EPILEPSY
A COMPREHENSIVE
TEXTBOOK
SECOND EDITION
VOLUME ONE
JEROME ENGEL, JR.
TIMOTHY A. PEDLEY
Wolters Kluwer | Lippincott Williams & Wilkins
Williams & Wilkins
Williams & Wilkins

Table Of Contents

VOLUME I

Introduction: What Is Epilepsy?

SECTION 1 EPIDEMIOLOGY, PATHOLOGY, AND GENETICS OF EPILEPSY

Overview: Epidemiology, Pathology, and Genetics

Epilepsy: Historical Perspectives Neuropathology

EPIDEMIOLOGY

Incidence and Prevalence

The Natural History and Prognosis of Epilepsy

NEUROPATHOLOGY

General Neuropathology of Epilepsy

Hippocampal Sclerosis

GENETICS

Genetic Epidemiology

EEG Traits

SECTION II THE NEUROBIOLOGY OF EPILEPSY

Overview: The Neurobiology of Epilepsy

MECHANISMS OF NORMAL NEURONAL EXCITABILITY

Control of Neuronal Excitability

Excitatory Synaptic Transmission

Neocortical Anatomy and Physiology

Thalamocortical Anatomy and Physiology

MECHANISMS OF EPILEPTOGENESIS AND EPILEPTOGENICITY

Genetic Models of Epilepsy

Seizure Mechanisms and Vulnerability in the Developing Brain

SECTION III PHENOMENOLOGY

Overview: Phenomenology

EPILEPTIC SEIZURES

Simple Motor Seizures

Limbic Seizures

Epileptic Spasms

STATUS EPILEPTICUS

Generalized Convulsive Status Epilepticus

Absence Status Epilepticus

Myoclonic Status Epilepticus

EPILEPTIC DISORDERS

Classification of the Epilepsies

SECTION IV DIAGNOSTIC EVALUATION

Overview: Diagnostic Evaluation

ROUTINE INVESTIGATIONS

History and Physical Examination

EEG

Physiologic Basis of the Electroencephalogram and Local Field Potentials

Ictal Electroencephalogram

Polygraphic Recordings

NEUROIMAGING

Positron Emission Tomography

Magnetic Resonance Spectroscopy

Computational Anatomy

NEW DIRECTIONS

Seizure Prediction

Microdialysis

Transcranial Magnetic Stimulation

Cellular Imaging of Epilepsy

NEUROPSYCHOLOGICAL EVALUATION

LONG-TERM MONITORING

VOLUME II

SECTION V GENERAL TREATMENT CONSIDERATIONS

Overview: General Approaches to Treatment

GENERAL CONSIDERATIONS

PRINCIPLES OF DRUG TREATMENT

STRATEGIES FOR PHARMACOTHERAPY

SPECIAL THERAPEUTIC CONSIDERATIONS

ALTERNATIVE APPROACHES

SECTION VI ANTIEPILEPTIC DRUGS

ANTIEPILEPTIC DRUG DEVELOPMENT

ANTIEPILEPTIC DRUGS

SECTION VII SURGICAL THERAPY

CANDIDATE SELECTION

INVASIVE MONITORING TECHNIQUES

FUNCTIONAL MAPPING TECHNIQUES

THERAPEUTIC SURGICAL PROCEDURES

POSTOPERATIVE FOLLOW-UP

SECTION VIII CLINICAL BIOLOGY OF EPILEPSY>/b>

BIORHYTHMS AND THE AUTONOMIC NERVOUS SYSTEM

COMORBIDITY

NEUROENDOCRINOLOGY

VOLUME III

SECTION IX PSYCHIATRIC AND SOCIAL ISSUES

PSYCHIATRIC ISSUES

SOCIAL ISSUES

SECTION X EPILEPSY SYNDROMES

NEONATAL SYNDROMES

SYNDROMES OF INFANCY AND EARLY CHILDHOOD

SYNDROMES OF LATER CHILDHOOD AND ADOLESCENCE

NON AGE-RELATED AND SPECIAL SYNDROMES

DISEASES ASSOCIATED WITH EPILEPSY

SECTION XI DISORDERS THAT CAN BE CONFUSED WITH EPILEPSY

SYSTEMIC DISTURBANCES

NEUROLOGICAL DISTURBANCES

PSYCHIATRIC DISTURBANCES

SECTION XII DELIVERY OF HEALTH CARE AND SOCIOECONOMIC ISSUES

ORGANIZATION OF HEALTH CARE IN DIFFERENT COUNTRIES

SPECIALIZED CENTERS FOR EPILEPSY

COST AND ALLOCATION OF RESOURCES

2008

Editors: Engel, Jerome; Pedley, Timothy A.
Title: *Epilepsy: A Comprehensive Textbook, 2nd Edition*

Editors

Jerome Engel Jr. MD, PhD
Jonathan Sinay Distinguished Professor of Neurology
Neurobiology, and Psychiatry and Behavioral Sciences; Director of the UCLA Seizure Disorder Center, David Geffen School of Medicine at UCLA, Los Angeles, California

Timothy A. Pedley MD
Henry and Lucy Moses Professor of Neurology and Chairman
Department of Neurology, College of Physicians and Surgeons of Columbia University; Neurologist-in-Chief, The Neurological Institute of New York, The New York-Presbyterian Hospital at Columbia University Medical Center, New York, New York

Associate Editors

Jean Aicardi MD, FRCP
Professor of Neurology
University Hospital Robert Debre, Epilepsy Unit, Child Neurology and Metabolic Disease, Paris, France

Marc A. Dichter MD, PhD
Professor of Neurology and Pharmacology
University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Emilio Perucca MD, PhD, FRCP
Professor
Clinical Pharmacology Unit, Department of Internal Medicine and Therapeutics, University of Pavia; Director, Laboratories for Diagnostics and Applied Biological Research, Institute of Neurology IRCCS C. Mondino Foundation, Pavia, Italy

Solomon L. Moshé MD
Vice Chair and Professor of Neurology
Neuroscience and Pediatrics, Albert Einstein College of Medicine of Yeshiva University; Director of Child Neurology and Clinical Neurophysiology, Department of Neurology and Pediatric Neurology, Montefiore Medical Center, Bronx, New York

Michael R. Trimble MD
Professor of Behavioral Neurology
Institute of Neurology, London, United Kingdom

Contributing Authors

Eric Abadie
Director

Therapeutic Evaluation, Agence Francaise de Secunte Sanitaire des Products de Sante, Paris, France

Carlos Acevedo MD, SCH
Professor of Pediatric Neurology
Universidad de los Andes, Department of Pediatric Neurology, Clinica Alemana de Santiago, Santiago, Chile

Keryma A. Acevedo MD
Assistant Professor
Department of Pediatrics, Northern Campus, University of Chile; Staff of Pediatric Neurology, Emergency Department, Clinica Alemana de Santiago, Santiago, Chile

Bola Adamolekun MD, FWACP
Director of Epilepsy
Department of Neurology, University of Tennessee Health Science Center, Memphis, Tennessee

Jean Aicardi MD, FRCP
Department, University Hospital Robert Debre, Epilepsy Unit, Children Neurology and Metabolic Disease, Paris, France

Fiorenzo Albani MD
Laboratory of Clinical Neuropharmacology, Department of Neurological Sciences, University of Bologna, Bologna, Italy

Albert P. Aldenkamp PhD
Professor of Epileptology
Department of Neurology, University of Maastricht, University Hospital Maastricht; Head Department of Behavioural Sciences, Epilepsy Centre Kempenhaeghe, Heeze, The Netherlands

Brian K. Alldredge Pharm.D
Professor of Clinical Pharmacy and Neurology
University of California, San Francisco, California

Abdul Aziz Al Semari MD
Director
Comprehensive Epilepsy Program; Chairman, Epilepsy Support and Information Center and Head, Section of Neurology, Department of Neurosciences, King Faisal Specialist Hospital and Research Center, Kingdom of Saudi Arabia

Michael J. Aminoff MD, DSc, FRCP
Professor and Executive Vice Chair of Neurology
University of California School of Medicine; Attending Physician, Department of Neurology, University of Calfornia Medical Center, San Francisco, California

Eva Andermann MD, PhD
Professor of Neurology and Neurosurgery
Montreal Neurological Institute and Hospital, McGill University, Montreal, Canada

Frédérick Andermann MD, FRCPC
Professor of Neurology and Neurosurgery
Montreal Neurological Institute and Hospital, McGill University, Montreal, Canada

V. Elving Anderson PhD
Professor Emeritus
Department of Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, Minnesota

Santiago Arroyo MD, PhD
Clinical Discovery Neurosciences, Bristol-Myer-Squibb, Lawrenceville, New Jersey

Alexis Arzimanoglou MD
CTRS-IDEE, University of Lyon, Lyon, France; Head, Department of Neurology, University Hospital Robert Debré, Paris, France

Joan K. Austin DNS
Department of Environments for Health, Indiana University School of Nursing, Indianapolis, Indiana

Giuliano G. Avanzini MD
Professor of Neurology
Division of Clinical Epileptology and Experimental Neurophysiology, Istituto Nazionale Neurologico, Milano, Italy

Thomas L. Babb PhD
Professor of Pediatrics and Neurology
Children's Hospital of Michigan, Wayne State University, Detroit, Michigan

Torbjörn Backström MD, PhD
Professor
Department of Clinical Sciences, Umeå University; Consultant, Department of Obstetrics and Gynecology, Norrlands University Hospital, Umeå, Sweden

Gus A. Baker PhD, FBPsS
Professor of Clinical Neuropsychology, Consultant Clinical Neuropsychologist
Division of Neurosciences, University of Liverpool, Walton Centre for Neurology & Neurosurgery, Liverpool, United Kingdom

Poonam Nina Banerjee PhD
Department of Neurology and Sergievsky Center, College of Physicians and Surgeons, Department of Epidemiology, Mailman School of Public Health, Columbia University, New York, New York

Tallie Z. Baram MD, PhD
Professor of Pediatrics, Anatomy/Neurobiology, and Neurology, Scientific Director
Comprehensive Epilepsy Program, University of California, Irvine, Irvine, California

Amit Bar-Or MD, FRCPC
Associate Professor of Neurology and Neurosurgery, Associate

Microbiology and Immunology, McGill University; Director, Program in Experimental Therapeutics; Scientific Director, Clinical Research Unit, Montreal Neurological Institute, Montreal, Quebec, Canada

William B. Barr PhD
Comprehensive Epilepsy Center, New York University Medical Center, New York, New York

Shehzad Basaria MD
Assistant Professor of Internal Medicine
Johns Hopkins University School of Medicine, Johns Hopkins Bayview Medical Center, Baltimore, Maryland

Agatino Battaglia MD
Stella Maris Clinical Research Institute for Child and Adolescent Neuropsychiatry, Calambrone, Pisa, Italy

Dina Battino MD
Division of Neurophysiology and Epileptology, Carlos Besta, National Neurological Institute, Milan, Italy

Michel Baulac MD
Professor
University Pierre et Marie Curie (Paris VI), INSERM Unit U739 Cortex and Epilepsy, CHU Pitie-Salpetriere; Physician and Chief of Department, Unit of Epileptology, Hôpital Salpêtrière, Batiment Paul Castaigne, Paris, France

Christoph Baumgartner MD
Associate Professor of Neurology, Head
Comprehensive Epilepsy Program, Medical University of Vienna, Vienna, Austria

Carl W. Bazil MD, PhD
Associate Professor of Neurology
Columbia University Medical Center; Attending Neurologist, New York-Presbyterian Hospital, New York, New York

Heinz Beck MD
Head
Laboratory of Experimental Epileptology; Professor, Department of Epileptology, University of Bonn Medical Center, Bonn, Germany

Ettore Beghi MD
Epilepsy Center, Ospedale “San Gerardo” Monza, Monza, Milan, Italy

Elinor Ben-Menachem MD, PhD
Sahlgren University Hospital, Department of Neurology, Institute of Clinical Neuroscience, Goteborg, Sweden

Roy G. Beran MD, FRACP, FRCP, FRACGP, FACLM, B Leg S, MHL
Conjoint Associate Professor
University of New South Wales; Professor School of Medicine, Griffith University, Chatswood, New South Wales, Australia

Anne T. Berg PhD
Associate Professor
Department of Biology, Northern Illinois University, DeKalb, Illinois

Gregory K. Bergey MD
Professor of Neurology
Department of Neurology; Director, Johns Hopkins Epilepsy Center, Johns Hopkins School of Medicine and Hospital, Baltimore, Maryland

