortical region underlying SISCOM focus. (From O'Brien T, So E, Mullan B, et al. Subtraction peri-ictal SPECT is predictive of extratemporal epilepsy surgery outcome. *Neurology*. 2000;55:1668â€“1677, with permission.) (See the color insert.)

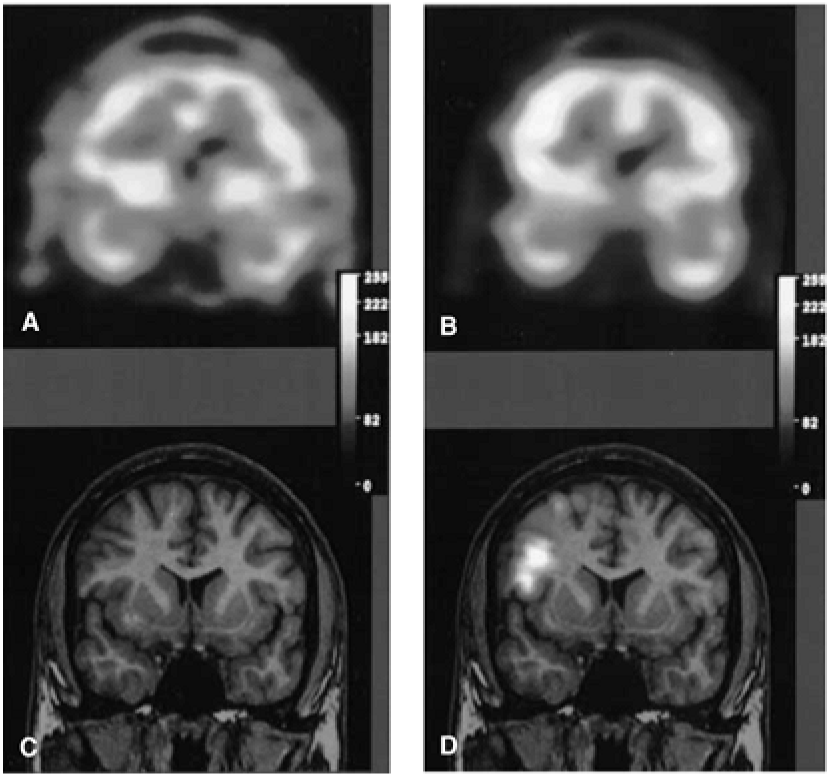

FIGURE 4. Subtraction ictal SPECT (single photon emission computed tomography) coregistered to MRI (magnetic resonance imaging) (SISCOM) with â€œpositiveâ€ subtraction for detecting hyperperfusion

focus and â€œnegativeâ€ subtraction for detecting hypoperfusion focus. **A:** Postictal SPECT image obtained from radiotracer injection at 88 seconds after seizure termination. **B:** Interictal SPECT image. **C:** â€œPositiveâ€ subtraction shows no hyperperfusion focus. **D:** â€œNegativeâ€ subtraction shows a hypoperfusion focus at the right frontal region. (See the color insert.)

Clinical Usefulness of SISCOM in Epilepsy Evaluation

SISCOM was clinically validated in 51 patients whose seizure focus could not be adequately localized by standard tests for epilepsy surgery.[35] Study reviewers detected a hyperperfused SISCOM focus in 88% of patients, compared with only 39% with the conventional visual comparison method. The agreement rate between blinded reviewers was significantly better with the SISCOM method (84% vs. 42%). Postsurgical outcome was better when the SISCOM focus was present and included in the surgical resection than when it was not (excellent seizure outcome in 63% vs. 20%; Fig. 3).

We also used the computer-aided subtraction and coregistration technique to detect the phenomenon of reduced focal perfusion that occurs typically during the postictal state (Fig. 4).[37] Two thirds of the 35 postictal SISCOM studies disclosed a hypoperfusion focus, whereas one third still showed a hyperperfusion focus. Hogan et al.[12] also showed that hyperperfusion abnormalities can persist into the postictal period. Because of these observations, we have been performing both â€œpositiveâ€ subtraction for detecting hyperperfusion abnormalities and â€œnegativeâ€ subtraction for detecting hypoperfusion abnormalities regardless of the timing of radiotracer injection. When reviewed independent of each other, 66% of the postictal â€œpositiveâ€ subtraction SISCOM disclosed a hyperperfusion focus, whereas 74% of the postictal â€œnegativeâ€ subtraction SISCOM showed a hypoperfusion focus.[37] Combined use of â€œpositiveâ€ and â€œnegativeâ€ subtraction SISCOM images, however, detected a focus of perfusion abnormality in 83% of the postictal injection studies. We observed that the intensity is less and the distribution is wider with hypoperfusion abnormalities than with hyperperfusion abnormalities. To adjust for these observations, the difference image that results from the subtraction has to be threshold to display the pixels separately at one and at two standard

deviations above (hyperperfusion) and below (hypoperfusion) the baseline.

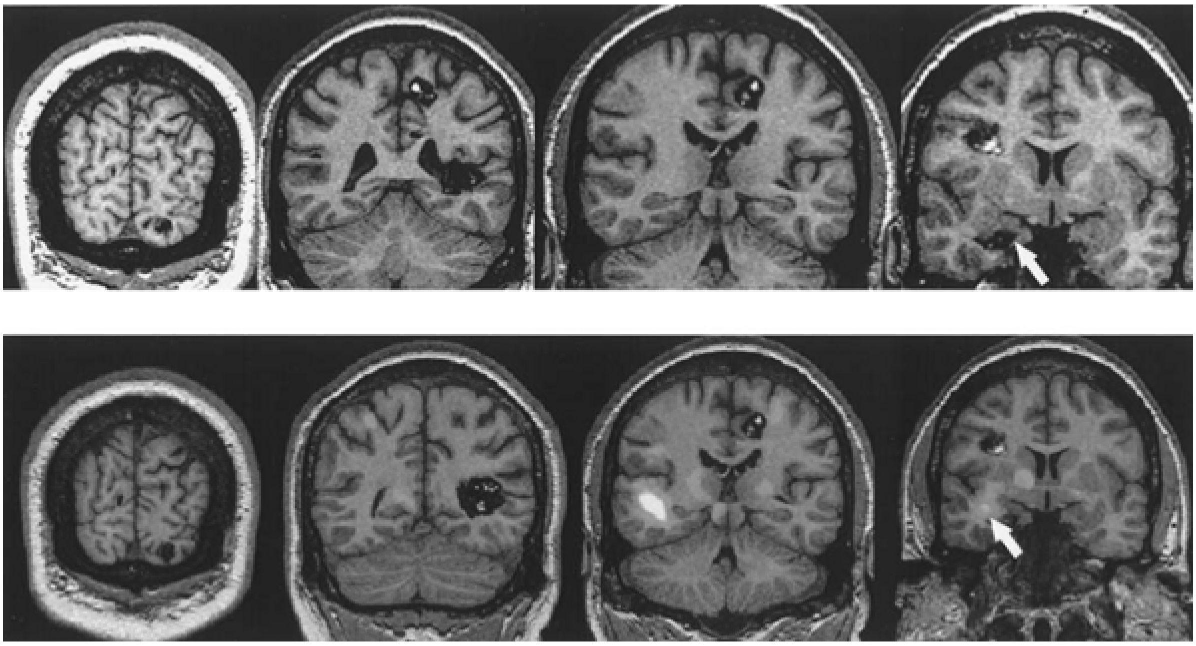

FIGURE 5. Coronal MRI (magnetic resonance imaging) (*top row*) and subtraction ictal SPECT (single photon emission computed tomography) coregistered to MRI (SISCOM) (*bottom row*) images of a patient who had medically refractory partial epilepsy associated with multiple cavernous angiomas. Electroencephalography did not localize seizure onset. SISCOM shows ictal hyperperfusion focus at the right mesial temporal angioma, and seizure semiology was compatible with right temporal onset seizures. Resection of the right temporal angioma and its immediate surrounding tissues resulted in seizure freedom. (See the color insert.)

The combined use of â€œpositiveâ€ and â€œnegativeâ€ subtraction SISCOM images is helpful in evaluating patients whose seizures are especially difficult to localize. In lesional and nonlesional extratemporal epilepsy, the presence of a SISCOM focus that is subsequently resected has a better probability for postsurgical seizure control than when the SISCOM is either unresected or absent (58% vs. 18%).[37] In our study, the rate of excellent postsurgical outcome was 100% for complete resection of the extratemporal SISCOM focus, 60% for partial resection, and 20% for nonresection. In patients with malformations of cortical development, the inclusion of the SISCOM focus in the surgical resection is also associated with better postsurgical outcome than its absence or exclusion.[34] Moreover, peri-ictal SISCOM was localizing in 86% of patients with malformations of cortical development. As for patients who had failed prior epilepsy surgery, peri-ictal SISCOM study showed a hyperperfusion focus in 80%. Fifty percent of the patients had favorable outcome when repeat epilepsy surgery did include the SISCOM focus, compared to none when the surgery did not.[54] Another application of peri-ictal SISCOM is in patients with multiple potentially epileptogenic lesions such as multiple cavernous angiomas and tuberous sclerosis. Peri-ictal SISCOM may help to identify the lesion that is responsible for the patient's habitual seizures (Fig. 5). Finally, peri-ictal SISCOM is helpful in guiding the location and extent of intracranial electrode implantation.[46,49]

SPECT injection in children is sometimes easier to anticipate and perform than in adults because many children have frequent seizures, including daily multiple seizures. Some children may require sedation for SPECT scanning following injection of the radiotracer. The usefulness of SISCOM in children is comparable to that in adults.[4,5,15,39]

Single Photon Emission Computed Tomography with Statistical Parametric Mapping Analysis

Statistical parametric mapping is more commonly used in the analysis of activation images in PET and functional MRI studies. Few studies have applied SPM to analyze SPECT data. Lee et al.[19] analyzed ictal SPECT with SPM and correctly lateralized seizures in 18 of 21 mesial temporal lobe patients, compared with ictalâ€"interictal subtraction studies that correctly lateralized seizures in 16 patients and falsely lateralized seizures in 1. More recently, McNally et al.[23] used a method of ictalâ€"interictal subtraction SPECT analyzed by SPM (ISAS) in patients with well-localized epilepsy. All SPECT studies were of seizures that did not generalize. They identified seizure onset in five of seven mesial temporal lobe epilepsy patients and in five of six neocortical epilepsy patients. There were no false-positive localizations. It should be noted that with the ISAS method, SPM analysis is applied to the difference between ictal and interictal SPECT data, whereas Lee et al. analyzed only ictal data with SPM. Between the two methods, ISAS has the theoretical advantage of avoiding the phenomenon of â€œpseudonormalization,â€ in which the ictal hyperperfusion is only relative to a more intense degree of interictal hypoperfusion at the same site. In such a situation, SPM analysis of the ictal data alone

may disclose perfusion that approximates the control values but does not exceed them to produce the characteristic hyperperfusion finding.

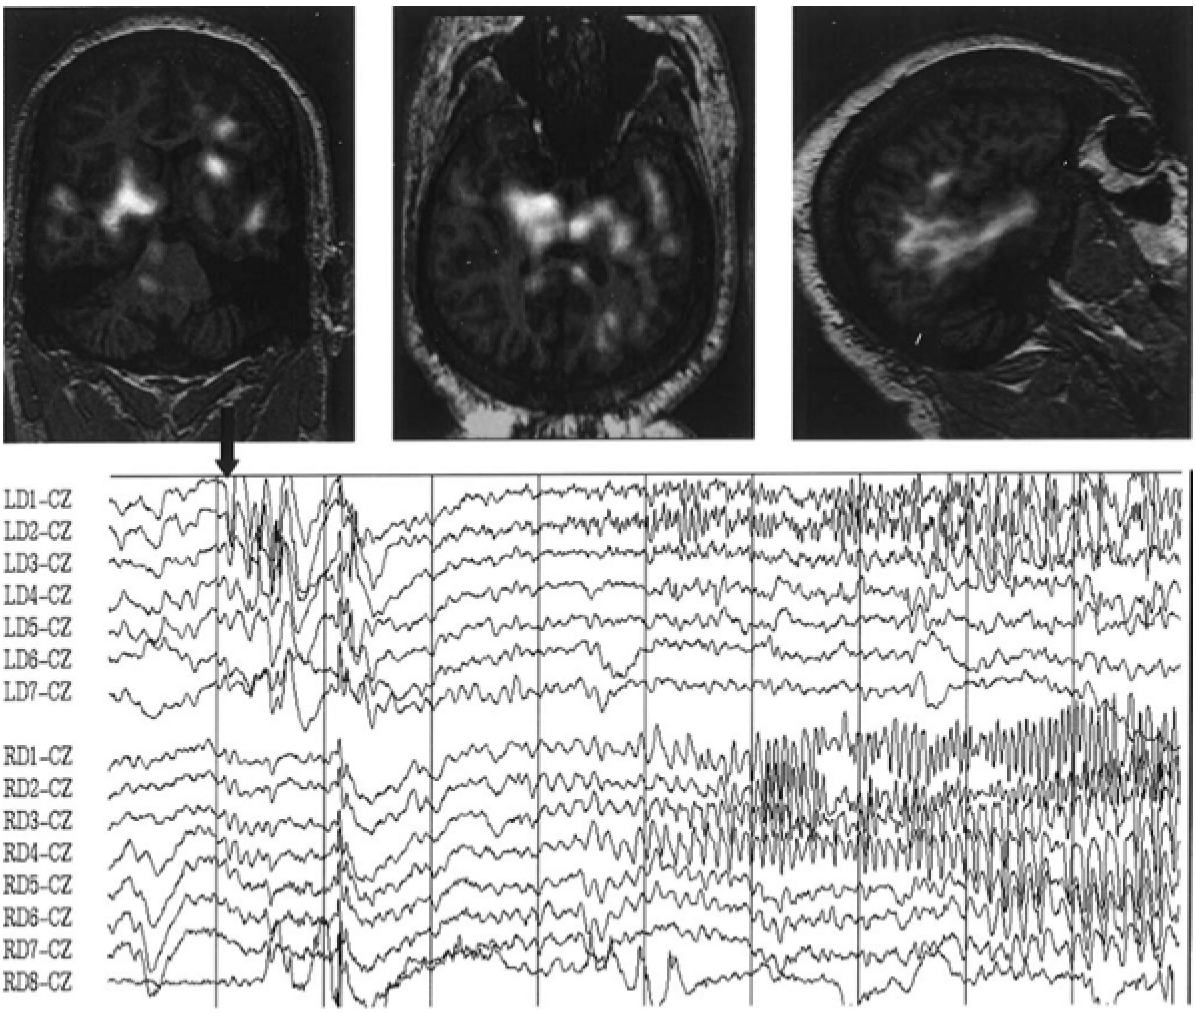

FIGURE 6. Subtraction ictal SPECT (single photon emission computed tomography) coregistered on MRI

(magnetic resonance imaging) (SISCOM) images (*top*) and bilateral mesial temporal depth electrode recordings (*bottom*) in a patient with left mesial temporal sclerosis and seizure onset. SISCOM shows dominant hyperperfusion focus involving the right mesial temporal and thalamic regions (*upper left* and *middle*). There is also a streak of less intense hyperperfusion at the left temporal region (*upper right*). Left mesial temporal depth electroencephalogram (LD1â€“7 referred to Cz) shows seizure onset (*arrow*) with subsequent rapid spread to involve the right mesial temporal depth electrodes (RD1â€“8 referred to Cz). (See the Color insert.)

Limitations of Single Photon Emission Computed Tomography

Regardless of the technique of image analysis, SPECT should always be used in conjunction with clinical information and other laboratory tests to confirm the seizure focus for epilepsy surgery.[46,49] Seizure localization in epilepsy surgery evaluation is rarely based on one modality alone; convergence of localizing information must be sought to ensure accurate delineation of the epileptogenic zone. When SPECT localization is incongruent with other information, the possibility of SPECT false localization must be considered. False localization by any type of SPECT image analysis can be due to procedural or biologic factors. Late ictal or postictal injection may result in hyperperfusion changes in a region that is distant from the focus of seizure origin (Fig. 6). SPECT interpretation should always be made in the context of seizure semiology, ictal EEG, and latency of radiotracer injection (time between injection and time of seizure onset and offset). Late ictal or postictal injection may also result in hypoperfusion instead of hyperperfusion abnormalities. As discussed earlier, image processing and analysis must be made in every study to detect these two types of perfusion abnormalities. If both intense hypoperfusion and hyperperfusion foci are present in the same study, it is probable that the hypoperfusion focus represents earlier and possibly originating seizure activity and the hyperperfusion focus represents late or propagated seizure activity.

A SPECT study provides information about the seizure that was occurring when the injection was performed, but the particular injection and images derived do not evaluate other seizure foci in patients with multifocal epilepsy. We routinely show the video recording of the injected seizure to the patient's family or friend to help establish that the injected seizure is representative of the patient's single or dominant habitual seizure type. Other than the injected seizure, several seizures should be recorded and analyzed to confirm that the seizures are stereotypic and relevant to the patient's burden from the epilepsy. This is especially important when there is evidence to suggest the possibility of multifocal epilepsy (i.e., multiple clinical seizure types, multiple MRI lesions, or multiple EEG abnormalities).

It should be noted that the abnormal conventional or subtraction SPECT focus localizes seizure activity to a region rather than a specific anatomic structure. This is especially true of an abnormal hypoperfusion focus, which tends to be more widespread than a hyperperfusion focus. SPECT focus often appears at the lateral temporal region in patients with mesial temporal onset epilepsy. Therefore, intracranial electrode recording may be needed when surgical resection requires more accurate delineation of the electrophysiologic abnormalities and eloquent function associated with the region of SPECT abnormality.

Research Applications in Single Photon Emission Computed Tomography

Techniques of quantifying the degree of peri-ictal blood flow change have been used to study perfusion patterns and their corresponding locations in different seizure types or modes of seizure propagation.[2,20,43] Other than SPM, objective detection of blood flow changes that are statistically significant and clinically meaningful should continue to be developed and assessed. Brinkmann et al.[3] developed the voxel variance method, which takes into account the expected baseline variation between two nonactivated or interictal images when analyzing a patient's ictalâ€“interictal subtraction SPECT image. Instead of thresholding the patient's subtracted image at two standard deviations as in SISCOM, the voxel variance method detects and displays only pixels in the patient's subtracted image that differ from the expected baseline variation to a statistically significant degree. Preliminary application of this method in a small group of patients showed that images generated by the voxel variance method were rated higher in quality than SISCOM images, but the localization rates were the same between the two methods.

The precise relationship between injection timing and the pattern of peri-ictal blood flow changes remains to be defined. Improvements in radiotracer injection techniques, including use of automated injection systems, may help in studying this relationship. The logistics in performing ictal SPECT injections is complex and expensive, and many institutions are not performing SPECT studies on a regular basis.[24] New types of radiotracers and new methods for their delivery may simplify and widen the use of peri-ictal SPECT, thus making it also possible for multicenter studies to be conducted with a uniform protocol to further define the usefulness of SPECT in epilepsy evaluation.

Summary and Conclusions

Ictal SPECT has been established in the last two decades as a useful test to help identify the surgical seizure focus. Subtraction SPECT methods such as SISCOM has also been shown in the last decade to improve the usefulness of ictal SPECT in both lesional and nonlesional temporal and extratemporal focal epilepsies. More advanced methods using SPM have been reported with encouraging results, but further clinical experience is needed to better define their usefulness and limitations. Regardless of the method of SPECT acquisition and post-acquisition data analysis used, the principles and limitations of SPECT studies must be fully appreciated to avoid poorly localizing or false positive results. Prompt injection of the SPECT radioligand early during the seizure must be attempted to improve the yield of the study. Moreover, SPECT results have to be integrated with other data of seizure localization from the clinical history, neurological examination, seizure semiology, ictal EEG, and structural and functional imaging tests.

Acknowledgments

We acknowledge the invaluable contributions of the following persons to the development and application of SISCOM: Dr. Brian P. Mullan of the Section of Nuclear Medicine; colleagues in the Biomedical Imaging Resource, Departments of Neurology and Neurosurgery at the Mayo Clinic College of Medicine; and colleagues in the Departments of Neurology and Neurosurgery at the Royal Melbourne Hospital.

Chapter 82

Magnetic Resonance Spectroscopy

Ognen A. C. Petroff

John S. Duncan

Introduction

In this chapter we review the application of magnetic resonance spectroscopy (MRS) to the investigation of the epilepsies in humans from both research and clinical perspectives. Initially we deal with proton MRS of the major metabolites that are detectable in vivo in focal and generalized epilepsies. We then consider the measurement of glutamate, glutamine, and Î³-aminobutyric acid (GABA). Finally, we address the use of phosphorus MRS interictally and postictally and the effect of therapies on the spectra.

Hydrogen (Proton) Magnetic Resonance Spectroscopy

The principal signals, measured using long-echo-time (TE) proton (^{1}H) magnetic resonance spectroscopy, include the singlet resonances of *N*-acetyl aspartate (NAA) (2.01 parts per million [ppm]), creatine plus phosphocreatine (CR; 3.0 and 3.9 ppm, respectively), choline-containing compounds (Cho; 3.2 ppm), and lactate (Lac; doublet signal centered at 1.35 ppm). The long TE suppresses signals from most other brain metabolites and macromolecules (lipids, proteins, and glycoproteins). N-acetyl-aspartate is the most concentrated organic metabolite unique to the central nervous system (CNS). The singlet resonance from the three hydrogen atoms of the terminal methyl group of the *N*-acetyl portion of NAA serves as a useful marker of normal adult nervous tissue (Fig. 1). The epileptic state appears to be characterized by a widespread though modest decrease in NAA, which is centered on the seizure onset zones in the focal epilepsies. Paradoxically, the loss of neurons in the epileptogenic focus exceeds the modest decrease in NAA, which suggests that NAA levels are above normal in the remaining cells, predominantly glia, but the area of NAA reduction may be more extensive.

The Acute Effects of Seizures

Relatively few patients have been studied during or soon after seizures using MRS. A recent review has summarized these case reports involving patients with partial status epilepticus.[15] Lactate levels were increased and NAA levels reduced in the acute phase of the seizure. The difficulty in interpretation lies in distinguishing the contribution of neuronal injury from the metabolic effects of the prolonged seizure. Two epilepsy centers reported MRS studies of patients measured soon after mesial temporal lobe seizures.[18,19] Lactate levels were elevated in the epileptogenic mesial temporal lobe obtained during complex partial seizures or within 4 to 24 hours after the seizures. Although NAA levels were below normal in all patients, there was no difference in NAA levels among serial spectra taken in the ictal, postictal, and interictal states. Generalized seizures were not associated with raised ictal lactate levels or decreased NAA levels. A significant decrease in the magnetization transfer ratio (MTR) of Cho was seen after seizures. Reduced MTR of Cho indicates a shift from a bound to a more mobile fraction. These changes might indicate membrane perturbation in areas of seizure spread.[44]

N-Acetyl Aspartate Levels of the Temporal Lobe Epilepsies

Several series of 30 to 100 patients with temporal lobe epilepsy (TLE) report that NAA and NAA/Cr ratios are decreased in the epileptogenic temporal lobe.[17,21,28,46,57,122] In TLE, low NAA levels are often widespread and can affect the temporal lobe contralateral to the epileptogenic hippocampus and correlate with interictal hypometabolism measured using positron emission tomography (PET).[80,96,102,113] The widespread changes seen using PET and MRS are attributed to diaschisis. Low NAA levels in the contralateral temporal lobe often herald a poor outcome from surgery in terms of seizures and cognitive function.[47,92] Below-normal NAA levels can provide evidence of temporal lobe or hippocampal abnormalities in patients with TLE who show no abnormality on magnetic resonance imaging (MRI).[29,111,167,183] Lesser decreases in NAA levels are seen in the temporal lobe contralateral to the epileptogenic one. About half of the patients with newly diagnosed TLE and unremarkable MRI have low NAA/Cr ratios.[97] There may be subtle decreases in neuronal density in a hippocampus that appears normal on MRI.[33]

What Is the Impact of Seizure Frequency on N-Acetyl Aspartate Levels in Temporal Lobe Epilepsy?

The NAA/Cr ratios of the mesial temporal lobe ipsilateral to the seizure focus correlated with seizure frequency but not with the duration of the epilepsy.[50] Similar findings were reported for frontal lobe epilepsy. Mesial temporal NAA levels and the NAA/(choline plus creatine) ratios were normal in patients with neocortical epilepsy, from which the authors inferred that repeated neocortical seizures did not cause secondary damage to the hippocampus.[185] However, 5 of 10 patients with neocortical epilepsies had low NAA/(creatine plus choline) ratio in the mesial temporal lobe ipsilateral to the seizure focus, which suggests that seizure activity arising elsewhere in the same cerebral hemisphere may reduce hippocampal NAA levels and, by inference, neuronal function.

P.976

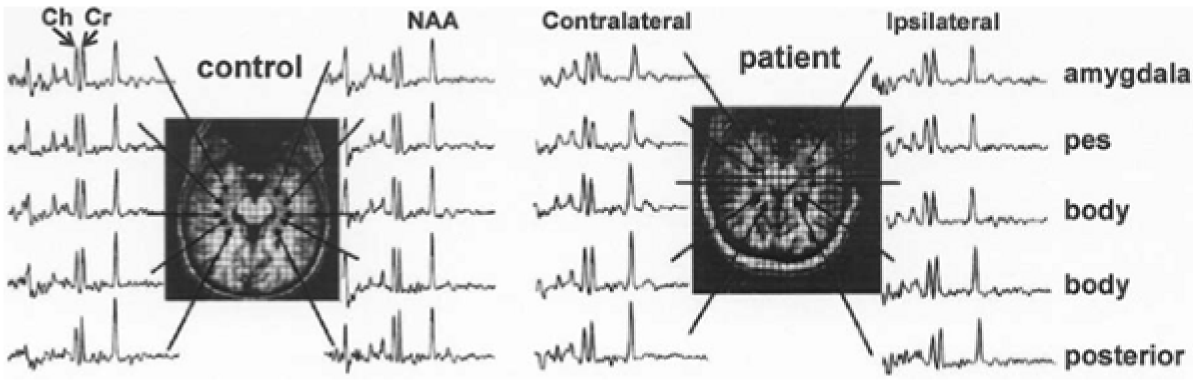

FIGURE 1. Long-spin-echo time (TE = 72 msec) proton magnetic resonance spectroscopic imaging of the human hippocampus at 4 T with intermediate spin-echo time (TE = 50). **Left:** A healthy volunteer. **Right:** A patient with mesial temporal lobe epilepsy (MTLE). Signals from the methyl groups (singlets) of *N*-acetylaspartate (NAA), creatine (Cr), and choline (Ch) are seen clearly. The spectra ipsilateral to the epileptogenic hippocampus have lower NAA signals and a lower NAA/creatine ratio than the contralateral side and the control subject. (Adapted from Cohen-Gadol AA, Pan JW, Kim JH, et al. Mesial temporal lobe epilepsy: a proton magnetic resonance spectroscopy study and a histopathological analysis. *J Neurosurg*. 2004;101:613â€"620.)

What Is the Impact of Interictal Epileptiform Discharges on N-Acetyl Aspartate Levels?

There have been several correlations of MR spectroscopic imaging (MRSI) with interictal epileptiform discharges (IEDs). In 9 patients with TLE and five with frontal lobe epilepsy there was a negative association between IED frequency and the decrease in NAA/Cr ratios, and the NAA/Cr ratio of the voxels nearest to the surface electrode with the highest IED frequency tended to be lowest.[159] In 31 patients with TLE there was a high degree of concordance between unilateral IED and the number of voxels with below-normal NAA/Cr ratios and a moderate concordance between the distribution of NAA abnormalities and the field of the IED.[106] In patients with lateralized NAA abnormalities and lateralized ictal EEG onset, however, the data were discordant in 6 of 22 (27%). In 32 patients with mesial temporal sclerosis (MTS), the NAA/Cr ratios in the ipsilateral medial temporal lobe were significantly lower than in the contralateral side and NAA/Cr ratios of both mesial temporal lobes. There was no significant correlation between the NAA/Cr ratio and IED frequency on the side with MTS, but there was a significant inverse correlation between IED and NAA/Cr contralaterally. The clinical significance of these data are unclear, but they suggest a relationship between IED and lower NAA levels in hippocampi that appear normal on MRI.[123] Alterations in NAA levels also were reported in focal areas of IED, which were identified by magnetoencephalography (MEG), in nonlesional temporal lobe epilepsy.[163] The NAA/choline ratios were decreased significantly in the spike zone compared with the contralateral homologous region but did not correlate with IED frequency.

Do N-Acetyl Aspartate Levels Progressively Decline in Temporal Lobe Epilepsy?

NAA/CR ratios were lower with longer duration of epilepsy in refractory TLE, both ipsilateral and contralateral to the epileptogenic temporal lobe.[10,34,176] Declining NAA levels ipsilateral to the seizure focus may be attributed to neuronal loss. The decline in NAA/Cr ratios in the contralateral mesial temporal lobe is not as easily attributed to neuronal loss alone. Axonal injury can contribute to decreased NAA levels in the absence of neuronal loss.[45,145] Frequent seizures spreading to the contralateral hippocampus potentially could reduce NAA levels in the contralateral hippocampus. Patients with TLE and a history of secondarily generalized tonicâ€“clonic seizures are more likely to have bilaterally low NAA levels than are patients who have infrequent generalized seizures.[92] Other, smaller studies have not found a significant relationship between duration of the epilepsy and NAA levels.[16,37,185] Several groups have reported further, age-related decreases in hippocampal NAA levels in healthy volunteers, and so inclusion of an age-matched control group is essential to interpreting findings in those with epilepsy.[175]

N-Acetyl Aspartate Levels and the Pathology of the Epileptogenic Hippocampus

It is not clear whether decreased NAA levels in the mesial temporal lobe reflect hippocampal neuron loss. Initial studies attributed the low NAA/Cr ratio of the epileptogenic temporal lobe to neuronal loss and the accompanying loss of neuropil and axons.[65] A study of the epileptogenic human hippocampus resected at surgery reports that NAA content is significantly lower in â€œsclerotic glioticâ€ specimens than those that are â€œhistologically unremarkable.â€[126] Another semiquantitative study suggested that there is an association between low NAA levels measured in vivo with MRS and the severity of hippocampal sclerosis.[34] There was no association between the hippocampal Cr/NAA ratios measured in vivo by MRS and neuron/glia ratios of the portion of the resected hippocampi.[87] It was suggested that metabolic alterations associated with seizure activity contributes as much as altered neuron/glia ratios to the NAA/Cr ratio. Hippocampi with severe neuronal loss and gliosis had the same or higher NAA levels as did hippocampi with little neuron loss. This would appear to suggest that NAA levels, although lower than normal, are much higher in hippocampi in MTS than would be anticipated from nonepileptogenic hippocampi with similar degrees of neuronal loss, for example, Alzheimer disease or stroke. A recent surgical series found no significant associations between hippocampal neuron loss and the cellular content of NAA despite a more than a threefold difference in neuron loss and a twofold increase in glial density.[140,142] The modest decrease in NAA levels and the NAA/Cr ratios of the hippocampi with >70% neuron loss and a doubling of glial density were unexpected. The NAA

P.977

content, measured in hippocampal sclerosis with TLE, was too high for the degree of neuron loss with the attendant loss of NAA synthetase expression. In the adult nervous system, NAA appears to be localized to neuronal cytosol; it would appear to be unlikely that the intracellular NAA content is increased two-to-threefold in the remaining neurons of the most gliotic hippocampi. A more probable explanation is that the glial cells contain significant amounts of NAA. One hypothesis is that NAA is synthesized by glial precursor cells or abnormal glia. Enzyme and transporter expression, function, and localization are altered in the epileptogenic human hippocampus with sclerosis. In cell cultures, the NAA and total creatine content of O2A-oligodendrocyte precursor cells are higher than in cerebellar neurons.[178] A recent study shows that â€œmature oligodendrocytesâ€ grown in cell culture with ciliary neurotrophic factor (CNTF) contain high levels of intracellular total creatine and NAA, comparable to levels reported in a variety of neuronal cultures.[13]

Spectroscopic imaging at 4 T before surgery found that NAA/CR ratios decrease from 78% of normal values in the posterior hippocampus to a nadir of 68% of normal in the anterior epileptogenic hippocampus in patients with MTS.[61] The contralateral hippocampus also had lower NAA/CR ratios ranging from 80% of normal in the posterior hippocampus to 86% to 87% of normal in the anterior hippocampus. There was no significant correlation between NAA/Cr in the epileptogenic hippocampus, measured in vivo before surgery, and neuronal counts of the resected hippocampus. There was, however, a significant correlation between NAA/Cr and reactive glial counts averaged over CA1-CA4 and the dentate. There was no significant correlation between glial fibrillary acidic protein (GFAP) staining and neuronal counts. This suggests that in TLE, reductions in the hippocampal NAA/Cr ratios inversely correlate with the presence of reactive astrocytes, an accepted marker for injury, rather than with the loss of neurons, and that reactive glia are able to metabolize NAA to some degree. An alternative hypothesis is that there is a pool of NAA in astrocytes with a very slow turnover rate and both oligodendrocytes and astrocytes avidly take up NAA.

N-Acetyl Aspartate Levels Recover Following Successful Temporal Lobe Resection

In regions with low levels prior to surgery, NAA can recover to nearly normal values following successful temporal lobe resection.[20,66,172,186] Most of the recovery occurs within 6 months and 95% by 2 years.[160] The recovery of NAA following surgery indicates that neuronal loss probably is not the main cause of low NAA levels in the nonepileptogenic hippocampus. Seizure activity may inhibit mitochondrial synthesis of NAA; in addition, frequent seizures may enhance neuronal release of NAA with subsequent enhanced glial catabolism. It is not clear whether decreased NAA levels are an adaptive response to seizure activity, which may downregulate hippocampal excitability. Some investigators have suggested that improved NAA levels may contribute to improved cognitive functions with seizure freedom, perhaps through improved neuronal functioning.

N-Acetyl Aspartate Levels of the Nonlesional, Focal Neocortical Epilepsies

Nonlesional neocortical epilepsies are defined by a normal-appearing MRI; the epileptogenic region of the neocortex is defined usually by surface or intracranial video-electroencephalographic (EEG) monitoring. Spectroscopic imaging to measure NAA levels, NAA/Cr ratios, or NAA/choline ratios may be useful for localizing the epileptogenic zone.[49,56,104,114,173] Findings in nonlesional neocortical epilepsies parallel those reported for nonlesional TLE. Seizure frequency correlates with the magnitude of the decrease in NAA/Cr ratios in the seizure focus in several studies. Decreased NAA levels also were seen in regions outside of the seizure onset zone in most patients, including the ipsilateral hippocampus in nearly half.[56,92,114,173]

N-Acetyl Aspartate Levels of Epileptogenic Focal Cortical Dysplasia

Several studies have measured interictal NAA levels or NAA/CR ratios of epileptogenic focal cortical dysplasia.[85,104,187] Mean NAA levels of the dysplasia were lower by 17% to 27%, and the mean NAA/CR ratios decreased to 71% to 79% of normal. One study reported MRSI and quantitative cell counts for focal cortical dysplasia.[85] The mean neuron-to-glia ratio was the same in the autopsy control and the patients. There was no evident correlation between the rate of IED and the NAA/CR ratios. However, the ratios were lower in patients with frequent seizures. The metabolic abnormalities closely correlated with the location of the epileptogenic focus among patients with focal cortical dysplasia with normal NAA/CR ratios in other cortical areas.

Spectroscopic Imaging of Heterotopia and Polymicrogyria

Malformations of cortical development (MCD) include diverse pathologies. The mean lesional NAA/CR ratios are variably altered in epileptic patients with heterotopia and polymicrogyria.[95,115,195] There are many reports of no significant differences in the mean NAA/CR ratio between the heterotopia and the cortex or white matter of control sub-jects.[85,116,192] Others have reported small decreases in the lesion.[72,95,171,195] Similarly, there are reports of no significant metabolic alterations in the regions affected by polymicro-gyria,[72,85,192] and others report significant decreases in the mean NAA/Cr ratio.[171] MRSI studies have reported considerable heterogeneity within the volume involved with the MCD or the perilesional brain.[95,115,195] NAA and creatine levels and their ratios may be decreased in one voxel within the lesions seen by MRI and increased in another voxel, with much of the lesion having normal levels. What is unclear is the relationship between these metabolic alterations and the seizure focus. Quantitative histopathology correlated to the metabolic measurements remains to be published. The clinical value of MRSI in addition to conventional MRI in this context remains to be assessed.

N-Acetyl Aspartate Levels in Idiopathic and Cryptogenic Epilepsies

Overall, the mean hippocampal NAA/CR ratio of children with rolandic epilepsy was increased by 12% to 14% compared with healthy children matched for age and development.[103] However, lateralization of the lower NAA/CR ratios was concordant with the lateralization of the IED in 10 of 13 children. The mean NAA/CR ratio of the hippocampus contralateral to the IED was 20% above normal. The ipsilateral ratio was in the normal range (6% higher). In cryptogenic occipital lobe epilepsy, NAA

levels and NAA/CR ratios measured in the occipital lobe (61% cortical grey matter) were reported as normal.[167] There have been several studies of idiopathic generalized epilepsies (IGEs), primarily of patients with juvenile myoclonic epilepsy (JME) or generalized tonicâ€“clonic seizures (GTCS).[11,19,110,155,156,169] Overall, the mean NAA/CR ratios have been about 10% below normal in the thalamus, 5% below normal in the frontal lobes, and within the normal range in the occipital lobes of those with idiopathic generalized epilepsies.

Summary on the Utility of N-Acetyl Aspartate Measurements in the Human Epilepsies

Measurements of NAA levels using MRSI appears to be most useful in focal epilepsies without lesions seen using conventional MRI. Low NAA levels and NAA/Cr ratios are widespread, with the lowest values associated with the areas most frequently and intensively involved by the seizures. NAA imaging may offer clues to the regions where the seizures start or those areas that facilitate the spread of the seizure to more normal cortex. Detailed NAA images may complement EEG- and MEG-based maps of epileptogenic networks. NAA images may help lateralize mesial TLE, but bilateral abnormalities are common. Based on the use of single voxels, the reported sensitivity of the NAA/CR ratio in determining the epileptogenic hemisphere was 60% to 65%.[28,92] With the use of MRSI, the lateralization improves to 85% to 98%.[17,21,83,86,98] More important, severe bilateral hippocampal involvement appears to be associated with less desirable surgical outcomes. Combined measurements of NAA/CR with MRSI and volumetric MRI correctly predicted the surgical outcomes of 39 of 52 (75%) patients with TLE who became seizure free and of 21 of 29 (72%) patients who did not.[2] Combined measurements of the NAA/Cr ratio in the ipsilateral midtemporal region, asymmetry of the NAA/Cr ratio in the ipsilateral midtemporal region, ipsilateral hippocampal volume, and hippocampal asymmetry correctly predicted the surgical outcomes of 92% of patients who experienced a >90% reduction of seizure frequency and 63% of patients who did not. The biology of the lesion appears to interact with seizure frequency to affect NAA levels in focal cortical epilepsies with lesions evident by MRI. Further studies at higher field strength may offer the spatial resolution needed to distinguish the epileptogenic regions from the metabolic changes produced by the biology of the anatomic abnormalities. When there are multiple lesions, this approach may reveal the epileptogenic abnormalities. In patients with extensive cortical malformations, detailed NAA images may offer insights into the pathophysiology of these epilepsies. Overall, the spectroscopic imaging of NAA has not offered much insight into idiopathic generalized epilepsy. The interictal changes in NAA metabolism are small, with the greatest involvement localized to the thalamus.

Glutamate Metabolism

Glutamatergic neurons contain 80% to 88% of total brain glutamate, GABAergic neurons contain 2% to 10%, and astrocytes contain about 10%.[68] Decreases in brain glutamate content, therefore, usually primarily reflect the loss of glutamatergic neurons and synapses.[59] The glutamate content of human white matter is lower than that of gray matter.[32,130] In normal brain, glutamate is known to be in high concentration in neurons, and astrocyte glutamate concentrations have been estimated in vivo to be comparatively low (<1 mM).[118] The low intraglial glutamate concentrations are maintained primarily by the conversion of glutamate and ammonia into glutamine by glutamine synthetase.[39] In addition, glutamate is oxidized by glutamate dehydrogenase (GDH) and enters the tricarboxylic acid (TCA) cycle. Neuronal glutamate is lost during glutamate transmitter release and is taken up by glia, where it is recycled by glutamine synthetase.[31] Glutamate lost from the neuron is replaced through phosphate-activated glutaminase (PAG) acting on glutamine synthesized in the glia and transported into neurons.[89,181] All glutaminases, including neuronal PAG, produce glutamate and ammonia. Ammonia is a mitochondrial toxin and is detoxified primarily by glial glutamine synthetase. If there is no neuronal loss, changes in tissue glutamate content reflect changes in neuronal glutaminase activity and indirectly the net synthesis of glutamate from glucose.

Proton Spectroscopy of Glutamate in the Human Epilepsies

The signals from glutamate and glutamine are difficult to measure because of low signal-to-noise ratios and spectral crowding. Investigators using 1.5-T clinical spectrometers and short-TE pulse sequences have used the broad signals located between 2.1 to 2.5 ppm, which comprise resonances from glutamate, glutamine, NAA, various macromolecules, and, to a lesser extent, GABA, succinate, homocarnosine, glutathione, and *N*-acetylaspartylglutamate (NAAG), as a surrogate for glutamate plus glutamine (GLX) signals. Initial studies suggested that GLX might be useful in focal epilepsies with a normal MRI.[154,194] GLX signals and the GLX/NAA ratios were reported to be above normal in the MRI-negative epileptogenic hippocampus (Fig. 2) or the epileptogenic areas of the nonlesional neocortical epilepsies. Subsequent studies reported greater variability of the GLX signals and GLX/NAA ratios, which were the same as or above normal values in various regions outside of the presumed seizure focus, that is, frontal lobes or contralateral hippocampus in TLE.[44,167,190] The GLX signals showed considerable inter- and intrasubject variability in patients with MCD or Rasmussen encephalitis.[191,195] Studies of patients with idiopathic generalized epilepsy suggest that the GLX signals and the GLX/NAA ratios of the frontal lobes are above normal.[168,169] Stronger magnetic fields, reduced magnetic field inhomogeneity (shimming), better receiver design, and advanced pulse sequences facilitate the measurement of glutamate and glutamine by improving the signal-to-noise ratio, reducing spectral crowding, and ensuring a flat baseline.[8,32,73,121,149]

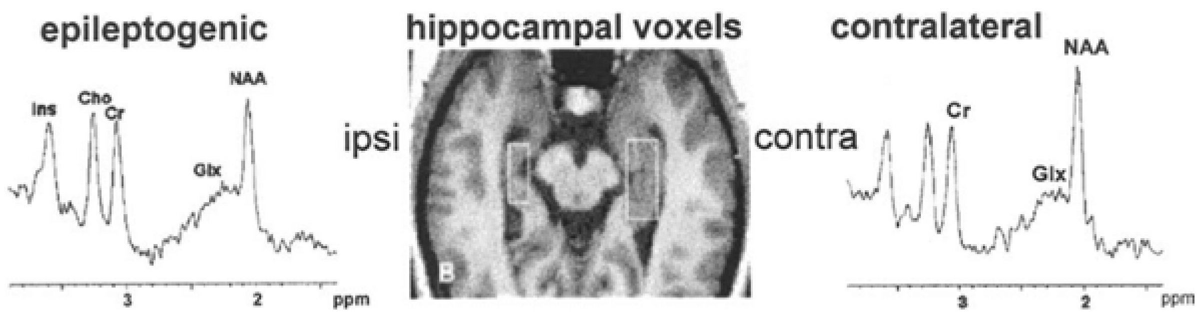

FIGURE 2. Left: Magnetic resonance spectroscopy using a short spin-echo sequence at 1.5 T with the voxel

size tailored to the epileptogenic human hippocampus with mesial temporal sclerosis (MTS). The spectrum of the contralateral hippocampus is shown on the right. In MTS, mean GLX (glutamine, Î³-aminobutyric acid, and glutathione) values are 95% of the values of control subjects and contralateral GLX values are also low (93%). In magnetic resonance imagingâ€"negative patients, mean GLX values are above normal (108%) ipsilateral to seizure onset. Cho, choline compounds; Cr, total creatine; Ins, myo-inositol; NAA, *N*-acetyl aspartate. (Adapted from Woermann FG, McLean MA, Bartlett PA, et al. Short echo time single-voxel 1 H magnetic resonance spectroscopy in magnetic resonance imagingâ€"negative temporal lobe epilepsy: different biochemical profile compared with hippocampal sclerosis. *Ann Neurol*. 1999;45:369â€"376.)

The glutamate content of gray matter, which contains a high density of synapses, is higher than values for white matter, which has less water content, more myelin, and few synapses.[130] The glutamate concentrations of extracellular fluid (ECF) and cerebrospinal fluid (CSF) are 10,000-fold lower than neuronal intracellular values. Parsing each voxel into gray matter, white matter, and CSF (segmentation) helps to reduce variability in metabolite measurements.[32,121] As expected, voxels that contain a greater fractional volume of gray matter have higher glutamate levels than those containing more white matter. In vivo measurements show that the glutamine content of white matter appears to be 50% to 60% of gray matter values. Biopsy material, however, has shown a uniform glutamine content between lateral temporal neocortex and subjacent white matter.

The Effects of Antiepileptic Drugs on Cortical Glutamate and Glutamine Levels

Antiepileptic drugs may contribute to the variability in GLX, glutamate, and glutamine levels in patients who take these

P.979

medications.[131,134,136] Measurements made in the visual cortex of patients with refractory complex partial seizures, primarily temporal or frontal lobe epilepsies, suggest that glutamate levels are modestly but significantly increased in patients taking carbamazepine, phenytoin, or gabapentin and are low in patients taking phenobarbital or primidone. Whether barbiturates lower tissue glutamate content remains to be determined. Cortical glutamate content decreases by 16% to 28% with pentobarbital anesthesia.[124,165] Valproate and vigabatrin increase human brain glutamine levels by 50% to 80%. Valproate increases blood ammonia levels through its effects on human kidney glutamine metabolism. Vigabatrin is an irreversible inhibitor of GABA-transaminase and may inhibit, albeit to a lesser degree, the other transaminases, including ornithine aminotransferase, thereby raising ammonia levels.[62] Whether the use of valproate contributes to the increase of frontal lobe GLX levels in patients with idiopathic generalized epilepsy remains speculative.

Hippocampal Glutamate Content in Temporal Lobe Epilepsy

In a surgical series of 151 patients, there was >60% cell loss in MTS and 23% loss in nongliotic hippocampi.[33] The large glutamatergic principal cells are primarily lost in TLE, whereas specific populations of interneurons are preserved and undergo complex synaptic reorganization.[105] Histopathologic studies show greater cell loss and synaptic reorganization in the more anterior portions of the hippocampus.[144] The glutamate content of the resected epileptogenic hippocampus with MTS is significantly less than values measured in the nongliotic ones.[126,140] It is surprising, however, that the glutamate content in MTS, despite the 67% neuronal loss, is not significantly less than the mean values measured at autopsy (8.2 mM) or in vivo (8.0 and 8.8 mM) of nonepileptic subjects.[73,108,121] Similarly, the hippocampal glutamine content in MTS is at the lower end of normal, despite an 82% increase in glial density.[141] The neuron-to-glia ratios are significantly altered in the epileptogenic hippocampus, yet both glutamate and glutamine concentrations remain nearly normal. These findings suggest that the intracellular concentration of glutamate of the remaining cells must be markedly increased because of the loss of glutamatergic neurons and synaptic density that characterizes MTS. The loss of glutamine synthetase expression and activity in the setting of increased GFAP expression in MTS suggests that astrocytes probably contain the excess glutamate.[38,182]

Spectroscopic imaging of MTS at 4 T showed that mean hippocampal glutamate content was 30% below normal ipsilateral to the seizure focus.[121] The glutamate content of the contralateral hippocampus, which appeared normal by MRI, was 12% below normal. NAA levels were 20% lower than normal ipsilateral and the same as normal contralateral to the sclerotic, epileptogenic hippocampus. The glutamate/NAA ratios were the same for all three groups, which suggests, but does not prove, that glutamate and NAA are colocalized in the same cell type. The reductions in glutamate and NAA content were surprisingly small in view of the >60% neuron loss and >80% increase in glial density that are the hallmarks of MTS (Fig. 3).

Spectroscopic Methods for Measuring Î³-Aminobutyric Acid

Continuing MRS development has resulted in techniques for the measurement of intracellular GABA and its major metabolites noninvasively in the brain of healthy human subjects.[76,150,162,177] Recently, MR methods have been developed to image GABA.[70,161] Because of low tissue concentrations (about 1 mM), spinâ€"spin interactions (multiplet resonances), and resonance overlap (spectral crowding), quantitative measurements of GABA require specialized receiver coils and advance pulse techniques.[23,58,67] Although GABA signals may be detected using a 1.5-T clinical imager with a whole-head volume transceiver, the signal-to-noise ratios are insufficient to measure small changes in GABA content. The availability of stronger magnetic fields of 3, 4, and 7 T for human subjects, which improve the signal-to-noise ratio two- to fivefold, simplify spinâ€"spin interactions, and reduce spectral

crowding, has led to more robust quantitative measurements of brain GABA.

Tissue Î³-Aminobutyric Acid Levels and Seizure Activity

An increase in cytosolic GABA will enhance both vesicular and nonvesicular GABA release during seizures and slow clearance of GABA from the synaptic cleft, thereby prolonging its effects.[51,53] GABA release is decreased in the epileptogenic human hippocampus compared with the contralateral one.[35] The deficiency of GABA release was attributed in part to a dysfunction of the GABA transporter system (GAT).[36,125] However, low cytosolic GABA levels could contribute to the deficiency. Synaptic and extrasynaptic (tonic) GABA concentrations serve critical roles in modulating cortical excitability.[14,148,189]

Studies using MRS have found reduced cellular GABA plus homocarnosine levels in the human visual cortex in focal epilepsies. Two thirds of patients with refractory, focal epilepsy treated with traditional antiepileptic drugs have below-normal occipital lobe GABA levels.[136] Below-normal GABA levels in the visual cortex are associated with poor seizure control (Fig. 4).[132] Whether low GABA levels facilitate the spread of seizures from the seizure onset zone to the occipital neocortex or reflect the result of frequent generalized seizures involving the occipital cortex is unknown. Low cellular GABA levels in the visual and somatosensory cortex contribute to enhanced cortical excitability and therefore to the potential for seizures.

In patients with TLE, GABA-plus/CR ratios in the occipital lobe ipsilateral to the seizure focus were lower than the

P.981

levels measured contralateral to the epileptogenic hippocampus. Whether the lower GABA-plus/CR ratios reflect functional downregulation of net GABA synthesis or a loss of GABAergic neurons and synapses of the occipital cortex is unknown.[112] After accounting for proportion of gray matter in voxels, GABA levels were not significantly different from controls in the occipital lobes in occipital lobe epilepsy or IGE or in the frontal lobes in IGE.[168,169]

The Effects of Interictal Epileptiform Discharges on Î³-Aminobutyric Acid Metabolism

Intracellular GABA plus homocarnosine levels measured in the visual cortex remote from the presumed seizure focus in the temporal or frontal lobes are lowest in those patients with interictal epileptiform discharges on

EEG.[132] The associations between the interictal EEG and cellular GABA plus homocarnosine are similar to the associations between the EEG and the likelihood that seizures will recur. Low cortical cellular GABA levels could contribute to increased cortical excitability that allows the focal seizure to spread and become generalized. Some studies have shown that patients with IED recorded soon after a seizure are more likely to have another seizure within 2 years than are patients with normal EEGs.[179] The presence of IEDs extending beyond the area of resection correlates with poor surgical outcome in patients with extrahippocampal epilepsy.[7] These IEDs probably reflect increased cortical excitability and serve as a biomarker of epileptogenicity. Low cellular GABA plus homocarnosine, as measured by in vivo MRS, could become a useful marker for epileptogenicity.

Cortical Î³-Aminobutyric Acid Levels Increase With Electroconvulsive Seizures

Serial MRS of patients with severe depression before and after a 2-week course of electroconvulsive therapy showed that occipital GABA plus homocarnosine levels increase by 56%.[152] The finding is similar to the MRS-based observations made using an amygdala-kindled rat model, which reported a 22% increase in GABA content of the epileptogenic hippocampus and a 14% increase contralaterally 2 weeks after the onset of stage 5 seizures.[164] The increase in cortical and hippocampal GABA levels with recurrent electrically induced seizures is the opposite to the finding of decreased cortical GABA seen in patients who had a seizure within 24 hours of the MRS measurement (see earlier comments).[132] Studies of epilepsy patients that measured the rate of GABA increase following inhibition of GABA catabolism with the GABA-transaminase inhibitor vigabatrin suggest that patients with lower occipital GABA content have slower rates of GABA synthesis.[141]

Antiepileptic Drugs Have Different Effects on Human and Rodent Î³-Aminobutyric Acid Metabolism

Human and rodent GABA metabolism differs considerably in the response to gabapentin, topiramate, and lamotrigine. In healthy human subjects, gabapentin, topiramate, or lamo-trigine increased occipital cortical GABA levels within hours of the first dose.[88] These changes are sustained over 1 month of daily medication. Similar large increases in occipital cortical GABA levels were observed with the start of gabapentin, topiramate, or vigabatrin in patients with epilepsy.[135,137,138] Studies in rodents using a dose of gabapentin, topiramate, or lamotrigine several orders of magnitude greater failed to show any significant effect on cortical GABA content.[1,30,43,166] Gabapentin, however, does not increase the cortical GABA content of rat or mouse forebrain.[43,91] Gabapentin increased intracellular GABA content in human neocortex brain slices but did not increase the GABA content of rat neocortex slices prepared in the same way.[42] Caution, therefore, must be used in extrapolating negative results obtained in rodent models to the human situation, and animal models must be validated by patient-based studies. Valproate increases brain GABA in a number of animal models.[100] In patients with epilepsy, valproate is not associated with increased brain GABA.[134] Clonazepam reduced GABA plus homocarnosine levels by 24% in 90 minutes.[52] Several other drugs, including citalopram, fluoxetine, and pramipexole, have been shown to increase GABA levels in humans.[12,151,174] The observed differences between human and rodent responses to clonazepam, gabapentin, topiramate, lamotrigine, valproate, and other medications have profound implications for the use of rodent models in the development of new drugs affecting GABA metabolism.

Homocarnosine and Human Epilepsy

Homocarnosine is a dipeptide of histidine and GABA unique to brain.[79,127] Intracellular homocarnosine concentrations are higher in human brain (0.3â€“1.6 mM) than in the brains of nonprimate mammals (<0.07 mM). Human CSF total GABA levels consist of micromolar concentrations of homocarnosine and pyrrolidinone (the internal lactam of GABA), small amounts of other GABA-containing peptides, and only nanomolar quantities of unconjugated (free) GABA.[55] Rodent models contain virtually no homocarnosine and little pyrrolidinone. Homocarnosine comprises ~40% of the total GABA and histidine activity measured in human CSF and has been proposed as an inhibitory neuromodulator.[69] The reasons for the uniquely elevated intracellular and extracellular concentrations of homocarnosine in human brain remain unknown.

The Effects of Antiepileptic Drugs of Human Homocarnosine Metabolism

Few studies have addressed the in vivo regulation of brain homocarnosine concentrations. Virtually all published studies have stimulated homocarnosine synthesis by increasing brain GABA concentrations by inhibition of GABA-transaminase, thereby reducing GABA catabolism.[54] Cerebrospinal fluid GABA and homocarnosine increase in parallel following a single dose of the irreversible GABA-transaminase inhibitor vigabatrin (50 mg/kg). Human CSF homocarnosine concentrations remain elevated for >1 week.[9] Cortical homocarnosine levels increase within 4 hours of the first dose of vigabatrin (3,000 mg). A second dose 2 days later had no significant impact. Daily doses of vigabatrin (3,000 mg) increased intracellular homocarnosine levels twofold (Fig. 5).[135]

Other drugs that are not direct GABA-transaminase inhibitors also increase human intracellular homocarnosine.[137,138] Topiramate, gabapentin, and levetiracetam increase cortical homocarnosine concentrations by mechanisms that are unknown. Unlike vigabatrin, none of these drugs alters intracellular GABA concentrations in rodent models.[43,101,166] Topiramate and gabapentin increase human

P.982

cortical GABA levels within 2 hours of the first dose and homocarnosine levels rise after 1 day (with topiramate) to 1 week (with gabapentin) of daily use. Levetiracetam has been studied only after 2 weeks of treatment.

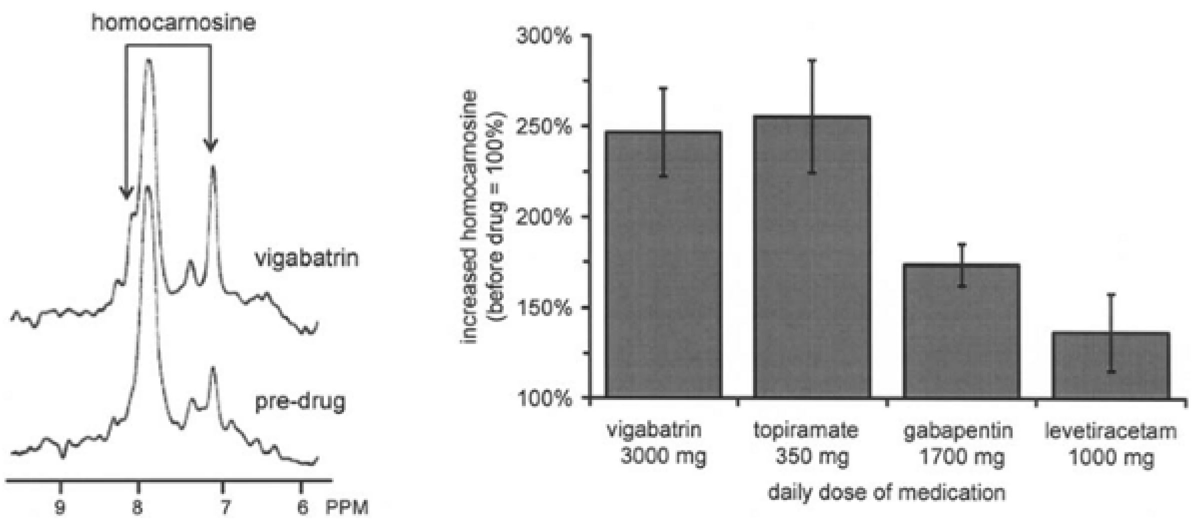

FIGURE 5. Serial spectra on the left show the increase in the signals from the histidyl resonances of homocarnosine after the start of vigabatrin. Daily add-on therapy with vigabatrin, topiramate, gabapentin, or levetiracetam increases occipital homocarnosine levels. (Data from Petroff et al.[135,137,138])

Homocarnosine and Seizure Control

Increased cortical levels of intracellular homocarnosine appear to be associated with decreased cortical excitability. Low intracellular homocarnosine and GABA levels measured in the occipital lobe using MRS are associated with frequent complex partial seizures in patients treated with valproate or lamotrigine. Patients with juvenile myoclonic epilepsy with excellent seizure control and treated with the same drugs usually have high homocarnosine levels but very low intracellular GABA levels.[139] What is unknown is whether higher levels of intracellular homocarnosine are a characteristic of patients with idiopathic generalized epilepsies, perhaps compensating for the low intracellular GABA levels and contributing to better seizure control, or low intracellular homocarnosine levels reflect frequent seizures. Patients with refractory complex partial seizures with better seizure control have higher homocarnosine levels than those with poor seizure control.[133,143] Cortical intracellular GABA levels are the same in patients who responded compared with those who failed to benefit. The findings again suggest but do not prove that homocarnosine may decrease cortical excitability. The alternative explanation is that frequent seizures may decrease the synthesis of homocarnosine or enhance its catabolism. Taken as a whole, these findings suggest but do not prove that homocarnosine may decrease cortical excitability.