Samuel F. Berkovic MD, FRS
Professor
Epilepsy Reseach Centre, University of Melbourne; Director of Comprehensive Epilepsy Program, Austin Health, Heidelberg, Victoria, Australia

Christophe Bernard PhD
Professor
Inserm U751, Université de la Mediterranee, Marseille, France

Gianna Bertani MD
Physician
Child Neurology Unit, Arcispedale s. Maria Nuova, Reggio Emilia, Italy

Edward H. Bertram MD
Professor of Neurology
Department of Neurology, University of Virginia, Charlottesville, Virginia

Frank M.C. Besag MB, ChB, FRCP, FRCPsych, FRCPCH
Visiting Professor of Neuropsychiatry, Faculty of Health and Social Sciences
University of Bedfordshire, Luton, Beds; Consultant Neuropsychiatrist, Child and Adolescent Mental Health Services, Bedfordshire and Luton Partnership NHS Trust, Bedford, Beds, United Kingdom

Tim Betts
Seizure Clinic and Epilepsy Liaison, Birmingham University, Edgbaston, Queen Elizabeth Psychiatric Hospital, Birmingham, United Kingdom

Ahmad A. Beydoun MD
Professor of Neurology
Department of Internal Medicine, American University of Beirut Medical Center, Beirut, Lebanon

Nadir E. Bharucha MD
Bombay Hospital Medical Research, Department of Neuroepidemiology, Mumbai, India

Meir Bialer PhD, MBA
David H. Eisenberg Professor of Pharmacy
Department of Pharmaceutics, School of Pharmacy, Faculty of Medicine, Hebrew University of Jerusalem, Jerusalem, Israel

Christian G. Bien MD
Senior Neurologist and Leading Assistant Medical Director
Department of Epileptology, University of Bonn, Bonn, Germany

Devin K. Binder MD, PhD
Assistant Professor
Department of Neurological Surgery, University of California, Irvine, Orange, California

Gretchen L. Birbeck MD, MPH, DTMH
Director and Associate Professor
International Neurologic and Psychiatric Epidemiology, Michigan State University, East Lansing, Mississippi; Director, Epilepsy Care Team, Chikankata Health Services, Mazabuka, Zambia

Jonathan M. Bird MD
Burden Centre for Neuropsychiatry, Frenchay Hospital, United Kingdom

Angela K. Birnbaum PhD
Associate Professor
Experimental and Clinical Pharmacology, University of Minnesota, Minneapolis, Minnesota

Peter F. Bladin MD, BS, BSc, FRACP, FRACPEd
Professor, Faculty of Medicine
Dentistry, Health Sciences, University of Melbourne, Neurologist, Comprehensive Epilepsy, Austin Hospital, Melbourne, Victoria, Australia

Thomas P. Bleck MD, FCCM
Professor of Neurology and Neurosurgery
The Ruth Cain Ruggles Chairman of Neurology, Northwestern University Feinberg School of Medicine, Evanston Northwestern Healthcare, Chicago, Illinois

Ingmar Blümcke MD
Department of Neuropathology, Friedrich Alexander University, Erlangen, Germany

Warren T. Blume MD
Professor of Neurology Emeritus
Clinical Neurological Sciences, University of Western Ontario, London, Ontario, Canada

Hal Blumenfeld MD, PhD
Director of Medical Studies
Clinical Neurosciences; Associate Professor, Departments of Neurology, Neurobiology, Neurosurgery, Yale University School of Medicine, New Haven, Connecticut

Dietrich Blumer MD
Professor of Psychiatry, Head of Neuropsychiatry
University of Tennessee, Memphis, Tennessee

Joshua L. Bonkowsky MD, PhD

Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, Utah

Harold E. Booker MD
Carolina Neurological Clinic, Charleston, South Carolina

Susan Y. Bookheimer PhD
University of California at Los Angeles Departmentof Psychiatry and Biobehavioral Sciences, Los Angeles, California

Paul Boon MD, PhD
Professor and Chairman
Department of Neurology, University Hospital, Ghent, Belgium

Carmel H. Bouclaous MD
Division of Neurosurgery, American University of Beirut, Beirut, Lebanon

Blaise F. D. Bourgeois MD
Professor of Neurology
Harvard Medical School; Director, Division of Epilepsy and Clinical Neurophysiology, Children's Hospital, Boston, Massachusetts

Martin J. Brodie MD, FRCP
Professor of Medicine and Clinical Pharmacology
Division of Cardiovascular and Medical Sciences, University of Glasgow; Consultant Physician and Clinical Pharmacologist, Division of Cardiovascular and Medical Sciences, Western Infirmary, Glasgow, United Kingdom

Eylert Brodtkorb
Department of Neurology and Clinical Neurophysiology, Trondheim University Hospital, Trondheim, Norway

Edward B. Bromfield MD
Chief
Division of Epilepsy and EEG, Division of Neurology, Brigham & Women's Hospital; Associate Professor of Neurology, Harvard Medical School, Boston, Massachusetts

Richard J. Brown PhD, Clin. Psy. D
Lecturer in Clinical Psychology
University of Manchester; Clinical Psychologist, Department of Clinical and Health Psychology, Manchester, United Kingdom

Stephen W. Brown FRCPsych
The David Lewis Centre for Epilepsy, Cheshire, United Kingdom; Clinical Director, Learning Disabilities Service, Norwich Community Health, Norwich, Norfolk, United Kingdom

Thomas R. Browne MD
Boston University School of Medicine, Fairmouth, Massachusetts

John C. M. Brust MD

Professor of Clinical Neurology
Columbia University College of Physicians and Surgeons; Director, Department of Neurology, Harlem Hospital Center, New York, New York

Michelle Bureau MD
Head of Neurophysiology (emer.)
EEG Laboratory, Centre Saint Paul, Marseille, France

György Buzsáki MD, PhD
Center for Molecular and Behavioral Neuroscience, Rutgers, The State University of New Jersey, Newark, New Jersey

Carol S. Camfield MD, FRCP(C)
Professor of Pediatrics
Dalhousie University, Halifax, Nova Scotia, Canada

Peter R. Camfield MD
Professor of Pediatrics
Dalhousie University, Halifax, Nova Scotia, Canada

Rochelle Caplan MD
Semel Institute for Neuroscience and Behavior, Los Angeles, California

Roberto Caraballo MD
Department of Neurology, Hospital de Pediatria, Buenos Aires, Argentina

Arturo Carpio MD
Professor of Neurology
School of Medicine, University of Cuenca, Neurologist, Comprehensive Epilepsy Center, Hospital "Vicente Corral M.", Cuenca, Ecuador

Romeo Carrozzo MD
Medical Genetics and General Pediatrics, National Health Service, Milan, Italy

Gregory D. Cascino MD
Department of Neurology, Mayo Clinic, Rochester, Minnesota

Idil Cavus MD, PhD
Assistant Professor of Psychiatry and Neurosurgery, Assistant Professor of Psychiatry
Yale University School of Medicine, Connecticut Mental Health Center, New Haven, Connecticut

Jennifer Cavitt MD
Assistant Professor of Neurology
University of Cincinnati, Cincinnati, Ohio

Fernando Cendes MD, PhD
Associate Professor of Neurology

University of Campinas, Campinas, Brazil

David W. Chadwick DM, FRCP, FMedSci
Professor of Neuroscience
University of Liverpool, Walton Centre, Liverpool, United Kingdom

Roukoz B. Chamoun MD
Division of Neurosurgery, American University of Beirut, Beirut, Lebanon

Gian-Emillio Chatrian MD
Professor Emeritus
Department of Neurology, University of Washington Medical Center, Seattle, Washington

Patrick Chauvel MD
Service de Neurophysiologie Clinique et Epileptologie, CHU Timone et Universite de la Mediterranee, Marseille, France

Catherine Chiron MD
Service de Neurologie et Metablolisme, Hopital Necker, Paris, France

Dan Chisholm
Department of Health Systems Financing, World Health Organization, Geneva, Switzerland

Harry T. Chugani MD
Children's Hospital of Michigan, Detroit, Michigan

Maria Roberta Cilio MD, PhD
Attending Physician
Department of Neurology, Bambino Gesu Children's Hospital, Rome, Italy

Robert R. Clancy MD
Professor of Neurology and Pediatrics
University of Pennsylvania School of Medicine; Director, Pediatric Regional Epilepsy Program, Division of Neurology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

David C. Clemmons PhD
Vocational Services, University of Washington Regional Epilepsy Center, Seattle, Washington

Mark S. Cohen PhD
Professor-in-Residence
Department of Psychiatry, Neurology, Radiology, Psychology, Biomedical Physics, University of California at Los Angeles, Los Angeles, California

Youssef G. Comair MD, FRCP
Department of Neurosurgery, Cleveland Clinic Foundation, Cleveland, Ohio

Barry W. Connors PhD
Professor and Chair
Department of Neuroscience, Brown University, Providence, Rhode Island

Douglas A. Coulter PhD
Department of Pediatric Neruology, University of Pennsylvania, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Joyce A. Cramer BS
Associate Research Scientist
Department of Psychiatry, Yale University School of Medicine, West Haven, Connecticut

Peter B. Crino MD, PhD
Assistant Professor
Department of Neurology, University of Pennsylvania, Philadelphia, Pennsylvania

J. Helen Cross MB, ChB, PhD, FRCP, FRCPCH
Professor
Neurosciences Unit, UCL-Institute of Child Health; Honorary Consultant/Clinical Lead, Paediatric Neurology (Epilepsy), Great Ormond St Hospital for Children NHS Trust, London, United Kingdom

Patricia K. Crumrine MD
Professor of Pediatrics, Director of Pediatric Epilepsy and EEG
Department of Child Neurology, University of Pittsburgh, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Bernardo Dalla Bernardina MD, PhD
Professor and Director
Service of Child Neuropsychiatry, University of Verona, Policlinico G.B. Rossi, Verona, Italy

Michael D. Daras MD, PhD
Clinical Professor of Neurology
Department of Neurology, Columbia University; Attending Neurologist, New York Presbyterian Hospital, New York, New York

Hanneke M. de Boer
Senior Officer International Relations
Epilepsy Centres of The Netherlands Foundation, Haarlem, The Netherlands

Nihal C. De Lanerolle DPhil, DSc
Associate Professor of Neurosurgery
Yale University School of Medicine, New Haven, Connecticut

Oscar H. Del Brutto MD
Department of Neurological Sciences, Hospital-Clínica Kennedy, Guayaquil, Ecuador

Robert J. DeLorenzo MD, PhD, MPH

Professor of Neurology
Biochemistry, Pharmacology and Toxicology, Virginia Commonwealth University, Richmond, Virginia

John De Toledo MD
International Center for Epilepsy, University of Miami, Miami, Florida

John A. Devereux BA, LLB, DPhil
Professor of Common Law
T.C. Beirne School of Law, University of Queensland, Brisbane, Queensland, Australia

Orrin Devinsky MD
Professor of Neurology, Director
New York University Epilepsy Center, New York University Medical Center, New York University School of Medicine

Darryl C. De Vivo MD
Sidney Carter Professor of Neurology and Pediatrics
Neurological Institute of New York, New York, New York

Marc A. Dichter MD, PhD
Departments of Neurology and Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Salvatore DiMauro MD
Lucy G. Moses Professor of Neurology
H. Houston Merritt Clinical Research Center for Muscular Dystrophy and Related Diseases, Department of Neurology, College of Physicians and Surgeons, New York, New York

Raymond Dingledine PhD
Professor and Chair
Department of Pharmacology, Emory University School of Medicine, Atlanta, Georgia

Amadou Gallo Diop MD, PhD
Clinique Neurologique, Hopital Universitaire de Fann, Dakar, Senegal

Aleksandra Djukic MD, PhD
Assistant Professor
Department of Neurology, Albert Einstein College of Medicine; Attending Physician of Neurology, Montefiore Medical Center, Bronx, New York

W. Edwin Dodson MD
Professor of Neurology and Pediatrics
Washington University School of Medicine, Neurologist, Division of Pediatric Neurology, St. Louis Children's Hospital, St. Louis, Missouri

Werner Doyle MD
Department of Neurosurgery, New York University Medical School, New York, New York

Charlotte Dravet MD
Honorary Consultant Ospedale A. Gemelli
Department of Child Neurology and Psychiatry, Catholic University School of Medicine, Rome, Italy; Honorary Consultant IRCCS, Stella Maris Foundation, Epilepsy, Neurophysiology, Neurogenetics Unit, IRCCS, Stella Maris Foundation, Calambrone, Pisa, Italy