Phosphorus Magnetic Resonance Spectroscopy

Cerebral metabolites detectable by phosphorus spectroscopy (^{31}P-MRS) that are relevant to epilepsy include compounds related to high-energy phosphate and phospholipids metabolism, such as adenosine triphosphate (ATP), phosphomonoesters (PME), phosphodiesters (PDE), phosphocreatine (PCr), and inorganic phosphate (Pi). ^{31}P -MRS is the best method for measuring high-energy phosphates because it completely avoids disrupting the energy state of the tissue being investigated. Because ^{31}P -MRS is completely noninvasive, serial observations are easily made, allowing dynamic measurements of the response to repeated physiologic perturbations.[146,147,158] Magnetization transfer experiments can be used to measure the rates of ATP and phosphocreatine synthesis and utilization using ^{31}P -MRS or imaging (^{31}P -MRSI).[22,93,109] Using the information provided by the chemical shifts of Pi and ATP, we can use ^{31}P -MRS to measure brain pH and intracellular magnesium concentrations in healthy and diseased conditions.[5,6,147] Dynamic measurements of phosphocreatine, inorganic phosphate, and pH using ^{31}P -MRSI complement EEG, evoked potentials, functional MRI, and other types of MRS studies, which can be made simultaneously or using an interleaved design.

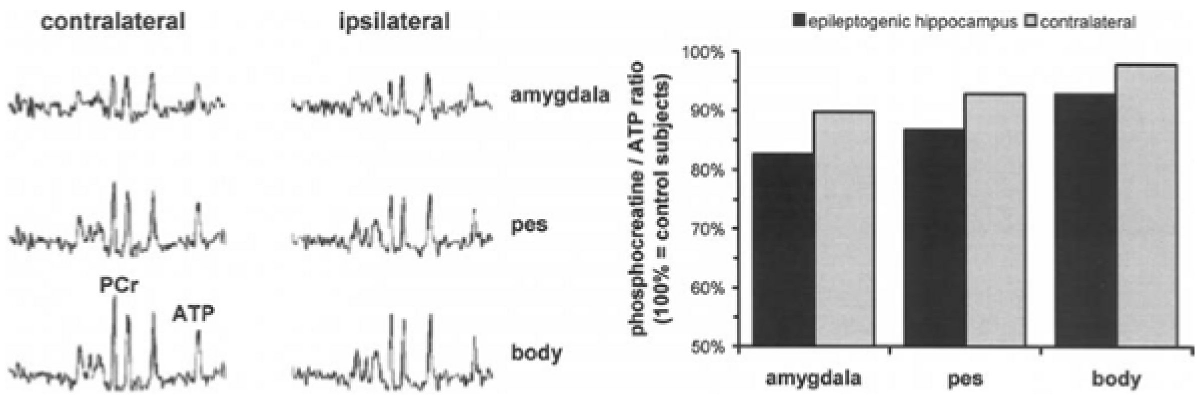

FIGURE 6. In the interictal state, the phosphocreatine/adenosine triphosphate (ATP) ratios are decreased in the epileptogenic hippocampus compared to the contralateral one. The decrease in energy state is worse in the anterior portions of the hippocampus compared with the body. (Adapted from Hetherington HP, Kim JH, Pan JW, et al. 1 H and 31P spectroscopic imaging of epilepsy: spectroscopic and histologic correlations. *Epilepsia*. 2004;45(Suppl 4):17â€“23.)

Energy Metabolism and the Creatine Kinase Equilibrium

Phosphorus spectroscopy provides quantitative data on ATP, phosphocreatine, and inorganic phosphate, which can be used directly to evaluate changes in cerebral high-energy phosphate compounds, primarily phosphocreatine and ATP. Inorganic phosphate has a chemical shift that is pH dependent. At neutral pH, Pi exists principally as HPO_4 and H_2PO_4, with an equilibrium constant (pK_a) of 6.77 in brain tissues.[129] The pH measure in vivo reflects the weighted average of the pH of all intracellular (neurons, glia, etc.) and extracellular compartments, including blood.[78] All neurons and glia express creatine kinase (CK), the enzyme that catalyzes the equilibrium among phosphocreatine, ADP, creatine, and ATP.

Through the creatine kinase equilibrium, phosphocreatine preserves a high-energy ratio of ATP to ADP by maintaining low ADP concentrations.[27,117,184] The ratio of phosphocreatine

to ATP therefore reflects the availability of phosphocreatine and serves as a marker of the energy state of the brain using ^{31}P-MRS if brain pH remains constant. The phosphocreatine-to-inorganic phosphate ratio (PCr/Pi) directly mirrors alterations in energy state (thermodynamic free energy) during pathologic conditions involving acidosis, low magnesium, or low total creatine content.

In the brain, the primary role of phosphocreatine is to shuttle energy from the mitochondria to areas of high rates of energy (ATP) consumption.[184,188,196] Phosphocreatine diffuses through the cytosol considerable faster than ATP, which may be important for the neuronal dendrites and spines and the processes of astrocytes.[75,99] Saturation transfer experiments using ^{31}P-MRS directly measure the rates of ATP synthesis, ATP utilization, and metabolite flow through the creatine kinase.[22,63,153] The forward flux from phosphocreatine to ATP doubles during seizures, which indicates that mitochondrial oxidative metabolism doubles during bicuculline-induced status epilepticus. ATP levels remained essentially the same from barbiturate anesthesia through to status epilepticus. The ^{31}P-MRS saturation and inversion transfer experiments involve applying magnetic label to the frequencies of the phosphate precursors of metabolic reactions and observing the appearance of the magnetic label in the product of the reaction.[93,109] This type of spectroscopy is used to study fast chemical reactions because the magnetic label rapidly decays after it is transferred to the new metabolite.

Phosphorus Spectroscopy During Epileptic Seizures

Ictal studies in human patients are rare.[197] Seizures cause a 33% decrease in brain phosphocreatine and a 50% decrease in the phosphocreatine-to-inorganic phosphate (PCr/Pi) ratio. Focal seizures cause lateralized decreases in the PCr/Pi ratio; generalized seizures cause bilateral decreases. Postictal spectra show increased PCr/Pi ratios, presumably due to postictal inhibition. One patient's seizures were successfully treated with intravenously administered phenobarbital during MR data acquisition, causing an immediate increase in the PCr/Pi ratio from 0.7 to 1.2. No significant alteration in intracellular pH is seen. A decrease in PCr without a change in pH implies a significant increase of ADP. Both ADP and Pi are important modulators of energy metabolism, stimulating glycolysis and mitochondrial metabolism.[41,77]

Interictal Phosphorus Spectroscopy

An altered energy state characterizes the interictal state of the involved brain regions of focal seizures. Initial interictal studies using ^{31}P-MRS found a 73% increase in inorganic phosphate and an increase in brain pH (mean alkalosis of 0.11 and 0.17 units) ipsilateral to the seizure focus without significant asymmetries between ipsilateral and contralateral temporal lobe concentrations of ATP, PCr, or PDE.[64,60,180] In a later study of eight patients with frontal lobe epilepsy, increased pH in all eight and decreased PME in seven were found in the epileptogenic frontal lobes, but no alterations in Pi levels were detected.[48] These three studies indicate that energy state (PCr/Pi ratio) is reduced in the epileptogenic region. Another group reported that the PCr/Pi ratios were lower in the ipsilateral than the contralateral temporal lobe of the patients and lower in both sides than the control data.[84] Subsequent studies also reported widespread alterations in bioenergetic parameters (decreased PCr/Pi and PCr/ATP ratios), but failed to show any alteration in brain pH (Fig. 6).[24,25,60] No significant decreases in ATP levels were reported. Phosphorus spectroscopic imaging (^{31}P-MRSI) showed that the maximal decrease in cerebral energetics appears to be centered in the epileptic focus. Reduced PCr/ATP or PCr/Pi ratio of the temporal lobe was predictive for the side of the seizure focus in >70% of patients studied.[85]

Recently, it has been shown that PCr/ATP was reduced to the greatest extent in the amygdala ipsilateral to the seizure focus, followed by the ipsilateral pes, hippocampus, and thalamus with decreasing severity. A similar pattern was seen in the contralateral hemisphere, albeit to a lesser extent.[61,120] These data are consistent with a network connecting the thalamus, hippocampus, and bilateral striatum. These observations suggest that the epileptic state is characterized by widespread mitochondrial dysfunction, particularly in regions involved in the epileptic network as defined by EEG and alterations of cerebral glucose and oxygen metabolism.

Hippocampal Excitability and Low Phosphocreatine Levels

The 5% to 15% decreases of the PCr/ATP ratios observed in the epileptogenic human hippocampus using ^{31}P-MRSI appear to have significant electrophysiologic consequences, which can be measured using a standard brain slice preparation made from the resected tissues.[193] A significant negative correlation was seen between the ability to fire multiple spikes in response to single synaptic stimulation applied to the hippocampal slice and PCr/ATP ratios measured before surgery. This type of increased â€œburstingâ€ response is rarely seen without extensive hippocampal cell loss and synaptic reorganization and is characteristic of granule cells obtained from patients with MTS. An increased bursting score that is seen with low PCr/ATP ratios reflects increased excitability of the brain slice and presumably the hippocampus in vivo. There was, however, no correlation between the frequency of spontaneous excitatory activity and PCr/ATP ratios. These data are consistent with the hypothesis that baseline asynchronous activity is not impaired by a modest reduction in the PCr/ATP ratio, but that evoked stimulation, which activates numerous presynaptic and postsynaptic elements and activates mitochondrial metabolism to restore ionic homeostasis, becomes uncontrolled with a 10% to 15% decrease in the PCr/ATP ratio. Another test of the functional reserve in the hippocampus also fails with low PCr/ATP ratios. There was a strong correlation between PCr/ATP ratios and the recovery of the membrane potential following a stimulus train, with low PCr/ATP being associated with prolonged recovery times. More-normal PCr/ATP ratios were associated with rapid rates of recovery of membrane potential following a 10-Hz, 10-second train electrical stimulus. In summary, low PCr/ATP ratios were associated with those measures of increased excitability that are associated with a high energy demand. A marker of inhibitory function in the hippocampus, inhibitory postsynaptic potential (IPSP) conductance (GIPSP), is impaired by a 5% to 10% reduction in the presurgical PCr/ATP ratio. The strength of inhibition is positively associated with PCr/ATP ratio. The fact that both bursting score and GIPSP correlated inversely with PCr/ATP ratio supports the hypothesis that both abnormal excitatory and inhibitory physiologic responses depend on altered energetics.[71]

Improved Seizure Control and Improved Phosphocreatine Levels with the Ketogenic Diet

Serial ^{31}P-MRS measurements show that successful use of the ketogenic diet improves PCr/Pi and PCr/ATP ratios toward normal as seizure control improves.[119] Whether improved mitochondrial function and energy state reflects the metabolic effects of the ketogenic diet directly or is an epiphenomenon of improved seizure control remains to be determined. However, low phosphocreatine levels or low PCr/ATP ratios clearly are associated with poor seizure control.

Creatine Supplementation Treats the Epilepsy Associated with Creatine Deficiency

Three genetic causes of creatine deficiency are known, which are associated with various forms of epilepsy.[94,157,196] All are characterized by exceedingly low or absent phosphocreatine concentrations in the brain measured using ^{31}P-MRS. Neurologic symptoms associated with creatine deficiency have some variability but present overall as mental retardation, developmental regression, behavioral problems, and epilepsy, which varies from intractable seizures in guanidinoacetate methyltransferase (GAMT)â€"deficient patients to febrile convulsions with arginine:glycine amidinotransferase (AGAT) deficiency and mild epilepsy in X-linked creatine transporter (CrT1)â€"deficient patients. When oral creatine supplementation raises brain phosphocreatine levels, monitored using serial ^{31}P-MRS, seizure control improves in parallel with rising brain phosphocreatine concentrations. Improvement in seizure control with creatine supplementation was documented in an adult patient who was diagnosed with guanidinoacetate methyltransferase deficiency at age 26 years.[158]

Phosphocreatine is Low in Mitochondrial Diseases

Epilepsy is part of the phenotype of several mitochondrial cytopathies.[81,170] The observations reported in focal epilepsies are similar to those reported in the mitochondrial cytopathies, including low phosphocreatine levels and low PCr/ATP and PCr/Pi ratios measured using ^{31}P-MRS.[3,4,40,107] Phosphocreatine levels, measured in the occipital lobe using ^{31}P-MRS, decreased with photic stimulation in patients with mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke (MELAS).[74] The response in patients with chronic progressive external ophthalmoplegia (CPEO), who did not appear to have overt CNS involvement, was more complicated.[147] Under basal conditions, the PCr/ATP and PCr/Pi ratios and brain pH were normal. In control subjects, phosphocreatine levels and the PCr/Pi ratio remained unchanged during photic stimulation and increased during the recovery following photic stimulation. Patients with CPEO differed from the control subjects in that the PCr/Pi ratio dropped during the recovery period.

Summary of the Usefulness of Phosphorus Spectroscopy in the Human Epilepsies

The interictal state appears to be characterized by low phosphocreatine levels with normal ATP levels and normal pH. The lowest phosphocreatine levels are measured in the epileptogenic regions of the brain. With the onset of seizure activity, phosphocreatine levels decrease further and an acidosis develops.[128] The low phosphocreatine levels reflect mitochondrial dysfunction, which is a potential cause of epileptic seizures. Impairment of mitochondrial function is present in the seizure focus of human and experimental epilepsy. Low phosphocreatine levels, which are seen in the epileptogenic human hippocampus, are associated with specific changes in excitatory and inhibitory neuronal responses to synchronized synaptic inputs.[193] Mutations of mitochondrial DNA that lead to the inhibition of mitochondrial oxidative phosphorylation selectively in epileptogenic areas of the human brain are associated with epileptic phenotypes.[81] Treatments that raise phosphocreatine levels improve seizure control in some patients.[119,158]

Summary and Conclusions

Multivoxel spectroscopy consumes at least 30 to 60 minutes of instrument time and requires skilled personnel for acquisition and interpretation, limiting the utility of MRS in the clinical setting. Scheduled interictal studies, rather than ictal studies that are inherently inefficient, are the most practical, unless a dedicated imager-spectrometer is available. Spectroscopic imaging

is useful when conventional neuroimaging fails to detect a lesion. N-acetyl-aspartate measurements using MRSI can lateralize the epileptogenic hemisphere with a sensitivity of 85% to 98%. Low NAA level can lateralize mesial TLE, but bilateral abnormalities are common. Severe bilateral hippocampal involvement is associated with poor surgical outcomes from anterior temporal lobe resection. Combined MRSI and volumetric MRI correctly predicted the surgical outcomes of 75% to 92% of patients with TLE who became seizure free and 63% to 72% of patients who did not.

Spectroscopic imaging of phosphocreatine and ATP can localize the epileptogenic regions and map the epileptogenic network. However, phosphorus spectroscopy requires a dedicated set of transceiver arrays and amplifiers that are not widely available. Low levels of NAA and PCr reflect interictal mitochondrial dysfunction that is characteristic of regions of the brain that are involved most frequently and intensively by seizures. NAA and PCr imaging offers clues as to where the seizures start and the areas that facilitate the spread of the seizure.

With the dissemination of 3-Tesla imager-spectrometers, lactate images may prove most useful in localizing regions of the brain that were most involved with the seizure. Lactate levels rapidly rise with seizure onset and slowly decline over many hours; post-ictal spiking further slows the decline of lactate. High lactate levels reflect populations of glia that are activated by depolarizing stimuli including extracellular potassium, glutamate, cytokines and other stimulators of glial metabolism rather than merely reflecting focal cerebral hypoxia.

Spectroscopic measurements of glutamate, glutamine, GABA, homocarnosine, glutathione and N-acetyl-aspartyl-glutamate require high-field (3-, 4-, 7-, 9-Tesla) spectrometer-imagers for quantitative measurements and should therefore be considered experimental. Similarly, dynamic spectroscopic measurements using stable (non-radioactive) isotopes of carbon (13C), nitrogen (15N) and oxygen (17O) should be considered experimental too. In vivo tracer studies using substrates labeled with these stable isotopes have revolutionized our understanding of cerebral metabolism by providing new insight into the dynamics of neural-glial signaling.

Chapter 83

Functional Magnetic Resonance Imaging

Mark S. Cohen

Susan Y. Bookheimer

Introduction

The signal derived from magnetic resonance has dynamic properties that make it possible to derive physiologic information from a series of otherwise static images. The field of functional magnetic resonance imaging (fMRI) encompasses the study of such time series to interrogate otherwise covert brain processes. In both the clinical management of epilepsy and in understanding its fundamental etiology, fMRI has become an important component of the epileptologist's toolkit. In particular, fMRI applications using cognitive activation paradigms include attempts to determine language laterality, measure hippocampal function in the affected and unaffected hemisphere, and contribute to diagnosis of the epileptic focus. A growing interest in multimodality imagingâ€"particularly in combining fMRI with electroencephalographic (EEG) measuresâ€"suggests the potential for functional identification of epileptogenic zones while maintaining the MRI advantage of a relatively simple, quick, and noninvasive diagnostic procedure that is cost effective when placed in the context of other available tests. This chapter offers an introductory explanation of the fMRI method and reviews its use in clinical practice. It then addresses the likely directions for technical improvements that may ultimately make fMRI a truly comprehensive method for seizure focus localization, offering both guidance to neurosurgery and perhaps a proxy measure for medical treatment without surgery.

Static (structural) imaging by magnetic resonance imaging is capable of showing diagnostic features in the epileptic brain such as polymicrogyria, cortical dysplasias, and atrophic change in the more common mesial temporal lobe (MTL) epilepsies with great precision and resolution and is an essential part of the workup for any surgical intervention and indeed for considering the possibility of resective treatment at all.

Functional MRI is now a well-accepted method that takes advantage of the coupling between neuroelectric activity and blood flow to offer a window into the spatial distribution of brain activity. It is used widely in the cognitive neurosciences to characterize the engagement of various brain regions in tasks from visual perception to abstract cognition and ethical decision making. The sensitivity of fMRI is such that it is also possible to localize eloquent cortex at the single-subject level, making it an attractive means of performing clinical diagnostic examinations. Increasingly, fMRI has become an integral part of the surgeon's planning for resection of tumors or arteriovenous malformations because it offers reliable guidance as to which structures must be avoided to retain maximal normal brain function. Coupled with structural imaging by MRIâ€"and often an integral portion of the same examâ€"fMRI greatly improves the safety and confidence with which epilepsy can be surgically managed.

Structural images, however, frequently are not on their own sufficient either to identify any abnormality at all or to distinguish epileptogenic zones from other brain abnormalities that might be without clinical sequelae. Even quantitative analyses of MRI parameters such as T2 relaxation times or analogous analyses such as spectroscopic quantification of *N*-acetyl aspartate often are inadequate for this purpose for many reasons. For example, bilateral atrophic changes may be present in the MTL, whereas only one side may contribute directly to the seizure disorder, and bilateral resection would clearly be unacceptable. There is thus a need for improved imaging that might help to identify functional markers that can distinguish pathologic from normal brain. It is likely that advances in fMRI will be able to fill that role, effectively bridging the structural and functional data collections.

The Physiologic and Physical Bases of Functional Magnetic Resonance Imaging

We focus on functional signal interpretation in MRI because many excellent resources exist for learning the basic principles of magnetic resonance imaging. Nevertheless, it is useful to present a short review of the general MRI method to provide a better understanding the fMRI technique.

Hydrogen protons and several other atomic nuclei carry a small magnetic moment that gives them a preferential alignment to an applied external magnetic field. Furthermore, the nuclei have angular momentum, known as â€œspinâ€ (a quantum property), which is conserved and causes them to rotate or â€œprecessâ€ about any applied magnetic field at a rate governed by the â€œgyromagnetic ratio,â€ which for protons is about 42.58 Ã— 10^6 Hertz per tesla of applied field. These two properties are exploited in collecting the magnetic resonance signal.

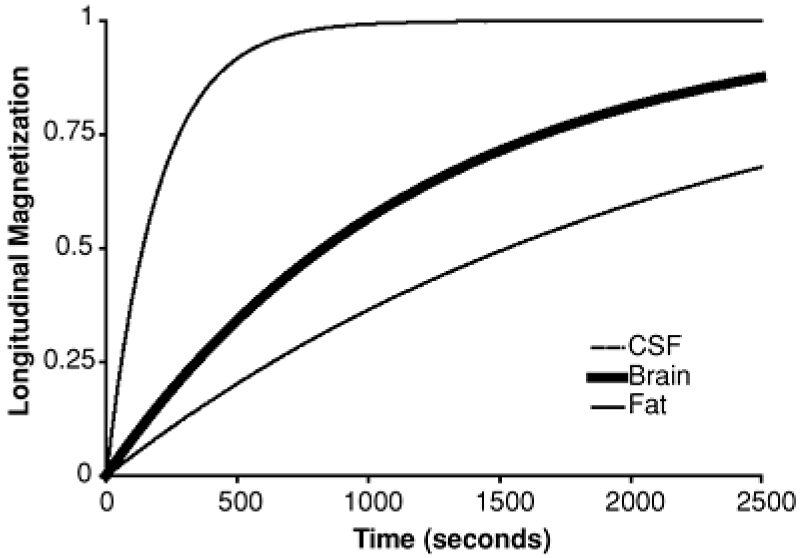

FIGURE 1. Tissues become magnetized (i.e., the proton magnetic moment reaches equilibrium) over an extended period of seconds. This so-called longitudinal relaxation rate can be characterized by a single time constant. CSF, cerebrospinal fluid.

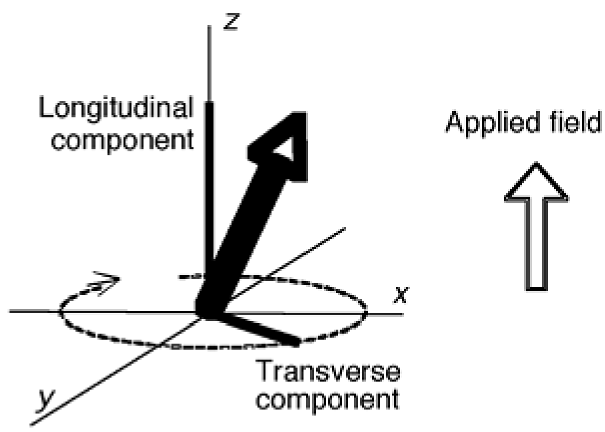

FIGURE 2. When protons are placed in a magnetic field, their angular momentum causes their magnetic moment to precess about that field. Conventionally, it is convenient to decompose the net proton magnetization into a stationary, *longitudinal*, component aligned in the direction of the applied magnetic field and a rotating, *transverse*, component that precesses about it.

When a sample, or a patient, is placed into a magnetic field, the protons immediately realign to the new field such that their precession is about the axis of the applied field (which is conventionally called B0). However, this is not an equilibrium condition because half of the protons will have their net magnetic moment in the same direction as the applied field (spin â€œupâ€) and half will be lined up opposed to it (spin â€œdownâ€), which is a lower energy state. Instead, there is a relaxation process (similar to thermal cooling) that takes some time to occur. The approach to the new equilibrium state follows an exponential time course (Fig. 1). The rate at which a tissue or other material approaches its equilibrium is considered to be characteristic of that sample and differs widely among human body tissues. The relaxation time (which is the inverse of the rate) can be conveniently and often very accurately described by a single parameter known as T1. The parameter T1 itself depends on factors such as the magnetic field strength, the temperature,

P.990

and micro and nanostructural physical properties, as well as on the presence of other magnetic or paramagnetic materials.

This approach to equilibrium is known a longitudinal relaxation. At equilibrium each of the individual protons will be precessing about the axis of the applied field in either the up or down direction (Fig. 2), such that the longitudinal components of their orientation are parallel. As the protons spin, however, their horizontal or transverse component is rotating within the plane orthogonal to the applied field and will be different for each of the spins in the sample. If we examine the vector sum of all of these magnetic moments, there will exist only a stationary vector in the longitudinal direction.

However, it is possible to create a condition in which the transverse components are aligned. This is performed by applying a second magnetic field (B1) rotating about the B0 field at the same rate as the spins are precessing. If the B1 field is left on for the correct duration at the correct amplitude, this can create a condition essentially equivalent to having rotated the longitudinal magnetization of the entire sample into the transverse plane, where it precesses about at a frequency determined by the gyromagnetic ratio. This time-varying signal can be detected easily by its induction of an electrical current into any nearby conductor. Typically, the signals in clinical imagers are in the range from tens to hundreds of megahertz, where they are detectable as radio energy. The B1 pulse is also therefore a â€œradioâ€ signal. When applied, it moves the sample out of equilibrium (because the longitudinal component is reduced when it is rotated into the transverse plane), and it is therefore called an â€œexcitation pulseâ€ or an â€œexcitatory RF (radiofrequency) pulse.â€ When the longitudinal component is rotated completely into the transverse plane, it is reduced to zero; this condition is known as a 90Â° pulse.

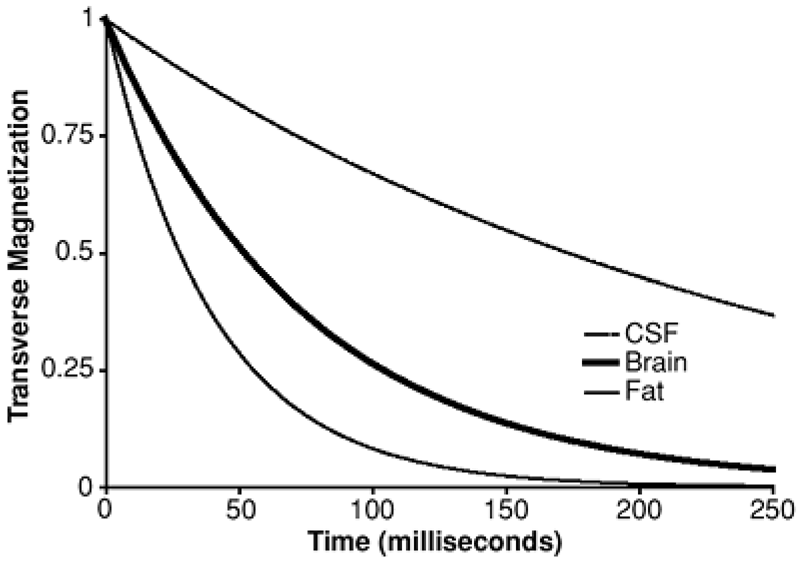

FIGURE 3. The loss of transverse coherence of multiple proton spins results in an exponential decay of the resultant magnetic resonance signal. The decay rate, T2, is tissue dependent, such that the T2 of cerebrospinal fluid (CSF), for example, is >10 times that of fat.

Even very tiny spatial variations in the magnetic field make the condition of transverse coherence unstable because over time the differences in spin frequency cause individual spins to precess more or less rapidly than their neighbors, so that the net summed magnetic moment decays over time. Like T1, this magnetic decay rate differs among tissues and can be described efficient by a single rate constant (for each tissue), known as T2 (Fig. 3).

Because the signal strength depends on the coherence of the transverse orientation of individual spins, the process of transverse decay results in a decrease in MRI signal. The time from RF excitation to signal detection is called TE and offers a means to adjust image contrast. Specifically, with a te near zero, the signal from all tissues is independent of T2, whereas when te is increased, the signal is increasingly dominated by the tissues with the longer T2; thus, adjusting te adjusts the T2-dependent contrast.

It is also possible to adjust the degree of T1-dependent contrast in MR images. Consider the case of a series of 90Â° pulses. After each, no longitudinal magnetization remains. Thus, the longitudinal relaxation process must start anew. If the time between excitatory pulses is short (compared to T1), the longitudinal equilibrium will not be reached by the time of the next RF pulse, and thus the MRI *signal* (whose magnitude is determined by the longitudinal magnetization prior to the pulse) will be reduced. The term â€œtrâ€ is used to describe the time between repeated RF pulses. In general, this means that tissues whose T1 is long compared to will have less signal (and will appear dark) compared to those whose T1 is short.

Functional Magnetic Resonance Imaging Contrast

Both T1 and T2 can be used to expose brain activity; at present, however, fMRI procedures that exploit changes in transverse

P.991

relaxation (T2) rates are most common. We present the physical principles of both methods in brief here.

Like positron emission tomography (PET), single photon emission computed tomography (SPECT), and autoradiography, the ability of fMRI to detect brain activity depends on the empirical fact that increases in synaptic activity are followed by localized increases in blood flow. Current thinking is that for excitatory synapses the relationship between electrically coupled synaptic activity and blood flow is approximately linear.[11,34,52] Although the deviations from linearity of the fMRI response overall are important,[9,17,51,53,64] they will not be considered in detail here. Although the biophysics that couples neuronal firing and blood flow is still the matter of some controversy (see, e.g., Villringer[72]), the basic findings are very robust.