Frank W. Drislane MD
Associate Professor of Neurology
Harvard Medical School, Neurologist, Comprehensive Epilepsy Center, Department of Neurology, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Maurice L. Druzin MD
Department of Gynecology and Obstetrics, Stanford University School of Medicine, Stanford University Medical Center, Stanford, California

François Dubeau MD
Associate Professor of Neurology and Neurosurgery
McGill University; Staff and Chief of EEG, Department of Neurology and Neurosurgery, Montreal Neurological Hospital and Institute, Montreal, Quebec, Canada

Michael S. Duchowny MD
Comprehensive Epilepsy Center, Miami Children's Hospital, Miami, Florida

Olivier Dulac MD
Neuropediatric Department, Hôpital Necker, Paris, France

John S. Duncan MA, DM, FRCP
Professor of Neurology
Department of Clinical and Experimental Epilepsy, Institute of Neurology UCL, London, United Kingdom; Medical Director, National Society for Epilepsy, Chalfont Centre for Epilepsy, Bucks, United Kingdom

David W. Dunn MD
Division of Child and Adolescent Psychiatry, Departments of Psychiatry and Neurology, Indiana University School of Medicine, Indianapolis, Indiana

Mervyn J. Eadie AO, MD, PhD, FRCP, FRACP
Department of Medicine, University of Queensland, Brisbane, Australia

John S. Ebersole MD
Professor of Neurology, Director
Adult Epilepsy Service; Co-Director, Comprehensive Epilepsy Center, Department of Neurology, The University of Chicago, Chicago, Illinois

Orvar Eeg-Olofsson MD PhD
Professor of Neuropediatrics
Department of Women's and Children's Health, Uppsala University; Consultant of Neuropediatrics, University Children's Hospital, Uppsala, Sweden

Jerome Engel Jr. MD, PhD
Jonathan Sinay Distinguished Professor of Neurology
Neurobiology and Psychiatry and Behavioral Sciences; Director of the UCLA Seizure Disorder Center, David Geffen School of Medicine at UCLA, Los Angeles, California

Leon Eisenberg MD
Professor of Child Psychiatry and Social Medicine
Emeritus, Department of Social Medicine, Harvard Medical Science; Honorary Psychiatrist, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Frances Elmslie MD, FRCP
Consultant Clinical Geneticist
Department of Medical Genetics, St. George's University of London, London, United Kingdom

Charles M. Epstein MD
Professor of Neurology
Emory University School of Medicine; Attending Physician, Emory University Hospital, Atlanta, Georgia

Kai J. Eriksson MD, PhD
Chief
Department of Pediatric Neurology, Tampere University Hospital, Tampere, Finland

Alan B. Ettinger MD
Department of Neurology, North Shore-LIJ Comprehensive Epilepsy Centers, New Hyde Park, New York

Stanley Fahn MD
H. Houston Merritt Professor of Neurology
Department of Neurology, Columbia University Medical Center, Neurological Institute or New York, New York, New York

Johan Falk-Pedersen Esq.
A/S Forretningsadvokatene, Solli, Norway

Erika E. Fanselow PhD
Postdoctoral Associate
Department of Neuroscience, Brown University, Providence, Rhode Island

Kevin Farrell MB, ChB, FRCPC
Professor
Division of Neurology, Department of Pediatrics, University of British Columbia, British Columbia's Children's Hospital, Vancouver, Canada

Michael A. Farrell MB
Department of Neuropathology, Beaumont Hospital, Dublin, Ireland

Edward Faught MD
Professor and Vice Chairman

Department of Neurology; Director, Division of Epilepsy, University of Alabama at Birmingham Epilepsy Center, Birmingham, Alabama

Natalio Fejerman MD
Hospital de Pediatria "Juan P. Garrahan", Beunos Aires, Argentina

Evan J. Fertig MD
Assistant Professor of Neurology
Neurosurgery, and Pediatrics, Yale University School of Medicine, New Haven, Connecticut

Alexandra Finucane Esq.
Epilepsy Foundation of America, Landover, Maryland

Bruce J. Fisch MD
Professor of Neurology; Director
LSU Epilepsy Center of Excellance School of Medicine, Louisiana State University, New Orleans, Louisiana

Robert S. Fisher MD, PhD
Maslah Saul MD Professor of Neurology
Department of Neurology and Neurological Sciences, Stanford University School of Medicine, Stanford, California

Robert T. Fraser PhD, CRC
Department of Neurology, University of Washington Epilepsy Center, Harborview Medical Center, Seattle, Washington

Jeremy L. Freeman MBBS, FRACP
Honorary Lecturer of Pediatrics
Monash University, Clayton, Victoria, Neurologist, Department of Neurology, The Royal Children's Hospital, Parkville, Victoria, Australia

John M. Freeman MD
Lederer Professor of Pediatric Epilepsy Emeritus, Director
Pediatric Epilepsy Center Emeritus; Professor of Neurology and Pediatrics, Johns Hopkins Medical Institutions, Baltimore, Maryland

Jacqueline A. French MD
Professor, Assistant Dean for Clinical Trials
Department of Neurology, University of Pennsylvania; Chief, Epilepsy Section, Department of Neurology, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Itzhak Fried MD, PhD
Division of Neurosurgery, University of California Los Angeles School of Medicine, Los Angeles, California, Functional Neurosurgery Unit, Tel-Aviv Medical Center and Sackler School of Medicine, Tel-Aviv University, Tel-Aviv, Israel

James D. Frost Jr. MD

Professor of Neurophysiology
Department of Neurology and Neuroscience, Baylor College of Medicine, St. Luke's Episcepal Hospital, Houston, Texas

Steven J. Frucht MD
Associate Professor of Clinical Neurology, Associate Attending Neurologist
Department of Neurology, Columbia University Medical Center, New York, New York

Cheryl A. Frye PhD
Departments of Psychology, Biology, and Centers for Neuroscience and Life Sciences Research, The University at Albany-State University of New York, Albany, New York

Lucia Fusco MD, PhD
Section of Neurophysiology, Bambino Gesu Children's Hospital, Rome, Italy

Eija Gaily
Associate Professor of Pediatric Neurology
Helsinki University; Chief of Epilepsy Unit, Pediatric Neurology, Hospital for Children and Adolescents, Helsinki, Finland

Karen Gale PhD
Department of Pharmacology, Georgetown University Medical Center, Washington, DC

Elena Gardella MD, PhD
Research Fellow
Department of Neurosciences, University of Bologna, Bellaria Hospital, Bologna, Italy

Pierre Genton MD
Neurologist, Centre Saint Paul Hospital, Marseille, France

Mark S. George MD
Distinguished Professor of Psychiatry
Radiologyand Neurosciences, Medical University of South Carolina, Charleston, South Carolina

Barry E. Gidal PharmD
Professor
School of Pharmacy and Department of Neurology, University of Wisconsin, Madison, Wisconsin

Christopher Gillberg MD
Section of Child and Adolescent Psychiatry
Department of Clinical Neuroscience, Annedals Clinics, Göteborg, Sweden

Frank Gilliam MD
Caitlin Tynan Doyle Professor of Neurology, Director
Comprehensive Epilepsy Center, The Neurological Institute, Columbia University, NewYork, NewYork

Michael Glantz MD

University of Massachusetts, Berkshire Medical Center, Pittsfield, Massachusetts

Tracy A. Glauser MD
Professor of Pediatrics and Neurology
University of Cincinnati College of Medicine; Director, Comprehensive Epilepsy Program, Division of Child Neurology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Giuseppe Gobbi MD
Chief of Child Neurology and Psychiatry
Ospedale Maggiore "Pizzardi" Hospital, Bologna, Italy

David B. Goldstein MD
Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, North Carolia

Jeffrey H. Goodman PhD
Research Scientist
Center for Neural Recovery and Rehabilitation Research, Helen Hayes Hospital, West Haverstraw, New York

Robert R. Goodman MD, PhD
Associate Professor
Department of Neurological Surgery, Columbia University College of Physicians and Surgeons, New York, New York

Jean Gotman PhD
Professor
Department of Neurology and Neurosurgery, McGill University and Montreal Neurological Institute, Montreal, Quebec, Canada

Salvatore Grosso MD, PhD
Researcher and Assistant
Department of Pediatrics, SS. Maria alle Scotte Hospital, University of Siena, Siena, Italy

Carlos A. M. Guerreiro MD, PhD
Professor of Neurology
State University of Campinas, Campinas, Brazil

Renzo Guerrini MD
Professor
University of Florence; Director of Child Neurology Unit, AOU Meyer, Florence, Italy

Robert J. Gumnit MD
Clinical Professor of Neurology
Neurosurgery and Pharmacy, University of Minnesota; President, MINCEP Epilepsy Care, Minneapolis, Minnesota

Houda Hachad PharmD
Senior Research Scientist

Department of Pharmaceutics, University of Washington, Seattle, Washington

Michael M. Haglund MD, PhD
Department of Neurosurgery, Duke University Medical Center, Durham, North Carolina

Mark Hallett MD
Chief
Human Motor Control Section, National Institute of Neurological Disorders and Stroke, National Institute of Health, Bethesda, Maryland

Marla Hamberger PhD
Associate Professor of Clinical Neuropsychology
Department of Neurology; Chief Neuropsychologist, Comprehensive Epilepsy Center, The Neurological Institute, New York, New York

Cynthia L. Harden MD
Professor of Neurology
Weill Medical College of Cornell University; Attending Neurologist, New York-Presbyterian Hospital, New York, New York

A. Simon Harvey MD
Department of Neurology, Children's Epilepsy Program, Royal Children's Hospital, Melbourne, Australia

W. Allen Hauser MD
Professor of Epidemiology and Neurology
G. H. Dergievsky Center; Associate Director, College of Physicians and Surgeons and Mailman School ofPublic Health, Columbia University Medical Center; Attending Neurologist, Neurological Institute, New York, New York

Sheryl Haut MD
Associate Professor of Clinical Neurology, Director
Adult Epilepsy Service, Albert Einstein College of Medicine, Bronx, New York

Philip G. Haydon PhD
Professor and Director
Silvio Conte Center for Integration at the Tripartite Synapse; Director, Center for Dynamic Imaging of Nervous SystemFunction, Department of Neuroscience, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Liyun He MD
Associate Professor
Clinical Evaluation Center, China Academy of Chinese Medicine Sciences, Beijing, China

Uwe Heinemann PhD
Head of Institute of Neurophysiology
Charite Medical University Berlin, Berlin, Germany

Christoph Helmstaedter PhD
Associate Professor of Clinical Neuropsychology
Department of Epileptology, University of Bonn, Bonn, Germany

Thomas R. Henry MD
Professor of Neurology
University of Minnesota, Minneapolis, Minnesota

Bruce P. Hermann PhD
Department of Neuropsychology, University of Wisconsin, Madison, Wisconsin

Dale C. Hesdorffer PhD
Assistant Professor
Gertrude H. Sergievsky Center, Columbia University, New York, New York

Andrew G. Herzog MD, MSc
Professor of Neurology
Harvard Medical School; Director of Neuroendocrine Unit, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Michio Hirano MD
Associate Professor of Neurology
H. Houston Merritt Clinical Research Center for Muscular Dystrophy and Related Diseases, Department of Neurology, College of Physicians and Surgeons of Columbia University, New York, New York

Edouard Hirsch MD
Professor of Neurology
HUS Strasburg, IDEE, Strasburg, France

Lawrence J. Hirsch MD
Associate Clinical Professor
Department of Neurology, Columbia University Medical Center; Associate Attending Neurologist, New York-Presbyterian Hospital, New York, New York

Daryl Hochman PhD
Department of Neurosurgery, Duke University Medical Center, Durham, North Carolina

Gregory L. Holmes MD
Professor of Neurology and Pediatrics
Neuroscience Center at Dartmouth, Dartmouth Medical School, Hanover, New Hampshire; Chief, Section of Neurology, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire

Mark D. Holmes MD
Professor of Neurology
University of Washington; Director, Clinical Neuropyhsiology, Regional Epilepsy Center, Harborview Medical Center, Seattle, Washington

Richard A. Hrachovy MD
Professor of Neurolgoy
Baylor College of Medicine; Associate Chief of EEG, Department of Neurophysiology, St. Luke's Episcopal Hospital, Houston, Texas

Yushi Inoue MD, PhD
Vice-director
National Epilepsy Center, Shizuoka Institute of Epilepsy and Neurological Disorders, Shizuoka, Japan

Graeme D. Jackson MD
Brain Research Institute, West Heidelberg, Australia

Ann Jacoby PhD
Professor of Medical Sociology
Division of Public Health, School of Population, Community and Behavioral Sciences, University of Liverpool, Liverpool, United Kingdom

Satish Jain MD, DM
Director
Indian Epilepsy Center, New Delhi, India

Pierre Jallon MD
Epilepsy and EEG Unit, University Hospital, Geneva, Switzerland

Damir Janigro PhD
Professor
Molecular Medicine, Department of Neurosurgery and Molecular Medicine, Cleveland Clinic Foundation, Cleveland, Ohio

Prasanna Jayakar MD, PhD
Chair
Brain Institute, Miami Children's Hospital, Miami, Florida

John G. R. Jefferys FMedSci
Professor of Neuroscience
Division of Neuroscience, School of Medicine, University Birmingham, Birmingham, United Kingdom

Frances E. Jensen MD
Professor of Neurology, Director of Epilepsy Research
Department of Neurology, Children's Hospital, Boston, Massachusetts

Svein I. Johannessen PhD
Director of Research
The National Center for Epilepsy, Sandvika, Division of Clinical Neuroscience, Rikshospitalet, Oslo, Sandvika, Norway

Marilyn Jones-Gotman PhD

Professor of Neurology and Neurosurgery
McGill University; Coordinator, Neuropsychology Epilepsy Service, Montreal Neurological Institute, Montreal, Quebec, Canada

Philippe Kahane MD, PhD
Neurophysiopathologie de l'Epilepsie, Clinique Neurologique, Grenoble, France

Ellie Kalichi RN
Chikankata Epilepsy Care Team Coordinator
Mazabuka, Zambia

Reetta Kälviäinen MD, PhD
Docent/Associate Professor of Neurology
University of Kuopio Academic Institution; Director of Neurology, Kuopio Epilepsy Center, Kuopio University Hospital, Kuopio, Finland

Anna Kaminska
Department of Pediatric Neurophysiology, Groupe Hospitalier Cochin-Saint Vincent de Paul and Necker Enfant, Paris, France

Kousuke Kanemoto
Department of Neuropsychiatry, Aichi Medical University, Nagakute, Aichi, Japan

Andres M. Kanner MD
Department of Neurology, Rush University Medical Center, Chicago, Illinois

Peter W. Kaplan MBBS
Professor of Neurology, Director of Epilepsy and Electrophysiology
Bayview Medical Center, Johns Hopkins University School of Medicine, Baltimore, Maryland

Russell Katz MD
U.S. Food and Drug Administration, Division of Neuropharmacological Drug Products, Rockville, Maryland

Noojan J. Kazemi MBBS
Doctorial Student
Department of Surgery, University of Melbourne; Registrar, Department of Neurosurgery, The Royal Melbourne Hospital, Parkville, Victoria, Australia

Michael P. Kerr MBChB, MRCEP, MRCPsych, MSc in Psychiatry
Professor of Learning Disability Psychiatry
Psychological Medicine, Cardiff University School of Medicine, Cardiff, United Kingdom

Sonia Khan FRCP (Lond), FRCP (Edin)
Director and Consultant
Department of Neurosciences, Riyadh Military Hospital, Riyadh, Kingdom of Saudi Arabia

Negar Khanlou

Section of Neuropathology, UCLA Medical Center, Los Angeles, California

Eliane Kobayashi MD, PhD
Assistant Professor
Department of Neurology and Neurosurgery, Montreal Neurological Institute and Hospital, McGill University, Montreal, Quebec, Canada

Steffi C. Koch-Stoecker MD
Head of Psychiatric Outpatient Clinic, Psychiatric Consultant of Epilepsy Center
Ev. Krankenhaus Bielefeld, Bielefeld, Germany

Barbara S. Koppel MD
Professor of Clinical Neurology
New York Medical College, Valhalla, New York; Chief, Neurology Service, Metropolitan Hospital, New York, New York

Maria D. Kostka-Rokosz Pharm D
Department of Pharmacy Practice, Massachusetts College of Pharmacy and Health Sciences, Boston, Massachusetts

Prakash Kotagal MD
Head
Pediatric Epilepsy, Epilepsy Center, Cleveland Clinic, Cleveland, Ohio

Dimitri M. Kullmann DPhil, FRCP
Professor
Institute of Neurology, University College London; Consultant Neurologist, National Hospital for Neurology and Neurosurgery, London, United Kingdom

Wolfram S. Kunz PhD
Divison of Neurochemistry, Department of Epileptology, University of Bonn Medical Center, Bonn, Germany

Harvey J. Kupferberg PhD, PharmD
Kupferberg Consultants, LLC, Chief
Preclinical Pharmacology Section (retired), Epilepsy Branch, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, Maryland

Ruben I. Kuzniecky MD
New York University Epilepsy Center, New York, New York

Patrick Kwan MB, BChir, MRCP, PhD
Division of Neurology, Department of Medicine, The Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong, China

W. Curt LaFrance Jr. MD
Departments of Psychiatry and Neurology, Rhode Island Hospital, Providence Rhode Island

Chi-Wan Lai MD
Professor of Neurology
Tzu Chi University Medical School, Hualien, Taiwan; Staff Neurologist, Department of Medicine, Sun Yat-Sen Cancer Center, Taipei, Taiwan

Frederick G. Langendorf MD
Associate Professor
Department of Neurology, University of Minnesota; Assistant Chief of Neurology, Hennepin County Medical Center, Minneapolis, Minnesota

John T. Langfitt PhD
Associate Professor of Neurology and Psychiatry
University of Rochester Medical Center, Rochester, New York

Barbara W. LeDuc
Assistant Professor
Department of Pharmacology, Massachusetts College of Pharmacology and Health Sciences, Boston, Massachusetts

Gabriel Lee MBS (Hons), MS, FRACS
Consultant Neurosurgeon
Department of Neurosurgery, Sir Charles Gairdner Hospital, Perth, Western Australia

Alan D. Legatt MD, PhD
Professor of Clinical Neurology
Department of Neurology, Albert Einstein College of Medicine; Director, EEG Laboratory, Department of Neurology, Montefiore Medical Center, Bronx, New York

Cynthia Lehman Esq
Epilepsy Foundation of America, Landover, Maryland

Klaus Lehnertz PhD
Associate Professor of Physics, Faculty of Mathematics and Natural Science
Head Neurophysics Group, Department of Epileptology, University of Bonn Medical Center, Bonn, Germany

Matilde Leonardi MD
Head, Department of Neurology
Public Health and Disability Unit (HEADNET), Neurological Institute Carlo Besta IRCCS Foundation, Milan, Italy

Ilo E. Leppik MD
Professor of Neurology and Pharmacy
University of Minnesota, Minneapolis, Minnesota

Ronald P. Lesser MD
Professor of Neurology and Neurosurgery, Member
Zanvyl Krieger Mind/Brain Institute, Department of Neurology, Johns Hopkins Medical Institutions, Baltimore, Maryland

Pierre LeVan M.Eng.
Graduate Student
Biomedical Engineering, McGill University, Department of Electroencephalogram, Montreal Neurological Institute, Montreal, Quebec, Canada

Michel Le Van Quyen PhD
INSERM Researcher
French National Institute for Health and Medical Research, Laboratory of Brain Imaging and Cognitive Neuroscience, Hopital de la Salpetriere, Paris, France

René H. Levy PhD
Department of Pharmaceutics, University of Washington, Seattle, Washington

Darrell V. Lewis MD
Professor of Pediatrics
Division of Pediatric Neurology, Duke University Medical Center, Durham, North Carolina

Samden D. Lhatoo MD
Department of Neurology, Institute of Clinical Neurosciences, Frenchay Hospital, University of Bristol, Bristol, United Kingdom

Shichuo Li MD
President
China Association Against Epilepsy, Beijing, People's Republic of China

Weiping Liao MD
Professor
Neuroscience Institute, Guangzhou Medical College, Guangzhou, China

Jack J. Lin MD
Assistant Professor of Neurology, Director
Clinical Neurophysiology Fellowship, University of California, Irvine, Irvine, California

Richard B. Lipton MD
Professor and Vice Chair of Neurology, Professor of Epidemiology and Population Health
Albert Einstein College of Medicine; Director, Montefiore Headache Unit, Innovative Medical AECOM, Bronx, New York

Brian Litt MD
Associate Professor
Department of Neurology and Bioengineering, University of Pennsylvania, Philadelphia, Pennsylvania

Iscia Lopes-Cendes MD, PhD
Associate Professor
Medical Genetics, University of Campinas, Campinas, Brazil

Fernando H. Lopes da Silva MD

Emeritus Professor
Center of Neuroscience, Swammerdam Institute for Life Sciences, University of Amsterdam, Amsterdam, The Netherlands

David W. Loring PhD
Professor of Neurology
Department of Neurology, McKnight Brain Institute, Gainesville, Florida

Wolfgang Löscher
Department of Pharmacology, Toxicology & Pharmacy, University of Veterinary Medicine, Hannover, Hannover, Germany

Daniel H. Lowenstein MD
Professor of Neurology, Director
Epilepsy Center, Department of Neurology, University of California, San Francisco, California

Guoming Luan MD
Professor of Neurosurgery
San Bo Brain Sciences Institute of Beijing, Beijing, China

Hans O. Lüders MD
Professor of Neurology, Director
Epilepsy Center, Case Western Reserve Medical Center, Cleveland, Ohio

Katarzyna Lukasiuk PhD
Associate Professor
Department of Molecular and Cellular Neurobiology, The Nencki Institute of Experimental Biology, Warsaw, Poland

Robert L. Macdonald MD, PhD
Professor and Chair of Neurology
Vanderbilt University Medical Center, Nashville, Tennessee

Mark W. Mahowald MD
Minnesota Regional Sleep Disorders Center, Hennepin County Medical Center, Minneapolis, Minnesota

Beth A. Malow MD, MS
Associate Professor
Department of Neurology; Medical Director, Vanderbilt Sleep Disorders Center, Vanderbilt University Medical Center, Nashville, Tennessee

Gary W. Mathern MD
Professor and Attending Physician
Department of Neurosurgery, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, California

Richard H. Mattson MD

Department of Neurology, Yale Medical Center, New Haven, Connecticut

John C. Mazziotta MD, PhD
Chair
Department of Neurology; Pierson-Lovelace Investigator, Stark Chair in Neurology; Director, Brain Mapping Center; Associate Director, Neuropsychiatric Institute, David Geffen School of Medicine at UCLA, Los Angeles, California

Dan C. McIntyre PhD
Chancellor's Professor
Department of Psychology, Institute of Neuroscience, Carleton University, Ottawa, Ontario, Canada

Guy M. McKhann II MD
Florence Irving Associate Professor of Neurological Surgery
The Neurological Institute, Columbia University Medical Center, New York, New York

William McLin
Merriman and Co., Washington, DC

Kimford J. Meador MD
Professor of Neurology
Melvin Greer, University of Florida, Gainesville, Florida

Harry Meinardi MD
Professor of Epileptology (Retired)
Department of Neurology; Medical Director, Instituut voor Epilepsiebestrijding, Heenstede, The Netherlands

Brian S. Meldrum MD, PhD
King College London, GKT School of Medicine, Hodgkin House, London, England

Roberto Michelucci MD, PhD
Director of Neurology Unit
Department of Neurosciences, Bellaria Hospital, Bologna, Italy

David Millett
Clinical Fellow
Department of Neurology, University of California Los Angeles, Los Angeles, California

Hajime Miyata MD, PhD
Department of Neuropathology, Institute of Neurological Sciences; Faculty of Medicine, Totori University, Yonago, Tottori, Japan

Eli M. Mizrahi MD
Head
Peter Kellaway Section of Neurophysiology; Vice-Chairman, Department of Neurology, Professor of Neurology and Pediatrics, Baylor College of Medicine; Chief, Neurophysiology Services, St. Luke's Episcopal Hospital, Texas Children's Hospital, Houston, Texas

Istvan Mody PhD
Professor
Departments of Neurology and Physiology, The David Geffen School of Medicine at UCLA, Los Angeles, California

Georgia D. Montouris MD
Assistant Professor
Department of Neurology, Boston University School of Medicine; Director of Epilepsy Services, Boston Medical Center, Boston, Massachusetts

Joan T. Moroney MD, MRCPI
Beaumont Hospital, Department of Neurology, Dublin, Ireland

Martha J. Morrell MD
Clinical Professor of Neurology
Stanford University Medical Center, Stanford, California