In its most commonly used form, fMRI is performed by using imaging protocols that confer a moderately strong T2 sensitivity to the image contrast. (More precisely, T2â€² contrast is used, which emphasizes signal losses from local perturbances of the magnetic field rather than from interactions among the nuclear spins. For more detail, see, e.g., Buxton,[12] Jezzard et al.,[43] or the older review by Cohen and Bookheimer.[18]) It is well known that in its deoxygenated state, hemoglobin has a magnetic moment equivalent to four unpaired nuclear spins; when oxygen is bound to hemoglobin, there is a significant reduction in the magnetic moment (to zero).[58] When deoxyhemoglobin is present, the magnetic field is disturbed locally, so that nearby spins precess more rapidly than those at a greater distance, causing the MR signal to decay rapidly and the apparent T2 of adjacent tissue to be shorter: Deoxyhemoglobin thus causes the magnetic resonance images to be slightly darker.

It is believed that the effects of neural activity on the magnetic resonance signal are coupled indirectly, as follows. When the energetic needs of the brain parenchyma are increased secondary to neural signaling, oxygen substrate (and possibly other factors) is delivered by the capillaries to the brain. As a result, the intraluminal oxygen tension is reduced and more of the capillary hemoglobin is in the deoxygenated state. The vascular system responds by increasing blood flow to the affected region, which keeps the substrate concentration in the blood higher in order to deliver more to the brain parenchyma. However, in the case of increased flow, the net result in the postcapillary arterioles is for the oxygen content to *increase*.[13] Because the oxygenated hemoglobin disturbs the magnetic field less, the transverse relaxation times are increased and the magnetic resonance signal is stronger. Thus, the consequence of increased neural activity is a brighter MR image. This method overall has been called blood oxygenation levelâ€"dependent (BOLD) fMRI.

The neuronally driven signal changes in MRI are typically 1% to 2% of the background signal level, depending on factors such as field strength as well as on experimental conditions, such as the magnitude of the stimulus that drives the neuronal signal. In practice, with only a few data points, this change is readily detectable when images are compared in active and baseline conditions. A series of MRI pictures acquired even from a nonliving subject, however, will show small signal intensity fluctuations from noise. Biologic baseline processes, such as respiration and cardiac pulsation, further vary the signal. On top of these, there appear to be spontaneous changes in the neurovascular signal itself, so that on average, the baseline signal fluctuates by 1% or so. Thus, statistical means ordinarily are used to detect the fMRI signal by assessing the significance of the change in mean signal when a series of images is acquired under rest and active conditions.[6] There are many tools for efficient statistical analysis of fMRI data, but they will not be considered further here. Note, however, that this method generally requires the comparison of MRI signal in two (or more) conditions to get a single result that localizes neuronal activity. Practiced in this manner, BOLD fMRI cannot show baseline metabolic state.

An alternative use of MRI exploits changes in apparent T1 during neural firing. Although it is currently less popular, it was actually presented at the time of the very first BOLD studies.[47] When a *slice* of tissue is subjected to repeated RF excitation pulses at TR short compared to T1, the recovered signal is less than at long TR (or short T1), which imparts T1-dependent image contrast, as noted earlier. If the excitatory pulses are presented slicewise, however, the replacement of blood within the slice by blood that flows in from elsewhere results in an overall stronger MR signal because the inflowing blood has its full magnetization at the time of the excitatory RF pulse, whereas the stationary tissue does not. T1-weighted imaging thus provides a means of visualizing blood flow more directly (as opposed to through its secondary effects on oxygen tension).

Consider now a different experiment, in which the blood outside of the target slice is â€œlabeledâ€ by exposing it first to an excitatory RF pulse. In this case, the replacement blood in the slice can be distinguished from the stationary tissue. It is important that under a variety of more or less tenable assumptions, the images derived from these flow-dependent strategies are in principle quantitative, expressing absolute perfusion in units convertible to milliliters of flow to milligrams of tissue. Several methods of arterial spin labeling (ASL) have been presented in the current MR literature, and they have been sparking a great deal of research interest.[21,24,26,77,79]

Functional MRI by BOLD and ASL share several important features. First and foremost, they rely on entirely endogenous mechanisms for contrast, unlike PET and SPECT, which require the patient to receive radioactive tracers either intravenously or by breathing. fMRI may therefore be performed repeatedly on single subjects without fear of inducing tissue or genetic damage. The fMRI methods may be performed on existing MRI devices, generally without any modification, making the technique widely available in hospital and university settings. Because the same instrument is used for fMRI and for structural MRI studies, the burden to the patient and clinical staff are much reduced and the cost is consequently less as compared to scheduling separate functional studies by alternative means such as PET, SPECT, magnetoencephalography (MEG), or others.

Applications of Functional Magnetic Resonance Imaging to Epilepsy

Surgical Planning

fMRI holds tremendous promise in the presurgical evaluation of patients with epilepsy. In principle, fMRI has the potential to augment or replace the Intracarotid Amytal Procedure (IAP, or Wada test) and electrocortical stimulation mapping in presurgical and intraoperative testing of eloquent cortex. However, fMRI differs in a fundamental way from these methods, in that both involve disruption of an ongoing process, thus reflecting brain regions that, if lesioned, should produce clear deficits. In contrast, fMRI reveals all regions associated with task performance, some of which may be involved in but not critical to task performance, or which may have redundant systems that can compensate after resection. In general, although numerous fMRI studies show associations between fMRI results and those of invasive methods at the group level, very few demonstrate the sensitivity and specificity of these techniques. Fewer still have examined a sufficient number of patients with atypical language organization to claim adequate reliability in these cases. Considering that numerous factors specific to the imaging center will affect the generated results (such as MRI field strength, stability, choice of paradigm, analysis approach, to

name a few), the routine use of clinical fMRI to make independent clinical decisions is probably not warranted at this time. Here we discuss some of the recent studies using fMRI for surgical planning and the outstanding problems that remain to be solved.

Language Lateralization

fMRI holds the promise of replacing some of the more invasive diagnostic procedures in patients with epilepsy, specifically the intracarotid Amytal procedure (IAP) and intraoperative electrocorticography. One hurdle in developing the technology is that of finding a reliable way to determine language laterality. Numerous language activation studies in normal volunteers (see Cabeza and Nyberg[14] for a review) present paradigms that reveal a lateralized response at the group level consistent with left hemisphere language in normal right-handers. Several studies have used fMRI during language activation in normal volunteers to demonstrate hemispheric dominance.

Binder et al. performed fMRI on 22 epileptic patients who also received a sodium Amytal (Wada) test to determine language lateralization. For the Wada test, participants performed four language tasks: (a) object naming, (b) repetition, (c) following commands, and (d) reading sentences. The authors determined language lateralization by rating both task performance and paraphasic errors for each hemisphere, generating a laterality index. During fMRI, they used a different set of language tasks, previously reported in normal volunteers: (a) tone discrimination (control condition) and (b) a semantic judgment task, determining whether a heard word was â€œnative to the U.S.â€ or â€œused by people.â€ A correlation analysis identified voxels significantly associated with task performance. Based on the number of voxels in each hemisphere that exceeded threshold, they calculated a laterality index. The authors reported that all patients showed concordant fMRI and Wada results. Eighteen of the 22 patients had strong left hemisphere dominance on both fMRI and Wada test. The remaining 4 patients showed less strong or atypical language dominance on fMRI; 3 of these patients had a right hemisphere language bias. Although the authors reported that these patients also showed â€œlessâ€ or â€œatypicalâ€ laterality on Wada measures, it is unclear whether, categorically, these patients were felt to have right hemisphere dominance on either measure. The question of mixed dominance was also not addressed directly. Although patients showing less strong laterality did so on both measures, whether this represented â€œbilateralâ€ representation or some other pattern is not clear. Because these are the very patients who are at risk for postoperative deficits, characterization of their results on both fMRI and

Wada might shed light on language organization in such patients.

Another study compared fMRI with Wada testing in seven patients with intractable seizures. Based on the Wada test, four patients were determined to have left hemisphere (LH) dominance, and three had right hemisphere (RH) dominance. During fMRI, participants were presented words visually and had to make a perceptual versus a semantic decision for each stimulus, and these images were subtracted. The authors found activation in frontal language areas that corresponded to language lateralization as determined by the Wada test, suggesting that fMRI can be used in lieu of the Wada exam to determine language lateralization. The regions activated in this study were similar to those observed in word generation studies performed in normal volunteers, and the method appears to support the use of such a paradigm to determine the lateralization of frontal language areas. In contrast to the Binder et al. paradigm, the semantic judgment task produced no activation of the posterior language areas. This is unfortunate because mixed-dominance patients may show differential laterality of anterior versus posterior language areas.[57] Neither study mentioned the basal temporal language area. Located in the inferior temporal gyrus, this region is close to the resection zone in many temporal lobe surgical procedures and is consequently an important region to study. Artifacts in the basal temporal area are accentuated in susceptibility-weighted imaging and may interfere with the ability to measure functional activation in this region. The largest fMRI study examining language laterality was reported by Woermann and Jokeit.[78] They scanned 100 epilepsy patients, all of whom underwent an IAP. The fMRI paradigm used a covert word generation task using 10 activation and rest blocks. Results were analyzed by visual inspection and rated as typical (left), atypical (right or bilateral), or artifactual. They found a 91% concordance rate in scans that were not artifactual, four cases in which lateralization was discordant (4%), and four in which either the fMRI or the IAP was not lateralizing. Notably, with this paradigm, 82% of patients with fMRI lateralization showed bilateral activation interpreted as greater on one side. The authors also noted a high failure rate of correct fMRI lateralization in patients with extratemporal epilepsy (25%).

Choice of Task

There is little agreement on which task is best to use for language lateralization in fMRI. Many studies have used a covert word generation task that has been studied repeatedly in normal controls. This paradigm has the advantage of requiring little in the way of presentation devices; however, it is acknowledged to be a poor activator of Wernicke's area. Indeed, a prior PET study showed that this task actually produces signal decreases in posterior temporal cortex.[28,68] A semantic decision task was compared to tone discrimination, finding a high degree of left lateralization among normal volunteers and patients with epilepsy; bilateral activity was found in most participants. They used a lateralization index (LI) approach, which compared all voxels in the two hemispheres.

Lehericy et al.[49] compared three language tasks in their correlation with IAP laterality across a range of regions. Different tasks produced different LIs across these regions; a fluency task showed a reliable L:R ratio of the number of voxels activated in the frontal lobe in the strongest of the word generation tasks (semantic fluency); other tasks, including story listening and silent repetition, showed less fMRI asymmetry in frontal cortex and correlated less well with IAP results. Compared to frontal cortex, activations in the temporal lobe regions did not lateralize as well and were less correlated with the IAP results; this may have reflected the inclusion of auditory cortex, which is bilaterally represented.

Although most of these studies use a single fMRI task to determine language laterality, a recent study[29] argued that a task-panel approach improves the predictive value of fMRI in determining laterality. Participants performed between three and five different tasks, including a generation task, reading comprehension, and auditory comprehension. The scans were interpreted by raters looking at the thresholded images rather than through a predetermined algorithm for calculating LI. Although agreement was somewhat better than reported in other studies, in several cases, fMRI results appeared to be bilateral to all raters when the IAP was unilateral, and there was 1 case of 26 in which a left-dominant fMRI result was at odds with the bilateral IAP. However, in no case did the fMRI yield unilateral data that contradicted a unilateral IAP, suggesting that the use of multiple activation tasks may indeed improve clinical utility of fMRI for determining laterality.

P.993

Metrics of Laterality

Most investigators calculate the number of voxels exceeding a statistical threshold to enter into a formula for laterality indices. This metric does not take into account the magnitude of the blood flow response or how tightly the fMRI changes correspond to the ideal function describing response to the task. One study comparing these metrics found that the number of voxels above a statistical threshold was an extremely unstable metric, with a standard deviation of 74% in primary visual and motor cortices, where the greatest stability would be expected.[19] In contrast, the slope of the regression line between the modeled time course and the data (the beta value) was far more stable (SD 14%). Thus, the most commonly used approaches, although effective in group statistics, may be considerably more problematic when drawing interpretations at the single-subject level.

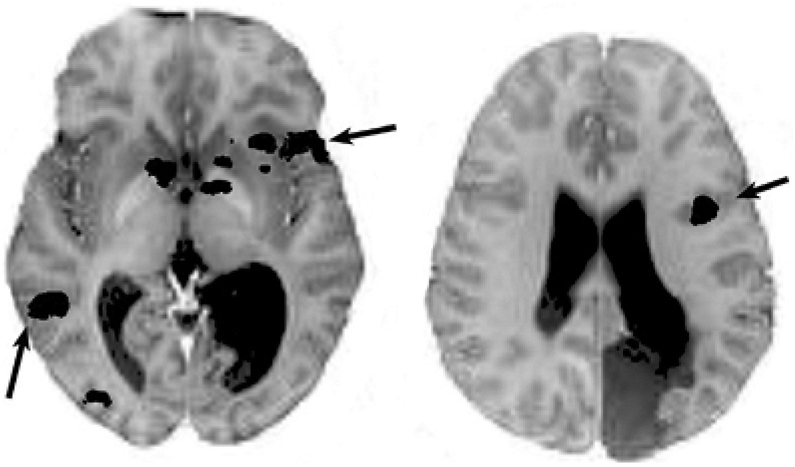

FIGURE 4. Congenital left hemisphere lesion shows anterior left, posterior right, hemisphere activation on functional magnetic resonance imaging.

The location of regions of interest (ROIs) chosen for determining laterality indices will also affect their validity. For instance, whole-hemisphere ROIs given a single task will include regions irrelevant to language function such as visual or auditory areas; because these are bilaterally organized, they will tend to reduce true interhemispheric differences in the LIs. Other brain regions involved in but not essential to language may include dorsolateral prefrontal cortex, which is involved in working memory but is also engaged when the task is challenging, may not correlate with language laterality but may be mistaken for nearby language areas.

Calculated laterality indices to obtain a single number to determine hemispheric dominance, whether in regard to Wada testing or fMRI, tend to assume a model of language in which language is either in one hemisphere or is bilateral. In our experience, bilateral or mixed-dominant language is rarely suggestive of overlapping representations in both hemispheres. Rather, patients tend to have one aspect of language, for example, expression or initiation of speech, in one hemisphere with comprehension in the other.

Such a case is presented in FIGURE 4. Here, a developmental lesion (arteriovenous malformation [AVM]) in Wernicke's area led to language reorganization. The fMRI shows left-dominant activity in the inferior frontal lobe but RH activity in the posterior temporal lobe. Such mixed dominance is usually found in cases with a clear structural lesion in eloquent cortex involving only one language area, and suggests that reorganization in a patient with genetic left hemisphere language will tend to be specific for the function that cannot be performed in the dominant hemisphere rather than global. Simple laterality indices will not capture such patients and can lead to incorrect interpretation of fMRI data. An alternative is separately to measure laterality in anterior versus posterior regions. Such an approach was taken by Pouratian et al.[59] in a group of AVM patients with preoperative fMRI and intraoperative validation with electrocortical stimulation mapping (ESM).

Whereas left hemisphere language dominance is virtually assured in right-handed, normal volunteers, there is a much higher incidence of right hemisphere or mixed language dominance among patients with temporal lobe epilepsy.[54,57] Only a few patients with atypical language organization have been studied. This sample is too small to determine language dominance in the more difficult cases using fMRI alone. Another issue that has not been explored well is the effect of language impairment on fMRI results. How language deficits might influence the magnitude and perceived direction of laterality is not known. Most patients with right hemisphere or mixed dominance have reorganized language because of a lesion, and patients with lesions in the left hemisphereâ€"whether or not language has movedâ€"may have deficits in language processing.

Base Rates and Right Brain Speech

Although many studies have reported large cohorts of individuals with Wada and fMRI concordance, few have had sufficient numbers of participants with confirmed right brain speech (RBS) to establish sensitivity and specificity figures in these cases. The base rate of RBS in the normal population is estimated to be quite low (<5%), but it is significantly more common among left-handers and among patients with epilepsy of either handedness. A study by Sabbah et al.[65] recruited left-handed epilepsy patients with a high rate of RBS; they compared fMRI and IAP laterality indices in 20 epileptic patients, of whom 11 were left-handed. On the Wada test, 7 of the left-handers and 2 of the right-handers had RBS. Using a word generation paradigm (both semantic and letter-cued), they compared the number of all supratentorial voxels in the hemispheres to derive an LI based on the fMRI results. The authors chose an arbitrary cutoff threshold LI of 20 (scale from -100 to 100), which correctly classified 19 of 20 individuals as having concordant fMRI and IAPs; 1 individual with RBS had an equivocal laterality index on fMRI, and several others were correctly categorized but had relatively low laterality indices. The Wada analysis did not appear to allow for mixed-dominant patterns, and there are no studies examining IAP/fMRI concordance in this population. Nonetheless, results from these studies do suggest that the larger majority of epilepsy patients show strong fMRI laterality using a variety of fMRI approaches; these cases show very high concordance with IAP laterality. Thus, for the purpose of establishing language laterality in epilepsy, especially mesial temporal epilepsy, a high laterality index is probably as reliable as the Wada test. In cases of neocortical epilepsy, space-occupying lesions, or more moderate laterality indices, fMRI has less potential for determining language laterality definitively.

Performance and Brain

Cortical stimulation studies typically use stimuli that the patient can perform accurately at baseline; consequently, errors during stimulation are sufficiently anomalous that they can easily be attributed to the stimulation. In activation imaging studies, task difficulty and performance variables affect the magnitude of the blood flow response; consequently, if performance levels and their effects on blood flow are not well characterized, results are interpretable. Consider, for an example, an early PET study. In this study, individuals were presented visual stimuli at different repetition rates. The magnitude of the blood

flow changes was proportional to the amount of motor activity: The harder the person worked, the greater did the blood flow change. Cognitively challenging tasks have been found to show greater changes in blood flow than simple tasks.[10] Given multiple trials of the same word generation task, Raichle et al. found differences in the magnitude and patterns of regional cerebral blood flow (CBF) using PET.[62] This finding has important implications for patients with epilepsy: There are typically neuropsychological impairments associated with the seizure focus, and consequently there may be performance impairments during the fMRI procedure. Tasks that are too simple may fail to produce sufficient signal changes; tasks that are overly practiced may show changes in areas other than those of interest; and tasks that are too difficult may result in negative results if the target cognitive skills are not sufficiently engaged. Therefore, to draw useful clinical conclusions about the function of a target brain region, one must know which tasks produce CBF changes in the target cortical region, which experimental parameters affect the expression and magnitude of those CBF changes, and how variations in task difficulty and subject performance affect the hemodynamic responses.

Memory Patency

Although fMRI applications for determining language laterality in epilepsy are rapidly moving toward clinical applicability, significantly less research has supported a role for fMRI in determining memory patency for presurgical evaluation. Because most centers use the IAP for both language and memory determination, the possibility of replacing the IAP with fMRI depends on valid and reliable memory activation paradigms that are predictive at the single-subject level. Although no studies have clearly developed an fMRI memory test with the sensitivity for within-subject interpretation, a rapidly increasing number of studies have explored memory lateralization paradigms at the group level leading toward this goal.

The first fMRI study to demonstrate significant memory-related activation of the medial temporal regions used a novel picture-encoding paradigm[69] in which participants viewed complex visual scenes in comparison to viewing two scenes repeated throughout the experiment. Although the results were primarily observed in the parahippocampal gyrus (PHG), and the resolution was not sufficient to disentangle PHG from hippocampus (HC) proper, the study provided the first strong indication that memory-related activity could be observed with fMRI.

This paradigm was adapted in several studies of patients with epilepsy.[61] An initial report of 10 epilepsy patients undergoing fMRI and IAP found asymmetry indices in the same direction for all patients, including 2 whose asymmetry was opposite to that predicted by the seizure focus (in contrast, normal volunteers had equal left and right activation). However, in a larger series of 36 patients undergoing fMRI, 27 of whom also underwent IAP exams, fMRI correlated with the IAP but the magnitude was relatively low (0.35), and the congruence between modalities was only moderate.

Richardson et al.[63] used groupwise activation data to create a valid region of interest, which was then applied to within-subject data using an aversive-word-encoding paradigm in an event-related design. During a retrieval condition, they presented a longer list of words and asked participants whether the words were on the encoding list, and, if they were, could they recall the encoding episode or did they have a â€œfeeling of knowing,â€ which is not associated with hippocampal activity.[25] These data were then used to evaluate fMRI activity for Remember versus Know items during encoding. Although visual inspection of the fMRI maps suggested that they were too noisy clearly to identify a lateralized memory response, the ROIs derived from the group data distinguished patients from controls. Across the group, LH activity predicted memory decline after surgery in a subset of patients who had surgical resections. Although the study did not determine, on a single-subject basis, which HC supported memory or whether a resection was possible, it does suggest a general approach to improving the predictive validity of fMRI in temporal lobe surgery; moreover, the results indicate that the most sensitive area for encoding is the left mid-anterior HC proper.

Using an imagery-guided navigation task, Jokeit et al.[44] studied activation in the left and right medial temporal regions in controls and patients with unilateral temporal lobe epilepsy (TLE). Although controls did not differ in lateralization, the patients showed decreased MTL activity in the side of the seizure focus (this activity was predominantly in the PHG rather than the HC); 90% of patients showed this pattern. However, two patients with left TLE and one with right TLE were misclassified. Furthermore, the magnitude of the lateral asymmetries was very small in many patients, suggesting that this approach, although promising, was not sufficient to avoid performing an IAP in most patients.

As paradigms evolve that produce activation of the normal hippocampus during memory processing, it will again be necessary to determine the relationship between performance and activation in patients with hippocampal damage.[76] One recent study in Alzheimer patients, who also have HC damage and atrophy, showed that when performance was controlled (by post hoc sorting of individual responses), AD patients showed as much activation as controls, whereas typically they show much less. Thus, paradigms that fail to account for performance may incorrectly show below-threshold activation. Furthermore, imaging memory activation in the hippocampus may be especially difficult in patients in whom the hippocampus is atrophic. Because the signal magnitude is proportional to the amount of tissue in each voxel, there may be a smaller proportion of potentially activating hippocampus in these patients. Thus, there is a greater risk of false-negative effects, a potentially dangerous error for with-in subject fMRI.

In summary, determining memory patency using fMRI is a critical step toward replacing the Wada test, but there remain serious concerns with the potential to cause harm. The base rate of Wada failure due to patients failing the memory test is quite low in our experience; thus a large degree of concordance between the Wada and fMRI memory evaluation is expected. The critical test for fMRI, however, is its ability to identify the Wada failures with essentially perfect sensitivity. A large sample of patients who have failed the Wada test is therefore needed, and no studies to date have a sufficient sample of such patients to allow meaningful conclusions as to the value of fMRI for this purpose.

Prediction of Seizure Focus and Clinical Outcome

Memory performance on the Wada test has been shown to predict seizure focus.[80] Bellgowan et al.[7] used fMRI to differentiate known right and left TLE patients, using a semantic-encoding paradigm in which they made a semantic decision about auditorally presented words in comparison to a tone discrimination task. The discrimination was made on the basis of the responses in the right TLE group, who showed significant left hippocampal activation in comparison to right hippocampus; the left TLEs did not show MTL activity. This study suggests the potential for fMRI to add to seizure focus localization in TLE.

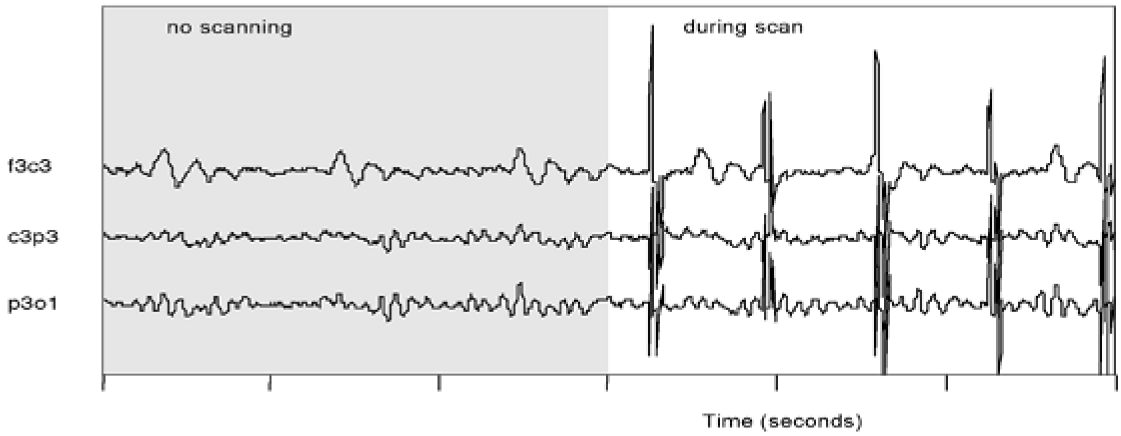

FIGURE 5. Electroencephalogram (EEG) recorded in the magnetic resonance imaging device contains artifacts from multiple sources. **Left:** Recordings from three electrode pairs, as indicated, while the patient rests within the scanner, but during a period when there is no acquisition taking place. **Right:** The EEG record during scanning. Note the prominent artifact in the left panel with a period of about 1 second, which derives from the ballistocardiogram. The scanning periods show a much larger artifact (already attenuated by spectral filtering) that derives from the switching of magnetic field gradients required for image formation.

Rabin et al.[61] used fMRI during a picture-encoding para-digm to determine whether asymmetric activation in a broad MTL region including HC, PHG (encompassing entorhinal and

P.995

perirhinal cortex as well), and fusiform, or a selective HC region, correlated with postsurgical memory outcome. Asymmetry in activation in the broader MTL region significantly correlated with memory performance on the fMRI task postsurgically. Although these predictions were made at the group level, the possibility that memory fMRI may add to clinical decision making in assessing postoperative risk is an important new step toward this goal.

Imaging Abnormal Tissue

Can abnormal cortex be eloquent? A recent study of five patients with polymicrogyria in language or motor cortex showed significant fMRI signal increases within the abnormal cortex.[4] AVMs or large tumors creating a mass effect may decrease the magnitude of the blood flow response, in some cases making laterality of language difficult to determine.

It is not clear how common pathologies in epilepsy such as medial temporal sclerosis affect fMRI activation, what degree of cell loss is necessary to change the fMRI response magnitude, or how great this decrease must be to conclude that the tissue is nonfunctional.

Intrahemispheric Localization of Language

In many patients, the seizure focus is known, and the critical diagnostic question becomes, What functions are subserved by this brain region? Eloquent cortex mapping relies on our preexisting hypotheses about what functions should be near this cortical region based on our knowledge of functional locations because we cannot practically test all known or putative brain functions for a given region. Not surprisingly, the best functional mapping is done in well-characterized functional regions such as primary motor and primary visual cortex.

Only a few cases have been reported that used functional MRI in epileptic patients for intrahemispheric functional mapping. Morioka et al.[56] used fMRI to determine function in a patient with en epileptogenic lesion in the central sulcus. They mapped both sensory and motor function using fMRI, MEG, and transcranial magnetic stimulation. All images were mapped onto MRI to determining colocalization of the functional zones. Both motor and sensory maps from fMRI matched those of the other techniques in this patient.

Puce et al.[60] mapped extrastriate cortex in 12 patients with epilepsy using fMRI. Patients were presented human faces in multiple trials, interspersed with presentations of scrambled versions of the same stimuli. They looked for cortical regions responding specifically to human faces. The authors found face-sensitive regions in the fusiform and inferior temporal gyri in 75% of their patients, with additional regions of activation in several occipital and superior temporal regions. Although this study did not report direct comparisons of fMRI findings with those from other techniques, previous work by this group in epilepsy patients identified face-processing regions in the same cortical zones, using electrical stimulation mapping.[3] The inferior temporal lobe is often resected in surgical treatment of medial temporal lobe epilepsy, although face-processing deficits are rarely associated with surgery (by some accounts, bilateral damage is required to produce prosopagnosia[67]). Nonetheless, this study indicates that fMRI may yield a high degree of functional specificity outside of primary sensory cortices.

Seizure Focus Localization

As noted earlier, most fMRI exams are performed by examining the blood flow response to a task challenge. Used in this way, they can efficiently identify the regional associates of normal brain function and identify brain areas that must be avoided in resective surgery. At least as useful, however, will be a method that might identify the epileptogenic zones directly.

Electroencephalogramâ€"Functional Magnetic Resonance Imaging

At some level, the seizure is essentially an electrical phenomenon, and it is rational to imagine that the electrical disturbance visualized in the EEG should offer both spatial and temporal localizing information useful in the planning of resective surgery. Unfortunately, the scalp EEG alone seldom offers great precision in locating the epileptogenic brain regions. However, the possibility of combining EEG with more precise imaging measures is extremely attractive. Thus, several teams have put substantial effort into the development of techniques suitable for such joint recordings.

From a purely technical perspective, combining EEG and MRI has proven extremely challenging. Both Ives and Huang-Hellinger reported early that such recordings were possible, but noted that large-amplitude artifacts were present in the EEG recordings.[36,37,38] The origin of these is well understood: The imaging process requires the creation of large-amplitude, time-varying magnetic fields from both the RF excitation pulse and the electromagnetic coils required to localize the magnetic resonance signal in space. These are coupled inductively to the recording loop created by the active and reference leads used in the EEG recording; such artifacts can be tens to hundreds of millivolts in amplitude and are therefore on the order of 1,000 times larger than the scalp EEG and the interictal epileptiform discharges (IEDs), making it difficult to discern the scalp signal during the imaging process. A second disturbance of the EEG recording results from the so-called â€œballistocradiogramâ€ (Fig. 5). With each heartbeat there is a displacement of the head of perhaps 100 Âµm. Although this might seem tiny, it results

P.996

in a motion of the EEG leads within the large magnetic field of the imager that produces an artifact of about 100 ÂµV that is highly variable with the patient. The features of this artifact cloud the interpretation of the

EEG.

FIGURE 6. Multichannel electroencephal-ogram (EEG) recording made during magnetic resonance imaging (MRI) recording, after suitable artifact suppression (electrode T5 made poor contact in this session). Paroxysmal interictal spikes are evident in these recordings and may be used to drive data analysis of combined EEG-functional MRI data.