Solomon L. Moshé MD
Vice Chair and Professor of Neurology
Neuroscience and Pediatrics, Albert Einstein College of Medicine of Yeshiva University; Director of Child Neurology and Clinical Neurophysiology, Department of Neurology and Pediatric Neurology, Montefiore Medical Center, Bronx, New York

Marco Mula MD, PhD
Research Fellow
Department of Clinical & Experimental Medicine, Section of Neurology, Amedeo Avogadro University, Novara, Italy, Department of Psychiatry, Neurobiology, Pharmacologyand Biotechnology, University of Pisa, Pisa, Italy

Karl O. Nakken MD, PhD
Chief Physician
Division of Clinical Neuroscience, The National Center for Epilepsy, Sandvika, Norway

Martha A. Nance MD
Adjunct Associate Professor
Department of Neurology, University of Minnesota, Minneapolis, Minnesota

Lina Nashef MBChB, MRCP, MD, FRCP
Honorary Senior Lecturer
Department of Clinical Neuroscience, King's College London, Institute of Psychiatry; Consultant Neurologist, Department of Neurology, King's College Hospital, London, United Kingdom

Wassim M. Nasreddine MD
Chief and Head
Neurology Division, Beirut Governmental University Hospital, Jnah, Beirut, Lebanon

Ibrahima Pierre Ndiaye MD
Department of Neurology, University Hospital of Fann, Dakar, Senegal

Astrid Nehlig PhD
Research Director
French National Institute for Health and Medical Research; Faculty of Medicine, Strasbourg, France

Brian G. Neville MD
The Wolfson Centre, London, United Kingdom

Jeffrey L. Noebels MD, PhD
Professor of Neurology
Neuroscience and Molecular Genetics, Baylor College of Medicine, Houston, Texas

Douglas R. Nordli Jr. MD
Associate Professor of Neurology and Pediatrics
Northwestern University Feinberg School of Medicine, Lorna S. and James P. Langdon Chair of Pediatric Epilepsy; Director, Epilepsy Center, Children's Memorial Hospital, Chicago, Illinois

Marc R. Nuwer MD, PhD
Professor of Neurology, Head
Department of Clinical Neurophysiology, Univeristy of California Los Angeles, Los Angeles, California

Terence J. O'Brien MBBS
St. Vincent Hospital, Department of Clinical Neurosciences, Victoria, Australia

Shunsuke Ohtahara MD, PhD
Professor Emeritus
Department of Child Neurology, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Shikatacho, Okayama, Japan

Yoko Ohtsuka MD, PhD
Professor
Department of Child Neurology, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Shikatacho, Okayama, Japan

George A. Ojemann MD
University of Washington, Regional Epilepsy Center, Harborview Medical Center, Seattle, Washington

Ruth Ottman PhD
Professor of Epidemiology
Sergievsky Center, Columbia University, New York, New York

Christoph Pachlatko Dr. oec. Pfr.
Managing Director
Swiss Epilepsy Center, Zürich, Switzerland

Alison M. Pack MD
Assistant Professor of Clinical Neurology
Department of Neurology, Columbia University, New York Presbyterian Hospital, New York, New York

Chrysostomos P. Panayiotopoulos MD, PhD
Consultant Emeritus
Department of Clinical Neurophysiology and Epilepsies, St. Thomas' Hospital, London, United Kingdom

Jack M. Parent MD
Associate Professor of Neurology
University of Michigan, Ann Arbor, Michigan

Elena Parrini PhD
Molecular Biologist
Neurogenetics Lab, Child Neurology Unit, AOU Meyer, Florence, Italy

Philip N. Patsalos FRCPath, PhD
Professor
Department of Clinical and Experimental Epilepsy, Institute of Neurology, London, United Kingdom; Professor, Pharmacology and Therapeutics Unit, Chalfont Centre for Epilepsy, Chalfont St. Peter, Buckinghamshire, United Kingdom

Timothy A. Pedley MD
Henry and Lucy Moses Professor of Neurology, Chairman
Department of Neurology, Columbia University; Neurologist-in-Chief, The Neurological Institute of New York, The New York-Presbyterian Hospital, Columbia University Medical Center, New York, New York

John M. Pellock MD
Division of Child Neurology, Medical College of Virginia, Richmond, Virginia

Jukka Peltola MD, PhD
Deputy Chief
Department of Neurology, Tampere University Hospital, Tampere, Finland

Emilio Perucca MD, PhD, FRCP(Edin)
Professor
Clinical Pharmacology Unit, Department of Internal Medicine and Therapeutics, University of Pavia; Director, Laboratories for Diagnostics and Applied Biological Research, Institute of Neurology IRCCS C. Mondino Foundation, Pavia, Italy

Ognen A. C. Petroff MD
Associate Professor of Neurology, Director of EEG and Attending Physician
Department of Neurology, Yale University, Yale-New Haven Hospital, New Haven Connecticut

Margarete Pfäfflin
Epilepsy-Center Bethel, Bielefeld, Germany

Fabienne Picard MD
Department of Neurology, University Hospital of Geneva, Geneva, Switezerland

Demetris K. Pillas MSc

PhD Candidate
Epidemiology and Public Health Department, Imperial College of London, London, United Kingdom

Antonella Pini MD
Physician
Child Neurology Unit, Ospedale Maggiore Ca Pizzardi, Bologna, Italy

Munir Pirmohamed PhD, FRCP, FRCP(E)
Professor of Clinical Pharmacology
Department of Pharmacology and Therapeutics, The University of Liverpool; Consultant Physician, The Royal Liverpool University Hospital, Liverpool, United Kingdom

Asla Pitkänen MD, PhD, DSc
Professor in Neurobiology
A.I. Virtanen Institute for Molecular Sciences, University of Kuopio, Kuopio, Finland

Perrine Plouin MD
Head of Clinical Neurophysiology
Necker Enfants Malades Hospital, Paris, France

Charles E. Polkey MD, FRCS
Professor Emeritus of Functional Neurosurgery
Department of Clinical Neurociences, Institute of Psychiatry, London, United Kingdom

Roger J. Porter MD
Adjunct Professor of Neurology
University of Pennsylvania, Philadelphia, Pennsylvania; Adjunct Professor of Pharmacology, Uniformed Services University of the Health Sciences, Bethesda, Maryland

Tiziano Pramparo PhD
Molecular Biologist
Department of Biology and Medical Genetics, University of Pavia, Pavia, Italy

Michael D. Privitera MD
Professor and Vice Chair Neurology, Director
Cincinnati Epilepsy Center, University of Cincinnati Medical Center, Cincinnati, Ohio

Mark Proctor MD
Department of Neurosurgery, Brigham and Women's Hospital, Boston, Massachusetts

Mark S. Quigg MD, MSc
Associate Professor of Neurology, Medical Director
EEG, Intensive Monitoring, Evoked Potential, and Neurological Sleep Laboratories, Health Sciences Center, University of Virginia, Charlottesville, Virginia

Kurupath Radhakrishnan MD
R. Madhavan Nayar Center for Comprehensive Epilepsy Care, Sree Chitra Tirunal Institute for Medical

Sciencesand Technology, Trivandrum, Kerala, India

R. Eugene Ramsay MD
International Center for Epilepsy, Miami, Florida

Peter M. Rankin
D. Clin. Psych., Honorary Senior Lecturer
Institute of Child Health, University College London; Consultant Paediatric Neuropsychologist, Department of Psychological Medicine, Great Ormond Street Hospital For Children NHS Trust, London, United Kingdom

Lawrence D. Recht MD
Professor of Neurolgoy
Stanford University, Stanford, California

Jean Régis MD
Professor of Neurosurgery
Stereotatic and Functional Neurosurgery Department, Timone Hospital, Marseille, France

Trevor J. Resnick MD
Associate Professor, Chief of Neurology
University of Miami, Miller School of Medicine, Miami Children's Hospital, Miami, Florida

Jong M. Rho MD
Associate Professor
Department of Neurology, University of Arizona College of Medicine, Children's Health Center, St. Joseph's Hospital and Medical Center, Phoenix, Arizona

Kristen A. Richardson PhD
Postdoctoral Associate
Department of Neuroscience, Brown University, Providence, Rhode Island

David W. Roberts MD
Section of Neurosurgery
Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire

Michael A. Rogawski MD, PhD
Epilepsy Research Section, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, Maryland

Guido Rubboli MD
Attending Physician
Department of Neurosciences, Bellaria Hospital, Bologna, Italy

Zarya A. Rubin MD, FRCPC
Comprehensive Epilepsy Center, Neurological Institute of New York, Columbia University, New York, New York

Anne Sabers MD

Chief of the Epilepsy Unit
Department of Neurology, Glostrup University Hospital, Glostrup, Denmark

Ralph L. Sacco MD
Department of Neurology and the School of Public Healthin the Sergievsky Center, Columbia University, Neurological Institute of New York, New York, New York

Noriko Salamon MD, PhD
Department of Neuroradiology, David Geffen School of Medicine, University of California Los Angeles Medical Center, Los Angeles, California

Josemir W. Sander MD, PhD, FRCP
Professor of Clinical and Experimental Epilepsy
Honorary Consultant Neurologist, Epilepsy Centre, National Hospital for Neurology and Neurosurgery, London, United Kingdom

Raman Sankar MD, PhD
Departments of Neurology and Pediatrics, University of California Los Angeles School of Medicine, Los Angeles, California

P. Satishchandra MBBS, DM (Neurology), FAMS, FIAN
Professor of Neurology
National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, Karnataka, India

Steven C. Schachter MD
Professor of Neurology
Harvard Medical School; Director of Research, Department of Neurology, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Helen E. Scharfman PhD
Associate Professor
Helen Hayes Hospital Center, New York, New York; Associate Professor of Clinical Pharmacology (in Neurology), Department of Pharmacology and Neurology, Columbia University, New York, New York; Director, Center for Neural Recovery and Rehabilitation Research, Helen Hayes Hospital, New York State Department of Health, West Haverstraw, New York

Ingrid E. Scheffer MBBS, PhD, FRACP
Professor of Paediatric Neurology Research
Department of Medicine, Austin Health, Department of Paediatrics, Royal Children's Hospital, The University of Melbourne, Parkville, Victoria; Director of Paediatrics, Department of Medicine, Austin Health Repatriation Hospital, Heidelberg, Victoria, Australia

Carlos H. Schenck MD
Department of Psychiatry, Hennepin County Medical Center, University of Minnesota Medical Center, Minneapolis, Minnesota

Mark S. Scher MD
Professor of Pediatrics and Neurology

Department of Pediatrics; Division Chief, Pediatric Neurology; Director, Pediatric Sleep/Epilepsy & Fetal/Neonatal Neurology Program, Rainbow Babies & Children's Hospital, University Hospital Case Medical Center, Cleveland, Ohio

Bernd Schmidt MD
Head
Neurology and Psychiatry Outpatient Clinic, Wittnau, Germany

Dieter Schmidt MD
Emeritus Professor of Neurology
Epilepsy Research Group, Berlin, Germany

Bettina Schmitz
Professor
Charite Neurologie, Berlin, Germany

Donald L. Schomer MD
Maslah Saul MD Professor of Neurology
Department of Neurology and Neurological Sciences, Stanford University School of Medicine, Stanford, California, Comprehensive Epilepsy Program, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Stephanie Schorge PhD
Assistant Professor
Institute of Neurology, University College London, London, United Kingdom

Johannes Schramm
Professor and Chairman
Department of Neurosurgery, University of Bonn, Bonn, Germany

Robert Schwarcz PhD
Professor of Psychiatry
Maryland Psychiatric Research Center, University of Maryland School of Medicine, Baltimore, Maryland

Philip A. Schwartzkroin PhD
Department of Neurological Surgery, University of California–Davis, Davis, California

Michael Seidenberg PhD
Department of Psychology, Finch University of Health Sciences, The Chicago Medical School, Chicago, Illinois

Masakazu Seino MD*
National Epilepsy Center, Shizuoka Medical Institute of Neurologic Diseases, Shizuoka, Japan

**Deceased*

Caroline E. Selai BA(Hons), MSc, PhD, DipPsych, CPsychol.
Senior Lecturer in Clinical Neuroscience
University College London, Institute of Neurology, National Hospital for Neurology and Neurosurgery, London,

United Kingdom

Patricia O. Shafer RN, MN
Division of Public Health, University of Liverpool, Liverpool, United Kingdom

Volney L. Sheen MD, PhD
Department of Neurology, Harvard Medical School, Beth Israel Deaconess Medical Center, Boston, Massachusetts

D. Alan Shewmon MD
Department of Neurology, Olive View-UCLA Medical Center, Sylmar, California

Hiroshi Shibasaki MD, PhD
Consultant
Takeda General Hospital, Kyoto, Japan

W. Donald Shields MD
University of California Los Angeles Medical Center, Department of Pediatric Neurology, Mattel Children's Hospital, Los Angeles, California

Hideo Shigematsu MD
Chief
Department of Pediatrics, National Epilepsy Center, Shizouka Medical Institute of Neurological Disorders, Shizouka, Japan

Shlomo Shinnar MD, PhD
Albert Einstein College of Medicine, Montefiore Medical Center, Bronx, New York

Simon D. Shorvon MD, FRCP
Professor in Clinical Neurology and Clinical Subdean Consultant Neurologist
University College of London, National Hospital for Neurology and Neurosurgery, London, United Kingdom

Margaret N. Shouse PhD
Professor
Department of Neurobiology, University of California Los Angeles School of Medicine, Los Angeles, Californina; Chief, Sleep Disturbance Research, VA Greater Los Angeles Healthcare System, North Hills, California

Stephen D. Silberstein MD
Professor of Neurology
Jefferson Medical College; Director, Jefferson Headache Center, Thomas Jefferson University Hospital, Philadelphia, Pennsylvania

Sanjay M. Sisodiya MBBChir, MA, PhD, FRCP
Professor
Department of Clinical and Experimental Epilepsy, UCL Institute of Neurology; Honorary Consultant Neurologist, Division of Neurology, National Hospital for Neurology and Neurosurgery, London, United

Kingdom

Mary Lou Smith PhD
Professor of Psychology
University of Toronto Mississauga, Mississaugo, Ontario; Psychologist, Department of Psychology and Neurology, Hospital for Sick Children, Toronto, Ontario, Canada

Michael C. Smith MD
Department of Neurological Sciences, Rush Epilepsy Center, Chicago, Illinois

Dee Snape
Division of Public Health, University of Liverpool, Liverpool, United Kingdom

O. Carter Snead III MD
Head
Division of Neurology, Hospital for Sick Children, Toronto, Ontario, Canada

Elson L. So MD
Professor of Neurology, Consultant and Director of Neurology
Section of Electroencephalography, Mayo Clinic College of Medicine, Rochester, Minnesota

Luigi Specchio MD
Clinic of Nervous System Diseases, University of Foggia, Foggia, Italy

Nicola Specchio MD
Section of Neurophysiology, Bambino Gesu Children's Hospital, Rome, Italy

Sarah J. Spence MD, PhD
UCLA Department of Psychiatry & Biobehavioral Sciences; Medical Director UCLA Autism Evaluation Clinic, Medical Director of the Autism Genetic Resource Exchange, Los Angeles, California

Dennis D. Spencer MD
Yale University, School of Medicine Neurosurgery, New Haven Connecticut

Susan S. Spencer MD
Professor of Neurology
Yale University School of Medicine; Attending Director, Epilepsy Unit, Department of Neurology, Yale New Haven Hospital, New Haven, Connecticut

Michael R. Sperling MD
Professor of Neurology
Thomas Jefferson University; Director, Jefferson Comprehensive Epilepsy Center, Thomas Jefferson University Hospital, Philadelphia, Pennsylvania

Carl E. Stafstrom MD, PhD
Professor of Neurology and Pediatrics, Chief

Section of Pediatric Neurology, University of Wisconsin, Madison, Wisconsin

Hermann Stefan Prof.Dr.Med.
Professor
Epilepsy Center, University Erlangen; Director of Epilepsy Center, University Hospital Erlangen, Erlangen, Bavaria, Germany

Christian Steinhäuser PhD
Professor and Director
Institute of Cellular Neurosciences, University of Bonn Medical School, Bonn, Germany

Ortrud K. Steinlein MD
Head of Department
Institute of Human Genetics, University of Munich, Munchen, Germany

Linda J. Stephen MBChB
Honorary Senior Lecturer
Division of Cardiovascular and Medical Sciences, University of Glasgow; Associate Specialist, Division of Cardiovascular and Medical Sciences, Western Infirmary, Glasgow, Scotland, United Kingdom

John B. P. Stephenson MA, DM
Honorary Professor in Pediatric Neurology
University of Glasgow, Fraser of Allander Neurosciences Unit, Royal Hospital for Sick Children, Glasgow, Scotland, United Kingdom

John M. Stern MD
Associate Professor of Neurology
David Geffen School of Medicine at UCLA, Los Angeles, California

Mark Stewart MD, PhD
Associate Professor
Department of Physiology and Pharmacology Neurology, State University of New York Downstate Medical Center, Brooklyn, New York

John W. Swann PhD
Professor
Department of Pediatric and Neuroscience, Baylor College of Medicine; Scientific Director, The Cain Foundation Laboratories, Texas Children's Hospital, Houston, Texas

Chong Tin Tan MD, FRCP
University of Malaya; Chair of the Commission on Asian and Oceanian Affairs, International League Against Epilepsy, Kuala Lumpur, Malaysia

Carlo Alberto Tassinari MD
Professor of Neurological Sciences
University of Bologna; Consultant, Department of Neurosciences, Bellaria Hospital, Bologna, Italy

David C. Taylor MD, MSc, FRCP, FRCPsych
Institute of Child Health and Great Ormond Street Hospital, The Wolfson Centre, London, United Kingdom

Joanne Taylor BSc
Postgraduate Research Student
Department of Neurological Science, The University of Liverpool, Clinical Science Centre for Research and Education, Liverpool, United Kingdom

Ludger Tebartz van Elst MD, PhD
Professor of Psychiatry and Psychotherapy, Consultant Psychiatrist
University of Freiburg, Freiburg, Germany

Nancy R. Temkin PhD
Professor
Departments of Neurological Surgery and Biostatistics, University of Washington, Seattle, Washington

Kiyohito Terada MD, PhD
Chief
Department of Neurology, National Epilepsy Center, Shizuoka Institute of Epilepsy and Neurological Disorders, Shizuoka, Japan

William H. Theodore MD
Chief
Clinical Epilepsy Section, National Institute of Neurological Disorders and Stroke, National Institute of Health, Bethesda, Maryland

Pierre Thomas MD, PhD
Professor of Neurology
Department of Medicine, University of Nice-Sophia-Antipolis; Chief, Department of Epileptology and Clinical Neurology, Hopital Pasteur, Nice, France

Rupprecht Thorbecke
Epilepsy Center Bethel, Klinik Mara, Bielefeld, Germany

Arthur W. Toga PhD
Professor of Neurology
University of California Los Angeles School of Medicine, Los Angeles, California

Torbjörn Tomson MD
Department of Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden

Roger D. Traub MD
Department of Physiology and Pharmacology, and Neurology, SUNY Downstate Medical Center, Brooklyn, New York

David M. Treiman MD
Newsome Chair in Epileptology; Vice Chair, Neurology; Director, Epilepsy Program, Barrow Neurological

Institute, Phoenix, Arizona; Research Professor, Harrington Department of Bioengineering, Arizona State University, Tempe, Arizona

Andrew J. Trevelyan MD
Department of Biological Sciences, Columbia University, New York, New York

Michael R. Trimble MD
Professor of Behavioral Neurology
Institute of Neurology, London, United Kingdom

John D. Van Horn PhD, MEng
Assistant Professor
Department of Neurology, University of California Los Angeles School of Medicine, Los Angeles, California

Paul C. Van Ness MD
Associate Professor of Neurology
University of Texas Southwestern Medical Center; Director, UT Southwestern Epilepsy Center, Department of Neurology, Parkland Memoral Hospital, Dallas, Texas

Faraneh Vargha-Khadem PhD
Professor of Developmental Cognitive Neuroscience/Head of Unit
Institute of Child Health, University College London; Consultant Paediatric Neuropsychologist, Department Neuropsychology, Great Ormond Street Hospital for Children NHS Trust, London, United Kingdom

Jana Velíšková MD, PhD
Assistant Professor
Department of Neurology and Neuroscience, Albert Einstein College of Medicine, Rose F. Kennedy Center, Bronx, New York

Paul M. Vespa MD
Associate Professor of Neurology in Neurosurgery
University of California, Los Angeles, Los Angeles California

Annamaria Vezzani PhD
Head of Experimental Neurology Laboratory
Department of Neuroscience, Mario Negri Institute for Pharmacological Research, Milano, Italy

Barbara G. Vickrey MD, MPH
Professor and Vice Chair
Department of Neurology, University of California, Los Angeles; Physician of Neurology, VA Greater Los Angeles Healthcare System, Los Angeles, California

Federico Vigevano MD
Professor of Neurology
Departments of Neurology and Neurophysiology, Bambino Gesu Children's Hospital, Rome, Italy

Flavio Villani MD

Staff Neurologist
Division of Clinical Epileptology and Experimental Neurophysiology, Fondazione IRCCS Istituto Nazionale Neurologico "C. Besta", Milano, Italy

Eileen P. G. Vining MD
Professor of Neurology and Pediatrics
Johns Hopkins University School of Medicine, Baltimore, Maryland

Harry V. Vinters MD
Section of Neuropathology, Brain Research Institute, Mental Retardation Research Center, University of California Los Angeles Medical Center, Los Angeles, California

Kenneth Vives MD
Chief of Stereotactic and Functional Neurosurgery
Department of Neurosurgery, Yale University School of Medicine, New Haven, Connecticut

Charles Vorkas MD
New York University Epilepsy Center, New York, New York

Thaddeus S. Walczak MD
Adjunct Professor
Department of Neurology, University of Minnesota; Director, Clinical Neurophysiology, MINCEP Epilepsy Care, Minneapolis, Minnesota

Nicole Walley
Institute for Genome Sciences and Policy, Center for Population Genomics and Pharmacogenetics, Duke University, Durham, North Carolina

Christopher A. Walsh MD, PhD
Bullard Professor of Neurology
Howard Hughes Medical Institute, Harvard Medical School; Chief of Genetics, Children's Hospital Boston, Boston, Massachusetts

Wenzhi Wang MD
Professor
Neuroepidemiology Department, Beijing Neurosurgical Institute, Beijing, China

Braxton B. Wannamaker MD
Clinical Professor
Department of Neurosciences, Medical University of South Carolina, Charleston, South Carolina

Claude G. Wasterlain MD
Chair
Department of Neurology, VA Greater Los Angeles Health Care System; Professor and Vice-Chair, Department of Neurology, David Geffen School of Medicine at UCLA, West L.A. VA Medical Center, Los Angeles, California

Kazuyoshi Watanabe MD, PhD

Faculty of Medical Welfare
Aichi Shukutoku University, Chikusa-ku, Nagoya, Japan

Donald F. Weaver MD, PhD
Departments of Medicine, Chemistry and Biomedical Engineering, Dalhousie University, Halifax, Nova Scotia, Canada

Peter J. West MD
Anticonvulsant Drug Development Program, Department of Pharmacology and Toxicology, University of Utah, Salt Lake City, Utah

H. Steve White PhD
Anticonvulsant Drug Development Program, University of Utah, Salt Lake City, Utah

Samuel Wiebe MD, MSc(Epidemiol.), FRCPC
Professor of Clinical Neurosciences
University of Calgary; Head, Division of Neurology, Foothills Medical Centre, Calgary, Alberta, Canada

Heinz Wiendl MD
Department of Neurology, University of Wuerzburg, Wuerzburg, Germany

Heinz Gregor Wieser MD
Professor of Neurology, Chief
Department of Epileptology and Electroencephalography, Neurology Clinic, University Hospital, Zurich, Switzerland

Karen S. Wilcox PhD
Department of Pharmacology & Toxicology, University of Utah, Salt Lake City, Utah

Alan J. Wilensky MD
Regional Epilepsy Center, Harborview Medical Center, Seattle, Washington

Peter D. Williamson MD
Department of Neurology, Dartmouth Medical School, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire

L. James Willmore MD
Professor of Neurology and Pharmacologyand Physiology Neurology
Saint Louis University School of Medicine; Attending Neurologist, Saint Louis University Hospital, St. Louis, Missouri

Charles L. Wilson PhD
Professor Emeritus
Department of Neurology, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, California

Melodie R. Winawer MD, MS

Assistant Professor, Attending Physician
Department of Neurology, Columbia University Medical Center, New York, New York

Peter Wolf MD, PhD
Professor of Neurology

Title: *Epilepsy: A Comprehensive Textbook, 2nd Edition*

Acknowledgments

Once again, we gratefully acknowledge the vital contributions of the associate and section editors, whose work and effort were instrumental in producing this second edition. We also thank our chapter authors, who tolerated constant badgering, criticisms (we hope helpful), and many editorial changes, all with good humor. A textbook of this size cannot be created without the committed efforts of a large number of individuals, including Keith Donnellan, our Development Editor at Dovetail Content Solutions, who worked with authors, kept track of submissions and the many revisions, and greatly assisted in keeping everything organized; the staff at Lippincott Williams & Wilkins, especially Leanne McMillan, our Managing editor and Chris Miller from Aptara who provided excellent service at the key points; and our own office staff, especially Malinda Walford and Grissel Coplin in New York, and Dale Booth and Sabrina Hubbard in Los Angeles, who daily - for nearly two years - bore the brunt of our overly ambitious goals.