Several variably effective means have been developed to mitigate these artifacts, the most effective being those that use statistical means to create a template of each of the characteristic artifact types. Allen and colleagues used a purpose-built EEG system that digitizes the EEG signal at an unconventionally high rate. An accurate template can be created by using an adaptive correction method that provides a progressive interpolation between acquired points.[2] An alternative method was developed by Cohen and Goldman, using a sampling system that is synchronized to the MR scanner itself.[20,30] Both methods, and a variety of others,[8,40,55] (e.g., 8) are capable of producing essentially artifact-free EEG recordings during continuous high-data-rate fMRI (Fig. 6).

As discussed elsewhere in this volume, the presence of paroxysmal IEDs in the scalp EEG of the epileptic patient is a common finding, although it is not universal. Studies have indicated that resective surgery of the anterior temporal lobe results in significant improvement, or cure, of up to 92% of patients showing IEDs.[23,74] Generally, these EEG features are prominent and relatively easy to detect. A computer-aided means of IED detection was developed, for example, by Gotman[27,31,32] that can identify these features with good accuracy. The power of the IED in seizure focus localization, however, is limited. For example, in two studies it was shown that in the overwhelming majority of patients with IEDs that localize bitemporally, the seizures originate from only one temporal lobe.[16,35] Walczak and Jayakar noted that the IEDs suggest that the entire cortex may display an electrical irritability in the epileptic brain that is a consequence of the presence of a focal lesion.[73] Nevertheless, it is likely that the IEDs themselves originate in the epileptogenic zone. This interpretation is supported by the finding that IEDs may be reduced or eliminated following successful surgery, although this finding, too, is complex because IEDs may also be increased after surgical intervention.[15]

Based on the hypothesis that the IED recorded at the scalp may be a distant or propagated reflection of a disturbance that originates in the generative zone for seizures, several investigators have attempted to use the timing of the IEDs as independent variables in the fMRI analysis, studying the fMRI signal changes that follow these spike discharges. Warach et al.,[75] using an MRI-compatible EEG system designed by Ives et al.,[38] compared MRI scans taken immediately after IEDs to those presumably acquired during periods of normal EEG and noted areas of focal signal increase. Of the two patients studied, one showed such focal signal change despite a history of generalized epilepsy. Although these authors speculated that the method might well detect true focal abnormalities in patients that generalize, this pattern is extremely rare,[42] and an alternative interpretation is that the spiking behavior may either be dissociated from the seizure or that the coupling between IEDs and fMRI signal is somehow variable. As noted later, the linkage between IEDs, focal fMRI signal, and seizure disorder has not been definitively established and remains an area of active research and some controversy.

One way to assess the reliability of the IED-fMRI correlations is to perform repeated studies of single patients to see whether the effects are in fact reproducible. Symms et al. reported, for example, that similar patterns of MRI signal were observed in one patient studied on four separate occasions.[71] Another approach is to determine whether the source localizations determined by dipole solutions to the scalp EEG colocalize with the fMRI data. Lemieux et al. performed such a study on six patients and noted that the localizations were reasonably consistent and that the discovered sites were frequently in proximity to abnormalities visible in the structural scans.[50] These results and others were sufficiently encouraging that there have now been several reasonably large-scale studies.

Using the newer EEG-MRI methods, it is possible to examine the fMRI responses to IED discharges over a relatively broad range of discharge rates and scalp topographies.[66] There have been several studies that address the potential of the combined method in terms of both its practical limitations and its added utility in diagnosis.[1,5,33,45] As noted in all of these reports, the method of IED-fMRI has a few technical limitations that restrict its application. In particular, even using optimal continuous data collections, patient data frequently must be excluded because spike activity is absent during the limited window of the scanning session; the sample by Al-Asmi et al. is the largest reported to date.[1] In their work, using patients selected based on the presence of frequent interictal spikes, some 25% of patients studied with continuous EEG monitoring could not be analyzed for this reason. Motion artifacts are a well-understood contaminant in fMRI studies.[18] Although there are remarkably effective postprocessing tools available to mitigate these problems, data loss to motion is a substantial problem in the epilepsy studies (on the order of 15% across reported studies). Other problems include patient compliance related to discomfort from wearing the electrode array during scanning and the presence of artifacts from materials such as dental work that are common to all fMRI studies. Even with technically adequate data there are still many studies that fail

to result in the identification of focal signal fMRI changes. Using spike-triggered acquisition with carefully selected patients with pharmacologically induced control states, Lazeyras et al. reached a 73% positive yield in a study of 11 patients.[48] Intracranial recordings confirmed the concordance of the fMRI localization of the epileptogenic zone in 5 of 6 patients on which it was performed. Al-Asmi et al. reported a lower yield of 50% in their study of 24 patients.[1] A study by JÃ¤ger et al. showed a 50% yield, although certain aspects of the data analysis were unusually liberal.[41] Overall, then, the combined IED-fMRI method is extremely promising as technical data quality continues to improve and as investigators gain a better understanding of the patient selection criteria that might make this an effective diagnostic means.

There have been scattered reports of fMRI data collection during ictus. Perhaps the first was that observed by Jackson et al. in 1994,[39] who showed that repeatable areas of focal signal increase were present during five consecutive seizures in a 4-year-old boy. Others have reported similar findings.[22,46,48,70] Although the diagnostic yield may well be higher during seizures, there are added practical problems. In a few cases, it may be possible to induce controlled seizures, but more generally it is unlikely that patients could be observed for long periods in the MRI device while waiting for seizures to occur. Because any subject motion can make data analysis impractical, only a subset of seizures not involving gross movement are amenable to study.

Summary and Conclusions

Functional MRI is now an established non-invasive tool for the study of human brain structure-function relationships, and thus of obvious interest in the diagnosis, characterization, and surgical management of the epilepsies. In surgical planning, it has been used with excellent success to guide surgeries that spare eloquent cortex, identify language lateralization with high accuracy and augment or replace the invasive Intracortical Amytal Procedure. While fMRI is superior in understanding complex patterns of language dominance, and the lack of a well-validated fMRI memory procedure means that the IAP will continue to have an important role. Newer methods are under development to detect and epileptogenic brain tissues by combining fMRI and electrophysiogic recording, and may provide an excellent avenue of access to restricted surgical resections for the management of seizure disorders.

Computational Anatomy

Jack J. Lin

John C. Mazziotta

Introduction

Improvements in magnetic resonance imaging (MRI) technology have significantly improved signal-to-noise characteristics, allowing in vivo visualization of brain anatomic structures at relatively high (<1 mm) resolution. With the use of mathematical modeling in computational anatomy, these high-resolution images can be manipulated to detect subtle differences in neuroanatomy beyond what is possible qualitatively with the human eye.[4]

Previously, quantitative magnetic resonance tools have focused on manually delineated volumes to assess brain size and regions of interest such as the hippocampus and the amygdala.[9,21] Volumetric changes may not be sensitive in detecting early or subtle changes. Even when volumetric changes are detected, these methods lack regional specificity because they cannot map the exact location of structural abnormalities. Region-of-interest studies can only evaluate the specific brain area in question, without assessing other structurally or functionally connected regions. Finally, volumetric studies cannot provide information relating to the change in shape of the neuroanatomic structure that maybe vulnerable to the underlying epileptic disease process.

With the advances in computational speed and automated image analysis, the emerging field of computational anatomy has recently been employed in epilepsy. Computational anatomy is the effort to develop algorithms that use mathematical techniques such as differential geometry, numerical analysis, and partial differential equations to model anatomic structures in brain image data.[46] Some of these techniques can be applied to the entire brain without a priori bias to study global changes associated with epilepsy.[10,11,30] Other techniques extend previous region-of-interest volumetric studies to map the precise location of atrophy and shape deviation in selected structures, such as the hippocampus.[25,33] These algorithms detect cross-sectional differences between an epilepsy group and appropriately matched controls or prospective changes over time. The regional-specific changes can also be related to clinical variables to elucidate the underlying structureâ€“function relationship. These studies provide a better understanding of the widespread cerebral changes associated with epilepsy, clinical factors that correlate with these anatomic differences, and anatomic predictors of surgical outcome. In this chapter, we review some of the basic algorithms of computational anatomy and discuss specific computational methods that have been employed in epilepsy. Finally, we highlight some of the important clinical findings resulting from these efforts.

Overview of Algorithms

Algorithms in computational anatomy can be divided into methods that evaluate whole brain or cortical structures versus those used to assess subcortical structures. Most whole-brain or cortical algorithms have all or some of the following steps in common: (a) brain extraction (remove voxels containing brain tissue from nonbrain voxels), (b) tissue classification (partition the voxels into gray and white matter and cerebrospinal fluid [CSF]), and (c) spatial normalization or registration. The great variability in human brain anatomy presents a particular challenge in developing strategies to average and compare brain structures across individuals. This is precisely the goal of spatial normalization, a pivotal step that differs greatly in different brain-mapping algorithms. Voxel-based morphometry and cortical pattern matching illustrate two potential approaches to some of these issues.[2,50] When studying subcortical structures such as the hippocampus, computational anatomists are no longer satisfied with volumetric information alone. Large-deformation, high-dimensional brain mapping (HDBM-LD) is a method for assessing morphologic shape changes such as inward or outward deviations that may give subtle but important clues to the underlying pathophysiologic process.[17,26] Surface-based anatomic mapping is another technique that maps the precise location of the atrophy pattern.[33,52] Specific disease processes may preferentially affect more vulnerable anatomic regions, and detailed visualization may further our understanding of the pathology. Diffusion tensor imaging (DTI) with probabilistic tractography allows the assessment of individual white matter bundle structural integrity that is not possible with conventional structural imaging.

Most computational methods require high-spatial-resolu-tion MRI with clear tissue differentiation among gray and white matter and CSF. Typically, T1-weighted, three-dimensional (3D) MRI such as spoiled-gradient-echo (SPGR) or magnetization-prepared rapid gradient-echo sequence (MP-RAGE) acquired on a 1.5- or 3-T magnet and 1-mm isotropic voxels across the entire cranium provides sufficient anatomic resolution for these analysis. These T1-weighted raw images can be improve with MR sequences using centric phase encoding rather than linear phase encoding.[18] Radiofre-quency inhomogeneity can be further corrected with a special excitation pulse to compensate these effects.[19] More recently, the development of the multichannel head coil array (iPAT-coil) has allowed parallel acquisition of independently reconstructed images, thus reducing scanner time and improving signal-to-noise characteristics.[56]

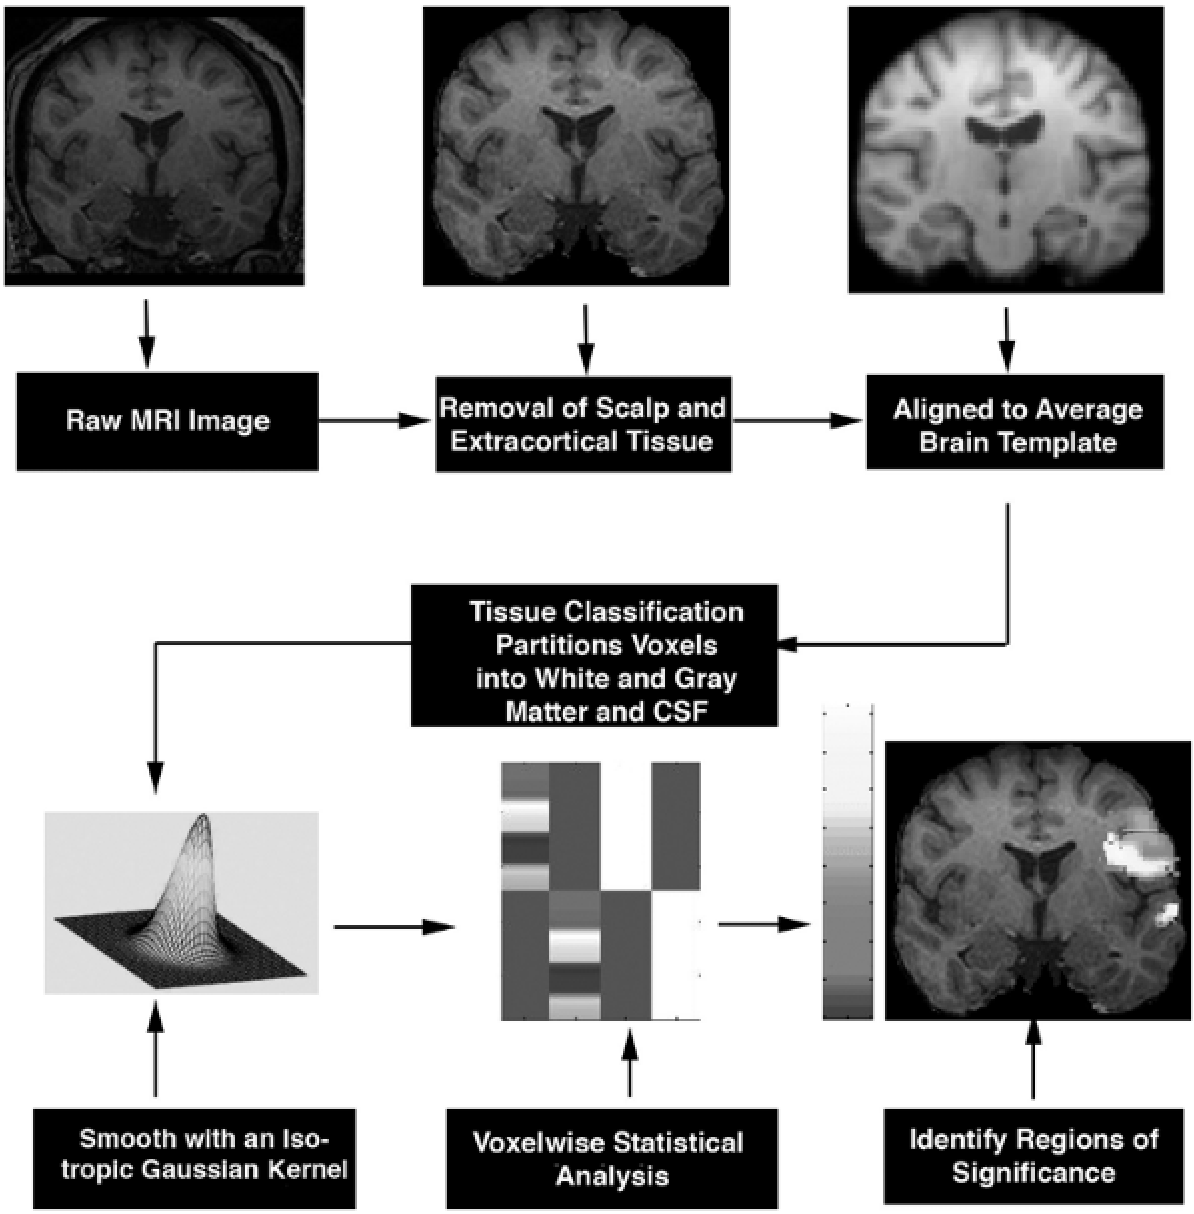

FIGURE 1. Steps in voxel-based morphometry. Scalp and extracortical tissues are removed from raw images, and the resulting brain images are normalized to a standard template. Gray and white matter and cerebrospinal fluid (CSF) are automatically classified based on voxel intensity values. Normalized images are smoothed with an isotropic Gaussian kernel. Voxelwise statistical analysis based on generalized linear model is applied to the images to identify regions of significance. MRI, magnetic resonance imaging. (See the color insert.)

Because temporal lobe epilepsy is the most common form of epilepsy, studies are particularly interested in defining lateral and mesial temporal lobe structural deficits. However, the temporal lobe, particularly the medial aspect, is partially surrounded by bone and tissue interfaces such as nasal sinuses, ear cavities, and perforated bone and thus is prone to susceptibility artifacts. Magnetic susceptibility differences between tissue/air and bone/tissue interfaces result in magnetic field gradients, which lead to intravoxel phase dispersion and image distortion. These susceptibility artifacts can affect computational results,

P.1000

and steps have been proposed to compensate for this static field effect. Spiral acquisition sequences use shorter TE and a single-shot acquisition, which can reduce geometric distortion.[23] Another approach to reducing local background gradient is to use Z-shimming, in which slice refocusing gradients are collected and combined.[22] More recently multiple array parallel image techniques have been employed to reduce susceptibility artifact and increase signal-to-noise characteristics (8).

Voxel-Based Morphometry

Voxel-based morphometry (VBM) is a whole-brain analysis tool in which voxelwise statistical comparisons of local gray matter concentrations are made between two groups of subjects.[2] VBM algorithms involve spatial normalization, tissue segmentation, smoothing, and finally application of statistical analysis to localize and infer group differences (Fig. 1). Spatial normalization involves the transformation of all of the subjects' images to the same stereotactic space to remove global brain difference between subjects. This step is important because the goal of VBM analysis is to detect regional brain tissue concentration, and, therefore, it must first remove global differences. Spatial normalization is achieved by registering the images to a standard template, such as the 152 normal data set from Montreal Neurological Institute (MNI152), using linear and nonlinear mathematical transformation based on prior knowledge of normal variability of brain size and correction for nonlinear shape differences.

More recently, an optimized VBM technique has been introduced that incorporates additional spatial processing steps in an attempt to improve image registration and segmentation. In this technique, instead of using a standard template such as the MNI152, a study-specific template created by averaging the spatially processed images of patients and controls is used to normalize the individual brain image. VBM spatial

P.1001

normalization steps do not attempt to match every cortical feature, but merely correct for intersubject global brain differences. Tissue classification partitions voxels into gray and white matter and CSF based on voxel intensity values. This model assumes that each tissue class fits in a mixture of intensity values with a Gaussian (normal) distribution and assigns the voxel with the highest probability of belonging to that particular class. Separate gray matter images can be derived after tissue classification. These images are then smoothed with an isotropic Gaussian kernel, rendering each voxel in the smoothed image to contain the average amount of gray matter from around the voxel. This is defined as the gray matter concentration at which the relative amount of gray matter in each voxel can be compared to that in another voxel in the same stereotactic space. Smoothing allows the data to be more normally distributed, increasing the validity of the parametric statistical tests. It also helps to compensate for the inexact nature of the spatial normalization. Whenever possible, the size of the smoothing kernel should be selected to reflect the expected regional tissue differences between the two study groups. The final step of this process is to use voxelwise statistical analysis based on a general linear model to discover regions of significance. This method identifies clusters of tissue with increased or decreased concentrations that are significantly related to the covariates under study, such as the differences between patient and control brains, duration of epilepsy, or epilepsy risk factors.

VBM offers a number of advantages in brain mapping. Many steps in this algorithm are automated, and, thus, inter- and intrarater errors and labor-intensive manual segmentation are reduced. It allows whole-brain analysis of both cortical and subcortical structures without preconceived bias for a particular structure. Because it uses voxel-by-voxel comparisons, this method can be modified to evaluate not only gray matter differences, but also white matter segmented images and indices of diffusion tensor images.[48a] However, spatial normalization is the most important step in this algorithm, and misregisteration of the image of interest to the template can produce systematic errors.[3,12] Furthermore, the gray matter concentration measurements in VBM are sensitive to losses in gray matter, increases in CSF volume, and differences in cortical surface curvature, which cannot be distinguished from each other.[13]

Cortical Pattern Matching

Cortical pattern matching is a technique that measures the topologic variability of the cortex. The wide anatomic variability among individual brains, especially gyral patterns of the cortex, presents a significant challenge when comparing brain structures across subjects.[49,54] By explicitly matching cortical gyral patterns, this technique eliminates much of the confounding anatomic variance when pooling data across subjects and increases the power to detect group differences.[51] Similar to VBM, all MR images are first globally aligned to a standardized anatomic template. Tissue classification algorithms then partition the aligned images into gray and white matter and CSF based on voxel intensity. Unlike VBM, additional steps are performed using parametric surface-based methods to generate a geometric 3D model of the cortex with deformation maps that explicitly associate corresponding cortical region across subjects (Fig. 2). A three-dimensional cortical surface model consisting of discrete triangular tiles is extracted from each individual brain image. Thirty-eight sulcal curves on the lateral and medial surface of each hemisphere are manually traced from each individual 3D cortical model (this protocol is available on the Internet at http://www.loni.ucla.edu/~khayashi/Public/medial_surface/). The cortical models along with the manually delineated sucal landmarks are flattened. A warping technique uses these sulcal landmarks to constrain the mapping of one cortex onto another by driving individual sucal features into correspondence with the average set of sulcal curves. This creates a flatten map that contains the average set of sulcal curves derived from many people. The warped images are averaged across subjects and decoded to produce an average cortical model for each group. Similar to VBM, a general linear model is applied to each cortical point to map regions that correlate with clinical variables.[53,55]

Although flattening the brain into a two-dimensional surface allows the explicit matching of the brain features across subjects, the deflation and inflation process also produce errors associated with compression and stretching of a three-dimensional structure. Several methods have been proposed to minimize these distortions. In the cortical pattern matching method, points on the flattened map contain color codes (red, blue, green) representing x, y, z coordinates in the original three-dimensional space.[54] Principles of continuum mechanics are applied to minimize distortion as one flat map is averaged onto another flat map. The average warped images can be inflated into a three-dimensional brain structure by decoding the embedded colored coordinate system. Another way of minimizing distortion of a flat map is to make a number of cuts in the medial surface of the three-dimensional brain, such as the corpus callosum, calcarine sulcus, and temporal poles.[20] Analogous to mapmaking, in which a spherical globe is transformed into a flat plane, these cuts remove most of the intrinsic curvature of the brain surface and allow it to be flattened with minor distortions. Geodesic metrics are used to calculate the shortest distances between vertices of the original folded surface. The cortical manifolds are unfolded onto a target surface and assigned normal vector fields with consistent orientation. The potentially large distortion from such a transformation is removed by a mathematical solution that minimizes the energy needed to unfold the original structure to the desired flattened shape. Thus, converting the brain into a two-dimensional plane allows topologic exploration of a highly folded and curved structure. However, computational solutions must be found to minimize distortion and maximize preservation of the original structural integrity.

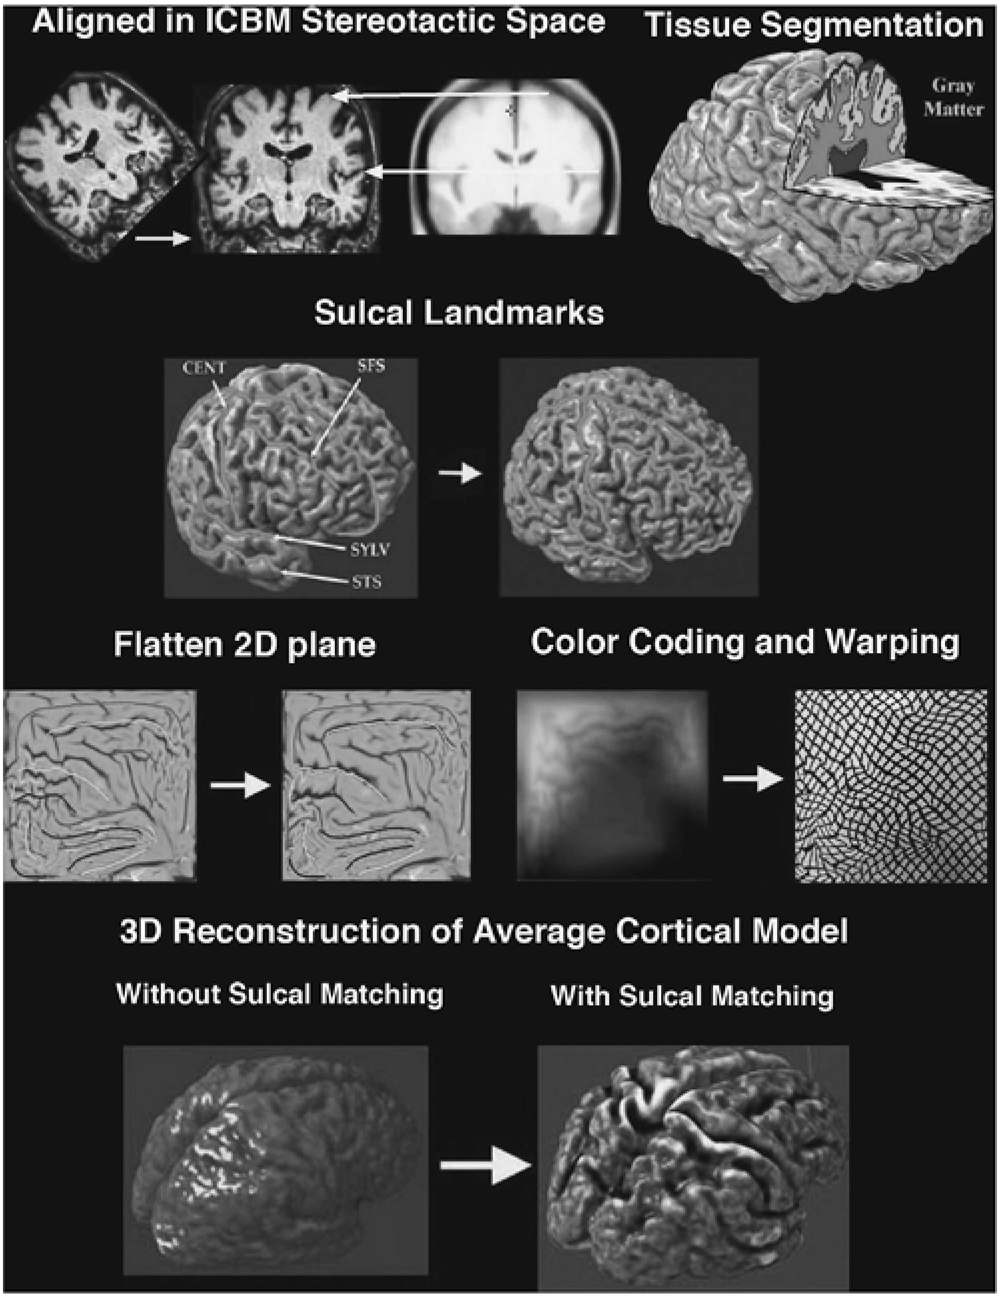

FIGURE 2. Steps in cortical pattern-matching algorithm. Raw images are first globally aligned to a standard template. Tissue classification partitions the image into gray and white matter and cerebrospinal fluid based on voxel intensity. A three-dimensional (3D) cortical model is extracted from each scan, and sulci are traced and labeled directly on the surface model. A geometric flattening process transforms the cortical model into two-dimensional (2D) space with retained sulcal landmarks. A color-coding system with intensities of the red, blue, and green corresponding proportionally to the x, y, z location of the three-dimensional cortical model plot the original coordinates onto the flat map. A warping technique uses the sulcal landmarks to constrain one cortical region onto another. The result produces an averaged cortical model for each group across subjects. Large-Deformation High-Dimensional Brain Mapping

HDBM-LD is a diffeomorphic mapping technique that analyzes subtle shape variations in subcortical brain structures.[17,29,37] This method has been applied to such enclosed structures as the hippocampus in epilepsy.[25,26] In this method, the typical brain structure is represented as a template and its variabilities determined by probabilistic diffeomorphic transformations applied to the template. A diffeomorphic transformation produces a map between topologic spaces that is constrained by laws of continuum mechanics while allowing all data points independent freedom to match. This allows the geometric properties of the neuroanatomic substructures to be preserved. The algorithm begins with semiautomatic segmentation of the hippocampus. Individuals with expert anatomic knowledge first manually segment a template hippocampus.[25] Brain images from target scans are then globally aligned to the template image with standard landmarks from a coordinate system such as that of Talairach and Tournoux.[47a] Hippocampal-specific landmarks such as the head and tail define the long axis of the hippocampus in the target scan. Several additional landmarks are placed in cross sections along the axis. Using these manually defined hippocampal

boundaries, a mapping algorithm generates transformation fields from template images to the target images, thus automatically defining the hippocampus. More important, the diffeomorphic transformation fields and the matrices derived from them contain information defining the composite shape and volume of the structure. Statistical tests can be applied to determine the degree of shape and volume change between groups and within individuals over time. The initial steps of defining the brain structure of interest in the template image and landmarks in the target images require knowledge of neuroanatomy. Once the template structure has been delineated and target boundary points have been chosen, this algorithm relies solely on the transformation to apply the neuroanatomic information to a large number of individual target scans.

Anatomic Surface Modeling

This method uses surface-based mesh modeling combined with surface-based statistics to map the three-dimensional profile of an enclosed structure such as the hippocampus or ventricle.[33,52] Images are first linearly aligned and manually registered to the average template stereotaxic space (Fig. 3). A standard neuroanatomic atlas is used as a guide to manually segment the hippocampus. Hippocampal models are then delineated in continuous coronal brain MR sections, including the hippocampus proper, dentate gyrus, and subiculum. Based on the use of interactive segmentation software, anatomic landmarks are followed by viewing images in all three orthogonal planes simultaneously. An anatomic mesh modeling method is used to match equivalent hippocampal surface points obtained from manual tracings across subjects and groups. Three-dimensional parametric surface mesh models are generated from manually segmented hippocampal tracings. This allows one to match the digitized points in the parametric surface model in each brain volume, and these corresponding surface points can be compared statistically in three dimensions. This surface matching method also allows the calculation of average hippocampal morphology across individuals belonging to a group and the variance among corresponding surface points relative to group averages.