Title: *Epilepsy: A Comprehensive Textbook, 2nd Edition*

Dedication

We dedicate this edition to our wives, Catherine and Barbara, and the others in our families who all too often lost us to these volumes. Above all, this book is for persons with epilepsy and their families, who daily give meaning to our work.

Editors: **Engel, Jerome; Pedley, Timothy A.**
Title: *Epilepsy: A Comprehensive Textbook, 2nd Edition*

Preface to the Second Edition

A decade has intervened between the first and second editions of *Epilepsy: A Comprehensive Textbook*. The process of revision afforded a unique opportunity to observe the extraordinary advances in research and the great improvements in clinical care that have occurred during this time. New insights into the basic mechanisms of seizures and epilepsy can be attributed largely to the increased application of cellular and molecular biology to the study of epileptic phenomena. In addition, there have been more direct investigations of patients using the tools of genetics and various brain imaging techniques. All aspects of treatment have improved, and both seizure control and quality of life for people with epilepsy are better today than ever before.

This progress is symbolized by noting that the second edition contains 20 more chapters than the first, of which 42 are completely new and 251 have been extensively rewritten. There were 351 contributors in the first edition; there are 444 in the second, of whom 225 are returning authors and 219 are new. As a result, although the book's outline follows that of the first edition, this is essentially an entirely new textbook.

As with the first edition, our objective with the second is to create a comprehensive textbook that addresses all aspects of epilepsy, from basic pathophysiology at cellular, molecular and organ levels to clinical phenomenology, diagnostic evaluation, treatment options, comorbidities, psychosocial rehabilitation and health care delivery. All chapters are written by distinguished experts in each field, and most have two or more authors representing different points of view to provide an authoritative consensus on each topic. Selection of editors and authors was designed to assure a perspective that is truly international. Therapeutic recommendations are evidence-based to the extent that is currently possible.

With completion of the second edition, we are acutely aware how much we owe to the section editors and, especially, our associate editors, all of whom are themselves internationally recognized experts in epilepsy. Without their help, chapters would not have been as consistently rigorous, balanced or current.

We also note with sadness the passing of colleagues who participated in the first edition, many of whom also contributed, or were scheduled to contribute, to the second. They include John Fred Annegers, Frank Benson, Fritz E. Dreifuss, John R. Gates, Richard W. Homan, Peter Kellaway, Pierre Loiseau, Eric Lothman, K. S. Mani, Frank Morrell, Claudio Munari, J. Kiffen Penry, Luis Felipe Quesney, A. James Rowan, Masakazu Seino, Arthur Sonnen and Sheila J. Wallace. We miss them, but they live on through their work and accomplishments, and the fond memories we have of them.

The first edition of *Epilepsy: A Comprehensive Textbook* was intended to be a work in progress, a basis for developing a comprehensive reference resource in a format that had the potential to be updated regularly. A CD-ROM was subsequently prepared that included additional materials and revisions of some chapters. The second edition will have a digital version that is Internet based for inclusion of additional figures and images, more color illustrations, and other enhancements, as well as advanced search capabilities. The Internet version of the textbook affords an opportunity for all authors to update their chapters on an ongoing basis, to ensure that the electronic version remains current with the very latest information.

As always, we welcome suggestions and constructive criticism from readers. This input will not only assist in improving future hard copy editions but also help us to provide an Internet-based digital version that is as useful as possible.

Chapter 1

Introduction: What Is Epilepsy?

Jerome Engel Jr.

Timothy A. Pedley

Introduction

Epilepsy is one of the most common disorders of the brain.[28] One of every ten people will have at least one epileptic seizure during a normal lifespan, and a third of these will develop epilepsy. Worldwide, epilepsy affects 50 million people. According to a World Health Organization (WHO) survey, epilepsy accounts for 1% of the global burden of disease, a figure equivalent to breast cancer in women and lung cancer in men.[15]

Epilepsy has been known since antiquity. An Assyrian-Babylonian textbook written over three millennia ago provides an accurate clinical description of the condition,[12] and Indian and Chinese physicians of that time were also familiar with it. The word *epilepsy* is derived from the Greek verb ÎµÎ»Î±ÂµÎ²Î±Î½ÎµÎ¹Î½ (*epilamvanein*) (â€œto be seized,â€ â€œto be taken hold of,â€ or â€œto be attackedâ€). In ancient Greece, as now, people spoke of â€œhaving seizedâ€ and of having had an â€œattack.â€ This terminology derived from the very ancient notion that all diseases represented attacks by the gods or evil spirits, usually as punishment. Because seizures were the most vivid example of demonic possession, epilepsy was considered to be â€œthe sacred disease,â€ and by the fifth century BC, the word had gradually acquired the specific and particular meaning associated with it today.[25] Indeed, the battle between prejudice and acceptance, ignorance and knowledge, myth and science, and charlatanism and rational therapy has been long and difficult, and even today it has not yet been fully won. Even in comparison with all the advances made during the last centuryâ€”more than at any other time in historyâ€”consider how enormous and fundamental was that first step attributed to Hippocrates in about 400 BC, that epilepsy is a disease of the brain that must be treated by diet and drugs, not religious incantations.[9]

Epilepsy is, of course, not a specific disease, or even a single syndrome, but rather a broad category of symptom complexes arising from any number of disordered brain functions that themselves may be secondary to a variety of pathologic processes. The terms *convulsive disorder*, *seizure disorder*, and *cerebral seizures* are used synonymously with epilepsy: They all refer to recurrent paroxysmal episodes of brain dysfunction manifested by stereotyped alterations in behavior. Modern concepts of epilepsy originate in the work of midâ€“19th-century physicians and scientists, the most important among them being John Hughlings Jackson.[10] At a time when epilepsy denoted disorders manifested by generalized convulsions, which were believed to arise from disturbances in the medulla oblongata, Hughlings Jackson established the important concept that there were different categories of seizures, each with its own physiology and semiology. His explanation of â€œdreamy statesâ€ and â€œuncinate group of fitsâ€ as focal seizures originating from discrete areas within the cerebral cortex comes close to present-day views of limbic seizures. Similarly, his recognition of focal motor seizures (â€œjacksonian seizuresâ€) not only identified the responsible locus within the brain, but also allowed him to draw inferences that have forever changed our concepts of cortical motor representation and cerebral control of voluntary movement. Hughlings Jackson, more than anyone, established a scientific approach to the study of epileptic phenomena.

Today, a large number of clinical phenomena are recognized as epileptic *seizures*, some of which (e.g., myoclonic and atonic seizures) are currently poorly understood and might, in fact, reflect neuronal mechanisms that are somewhat different from the pathophysiologic processes traditionally considered to be â€œepileptic.â€ A variety of conditions or *epilepsies* have been categorized and defined not only by the types of seizures they manifest, but also by other, associated clinical features. Specific *epileptic syndromes* have been identified by their characteristic seizure types, pattern of seizure recurrence, age of onset, associated neurologic and other clinical signs, electroencephalographic (EEG) findings, presence or absence of familial occurrence, and prognosis. Epilepsies and epileptic syndromes are broadly divided into *idiopathic* and *symptomatic* disorders. *Idiopathic* epilepsies are generally benign in the sense that they are not associated with brain lesions, neurologic abnormalities other than seizures, or mental impairment, and that they tend to be self-limited or respond readily to antiepileptic drugs. Genetic factors are important, and manifestations are typically age related. This is epilepsy *sui generis* (â€œby itselfâ€), which conforms to the original Greek meaning of â€œidiopathic,â€ in contrast to the commonly used but incorrect meaning of â€œcause unknown.â€ *Symptomatic* epilepsies are those in which seizures are the consequence of an identifiable lesion or other demonstrable physical or metabolic etiology. When epilepsies are presumably symptomatic but currently of unknown specific etiology, they have been termed *cryptogenic*,[2] a term also used in epidemiologic studies to mean unknown as to whether idiopathic or symptomatic.[4] Because of its ambiguity, â€œcryptogenicâ€ is a term that should be replaced by the more accurate â€œprobably symptomatic.â€[5]

The Role of Research

Advances in the understanding and treatment of epilepsy have occurred because of active and continuing research efforts. Indeed, it is not an exaggeration to say that many of the exciting developments in basic neuroscience in the middle and latter parts of the last century were related to epilepsy, either directly (e.g., in cellular studies of disease mechanisms) or indirectly (e.g., in investigations of cortical excitability and its control). Clinical investigation is an essential part of practice, and clinicians have played important roles in developing hypotheses that can be subjected to experimental investigation.

An important change that has occurred and accelerated in the last two decades has been the growing ability to carry out basic studies in humans. For example, intracranial monitoring

techniques used to evaluate patients with intractable seizures for surgery, and the removal of brain tissue during surgical procedures now offer investigators opportunities to investigate basic physiologic, biochemical, and molecular phenomena in patients that could previously be studied only in experimental animal models of epilepsy. Similarly, modern brain imaging methods, such as functional magnetic resonance imaging (fMRI), magnetic resonance spectroscopy (MRS), positron emission tomography (PET), and single-photon emission computed tomography (SPECT), allow noninvasive study of basic biologic questions in the living, intact brain. New insights derived from these studies make it possible to determine which abnormalities found in animal models of epilepsy have counterparts in humans, which experimental observations are valid for the human condition and which are not, and which experimental data fit within reasonable conceptual frameworks for developing further hypotheses that can be tested either in humans directly or in relevant animal models.

Epilepsy Is More Than Seizures

There have been many attempts to obtain a consensus on definitions of *epileptic seizure* and *epilepsy*. Recently, the International League against Epilepsy (ILAE) has proposed new definitions for both.[7] In this proposal, an epileptic seizure is defined as â€œa transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain.â€ This definition acknowledges that previous concepts of decreased inhibition and increased excitation were oversimplifications, because inhibition is actually increased in some forms of epilepsy where phasic inhibition is a central element in the primary epileptogenic abnormality. An epileptic seizure can also be a natural response of the normal brain to transient disturbance in function and, therefore, not necessarily an indication of an epileptic disorder. Such seizures are often referred to as *provoked*, *acute symptomatic*, or *reactive*. This accounts for a greater incidence of seizures (about 7% by age 80) than epilepsy (nearly 3%).

Epilepsy is a group of neurologic conditions, the fundamental characteristics of which are recurrent, usually unprovoked, epileptic seizures. A common operational definition of epilepsy is two or more unprovoked seizures occurring more than 24 hours apart.[4] However, the new ILAE proposal[7] offers a more fundamental definition of epilepsy: â€œA chronic condition of the brain characterized by an enduring propensity to generate epileptic seizures, and by the neurobiological, cognitive, psychological, and social consequences of this condition.â€ This definition emphasizes the existence of a persistent intrinsic epileptogenic abnormality that is a property of the brain itself and thus present even when seizures are not occurring. This contrasts with seizures that are dependent upon acute insults or other conditions that transiently affect an otherwise normal brain. An intrinsic epileptogenic abnormality of the brain necessary for a diagnosis of epilepsy, however, can resolve spontaneously, as in some age-related idiopathic epilepsies that typically remit.