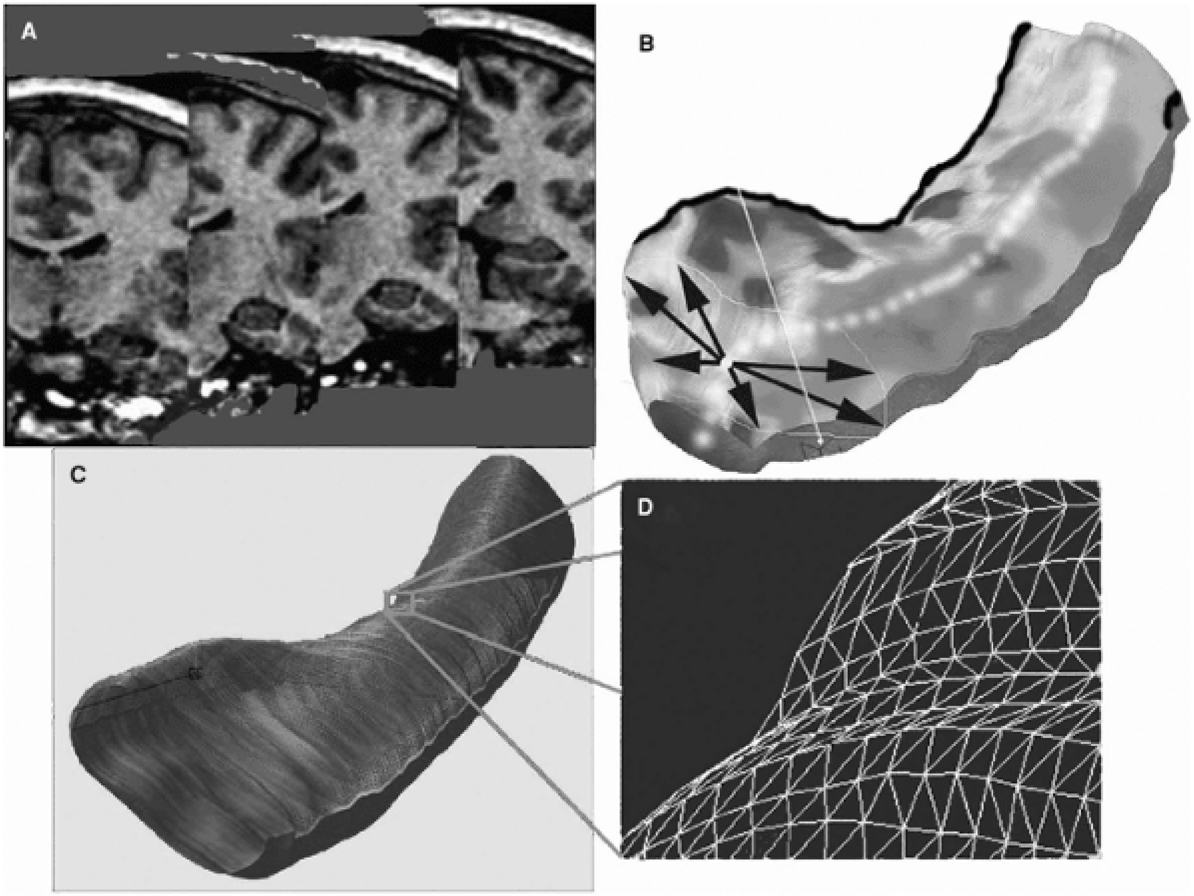

FIGURE 3. Steps involved in three-dimensional (3D) hippocampal modeling. Each individual's hippocampus is traced in consecutive coronal magnetic resonance imaging sections **(A)** and converted to a 3D parametric surface **(B)** in which the radial size of the hippocampus is measured from a centerline and plotted in color on the surface to index radial atrophy. These meshes are averaged across subjects **(C)**, and atrophy relative to control means is computed at each surface grid point **(D)**. (See the color insert.)

The 3D parametric mesh models of each hippocampus are analyzed to compute the average region-specific volume difference among groups. To measure the patterns of regional hippocampal atrophy, a â€œmedial curveâ€ is defined for each individual hippocampus as the 3D curve traced out by the centroid of the hippocampal boundary in each section. Radial distances from homologous hippocampal surface points to the central core of each surface model are determined to assess the radial distance of each hippocampal boundary point. These numerical distances assigned to each hippocampal boundary point can be thought of as a map of hippocampal radial volume. The radial measures can be compared across groups or within a group over time to generate region-specific maps of change. Multiple regressions are carried out to assess the extent of hippocampal change associated with clinical characteristics. The

resulting maps are visualized and their significance assessed by permutation to correct for multiple comparisons within each statistical map. This method measures the boundary changes relative to the medial core of an anatomic object. Thus, it is sensitive in localizing regional atrophy patterns but is not confounded by overall shift or rotation of the structure.

Defining Anatomic Boundaries of The Hippocampus

Both HDBM-LD and anatomic surface modeling require individuals with expert knowledge in anatomy and radiology to segment the hippocampus because the anatomic boundary is difficult to determine on MRI studies.[28] Earlier volumetric studies used variable landmarks to delineate the anterior and posterior boundaries of the hippocampus, with certain groups excluding the head[5,47] and another group excluding the tail.[27] Most recent work has traced the entire hippocampus by following a protocol such as that of Watson et al.[60] Even with similar protocols, differences in hippocampal morphometry still exist because the boundaries are determined by neighboring structures such as the crura of the fornices to delimit the posterior landmark and thus are prone to intra- and interrater errors. A small difference in how close an operator manually traces the in-plane hippocampal boundaries results in large differences in the eventual segmented structure. These discrepancies affect the computational results of any study that relies on manual hippocampal parcellation. Thus, it is imperative that each study follows well-defined anatomic boundaries with high inter and intrarater reliability.

Diffusion Tensor Imaging and Probabilistic Tractography

DTI is a relatively new MR sequence that provides a measure of the structural integrity of white matter tracts by measuring the diffusion of water and its directionality in three-dimensional space.[7,40] A medium that lacks a barrier to water diffusion, such as the cerebrospinal fluid, is isotropic. Membranes perpendicular to neuronal structures that have a highly parallel organization direct water diffusion. These structures have diffusion tensors aligned with their long axis, resulting in an anisotropic environment. Thus, fractional anisotropy can be quantified by assigning values between 0 (isotropic) to 1 (anisotropic). Due to the cylindrical geometry of white matter fibers, anisotropy is higher than in gray matter, where the cellular geometry is more globular. Thus, lower anisotropy values in white matter are indicative of poor structural organization of white matter tracts because highly organized fiber bundles constrain the motion of water molecules in a preferred direction parallel to the orientation of the fibers.

Probabilistic tractography has been developed to assess individual white matter bundles. The goal of tractography is to reconstruct the three-dimensional trajectories of white matter

tracts by following the continuous path of greatest diffusivity.[14] A commonly used method uses line-propagation algorithms by assuming that the orientation of the largest component of the diffusion tensor (principal eigenvector) represents the dominant axonal tracts.[39] Based on anatomic knowledge, a seed point is place as a starting point in a region of interest (e.g., the fornix at the level where fusion is visible).[16,59] A linear propagation model is used to convert the tensor information in each voxel to a continuous tracking line. Lines are terminated based on their anisotropy value and angle of curvature. Because gray matter has low anisotropy compared to white matter (typically 0.1â€“0.2), a line can be terminated if the anisotropy of the voxel falls below a preset threshold (e.g., 0.2 or 0.3). Large-angle transitions from one voxel to the next create large errors in the linear propagation model. In addition, the curvature violates the assumption that diffusion along an axis is normally distributed. Therefore, the tract will be terminated if consecutive voxels have a curvature greater than the predetermined threshold (typical range is from 50 to 70 degrees). Probabilistic tractography can delineate regions of interest based on fiber orientation and integrity.

Applications of Voxel-Based Morphometry and Cortical Sulcal Matching In Epilepsy

Previous MRI morphometric studies focused on manually segmented volumes derived from single brain regions such as entire cerebral cortex or its lobes.[38,48] Inferences from these data are limited, in that one cannot assess the precise localization of the abnormality within the delimited volume. For example, if a frontal lobe volume difference is found between two groups, it is impossible further to define whether the difference is localized in the orbital frontal or lateral frontal regions. Such differences may have important implications for associated functional or behavioral deficits. Furthermore, one cannot determine the relationship to other neuronal connected structures not under study. These image analysis procedures are also labor-intensive and suffer from difficulties related to defining reliable anatomic boundaries.

Voxel-based morphometry and cortical sulcal matching techniques permit whole-brain and cortical analysis of brain images, respectively. Most of the studies in temporal lobe epilepsy patients used VBM to evaluate extrahippocampal structural abnormalities associated with this epilepsy syndrome, although it is also sensitive in detecting hippocampal deficits.[31] In temporal lobe epilepsy, most studies show that structural deficits extend beyond the hippocampus and involve multiple neocortical regions. Patients with temporal lobe epilepsy exhibit marked white matter reduction, predominately in the temporal lobe ipsilateral to the presumed epileptogenic zone and in the corpus callosum.[10,36] In addition, VBM studies consistently have found gray matter reduction in bilateral frontal regions and the thalamus.[10,11,30] Both Keller's and Boniha's groups showed gray matter involvement bilaterally in the parietal-occipital regions,[30,11] whereas Bernasconi and coworkers only found decreases in the occipital regions of left temporal lobe epilepsy patients.[10] Different investigators have reported conflicting results in the temporal lobe neocortex, with some suggesting increases in gray matter concentration,[30] whereas others have reported decreases in this region.[10,11] These discrepancies may result from different VBM tissue registration and segmentation techniques. As previously noted, spatial registration is a critical step in VBM. In attempting to ensure that the same brain regions are comparable among different individuals, matching of an individual brain to the template may transform the shape of the brain, resulting in inflation and deflation of brain regions. These studies used different spatial registration techniques, which may in part account for the differences in detecting temporal occipital parietal deficits. Keller et al. compared standard and â€œoptimizedâ€ VBM and showed that â€œoptimizedâ€ VBM, which incorporates additional spatial processing steps to improve image registration and conservation of tissue volumes after normalization, yielded increased sensitivity in detecting extrahippocampal structural abnormalities in temporal lobe epilepsy.[31]

More recently, cortical pattern matching techniques have been applied in mesial temporal lobe epilepsy.[33a] As previously noted, this method allows the explicit matching of consistent neuroanatomic structures in the neocortex (i.e., sulcal landmarks and cortical surfaces) across subjects, thus enhancing the signal-to-noise ratio for detecting group differences. In fact, the sulcal pattern alignment results in a higher-dimensional alignment of brain structure across subjects than is typically achievable using automated nonlinear registration approaches. An algorithm has been developed to estimate gray matter cortical thickness in millimeters from T1-weighted MRI scans.[41,55] Compared to healthy controls, both right and left mesial temporal lobe epilepsy (MTLE) patients show regions with up to a 30% bilateral decrease in average cortical thickness. Significant thinning of the cortical ribbon is found in the bilateral frontal poles, frontal operculum, orbital frontal, lateral temporal, and occipital regions. In both MTLE groups, cortical thickness was also reduced in the right angular gyrus and primary sensorimotor cortex surrounding the central sulcus. Furthermore, longer seizure duration was correlated with decreased cortical thickness in the superior frontoparietal regions, including the primary sensorimotor cortex and the parahippocampal gyrus ipsilateral to the side of seizure onset.

For many years, functional studies such as interictal positron emission tomography (PET) have demonstrated widespread metabolic changes associated with temporal lobe epilepsy.[24] By visualizing the entire cerebrum, VBM and cortical pattern-matching techniques have determined that the presence of the structural deficit pattern in chronic unilateral temporal lobe epilepsy patients also extends to multiple cortical and subcortical regions. These regions are primarily located in the efferent limbic neocortical pathway. MR tractography studies have visualized the direct connectivity between limbic structures such as the hippocampus and neocortical areas such as temporal, orbitofrontal, and extrastriate occipital lobes.[45] A similar limbic neocortical network has also been demonstrated in patients with complex partial seizures using interictal and ictal single photon emission computed tomography (SPECT).[58] Thus, many authors have proposed that these deficits are due to limbic efferent disconnection from the chronic epileptogenic temporal lobe.[10,11] However, conclusions about disease progression and cause and effect issues between epilepsy and brain damage are limited in these cross-sectional studies.[34] A cross-sectional study cannot differentiate the underlying etiology of the structural changes, which may include acute damage associated with an initial precipitating injury, such as febrile seizure or head injury, that triggered epileptogenesis, chronic progression of damage caused by the initial insult, or possible damaging effects of recurrent seizures.[43]

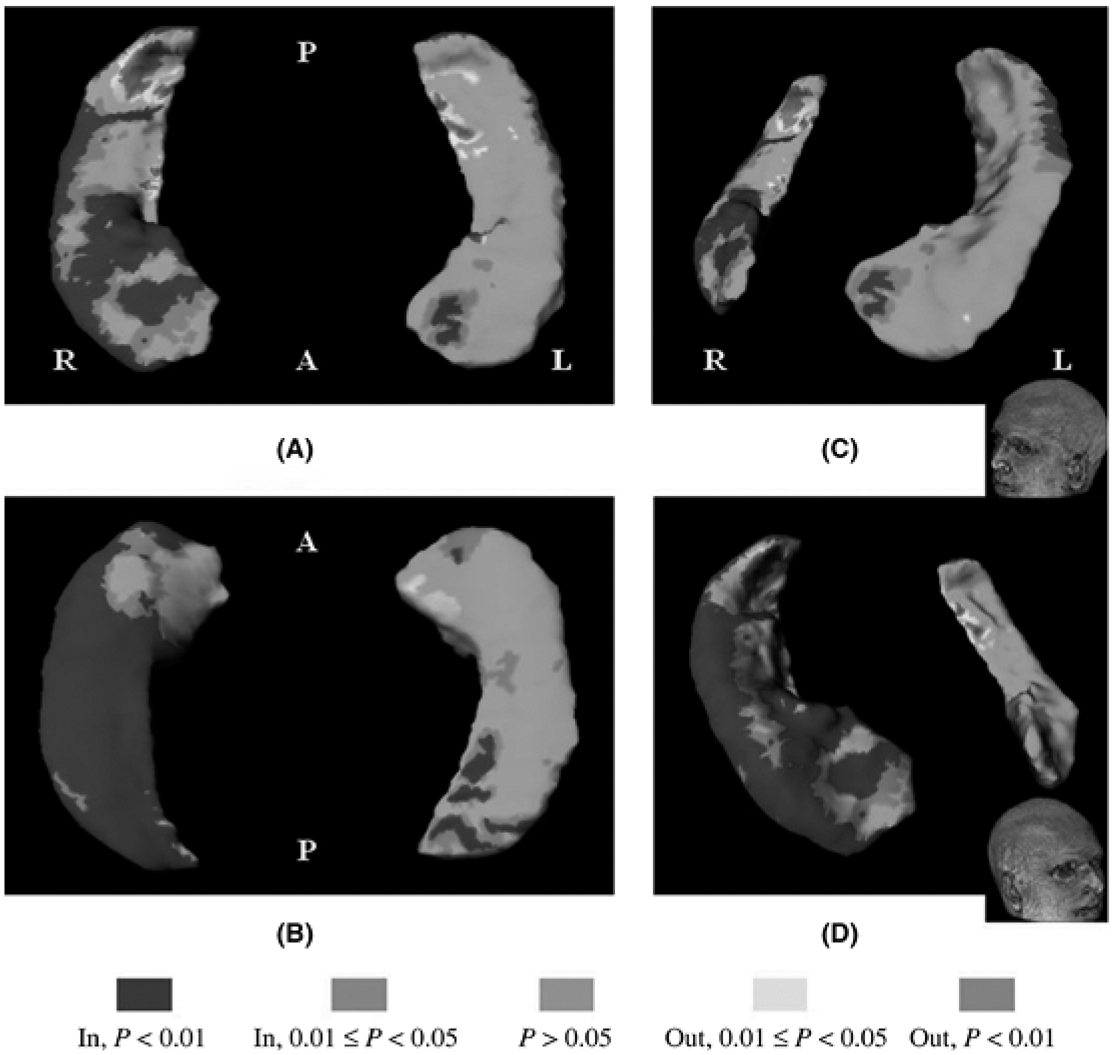

FIGURE 4. Large-deformation, high-dim-ensional brain mapping reveals bilateral hippocampal deformity in right mesial temporal lobe epilepsy patients. Similar bilateral changes were found in left temporal lobe epilepsy patients. Inward deviation is shown in purple (p <.01) and turquoise (.01 = p <.05). Outward deviation is shown in red (p <.01) and yellow (.01 = p <.05). **A:** View from above. **B:** View from below. **C:** View from a perspective slightly above and to the left of a midline plane, showing the top side. **D:** View from a perspective slightly above and to the right of a midline plane, showing the top side. A, anterior; L, left; P, posterior; R, right. (From Hogan RE, Wang L, Bertrand ME, et al. MRI-based high-dimensional hippocampal mapping in mesial temporal lobe epilepsy. *Brain*. 2004;127:1731â€"1740, with permission.) (See the color insert.)

A recent prospective longitudinal study examined the progression of neocortical damage in epilepsy.[35] This study used a voxel-based approach to examine neocortical changes in patients with focal and generalized epilepsy in a 3.5-year time span. Because this was a prospective study in which all subjects were scanned twice at two different time points, an image subtraction method was developed to detect differences over time. Thus, voxels of individual repeat scans were subtracted from the baseline scan to generate a difference image. However, to reduce false-positive results due to artifacts such as pulsation within the temporal lobe, a separate spatially

P.1005

normalized structural noise map was generated from difference images of healthy controls. This structural noise map was used as a threshold against the difference map in epileptic patients to define the genuine pathologic change. The resulting difference maps of epileptic patients were visually assessed by two raters to determine whether the changes in voxel pattern between the two scans were focal or generalized. Focal or generalized neocortical volume losses were found in 54% of patients with chronic epilepsy, 39% of patients with newly diagnosed epilepsy, and 24% of controls. The most common pattern of structural change was generalized volume loss, which was observed in both focal and generalized epilepsy syndromes. Generalized volume loss was associated with age and more commonly seen in patients with increased exposure to antiepileptic drugs. The less common pattern of focal neocortical changes was not related to the epilepsy syndrome, having been seen in both types of epilepsy.

Applications of Large-Deformation, High-Dimensional Brain Mapping In Epilepsy

Underlying neuronal connections influence neuronal anatomic shape during morphogenesis. For example, during early development, neurons migrate to the cortical plate along radial glial cells and emanate axons that connect target regions. The physical forces of these interconnecting regions affect the ultimate shape of the neuroanatomic structure.[57] Shape changes may be a particularly sensitive index of disturbances in the underlying anatomic connections and offer another window for analyzing a disease process.[17] This method has been applied this technique to evaluate hippocampal shape deformation in mesial temporal lobe epilepsy patients.[26] Compared to normal controls, the hippocampus with mesial temporal sclerosis (MTS) has large regions of significant inward deviation mapped to the CA1 subfield and the subiculum (Fig. 4). The hippocampus contralateral to MTS also showed significant inward deviation, but the pattern was markedly differently relative to the MTS hippocampus. The contralateral hippocampus showed smaller and more regional inward deviation in the medial hippocampal head and the inferior and lateral aspects of the hippocampal body. More important, the contralateral hippocampal volumes showed no difference between control and MTLE subjects. Thus, hippocampus shape change appears to be a more sensitive measurement of neuronal disturbance in this epilepsy syndrome. In the future, this technique may be useful in epilepsy surgical evaluation to help to define subtle anatomic abnormalities of the hippocampus that are not apparent by visual inspection or volumetric analysis.

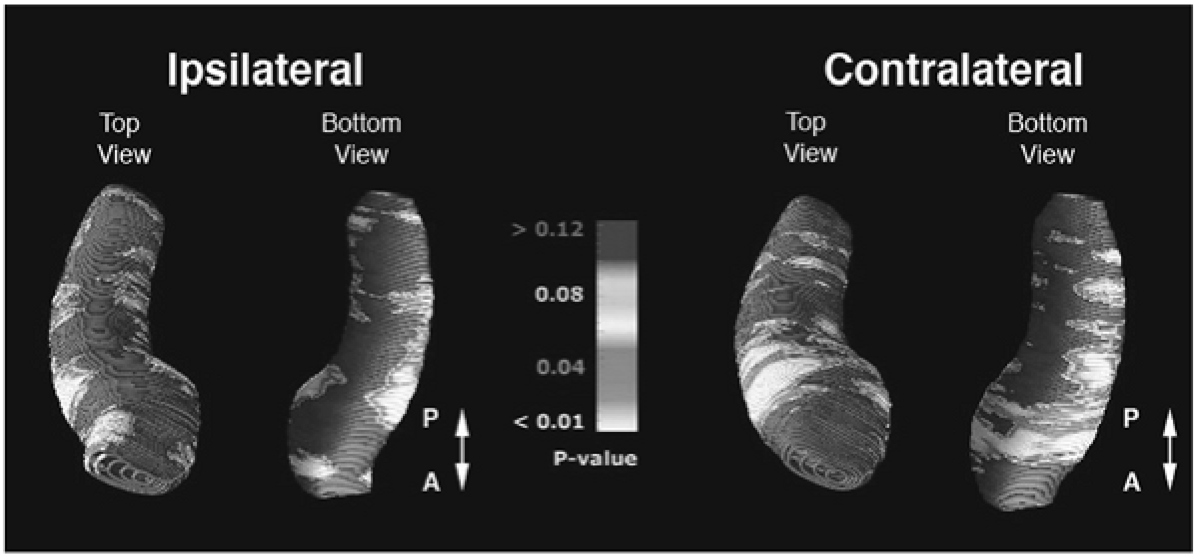

FIGURE 5. Maps identifying regions where seizure-free (SF) and not-seizure-free (NSF) surgical outcome groups differ in their degree of atrophy. Group difference maps show mean hippocampal volume differences ipsilateral **(left)** and contralateral **(right)** to the side of seizure onset. Areas of significant atrophy between the two surgical outcome groups are plotted as a map of *p* values. The NSF groups show significantly greater diffuse atrophy in the ipsilateral hippocampus, whereas the contralateral side shows a more region-specific

atrophy pattern. The maximal atrophy is seen in the anterior and lateral aspects of the contralateral hippocampus. A, anterior; P, posterior. (Adapted from Lin JJ, Salamon N, Dutton RA, et al. Three-dimensional preoperative maps of hippocampal atrophy predict surgical outcomes in temporal lobe epilepsy. *Neurology*. 2005;65:1094â€“1097, with permission.) (See the color insert.)

Application of Anatomic Surface Modeling In Epilepsy

Anatomic surface modeling combined with surface-based statistics has been applied to preoperative MRI studies of patients with MTLE to isolate hippocampal deficit profiles that are associated with better or poorer surgical outcome.[33] All patients had well-localized MTLE based on seizure semiology and ictal EEG and had preoperative MRI showing unilateral hippocampal atrophy. They underwent anteromesial temporal resection and were followed for at least 2 years. Three-dimensional hippocampal profiles of seizure-free (SF) patients were compared to those who continued to have seizures (NSF). Direct comparison of the ipsilateral and contralateral hippocampi between the SF and NSF group showed that the NSF group had greater bilateral hippocampal atrophy, but the

distribution of the atrophy was markedly different between the two hippocampi. The NSF group showed greater hippocampal atrophy in a relatively uniform pattern in the ipsilateral hippocampus when compared to the SF group (Fig. 5). However, the contralateral hippocampus showed a more regional atrophy pattern maximally involving the anterior hippocampus.

The visualization of a three-dimensional hippocampal atrophy map provides greater insight into the underlying mechanisms of hippocampal damage that may be associated with surgical outcome. The greater contralateral hippocampal involvement may suggest further disease progression in the NSF group, in which the sclerotic ipsilateral hippocampus would already be diffusely damaged (i.e., a floor effect), whereas the contralateral hippocampus may exhibit damage only in regions with the greatest susceptibility for epileptogenesis. In animal studies, the ventral hippocampus, analogous to the human anterior hippocampus, has much greater seizure susceptibility.[1] In human surgical specimens, there is greater neuronal cell loss in the anterior compared to the posterior hippocampus.[6] Seizure propagation from one hippocampus to the other over time may lead to damage first in the most vulnerable areas of the contralateral hippocampus.

Applications of Diffusion Tensor Imaging and Tractography In Epilepsy

Probabilistic tractography has permitted virtual in vivo dissection of white matter fasciculi by reconstructing three-dimensional trajectories of white matter tracts. Once these tracks are identified, the integrity of the white matter bundles can be evaluated with DTI indices such as fractional anisotropy. DTI analysis with fiber tracking has been applied to detect axonal degeneration in the fornix and cingulum in a group of temporal lobe epilepsy patients with MTS.[15] Previously, volumetric studies of the fornix in mesial temporal lobe epilepsy only revealed unilateral fornix atrophy concordant to side of hippocampal sclerosis.[32,42] Based on the use of DTI measurements, bilaterally symmetric reductions in fractional anisotropy were observed in the fornix and cingulum of patients with unilateral MTLE (Fig. 6). The presence of these bilateral abnormalities in unilateral temporal lobe epilepsy patients is an unexpected finding based on previous volumetric studies and may indicate that DTI is a more sensitive determinant of structural integrity. However, the clinical implication of the bilateral DTI abnormality in MTLE is limited because structureâ€“function relationships were not studied.

Another application of DTI tractography is for the identification of anatomic structures that are difficult to delineate on conventional MRI and have great variability in the normal population. Visual field defects are a significant morbidity associated with a minority of patients who undergo anterior temporal lobe resection for drug-resistant epilepsy due to disruption of Meyer's loop. Defining the preoperative location of this white matter tract and identifying those patients who are at risk for visual field defects has proved to be a challenge. Powel et al. used probabilistic tractography to define the optic tract and overlaid these results onto the postoperative anatomic MRI to assess the location of Meyer's loop in relation to the region of surgical resection.[44] Compared to a patient without postoperative complications, a patient with visual field defect had a Meyer's loop that extends more anteriorly and inferiorly, encroaching into the resection region and surgically disrupting this tract (Fig. 7). DTI tractography may help to define individual optic radiation anatomy and identify patients at risk for visual field defects after temporal resection.

Summary and Conclusions

Computational anatomy has been increasingly applied to characterize structural abnormalities in patients with epilepsy. Comparison of anatomic structures in terms of manifolds of points, curves, and surfaces governed by probability laws allows statistical inferences of group differences. Morphometric techniques such as VBM and cortical pattern matching have detected systematic differences in gray matter distribution in the frontal regions and the thalamus and white matter distribution in the temporal lobe and corpus callosum in TLE. More variable gray matter deficits have been found in the temporal,

P.1007

P.1008

parietal, and occipital regions, which may in part due to different spatial registration methods. Mapping of these neuroanatomic deficits in the three-dimensional space of the entire cerebrum have permitted greater understanding of the distributed network involved in the epileptogenic process. Metrics other than overall volume have been used to localize deficit patterns and assess changes in shape of a subcortical structure such as the hippocampus. Alterations in the shape of a structure may precede volumetric changes, reflecting more subtle disturbances in neuronal organization. Localizing the region-specific hippocampal atrophy patterns based on clinical outcome groups has allowed more precise characterization of anatomic changes associated with each disease state and provides clues to potential underlying pathophysiology. DTI tractography provides a sensitive measurement of white matter tract integrity and permits assessment of specific fasciculi that are not visible on conventional MRI. Thus, computational anatomy has already offered new approaches to investigating subtle neuroanatomic disturbances in epilepsy. With continuing improvement in computational algorithms, these tools will be further applied in epilepsy to study neuroanatomic markers of genetic variability, disease progression, and clinical outcome.

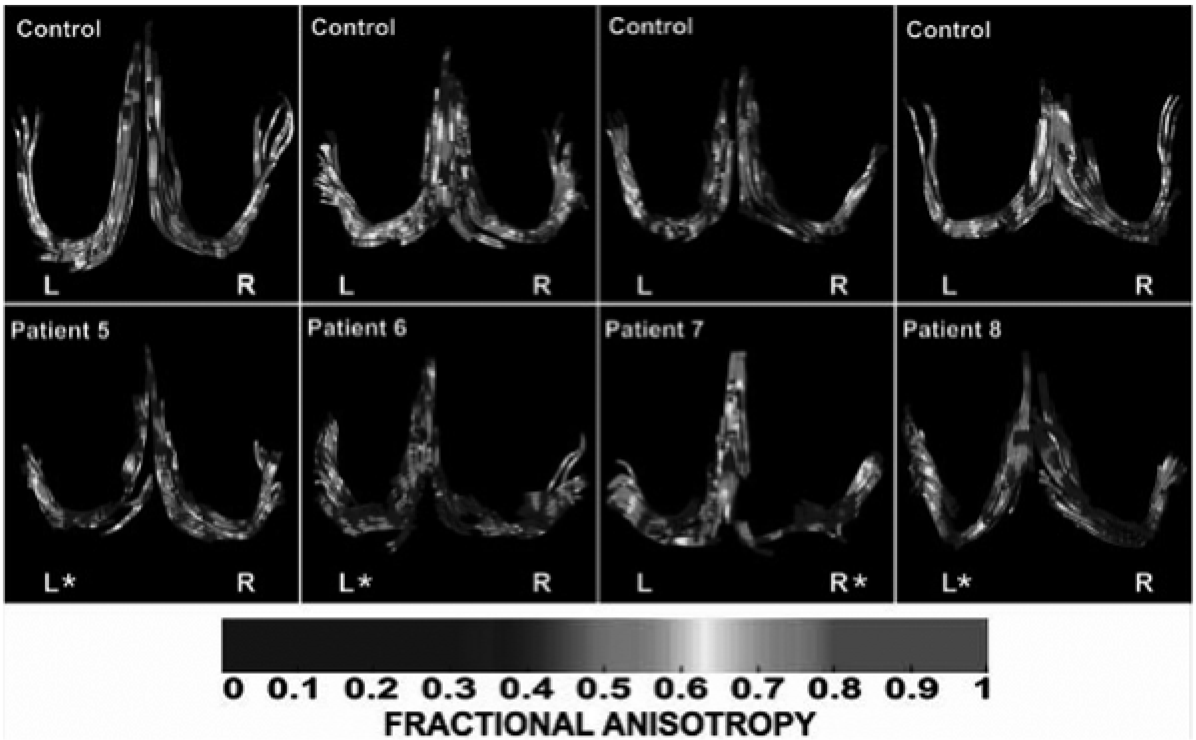

FIGURE 6. Diffusion tensor imaging tractography mapped the integrity of the fornix in four healthy controls

and four patients with unilateral mesial temporal lobe sclerosis (MTS). Fractional isotropy for each voxel is color coded, with higher values denoting greater structural organization. Fornix of patients with MTS has lower anisotropy and less continuous tracts. Asterisk indicates the side of MTS. L, left; R, right. (From Concha L, Beaulieu C, Gross DW. Bilateral limbic diffusion abnormalities in unilateral temporal lobe epilepsy. *Ann Neurol*. 2005;57:188â€“196; with permission.) (See the color insert.)

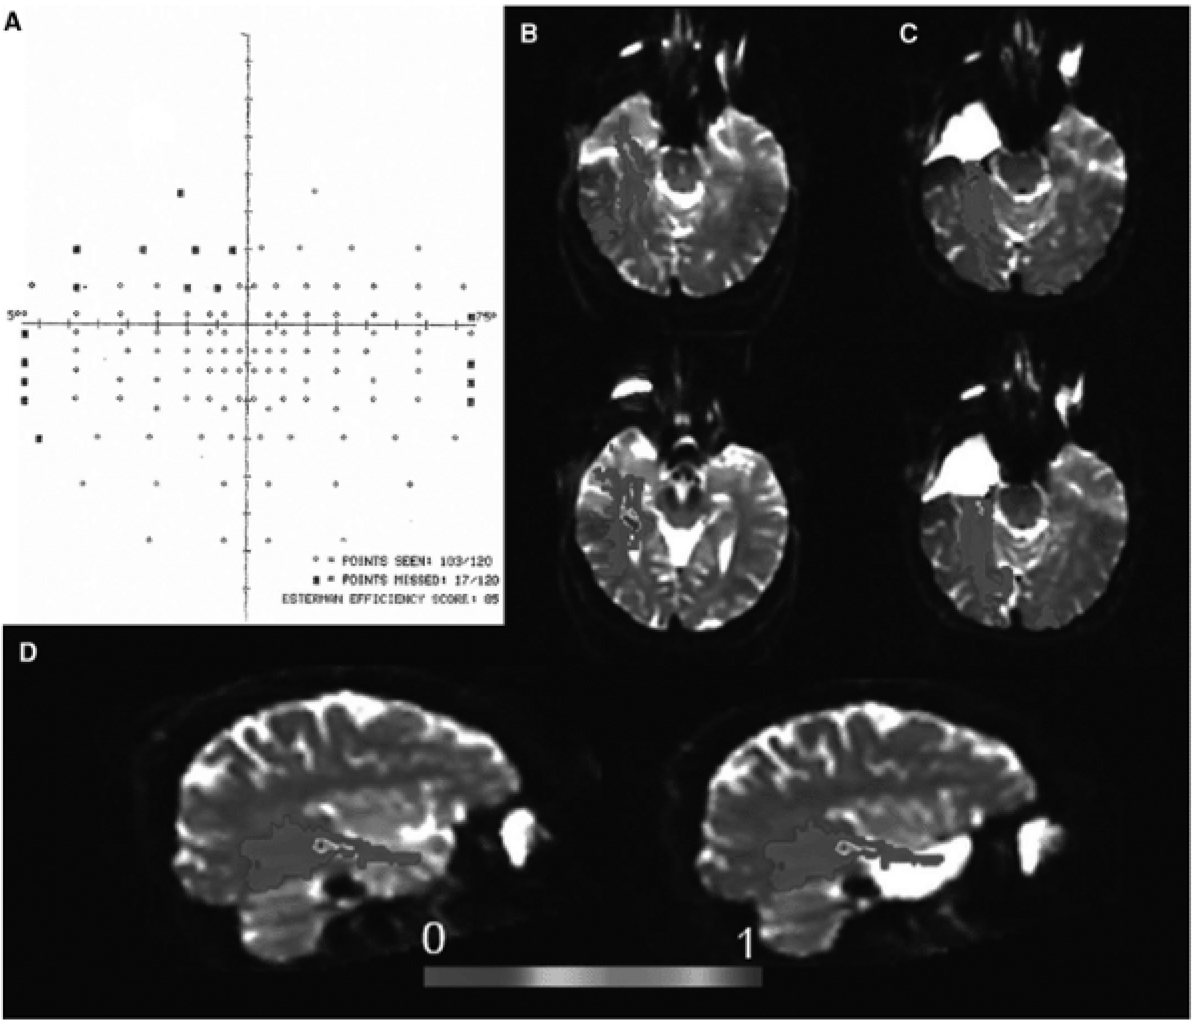

FIGURE 7. Postoperative visual field demonstrates a superior homonymous quadrantanopia **(A)**. Preoperative right optic radiation overlaid on preoperative axial **(B)** images; postoperative right optic radiation overlaid on postoperative axial image **(C)**; preoperative optic radiation overlaid on preoperative sagittal **(D, left)** image and postoperative optic radiation overlaid on postoperative sagittal **(D, right)** image. These images show that the preoperative tract overlies the resected anterior temporal lobe, resulting in postoperative visual field deficit. (From Powell HW, Parker GJ, Alexander DC, et al. MR tractography predicts visual field defects following temporal lobe resection. *Neurology*. 2005;65:596â€“599; with permission.) (See the color insert.)

Chapter 85
Seizure Prediction

Klaus Lehnertz

Michel Le Van Quyen

Brian Litt

Introduction

Seizure prediction, anticipation, or forecasting (despite their different meanings, these terms are currently used interchangeably) is a field of great interest in the clinical and basic neuroscience communities. This is not only because of its potential clinical application in warning and therapeutic antiepileptic devices, but also for its promise to increase our understanding of the mechanisms underlying epilepsy and seizure generation. The motivation for research into the predictability of seizures is straightforward. The fact that seizures occur without warning in the majority of cases is one of the most disabling aspects of epilepsy. If it were possible to predict seizures with high sensitivity and specificity, even seconds before their onset, therapeutic possibilities would change dramatically.[50] One might envision a simple warning system capable of decreasing both the risk of injury and the feeling of helplessness that results from seemingly unpredictable seizures. Side effects from treatment with antiepileptic drugs, such as sedation and clouded thinking, could be reduced by on-demand release of a short-acting drug[48,197] or electrical stimulation[62,175,213] during the pre-ictal state. Paired with other suitable interventions, such as focal cooling[70] or biofeedback operant conditioning,[56,170,198] such applications could reduce morbidity and mortality, and greatly improve the quality-of-life for people with epilepsy. In addition, identifying a pre-ictal state would greatly contribute to our understanding of the pathophysiologic mechanisms that generate seizures.

In most patients seizures appear to occur unpredictably, with no discernible pattern, while in others, seizures appear to be entrained to biologic rhythms, such as menstrual or sleepâ€“wake cycles. Clustering patterns, where one seizure appears to increase the likelihood of subsequent seizures, also appear common in clinical practice. Despite these observations, analyses of long-term patterns based upon seizure diaries[4,11,16,74,115,147,204] have yielded inconsistent findings. While some authors conclude that the timing of seizure recurrence is random, others hypothesize that seizures occur in a probabilistic nonlinear fashion. Because of this inconsistency, based upon clinical observations, the transition to a seizure has generally been thought of as an abrupt phenomenon, occurring without warning. Nevertheless, there is physiologic support for the idea that at least certain types of seizures are predictable.

Several seizure-facilitating factors are known. Lennox[125] defined seizure facilitation as the input of sensory, metabolic, emotional, or other yet unknown factors that â€œfill up some reservoir until it overflows,â€ which in turn results in a seizure. State of consciousness, sleep deprivation, being tense, disturbances of electrolytes and acidâ€“base balance, sensory stimulation, and exposure to certain drugs are factors known to potentiate seizures. Apart from the rare exception of sensory-evoked or reflex epilepsies, however, these factors are rather nonspecific and highly variable, since they depend on individual habits, susceptibility, and daily routine.

Clinicians who care for patients with epilepsy have long known that individual patients can identify periods when seizures are more likely to occur, though they can rarely specify an exact time when seizures will happen. Rajna et al.[174] found that the vague sensations that characterize these periods, called â€œclinical prodromes,â€ occurred in more than 50% of 562 investigated patients, though the reliability of these reports was not evaluated prospectively. Reported sensations included mood changes, irritability, sleep problems, nausea, and headache. There are also physiologic studies in small numbers of patients, usually collected serendipitously before seizures, that support the existence of a pre-ictal period. Weinand et al.[216] detected a significant increase in blood flow in the epileptic temporal lobe that started 10 minutes before seizure onset that spread to both temporal lobes 2 minutes before seizure onset. Similarly, Baumgartner et al.[14] demonstrated increased blood flow in the epileptic temporal lobe in two patients, 11 and 12 minutes, respectively, before seizure onset. Using near-infrared spectroscopy in three patients, Adelson et al.[2] reported an increase in cerebral oxygen availability that began more than 13.5 hours, and was identified as early as 1.5 hours, before documented seizure onset. Pre-ictal changes in other variables, such as Râ€"R interval on the electrocardiogram (ECG)[40,95,159] may also have predictive value, perhaps as epiphenomena related to seizure precursors, in some types of epilepsy. More recently, functional magnetic resonance imaging has demonstrated changes in perfusion prior to seizure onset.[55]

During recent years, a variety of potential ictogenic (seizure-generating) mechanisms have been identified in experimental models of focal epilepsy, including alterations in synaptic and cellular plasticity and changes in the extracellular milieu (see Section II). However, it is still a matter of debate whether these mechanisms can be regarded as specifically ictogenic, apart from their critical role in normal brain function. On the level of neuronal networks, focal seizures are assumed to be initiated by abnormally discharging neurons (so-called *bursters*[21,22,34,182,208]; see reference 226 for an overview) that recruit and entrain neighboring neurons into a critical mass. This build-up might be mediated by an increasing synchronization of neuronal activity that is accompanied by a loss of inhibition, or by processes that facilitate seizures by lowering the threshold for excitation or synchronization. In this context the term â€œcritical massâ€ might be misleading in the sense that it implies an increasing *number of neurons* that are entrained into an abnormal firing pattern. This *mass* phenomenon would be easily accessible to conventional electroencephalogram (EEG) analysis, which, to date, has failed to detect it. Rather, the seizure-initiating process might better be visualized as a process in which an increasing number of critical interactions between neurons in a focal region and connected units in an abnormal functional network unfold over time. Indeed, there is now converging evidence from different laboratories that quantitative analyses appears to be capable of characterizing this collective neuronal behavior from the gross EEG, allowing definition of a transitional pre-ictal phase, in a high percentage of cases.

P.1012

History of Seizure Prediction

As early as 1975, researchers considered analysis techniques such as pattern recognition, analytic procedures of spectral data,[44,189,214] or autoregressive modeling of EEG data[179,181] for the prediction of seizures. Their findings indicated that EEG changes characteristic for a pre-ictal state may be detectable a few seconds before their actual seizure onset on EEG. None of these mostly linear techniques has been implemented clinically.

Since spikes in the EEG are usually considered the hallmark of an epileptic brain, their possibly altered pre-ictal occurrence was investigated in several studies. Sherwin[188] noted increased correlation of epileptiform activity (spikes) between two adjacent cortical sites in the 15 to 20 minutes prior to EEG onset of focal seizures in a cat model of epilepsy. In 1983, Lange et al.[107] demonstrated a similar correlation of interictal spikes between the side of the seizure focus and the â€œnormalâ€ temporal lobe within the 20 minutes prior to EEG seizure onset in patients with temporal lobe epilepsy. While other authors reported a decrease or even total cessation of spikes before seizures,[63,64,221] re-examination did not confirm this phenomenon in a larger test set.[94]

With the advent of the physical-mathematical theory of nonlinear dynamics (colloquially termed *chaos theory*) in the early 1980s, new analysis techniques were developed to characterize apparently irregular behaviorâ€"a distinctive feature of the EEGâ€"and thus to extract features from the EEG that are not obvious to the human eye (see references 12, 45, 84, 118 for an overview). During the last two decades, these techniques have generated a large body of evidence for the existence of a pre-ictal state. The earliest attempts to use nonlinear time series analysis (see reference 91 for an overview) were started in the 1990s using the â€œlargest Lyapunov exponentâ€ to describe changes in brain dynamics.[78,79,83] The investigators observed transient drops in the temporal evolution of this measure several minutes prior to seizures and proposed that the EEG became progressively less chaotic as seizures approached. The first studies to describe characteristic changes in the EEG shortly before an impending seizure in a larger group of patients used the â€œcorrelation dimensionâ€ as an estimate for neuronal complexity[51,53,117,119,121,124] and the â€œcorrelation density.â€[141] These studies were followed by others using measures such as dynamical similarity index,[108,111,112,113,157] Kolmogorov entropy,[153,210,211] or marginal predictability.[43,126,127] In parallel, other techniques have focused on extracting neurophysiologic features from the EEG associated with epileptiform activity in human and animal physiology, such as bursts of complex epileptiform activity, slowing, chirps, and changes in signal energy.[60,133,158,225] Other methods focused on defining pre-ictal states include catastrophe theory,[25,26] self-organized criticality,[128,224] recurrent neural networks,[167] and simulated neuronal cell models.[186] Similar to the studies using the largest Lyapunov exponent, all of the above studies showed characteristic changes minutes to hours prior to seizure onset on the EEG, and were interpreted by their authors as defining pre-ictal states of various durations, some lasting hours.

A problem with most of these studies is that the measures used to characterize the EEG are difficult to interpret in terms of their physiologic correlate. Also, since almost all of these measures are univariate (i.e., related to only a single recording site), they fail to reflect any interactions between different regions of the brain. The epileptogenic process, on the other hand, is commonly accepted to be closely associated with changes in neuronal synchronization in a network of components that may be spatially distributed. The analysis of synchronization in the EEG can therefore a priori be regarded as a promising approach for the investigation of the spatiotemporal dynamics of ictogenesis. Based on newly developed physical-mathematical concepts for synchronization (see reference 169 for an overview), some researchers have focused on bivariate or, more generally, multivariate measures over the last 5 to 6 years that permit assessment of synchronous activity from multiple sites.[61,212] These measures include nonlinear interdependence,[9,110] measures for phase synchronization and cross-correlation,[28,76,109,149,150,152] the difference of the largest Lyapunov exponents of two or more channels,[27,75,80,82] nonlinear causality,[29] a classification approach based on a fusion of multiple EEG features from multiple sites.[38,133]

Results obtained indicate that seizures are not random events, but rather are related to ongoing dynamical processes that may begin minutes to hours to days beforehand (for an overview, see references 73, 132, 134, 192, 193). The fact that most of the approaches result in different prediction horizons indicates that they may reflect different aspects of ictogenesis, but it is likely that none of these techniques appears to depict the process fully. As many of these studies suggest, seizure precursors may wax and wane in attempts to ignite a clinical event, but the forces both driving and suppressing seizure generation remain hidden. Other concepts abstracted from the above body of work indicate that seizure precursors may begin locally and then expand spatially, and even â€œentrainâ€ other brain structures before reaching the critical mass required to initiate a clinical seizure. Patterns appear to be patient specific, within a finite range of pattern types, and it appears that different approaches may be required to predict seizures with clinically useful accuracy in different individuals or in different epilepsy syndromes. This may be a function of individual physiology or potentially confounding variables such as electrode placement and the amount and speed of medication taper during inpatient video-EEG monitoring.[132,134]

Scrutinizing the Field: The First International Collaborative Workshop on Seizure Prediction

At the beginning of the new millennium there was great enthusiasm for the ability of a variety of analysis methods to define the pre-ictal state. By that time work in the area had also extended to scalp EEG,[43,71,77,110,173] though the majority of researchers confined their investigations to intracranial EEG recordings. Careful review of the literature at that time, however, revealed considerable contradiction in results from different research groups. Of even more concern was that despite over a decade of excellent work in the field, convincing evidence demonstrating unequivocal seizure prediction in blinded, prospective, randomized clinical trials, with appropriate statistical validation, remained elusive. Central to the problem was the challenge of developing algorithms to detect unknown patterns associated with seizure generation, a process that remains poorly understood. Much of the EEG data analyzed in studies up to that time were highly selected and restricted with regard to seizure type, patient state, signal:noise ratio, duration of recordings, artefacts, etc. In addition, there were no standardized methods or nomenclature for marking continuous EEG data, no accepted methods for assessing algorithm performance, and no agreement on acceptable test data. Even clear definitions of exactly what constitutes seizure onset, seizure prediction, anticipation, and the definition of ictal events either clinically or by EEG were nebulous. For these reasons, beginning with an impromptu meeting at the American Epilepsy Society Meeting in Los Angeles, California, in 2000, the International Seizure Prediction Group (ISPG) was formed to provide an informal

structure for the major groups working in this area to share data and ideas.

The ISPG was established with the specific goal of moving the field of seizure prediction forward from â€œproof of principleâ€ experiments into validated, well-understood methods that could be applied to both basic science and clinical applications. The first international workshop of this group was held in Bonn, Germany, in 2002, funded by grants from the German Section of the International League Against Epilepsy, the German Section of the International Federation of Clinical Neurophysiology, and the American Epilepsy Society. At the core of the workshop was an assessment of the state of the field at that time by having each major group apply its methods to predict seizures from a shared set of continuous intracranial EEG data.[122] Findings obtained from applying a large number of analysis techniques are summarized in eight peer-reviewed articles published together in the journal *Clinical Neurophysiology*.[38,54,66,81,86,88,114,151] Although substantial efforts were made to provide uniform data in terms of disease type, conditions, and recordings, the results of all these investigations were inconsistent and at times contradictory. Three studies had positive results, predicting seizures for different time horizons; four studies had negative results; and one had both, depending upon which techniques were employed. In none of the investigations, even those with positive findings, could seizures be predicted with any exact timing. Rather, a state of increased seizure likelihood lasting up to several hours was identified. There was agreement that, at present, none of the EEG analysis techniques was sufficient for broad clinical application, and that there were major practical problems to overcome. Nevertheless, much was learned from the exercise, particularly with regard to the need for standardization of analyses, data requirements, performance criteria, and nomenclature. Some of the results were encouraging, while other results illustrated that certain approaches are unlikely to be worthwhile. The current impact of the latter point is stressed by recent controversies about the relevance of nonlinear approaches for the prediction of epileptic seizures[140,144,145,150,151] and by studies raising doubts about the reproducibility of previously reported claims.[10,39,67,105,106,123] These contradictory findings emphasize the need for reliable methods for evaluating the performance of seizure prediction techniques.

Overview of Electroencephalogram Analysis Techniques Used to Predict Seizures

Over the last three decades two main categories of analysis techniques have been used to extract pre-ictal information from the EEG: Linear and nonlinear techniques. Depending upon whether EEG data from two or more sites are analyzed independently, or for possible interactions, these techniques can further be divided into univariate and multivariate approaches. All techniques permit reduction of large amounts of EEG data to a small number of parameters for downstream processing.

Linear EEG analysis techniques (see reference 135 for an overview) are important contributors to understanding physiologic and pathophysiologic conditions in the brain. Nonparametric linear methods comprise analysis techniques such as evaluation of amplitude, interval or period distributions, and estimation of auto- and cross-correlation functions, as well as analysis in the frequency domain (using the Fast Fourier Transform or other time-frequency transformations) such as power spectral estimates, cross-spectral functions, or linear coherence.[23] Parametric linear methods include, among others, autoregressive (AR) and autoregressive moving average (ARMA) models,[57,87,88] and provide an alternative way to estimate properties of the power spectrum. These main branches are accompanied by pattern recognition methods involving either a mixture of techniques mentioned above or, more recently, taking features extracted from neurosignals and inputting them into a variety of novel classifiers, such as probabilistic artificial neural networks. Since linear methods provide only limited information as to the dynamical aspects of the EEG, it is argued that they cannot fully characterize the complicated, apparently irregular behavior of the complex nonlinear dynamical system *brain*. In this system, nonlinearity is introduced already on the cellular level, since the dynamical behavior of individual neurons is governed by integration, threshold, and saturation phenomena. There is evidence, that the epileptic process enhances the nonlinear deterministic structure in the EEG.[6,8,24] In order to allow for an improved characterization of complex dynamics, nonlinear analysis techniques have been developed that provide a methodologically different approach to EEG analysis. Within this framework, the dynamical behavior is embedded in a so-called *state space*. This generally high-dimensional cartesian space is spanned by all state variables (i.e., the number of degrees of freedom) of a system, and the system dynamics generate a *trajectory* through this space. Properties of the trajectory in state space can then quantitatively be characterized by nonlinear measures (see below). When embedding EEG time series, the number of state variables (i.e., the number of degrees of freedom of the system brain) are unknown. Fortunately, the theorem of Takens[202] allows to reconstruct a so-called *equivalent state space* even from a single time series using the so-called method of delays (*time-delay embedding*) (see also references 164 and 183). Here the basic assumption is that a single but long enough and accurate measurement of a stationary dynamics is sufficient to capture all the relevant system properties necessary to reconstruct the state space. In terms of EEG analysis, one may assume that an EEG signal reflects the influence of the multiple variables participating in brain dynamics.[49,143] The reconstruction of an *m*-dimensional state space (here *m* is the so-called *embedding dimension*) requires the generation of *m* time-delayed versions of an EEG time series; that is, each version consists of successive points of the original time series separated by a fixed time delay (Ï„). A variety of techniques have been proposed that allow one to estimate either *m* or Ï„ from a measured time series, assuming, however, that the other parameter has been chosen appropriately beforehand. Because of this mutual dependence, the time-delay embedding of an EEG time series in a high-dimensional state space is regarded as a crucial point in nonlinear EEG analysis. An improper state space reconstruction is a common source of errors and can lead to a mischaracterization of the dynamics. In case of multichannel EEG recordings, an alternative embedding scheme would be to use each channel as an axis of the cartesian space. In this case the embedding dimension *m* is fixed and equals the number of recording channels. Although this *spatial embedding* is regarded to be the more natural scheme, several assumptions have to be made beforehand that might lead to similar problems as with the time-delay embedding and are matter of debate.[103,172] These problems include the optimal distance between different recording sites, which is usually fixed, among others. It remains to be established whether the combined use of techniques (so-called *spatial-temporal embedding*[141]) can be regarded as more appropriate for EEG analysis.

Table 1 Studies on Seizure Prediction Using Different Univariate and Bivariate Measures Comprising Both Linear and Nonlinear Approaches along with the Observed Mean Prediction Times

Authors	Characterizing Measure	Mean Prediction Time (min)
Iasemidis & Sackellares, 1991[79]	Lyapunov exponent	up to 10
Lehnertz & Elger, 1998[119]	Correlation dimension	12

Studies that did not report prediction times were not included.

In order to characterize dynamics in state space, a number of univariate and bivariate approaches are available. Quantities such as an effective correlation dimension, correlation density, entropy-related measures, or Lyapunov exponents allow one to draw inferences about the number of degrees of freedom (or *complexity*), the amount of order/disorder, or the degree of *chaoticity* or predictability in a single time series. Other univariate measures aim at discriminating between deterministic

and stochastic dynamics[92] or provide an estimate of the amount of nonstationarity.[36,176,177,178]

Bivariate measures such as the similarity index,[111] phase synchronization,[104,109,152,203] nonlinear interdependency,[9,110,138] and other measures for generalized synchronization allow one to estimate dynamic interactions between two time series; some of these approaches can even provide information about the direction of interdependence.[9,29,180,190] A full description of the physical and mathematical concepts underlying these quantities along with their implementation details for EEG analysis is beyond the scope of this chapter. Instead, we summarize in Table 1 the various measures, concepts, and achievements of univariate and bivariate approaches used for seizure prediction.

Further details can be found in a number of tutorials, conference proceedings, or text books on nonlinear time series analysis.[1,45,49,52,58,65,69,84,90,91,93,118,134,163,171,187,195]

Despite their great potential for a detection of subtle changes in brain dynamics, both linear and nonlinear analysis techniques must be painstakingly applied, and the results obtained should be interpreted with great care. Many techniques place great demands on the recorded time series with respect to the precision of the data and the absence of noise. Almost all techniques assume the underlying dynamical system from which the recordings were taken to be stationary. None of these requirements, however, can be exactly fulfilled in practice. With respect to nonlinear EEG analysis, numerous studies have identified factors that might alter the absolute value of a measure: Properties of EEG electrodes, the precision of the analog-to-digital converter, amplifier and filter settings, and different recording montages might all strongly influence nonlinear measures. Finally, problems specific to the individual algorithms have to be taken into account. Based on these potential limitations, we feel that it is advisable to avoid claims on the existence of chaotic behavior in the EEG, and instead to use nonlinear measures as tentative indexes of different brain states when analyzing EEG data.

Statistical Considerations

The current state of seizure prediction is that there is strong evidence from several methods for identifiable precursors preceding partial-onset seizures. This conclusion, however, is based on retrospective analyses of mostly intracranial EEG data recorded during presurgical evaluation of patients during evaluation for resective surgery. Up to the time of this writing, no study has been published that demonstrates unequivocal seizure prediction in blinded, prospective, randomized clinical trials. Reasons for this become apparent when considering the major methodologic steps involved in seizure prediction algorithms along with problems posed by respective study design.

Typically, the first step in a retrospective seizure prediction study consists of calculating a certain characterizing measure from the EEG using a moving-window technique. The length of the time window is chosen so that there is a reasonable trade-off between approximate stationarity of the EEG signal and sufficient number of data points to characterize the EEG dynamics. The resulting temporal evolution of the measure (*measure profile*) is then scanned for prominent characteristics that can be related to the actual seizure times. These features might be

P.1015

drops or peaks (e.g., quantified as threshold crossings) or any other distinct pattern in the measure profile. In a second step the measure's capability to distinguish the pre-ictal state from the inter-ictal interval is evaluated with test statistics quantifying the occurrence of these features relative to the seizure times, which results in some kind of performance value. A high performance value is assumed to reflect the existence of a pre-ictal state and the capability of the applied measure to detect it.

The first question that arises from these types of analyses is which of all the characterizing measures presented above is the best, though with their different time horizons and processing methods they constitute different ways of viewing the same process. As some studies have demonstrated, it appears that some combination of measures will probably be required to carry out reliable seizure prediction tailored to individual patients.[38,117] Usually, algorithm performance requires optimizing numerous computational parameter choices and sometimes the choice of an estimation algorithm. Upon close inspection, these choices often rely on a posteriori knowledge, which interposes significant risk of in-sample overtraining. Certainly, what is true for a single measure holds also for a larger number of different measures. The application of a huge variety of measures to the EEG might yield seemingly good results just by chance (particularly on a limited database), if appropriate methods for dealing with statistical issues of multiplicity are not implemented. The resulting explosion in computational degrees of freedom emphasizes the need for control tests and independent validation. This is necessary to avoid the potential for fitting results to the data and to enable independently reproducible results. Many measures have a clear physical meaning since they are derived from mathematical-physical theories that allow one to characterize complex spatiotemporal dynamical systems. However, due to a huge number of influencing factors and constraints associated with analyzing EEG data, strict interpretation of particularly nonlinear measures (e.g., in terms of attractor dimensions, deterministic chaos, or entropy) is rarely justified. Nevertheless, many classical measures can still be used as tentative indexes of different brain states, and more recently developed measures often allow less ambitious but more straightforward interpretation. Ongoing research will clarify whether a meaningful physiologic interpretation in terms of underlying brain dynamics can be achieved.

The next issue concerns the EEG recording. Taking into account that epilepsy is a heterogeneous disorder, what constitutes an optimum spatial and temporal sampling of the ictogenic process? How to select optimum data acquisition parameters such as sampling rate, filter settings, resolution of the analog-to-digital converter, and electrode montage is not straightforward, and may depend on things that are currently unknown, such as the temporal and spatial resolution of physiologic events critical to seizure generation. How many electrodes are necessary? Is a noninvasive recording sufficient or does a good seizure prediction technique require the higher frequency components only available in intracranial recordings? More importantly, what constitutes a *good* data set for testing sensitivity and specificity (see below) of a seizure prediction algorithm? Many of these more technical issues have not been satisfactorily addressed yet, and there may be a number of reasons for this. Data acquisition parameters like sampling rate and filtering have to follow the demands of the sampling theorem, and have traditionally been based on analog paper-and-pen EEGs and the requirement that they allow for good visual inspection of the EEG. With modern digital equipment, cheaper computer storage, and recent interest in single unit recording, acquisition rates of tens of kilohertz per channel are now possible, but deriving meaning from terabytes of such data is a daunting prospect, particularly when searching for unknown patterns. Traditionally, acquisition parameters are chosen to allow adequate sampling of target waveforms, balanced with the need to keep data storage capacity as small as possible. Almost all EEG data sets that have been studied up to now were recorded with data acquisition parameters set by clinical EEG systems, without specific regard to prediction study requirements. It is well known that these parameters affect virtually all characterizing measures, and it still remains an open issue whether they must be regarded as potentially confounding variables in seizure prediction studies. The placement of EEG electrodes typically follows roughly common protocols, guided by the demands of the presurgical evaluation and limited by the need to protect patients, but there is little standardization from center to center in this regard. Without understanding more about seizure generation in the epileptic network, there is no way to know what might be optimal spatial sampling for seizure prediction studies. Clearly, more sensors would be better, including those placed into deep integrating structures, such as the thalamus, but this type of spatial sampling is currently only possible in animal studies, because of patient safety concerns. Even with the number of channels available from implanted electrodes in humans, the spatial information available for measuring the ictogenic process has been used insufficiently. Most researchers have confined analyses to at most one or several electrodes, relying on a posteriori knowledge as to location and extent of the ictal onset zone. At best, data from sites distant from the ictal-onset zone are included in these studies only for comparison to more â€œnormalâ€ regions. Others have developed optimization schemes that allow one to select certain electrodes out of a large number of electrodes[27,37,75,76,80,114] relying on a posteriori knowledge as to the dynamics of the ictogenic process. Due to the availability of more powerful computers, it is only recently that EEG data from all electrode sites have entered seizure prediction studies. Interestingly, some studies reported that the site selected as best for prediction was not in close vicinity to the epileptic focus but could be located in remote or even contralateral brain structures.[38,89,114,150,151,156] This seemingly counterintuitive finding may indicate the importance of brain outside of the ictal-onset zone but within the â€œepileptic networkâ€ in generating clinical seizures (see also references 218 and 219). This is also in accordance with findings showing that the synchronization of specific populations in relation to the epileptic focus may be of crucial importance to determine whether a seizure is likely to occur and to spread.[114,149,150,151] On the other hand, it may also indicate a rather nonspecific phenomenon whose temporal proximity to seizure onset was just by chance. Obviously, correct site selection would be a practical problem in instances where electrode contacts are limited. At present, it is not clear at all whether optimum recording sites can be identified.

Large amounts of well-documented, continuous, prolonged, multichannel EEG data are very difficult to acquire in a busy clinical environment, and storage of a diverse archive of data is an expensive prospect. Many institutions store short-lasting (typically a few minutes only) inter-ictal and/or peri-ictal epochs for documentation purposes or because of legal requirements for medical records and results. It is therefore not surprising that many past studies lack reference to the interictal state in terms of insufficient control data or baseline epochs. In other words, many studies have focused merely on sensitivity without considering specificity of the applied techniques. Maiwald et al.[140] reviewed 14 seizure prediction studies published between 1998 and 2003 and concluded that in only half of these studies was the performance of the applied seizure prediction technique tested against interictal control data. Proper selection of control data poses another problem, that even during the interictal period the epileptic brain is different from â€œnormal,â€ and that there may be abnormal dynamical changes that are not necessarily followed by a seizure. Other nonstationary variables such as sleepâ€“wake cycles or different cognitive states must definitely be regarded as potential

P.1016

confounding variables in seizure prediction studies. In addition, during presurgical monitoring an artificially high seizure frequency (0.15 seizures per hour, or 3.6 seizures per day[68]), seizure clustering, and atypical seizures may occur due to the reduction of anticonvulsive medication. Under normal conditions, patients with pharmacoresistant focal epilepsy have a seizure frequency of about three seizures per month, that is, 0.0042 seizures per hour.[13] In order to thoroughly evaluate the suitability of possible seizure prediction techniques, reference to continuous, prolonged, multichannel EEG data must be regarded as indispensable.

EEG data accompanying clinical information must be as complete as possible to account for other factors that may modulate seizure generation. Relating mathematical approaches to clinical, video, and neurophysiologic data, a massive undertaking, has begun only recently.[148,156] There are now attempts to identify and mark the broad range of physiologic and pathophysiologic changes that occur in these measures interictally and at seizure onset in a standardized and clear-cut manner. Given imperfect methods for determining exact clinical and EEG onset times for seizures, at present, reference to EEG onset of seizures, as opposed to clinical seizure onset, is preferred.[122]

The above considerations indicate that seizure prediction studies have to be designed with great care, and with an acute awareness that as we delve deeper into seizure generation we may be confronted with other, yet unforeseen problems. A thorough evaluation of potential predictors and potentially confounding variables requires large, high-quality, meticulously collected and annotated data archives that are well characterized and represent the heterogeneity of patterns and patients found in human epilepsy. Equally important, a review of the literature points to the need for proper statistical validation in order to assess the performance of seizure prediction algorithms. This is a major issue in the field at present, and one that has been neglected by many past studies.

Assessing the predictive performance for a given algorithm usually involves analysis of the so-called receiver operating characteristics (ROC) curve that is based on quantities such as sensitivity and specificity. *Sensitivity* is defined as the ratio of true positive classifications (or predictions, detections, or warnings) to total number of (true and false) positive classifications. *Specificity* is defined as the ratio of true negative classifications to total number of negative classifications. The *false-positive rate* is defined as the average number of false classifications per unit time, and is one accepted measure of specificity. Finally, *performance* can be defined as the square root of squared sensitivity plus squared specificity. Let us assume that a seizure prediction method requires adjustment of a parameter (e.g., some threshold). With ROC, values of the parameter are continuously varied, and the sensitivity of the classification for these parameter values is plotted against 1 minus the corresponding specificity. The resulting curve is termed the ROC curve, and each point on the curve corresponds to a different parameter value. An ideal classifier has a curve that goes from the bottom left corner to the top left and then from the top left to the top right (two perpendicular lines). An unspecific, random classifier produces a ROC curve that is a diagonal line.

The aforementioned considerations indicate the tight dependence between sensitivity and specificity (a high sensitivity may be achieved at the expense of a poor specificity, and vice versa) and the need to evaluate both quantities together[161,162] in order to achieve a meaningful estimate of the performance of a seizure prediction method. Many past studies have reported on the sensitivity of a given method only, and it appears that the mostly positive results had been achieved by an in-sample overoptimization of parameters and by using insufficient control data. Recently, Winterhalder et al.[222] suggested what they call the *seizure prediction characteristic* to evaluate seizure prediction methods. The authors proposed to extend the ROC approach (i.e., investigation of sensitivity and false prediction rate) by including additional assessment criteria that are based on clinical and statistical considerations. Since, at present, none of the current prediction methods is able to indicate the exact point in time when a seizure is to occur, the authors suggest considering this uncertainty by referring to the â€œseizure occurrence period,â€ defined as the period of time during which a seizure is to be expected. In addition, to render a therapeutic intervention possible, they refer to an important interval as the minimum window of time between an â€œalarmâ€ raised by the prediction method and the beginning of the seizure occurrence period. They and other investigators refer to this interval as the â€œseizure prediction horizon.â€ Due to the interdependence between sensitivity and specificity, and that it may not be possible to avoid false alarms completely, the authors suggest using a maximum false prediction rate as a measure for algorithm performance. This quantity can be derived from the average seizure incidence, which determines sensitivity. Finally, the authors propose to compare the achieved sensitivity values with those obtained from random and periodical prediction methods. Using this framework, the same group shows that the achieved performance values of three previously proposed prediction methods (dynamical similarity index, accumulated energy, and effective correlation dimension) are significantly better than the performance of unspecific methods.[140] They conclude that this finding indicates the existence of specific â€œpredictiveâ€ information in pre-ictal epochs and that the investigated methods are sensitive to this information. The resulting seizure prediction characteristics, however, were judged as not yet sufficient for clinical application.

Studies like these are important since they clearly point to deficiencies in current seizure prediction methods. Showing that a method is sensitive enough to detect a pre-ictal phenomenon is only the first step in developing a seizure prediction method. Unfortunately, a high sensitivity does not prove that the method is suitable for clinical applications. Even a highly sophisticated performance estimation, as the one above, is confronted with a number of problems for which there are currently no satisfactory solutions. Many quantities that enter performance evaluation tests require parameter optimization or a choice of parameter ranges. As an example, seizure prediction methods usually require adjustment of some threshold (or reference) level, and a deviation of some characterizing measure from this threshold is assumed to (truly or falsely) indicate a pre-ictal state. The threshold level is usually derived from analyses of control (also called baseline or reference) data that should represent all conditions and states of consciousness from which seizures can emerge (which again calls for large, high-quality, and meticulously annotated data archives). In this context, it should be mentioned that there is now consensus among the major groups in the field that choice of short reference periods, even if done randomly, could exert great influence over results. It is important to note that a properly designed study based upon randomly chosen data epochs could be made statistically sound, if strict statistical criteria are met that dictate a sufficient number of randomly chosen interictal segments. Unfortunately, there would still be concern that all patient states might not be adequately represented. Because of these considerations, recommendations from the First International Collaborative Workshop on Seizure Prediction include that it would be best to avoid the use of short reference periods.[122]

When calculating a threshold level, the question arises as to whether one should consider it as constant or whether one should account for possible slow drifts in dynamics (e.g., due to changing antiepileptic drug levels during medical tapering,[120] changes in vigilance states,[54,116,133] or other circadian fluctuations[101]) and use an adaptive threshold level instead. The latter makes a prospective implementation of an

algorithm for seizure prediction a nontrivial problem. Closely related to appropriately selecting a threshold level is the problem of defining false classifications, which requires a clear-cut delineation of a pre-ictal state from the inter-ictal state. Currently available information indicates that a pre-ictal state might last from minutes to hours to days. An *inappropriately* selected duration would lead to an increased number of false classifications. More importantly, the model of a pre-ictal state assumed by a prediction algorithm has enormous potential impact upon its performance. For example, the interictal-to-pre-ictal transition is usually assumed to follow some rectangular function, with a sharp boundary between states. If, however, this transition follows another function (e.g., linear or exponential or log-periodic), very early or intermittently occurring precursors would wrongly be classified as false positives. The situation becomes even more complicated when taking into account the spatial distribution of the interictal-to-pre-ictal transition. From their synchronization studies, Mormann et al.[152] concluded that an epileptic seizure might be interpreted as the climax of a process of changes in brain dynamics that starts long before the seizure. In an attempt to relate these dynamic changes to EEG-based physiology, Litt et al.[133] suggested a possible evolution of waxing and waning events, such as bursts of complex epileptiform activity, subclinical seizurelike bursts (chirps), and alterations in neuronal activity measured by energy changes that might characterize this process. Unfortunately, we still lack the physiologic or dynamic understanding to delineate a pre-ictal state both in time and space, particularly not from a level that relates to neurophysiology on the cellular and network level. Of interest, a recent study by Kalitzin et al.[89] indicates that important clues for possible dynamical scenarios that lead to epileptic seizure onsets may be obtained from analyzing the so-called phase demodulation of intracranial EEG recorded interictally during intermittent electrical stimulation.

The above considerations clearly indicate that assessing the performance of a seizure prediction algorithm strongly relies on assumptions of a model of seizure generation, including the spatiotemporal characteristics of the process and, more importantly, on the existence of a pre-ictal state. When reviewing the seizure prediction literature, it is important to note that if a pre-ictal state does not exist (null hypothesis), no information predictive of an impending seizure could be extracted from the EEG, but many algorithms could still perform better than an unspecific, or random, prediction algorithm. This is because any measure tested on recorded data will likely contain fluctuations, generating a nonzero probability of attaining any course within its range of definition. Even though this probability may be very small, the large number of potentially confounding variables discussed above is likely to lead to an increased probability for finding a combination of them, which then leads to a nonzero performance value. The influence of the different degrees of freedom on the statistical significance of the obtained results is difficult, if not impossible, to estimate on a theoretic basis. Hence, it is difficult to decide whether a given performance value indicates the existence of a pre-ictal state or whether it is consistent with the null hypothesis stated above. Although there are statistical methods for addressing these issues, these require careful sampling of distributions of feature values amassed over time, and only with adequate amounts of continuous data allow definition of expected measurement error and requirements for statistically significant results.

In order to address this ambiguity, Andrzejak et al.[7] proposed an alternative approach to the problem, using the concept of *seizure time surrogates.* In this method, original seizure onset times are replaced with â€œsurrogateâ€ times randomly chosen from the interictal intervals. Specified properties of the original sequence (such as total number of seizures, distribution of intervals between consecutive seizures, and clustering of seizures) can be imposed as constraints on the surrogate seizure onset times. A seizure prediction algorithm is then applied to the original seizure time sequence and the surrogates. Assuming that a pre-ictal state exists, and that the algorithm is able to detect it, the performance should be higher for the original seizure times than for the surrogate times. Alternatively, Kreuz et al.[101] proposed the concept of *measure profile surrogates,* in which the seizure onset times are kept fixed and instead a constrained randomization of a measure profile is performed using the method of simulated annealing. Using this method, the amplitude distribution of a measure and the autocorrelation function (accounting, for example, for circadian fluctuations) of the measure profile are preserved. As with the seizure time surrogate concept, a seizure prediction algorithm is applied to the original measure profile and the surrogates, and the highest performance is expected for the original measure profile, provided that a pre-ictal state exists and the algorithm is able to detect it. Both methods have conceptual advantages and disadvantages, and the concept of measure profile surrogates has a greater computational burden. Both concepts are based on null hypothesis tests, and the nominal size is determined by the number of surrogates. It is important to keep in mind, however, that the fact that the null hypothesis cannot be rejected does not prove its correctness. Rather, there may be alternative explanations for this result.

Taking into account the above considerations, and using the concept of seizure time surrogates, Mormann et al.,[151] within the scope of the First International Seizure Prediction Workshop, investigated the predictability of seizures by retrospectively analyzing multiday intracranial recordings from five patients recorded at different epilepsy centers comprising 51 seizures and a total recording time of 311 hours. They compared the performance (based on ROC statistics) of 30 univariate and bivariate measures, comprising both linear and nonlinear approaches, in terms of their ability to distinguish between the interictal state and the pre-ictal state. Using different evaluation schemes that take into account the majority of potentially confounding variables discussed so far, they were not able to detect a pre-ictal state, if one assumes a consistent effect on the EEG at all electrodes in all seizures of a patient and across patients, without comparison to some adaptive threshold level. If, however, one allows variable effects such as recording sites selected as best for prediction, a prolonged pre-ictal state (up to hours) could be detected using bivariate measures. Their findings suggest that a prospective seizure anticipation system is, in principle, possible and would perform better than random. Whether this is sufficient for a clinical application would need to be decided on an individual basis.

Studies in Animal Models of Epilepsy

In order to gain deeper insights into the neurobiologic mechanisms underlying pre-ictal dynamical changes, approaches that are based on experimental models of epilepsy are highly desirable. Although there is a considerable bulk of literature on animal models of epilepsy, the phase of transition to the seizure state is not yet fully explored. Early work on the neurophysiology of the interictal-to-ictal transition can be found as early as the late 1960s, in the work of Dichter and Spencer.[41,42] In a penicillin model of epilepsy, these studies demonstrate a progression in the complexity and amplitude of interictal discharges during the interictal-to-ictal transition. While other studies have demonstrated similar changes, it was not until more recently that in vivo studies in acute and chronic animal models reported distinguishable preseizure EEG patterns several minutes prior to seizure onset.[59,129,165,168] Other investigators[201] have showed seizure predictability from

stochastic models of temporal interdependence between the ictal and interictal states. Studying four pharmacologic epilepsy models, Widman et al.[220] reported on a reduced dimensional complexity of in vitro hippocampal recordings in the seconds to minutes prior to the manifestation of paroxysmal depolarization shifts in xanthine and penicillin models. The authors went on to demonstrate that there was no preceding loss of complexity in low-magnesium and veratridine models. In contrast, Chiu et al.[32] recently analyzed in vitro hippocampal recordings from a low-magnesium model using wavelets and artificial neural networks and claimed prediction of seizurelike events as early as 60 seconds before, and with more than 75% accuracy within a 30-second precision window.

Although these studies indicate that discernible pre-ictal patterns can be detected, at least in some experimental models of epilepsy, they must, at present, be regarded as â€œproof of principle studies,â€ since most lack a sound statistical validation, suffering from the same limitations of the human studies discussed above. In addition, a number of the studies used for seizure prediction from animal tissue, both in vivo and in vitro, have focused on acute seizure models whose behavior is not clearly analogous to spontaneous seizures in humans. These studies in animal models of epilepsy have considerable potential to address questions regarding the mechanisms regulating seizure generation; however, fundamental questions about underlying cellular mechanisms still remain unanswered. Earlier in vitro studies of ictogenesis suggested that the pre-ictal transition may reflect gradual changes in network excitability during the interseizure interval. In the 30 to 60 seconds preceding a seizurelike event, induced by high extracellular potassium, the excitability of CA1 pyramidal cells appeared to increase gradually to some threshold level, at which point the next incoming interictal burst precipitates a seizure.[209] These pre-ictal changes in neuronal excitability are hypothesized to reflect the slow recruitment of an increasing number of excitatory interconnected neurons into synchronous discharges.[146]

In chronic epilepsy, it is known that an increased propensity for hypersynchronization is associated with neuronal loss and synaptic reorganization that can be observed in human mesial temporal lobe epilepsy, and in kindling and kainic acid models.[15] The transition to ictal activity, however, is often attributed to a breakdown of the interneuronal inhibitory control, which is assumed to be the major factor responsible for ictogenesis in human temporal lobe epilepsy and analogous animal models of epilepsy. This assumption is supported by early animal model studies that indicate that the inhibition of neuronal activities peripheral to the epileptic focus can be of crucial importance in determining whether or not a seizure is likely to occur and to spread.[142]

A more recent hypothesis[17,97] suggests that a pre-ictal imbalance between inhibition and excitation might be due to some transient excitatory effect of GABAergic (Î³-aminobutyric acid) function, resulting in repetitive high-frequency epileptiform bursts. Supporting this hypothesis, the prolonged repetitive activation of inhibitory neurons has been shown to induce an intracellular accumulation of chloride in principal cells, leading to a transient disinhibition of the local networks and, thus, to a decreased threshold for subsequent epileptiform discharges and ictal events.[99] The potential ictogenic effect of GABA-mediated depolarization has also been observed in other studies[33] (for a review, see reference 35). Finally, slow changes in extracellular ion concentrations are assumed to contribute to the gradual depression of inhibitory mechanisms. In particular, some seizures are preceded by an increase in the extracellular potassium concentration,[166] and in vitro studies have confirmed a corresponding pre-ictal depolarization of the neuronal membrane potential.[85]

More recently, the cellular basis of pre-ictal changes has been investigated using a hippocampalâ€"entorhinal brain slice preparation exposed to high extracellular potassium[47] and to low magnesium concentrations.[98] In this network, predictable alterations in interictal activity were shown to precede the transition to ictal-like activity. These pre-ictal changes were characterized by alterations in the origin and spread of CA3 epileptiform discharges. Spectral analysis of the interictal epileptiform activity preceding the transition to ictal-like activity revealed a prominent increase in the high-frequency range (200 to 400 Hz). In a very active related area of research, microelectrode studies in vivo in the hippocampus of kainate-treated rats and depth EEG recordings from patients with mesial temporal lobe epilepsy have also revealed 200- to 400-Hz oscillations, termed â€œfast ripples,â€ which have been hypothesized to identify microscopic regions important to seizure generation.[18,19] These oscillations may uniquely occur in areas that generate spontaneous seizures, and may reflect pathologic hypersynchronous population spikes of bursting pyramidal cells.[46] In rat models of chronic epilepsy, fast ripples are seen during the latent period between the occurrence of an initial epileptogenic insult and the onset of recurrent spontaneous seizures.[20] These oscillations may thus be a possible marker of alterations in interictal activity that precede the transition to ictal activity.[207,208] Further investigations at a cellular level during the preseizure state are necessary to validate these hypotheses in humans.[194]

Applications: Clinical and Basic Science

In addition to its scientific appeal, two main motivations for seizure prediction research are (a) its potential to control therapy in antiepileptic devices and (b) to elucidate mechanisms underlying seizure generation. Initial research into antiepileptic devices demonstrated that open-loop stimulation (e.g., paradigms that stimulate in a set â€œonâ€"offâ€ cycle regardless of underlying brain activity) can reduce seizure frequency and severity.[72,96,131,139,205] While initial results are promising, this strategy has not yet made many patients seizure free, and none of these devices has achieved sustained clinical use.[72,131,215] One device, targeting the anterior thalamic nucleus, is in active clinical trials, and no definitive performance results are available as of this writing. Open-loop devices are attractive because of their relative simplicity; their analogy to successful cardiac devices, such as early pacemakers; and their modern origin in successful devices to treat movement disorders (e.g., Parkinson disease, tremor, etc.). While this research continues, focusing on different central targets and stimulation paradigms, an interest in more â€œintelligentâ€ responsive devices, designed using strategies similar to implantable cardiac defibrillators, is under way.

Over more recent years, research into responsive, closed-loop antiepileptic devices, which read and respond to features extracted â€œon the flyâ€ from implantable sensors and processors, has proceeded actively. This is primarily motivated by an attempt to improve upon results from open-loop devices.[100] While trials of these first-generation devices demonstrate proof of principle well, specifically that clinical seizures can be successfully stopped by electrical stimulation triggered after seizure onset is detected, these devices are not yet ready for widespread clinical deployment. Recent results from an initial safety trial, not designed to test efficacy, suggest that responding to seizure onset can reduce seizures by 50% or more in over 40% of refractory epilepsy patients. This result, however, also indicates that this method might not be the most effective path to making patients seizure free (Worrell et al., unpublished). The current state of these responsive devices suggests a significant potential role for therapy triggered in advance of seizure

onset on the intracranial EEG, perhaps controlled by seizure prediction algorithms.

The case that seizure prediction is a better method for controlling antiepileptic brain stimulation than seizure detection can be made on two fronts, though, unfortunately, there is not yet class one evidence to support this hypothesis. First, there is evidence from a number of seizure prediction studies quoted above[38,114,150,151] that there is considerable evolution of quantitative features in multiple channels, including changes in synchronization in the epileptic network, prior to the time of detectable seizure onset on the intracranial EEG. Given that abnormal brain activity is often broadly distributed by the time seizures are detected, it seems unlikely that stimulation over a limited region, as is the standard technique with first-generation responsive devices, will be effective in suppressing clinical events. Clinical evidence to support this conjecture is more difficult to come by, as there is little information published in peer-reviewed journals about experience to date with responsive antiepileptic devices. There are anecdotal reports of widespread stimulation, grouping four or more electrode contacts together to form one pole for stimulation of distributed electrodes. To date, only two groups have reported results from responsive stimulation in humans, and were lead by NeuroPace, Inc., and Osorio et al.[100,161] (Worrell et al., unpublished). Because of intense activity in industry to perfect effective antiepileptic devices and bring them to market, current concepts are largely shaped by anecdotal clinical experience, conference abstracts, lectures, posters, and personal communication. With clinical trials currently in progress, it is anticipated that publication in this area should increase substantially over the next 12 to 24 months.

Initial reports indicate that when detection algorithms are tuned to high sensitivity and short detection latencies, so that stimulation is triggered not only by seizures, but also by bursts of epileptiform and rhythmic oscillatory activity often found to occur during periods of increased probability of seizure onset, seizure frequency declined (Pless, unpublished). In addition, under this paradigm, subclinical seizurelike bursts, which appear to increase prior to seizure onset in some patients, have been reported to greatly increase in number but not lead to seizures when repetitively suppressed by responsive stimulation. This result, observed by several investigators, suggests a drive to seize that might be somewhat suppressed by electrical stimulation. An additional explanation might include a critical amount of energy or some other quantity that might need to be dissipated in order to interrupt the process of seizure generation. Again, in the absence of controlled, randomized clinical trials in an adequate number of patients, this information is suggestive, at best, that intervention based on seizure â€œprecursorsâ€ may be useful in suppressing clinical events. In responsive stimulation studies by Osorio et al.,[161] prediction paradigms were not tested in human stimulation trials.

While discussing the clinical application of seizure prediction algorithms, it is instructive to consider how such an algorithm might function in a responsive antiepileptic device. Since current thinking is that seizure generation is likely a probabilistic phenomenon, most investigators agree that prediction algorithms will, at best, be able to identify periods of increased probability of seizure onset. The most important factor governing application of prediction algorithms for device control is the nature of the therapy being administered. If the treatment has few or no side effects, then high false-positive rates can be tolerated, as administering therapy when seizures are not imminent carries little or no penalty. If the algorithm is able to calculate the probability of an impending seizure at a given time, then the intensity of therapy can be increased in proportion to the likelihood that a seizure is going to occur. This scheme would also make sense if seizures are more difficult to pre-empt as they progress in the generation process. Finally, therapy is administered more intensely and perhaps over a broader geographic area as seizure generation progresses and the probability of onset continues to rise, until a seizure is detected, and maximal therapy is administered. At this point it might be reasonable to issue an alarm to the patient that a seizure is imminent. Should therapy not be immediately effective, it is possible for the antiepileptic device to broadcast an alarm, perhaps over a broadband communications link, or contact some central station to call for help unless the patient deactivates this process, demonstrating that awareness has returned. While this is only one way in which a predictive antiepileptic device might be deployed, it gives some sense of how prediction algorithms might be translated into a practical therapy.

One important aspect of implantable antiepileptic devices is the potential, in some models, to provide data vital to understanding the process of seizure generation. Some current devices have the capability for storing EEG information at different points in the seizure cycle, a capacity that might be possible to expand. This capability provides, for the first time, a way for investigators to look at intracranial EEG data acquired in the steady-state human condition, in the absence of proximate surgery or medication taper. Though the buffering capacity of these devices is likely small, the ability to download information from them over time provides an unprecedented opportunity to observe the natural seizure cycle in human patients. The authors are hopeful that these data will eventually become available for analysis by groups using a variety of different techniques. More confined data downloads at different times in relation to seizures might also be used to reconstruct the process of seizure generation, but as discussed above, relying on fragmented data is a more challenging task than analyzing prolonged, continuous data streams.

The utility of seizure prediction in understanding mechanisms underlying seizure generation also remains largely uncharted territory. While a number of investigators have attempted to predict seizures in a variety of mechanism-driven experiments, this body of work suffers from the same statistical and methodologic limitations as the more clinical studies noted above. Primary knowledge from prediction studies with macroelectrodes that could be extremely useful in understanding ictogenesis are such things as the period of time over which seizures are generated, what components of the epileptic network are necessary for clinical events to occur, how seizure precursors are temporally and spatially distributed in brain, and what effective intervention strategies for modulating this process are. The answers to these questions might guide basic science investigations to specific mechanisms. For example, if the seizure prediction horizon turned out to be on the order of seconds, then mechanisms related to ion channel or neurotransmitter function might be areas of focus for seizure generation experiments. Longer periods of time, perhaps minutes, might point to slower second messenger systems for study. More prolonged periods of seizure generation, perhaps minutes to hours or longer, could point to protein transcription, synaptic plasticity, and other mechanisms that might better fit into this time frame. If the pre-ictal state is found to be a permissive one, waxing and waning between false starts that back to the interictal period and then only occasionally to seizures, this finding might point to some oscillating pathologic process that is *gated* by another, perhaps unrelated mechanism.

These same types of ideas might also better elucidate the functional structure of the epileptic network. For example, if very high-frequency precursor events are found that spread very rapidly through local cellular regions, mechanisms involving ephaptic conduction and gap junctions might be implicated. If precursor spread is measured in longer intervals, it might be attributed to more typical synaptic conduction. Lateral cortical spread versus dispersion of signals via large fiber tracts are

also questions that could be answered by appropriately crafted seizure prediction studies. These are just a few ways in which seizure prediction algorithms and study might contribute to our basic knowledge of seizure generation, and perhaps to the development of better therapies.

Challenges

The science of seizure prediction is now approximately 15 years old, and maturing. The overt initial enthusiasm that resulted from finding changes in â€œchaoticâ€ measures reliably associated with periods prior to seizure onset has now given way to careful introspection. There is now a focus on meticulous data acquisition, annotation, study design, and rigorous statistical design of prediction studies and validation of results. The last 5 years has seen established groups and methods come under increasing scrutiny, as new investigators enter the field and newer techniques are developed to benchmark algorithms against random predictor performance and against the null hypothesis that there is no pre-ictal state. There is also pressure to get an answer and develop methods ready for clinical deployment. This is driven by a keen awareness that patients are likely to benefit considerably through second-generation responsive antiepileptic devices if researchers can field working algorithms for seizure prediction and validate them in blinded, prospective, clinical trials. There is great need for establishing convincing, iron-clad evidence for the existence of a pre-ictal state and an appropriate model for its behavior in human epilepsy. Researchers are acutely aware of the heterogeneity of epilepsy and the fact that one model may not work in all epilepsy syndromes. An improved mathematical modeling of the dynamics underlying the transition to seizures[130,136,137,199,200,217,218,219] may help to test various hypothesis concerning pre-ictal brain dynamics and its relation to endogenous and exogenous control parameters. There is also a great need for new analysis methods, using multivariate techniques[5,30,155,184,185,223] to analyze data streams from multiple sensory sites simultaneously, and even to sample at multiple temporal and spatial scales, from single neurons to ensembles, local then global networks, to investigate the physiologic substrate for larger-scale quantitative observations. Along with these observations will come improvements in our ability to collect, store, and analyze longer, more complete, and broader-band data sets. This work is already under way as a collaborative effort through the International Seizure Prediction Group. Following initiation of an international collaborative working group in this area, in Bonn in 2002, the task of establishing an extensive archive of high-quality, broadband, meticulously collected and annotated data archive from humans and animal models of epilepsy is getting under way. New hardware and software platforms[154] will likely provide more computational power, such as through VLSI implementation of algorithms,[31,102,191] while an effort to reduce the complexity of algorithms continues.[196] Finally, more work on developing and understanding spontaneously seizing animal models of epilepsy for use in prediction research will allow us access to deep brain structures and other locations in the epileptic network that cannot be explored in human studies, due to safety concerns. Characterizing and verifying the clinical presentation, reliability, and reproducibly of these models will be vital to interpreting results involving these animals. All of these factors promise increasing progress in the field of seizure prediction, now tempered by experience and a knowledge that this is a complex, long-term problem. Most importantly, we are starting to appreciate exactly what the task is that we are trying to accomplish, including articulating the benchmarks required for knowing when we've succeeded in predicting epileptic seizures.

Summary and Conclusions

In this chapter we have tried to give a broad overview of the field of seizure prediction and its history, accomplishments, controversies, and potential for future development. In a work of this scope it is inevitable that some contributions may be over- or underemphasized, depending upon the points to be made in the text. Seizure prediction remains an exciting field, with the potential to have significant impact upon the quality of life of our patients with epilepsy, in the form of newer and more effective treatments and in expanding our knowledge of how seizures are generated in the brain. What is clear, after the seminal contributions of a few insightful research groups over 15 years ago, is that the problem is large, and will require the collaborative efforts of a dedicated international group of investigators to solve it. We are hopeful that the pace of discovery in this relatively new field will continue to accelerate, as we begin to deal with our growing appreciation of the complexity of the problem.