The new ILAE definition also acknowledges importantly the psychological and social consequences of epilepsy. This change recognizes that to the affected patient, epilepsy is more than seizures, and that the condition in its entirety comprises many facets, different for each individual, that contribute to disability and impaired quality of life (Fig. 1). Treatment that focuses solely on seizures often does little to lessen disability. This is most dramatically illustrated by the patient who, having undergone successful surgical resection of epileptogenic brain tissue, becomes seizure free but remains socially isolated and unemployed, with little evidence of an improved life. Therapeutic intervention can be optimal only when the multiple medical, psychological, and environmental factors that constitute epilepsy are addressed. Thus, the physician's role is properly defined, and sometimes circumscribed, by asking a series of questions: â€œWhat are the problems that are contributing to the patient's predicament?â€ â€œWhich of these can or need to be treated?â€ â€œWhat will be the consequences of treatment?â€ and â€œWhat outcome measures will appropriately gauge the treatment's success?â€

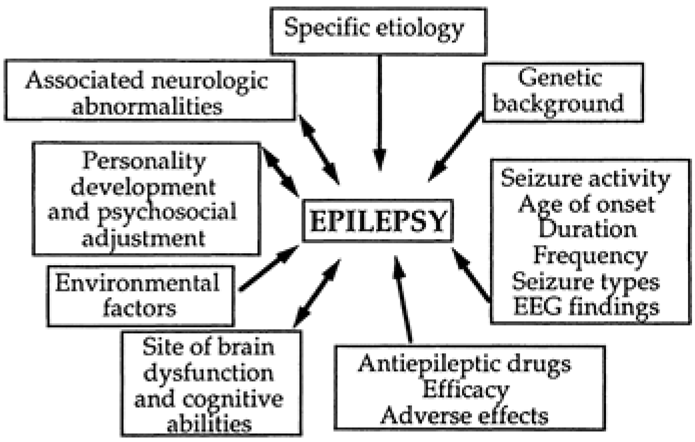

FIGURE 1. The multiple, interacting factors that contribute to the totality of epilepsy for an individual patient.

The existing ILAE Classification of Epilepsies and Epileptic Syndromes[2] and Classification of Epileptic Seizures[3] are presently under review. An ILAE Task Force on Classification and Terminology has proposed a diagnostic scheme for use when describing individual patients[5] (Table 1). Axis 1 consists of a detailed phenomenologic description of the ictal events, which is useful in certain situations, such as a presurgical evaluation, but otherwise can be abbreviated or omitted. Axis 2 is a new concept, recognizing seizure types as diagnostic entities based on distinct pathophysiologic and anatomic features that provide information useful for determining etiology, therapy, and prognosis. Diagnosis of a specific seizure type is especially important when diagnosis of an epilepsy syndrome is not possible. Axis 3 consists of accepted epilepsy syndromes and recognizes that a syndromic diagnosis is not always possible. An epilepsy syndrome as used here refers to â€œa complex of signs and symptoms that define a unique epileptic condition. This must involve more than just a seizure type: Thus, frontal lobe seizures per se, for instance, do not constitute a syndrome.â€ In contrast, an epileptic disease is defined as â€œa pathologic condition with a single, specific, well-defined etiology. Thus, progressive myoclonus epilepsy is a syndrome, but Unverricht-Lundberg myoclonic epilepsy is a disease.â€ Axis 4 is etiology, which includes a wide variety of genetic and nongenetic diseases associated with epilepsy, specific epilepsy genes, and acquired cerebral injuries such as trauma and infection. Axis 5, which assesses the degree of disability caused by the epilepsy, is taken from a WHO classification of impairment for neurologic disorders and is optional.

Physiologic Considerations

It is readily apparent from observing the diverse ictal phenomenology of patients with epilepsy that most seizures consist of evolving processes that depend on multiple pathophysiologic mechanisms and anatomic substrates. Two essential epileptogenic factors represent the net effect of many complex interrelated events. The first is an abnormality of cellular excitability that arises from mechanisms that affect membrane

depolarization and repolarization. The second is a â€œnetwork defectâ€ that derives from mechanisms underlying the development of aberrant neuronal integration, resulting in abnormal synchronization of neuronal populations and propagation of the epileptic discharge within neural pathways. Both sets of disturbances must be present before a seizure can occur.

Table 1 Proposed Diagnostic Scheme for People with Epileptic Seizures, and with Epilepsy

Epileptic seizures and epilepsy syndromes are to be described and categorized according to a system that utilizes standardized terminology and that is sufficiently flexible to take into account the following practical and dynamic aspects of epilepsy diagnosis:

1. Some patients cannot be given a recognized syndromic diagnosis.
2. Seizure types and syndromes change as new information is obtained.
3. Complete and detailed descriptions of ictal phenomenology are not always necessary.
4. Multiple classification schemes can, and should, be designed for specific purposes (e.g., communication and teaching; therapeutic trials; epidemiologic investigations; selection of surgical candidates; basic research; genetic characterizations).

This diagnostic scheme is divided into five parts, or Axes, organized to facilitate a logical clinical approach to the development of hypotheses necessary to determine the diagnostic studies and therapeutic strategies to be undertaken in individual patients:

- Axis 1: Ictal phenomenologyâ€”from the Glossary of Descriptive Ictal Terminology; can be used to describe ictal events with any degree of detail needed.
- Axis 2: Seizure typeâ€”from the List of Epileptic Seizures. Localization within the brain and precipitating stimuli for reflex seizures should be specified when appropriate.
- Axis 3: Syndromeâ€”from the List of Epilepsy Syndromes, with the understanding that a syndromic diagnosis may not always be possible.
- Axis 4: Etiologyâ€”from a Classification of Diseases Frequently Associated with Epileptic Seizures or Epilepsy Syndromes when possible, genetic defects, or specific pathologic substrates for symptomatic focal epilepsies.
- Axis 5: Impairmentâ€”this optional, but often useful, additional diagnostic parameter can be derived from an impairment classification adapted from the World Health Organization International Classification of Functioning, Disability, and Health 2.

From Engel J Jr. A proposed diagnostic scheme for people with epileptic seizures and with epilepsy: report of the ILAE Task Force on Classification and Terminology. *Epilepsia.* 2001;42:796â€“803, with permission.

Part of the diversity that characterizes the clinical expression of seizures is due to the fact that different brain areas are responsible for different aspects of epileptic phenomenology[14] (Table 2). Generally, these different regions are spatially proximate, although they are rarely congruent. Sometimes, however, quite distant areas give rise to some of the clinical or EEG features of a particular patient's seizures.

The *irritative zone* is the area of cortex that generates interictal EEG spikes. This is clearly related but frequently not identical to the *ictal onset zone*, which is the area of cortex that initiates seizures. Indeed, although the interictal EEG spike has provided an enormous impetus to basic laboratory research and has led to a definition of the cellular mechanisms underlying interictal discharges, it is still not known whether any given interictal spike reflects mechanisms important in triggering seizures, is a marker of inhibitory mechanisms involved in maintaining the interictal state, or is merely an interesting epiphenomenon unrelated in any direct way to seizure occurrence. In any event, in some instances the irritative zone can include multiple spike sites, some of which are located at a distance from the ictal onset zone, even in the opposite hemisphere. This became clear early in the experience with long-term, especially intracranial, EEG monitoring, in which recordings showed that interictal epileptiform discharges are commonly more widespread than had been suggested by routine EEG or than would be expected solely on the basis of the area of ictal onset. For example, in scalp recordings from patients with unilateral mesial temporal lobe epilepsy, contralateral temporal spikes are frequently encountered, although they are usually concentrated on the side of seizure onset, at least in the majority of patients who have successful surgical outcomes. Intracranial recordings frequently demonstrate widespread ipsilateral spikes, and postsurgical electrocorticograms show that many of these may remain after resection, apparently without major adverse consequences for seizure outcome. The classic scalp EEG â€œspike focus,â€ therefore, is a very limited reflection of complex underlying physiologic events. Interictal PET scans, too, consistently demonstrate that cerebral metabolic dysfunction is more extensive than clinical evidence, scalp EEG, and structural brain imaging would suggest.

In symptomatic epilepsies, the *epileptogenic lesion* is the pathologic substrate for the epilepsy; it can usually be identified on MRI, although EEG remains necessary to demonstrate epileptogenicity of a lesion. Seizures can arise within, adjacent to, or even sometimes distant from an epileptogenic lesion. The *symptomatogenic zone* is that portion of the brain responsible for producing the first clinical ictal symptoms or signs, whereas the *functional deficit zone* is the cortical area or areas exhibiting focal nonepileptic dysfunction. Finally, the *epileptogenic zone* is the total area of brain that is necessary and sufficient to generate seizures and that must be removed to abolish seizures. The fact that the epileptogenic zone cannot be defined with precision accounts for the lack of a uniformly successful outcome following resective surgery for focal seizures. The problem is greater in extratemporal than in temporal lobe epilepsy.

Table 2 Abnormal Brain Areas in Partial Epilepsy

Brain area	Definition	Measure
Irritative zone	Area of cortex that generates interictal spikes	EEG
Ictal onset zone	Area of cortex that initiates or generates seizures	EEG
Epileptogenic lesion	Structural pathology of the brain that is the direct cause of seizures	CT, MRI, tissue pathology

Symptomatogenic zone	Portion of the brain that produces the first clinical symptoms	EEG, behavioral observation
Functional deficit zone	Cortical area producing nonepileptic dysfunction	Neurologic exam, neuropsychology, PET, SPECT
Epileptogenic zone	Total area of brain that is necessary to generate seizures and that must be removed to abolish seizures	Unknown

CT, computed tomography; EEG, electroencephalography; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single-photon emission computed tomography.
Adapted from LÃ¼ders HO, Engel J Jr, Munari C. General principles. In: Engel J Jr, ed. *Surgical Treatment of the Epilepsies*. New York: Raven Press; 1993:137â€"153, with permission.

The Interictal State

There can be little question that at least some types of seizures, especially if prolonged or repeated frequently, can damage the brain.[24] Indeed, the association between chronic epilepsy and pathologic changes in the brain, especially hippocampal sclerosis, is one of the oldest and best-documented clinicopathologic correlations. The concept of an *epileptic encephalopathy* as a condition in which the epileptic processes themselves are believed to contribute to progressive disturbances in cerebral function is now accepted.[5] The question of the relationship between seizures and interictal neurologic or psychiatric findings still generates controversy, however, because it is often not possible to distinguish among the effects of epilepsy per se, cerebral disease, psychological and social factors, and toxicity from chronic use of antiepileptic drugs. Whether distinct behavioral traits or profiles are associated with temporal lobe or other forms of epilepsy remains a matter of debate. Although it seems to have been impossible to devise a definitive clinical study of this issue, it would be surprising if the profound and widespread disturbance of neuronal activity caused by some epileptiform events, and the neuropathologic

findings observed in surgical and autopsy specimens of epileptogenic brain areas, never produced enduring interictal consequences, even subtle, for behavior, personality, and social functioning.

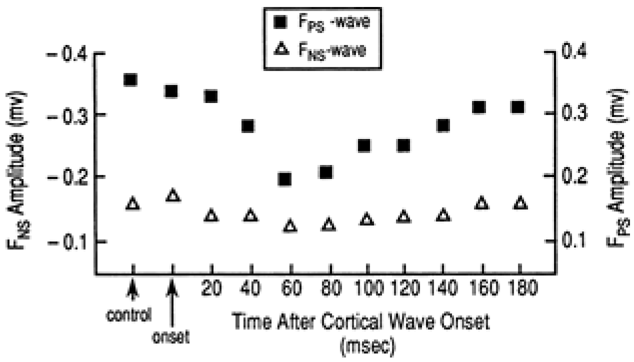

FIGURE 2. Graph showing the effect of the corticofugal volley from a cortical epileptiform discharge, evoked by stimulating a forepaw nerve, on the negative (*triangles*) and positive (*squares*) components of the cuneate nucleus field potential. Maximal inhibition of the cuneate sensory response occurred about 60 msec after the cortical spike. The amplitude of the positive component (F^{PS}) of the cuneate potential was affected much more than the negative component (F^{NS}). (From Schwartzkroin PA, van Duijn H, Prince DA. Effects of projected cortical epileptiform discharges on field potentials in the cat cuneate nucleus. *Exp Neurol.* 1974;43:88â€“105, with permission.)

It is even likely that interictal electrical abnormalities, although traditionally considered subclinical and â€œsilent,â€ also have important functional effects, because of the disruption they cause in normal information processing. Such disruption may be as much the result of excessive or abnormal inhibition as of â€œhyperexcitability.â€ Over 30 years ago, Schwartzkroin et al.[21] asked the question, â€œWhat is the downstream effect of focal cortical epileptiform activity, and can it influence incoming sensory inputs?â€ To study this, they recorded field potentials and unit activity in the cuneate nucleus of cats contralateral to an experimental cortical epileptogenic focus. They discovered that when an afferent sensory volley, triggered by stimulation of a forepaw nerve, occurred in close relation to a cortical spike discharge, the amplitude of the evoked cuneate field potential was substantially and predictably decreased (Fig. 2). In other words, isolated cortical epileptiform discharges had a powerful inhibitory effect on sensory signal transmission by cuneate relay neurons. Subsequently, Shewmon and Erwin[22,23] provided suggestive evidence in humans that interictal spikes, or more likely the after-going slow waves, can similarly result in transient dysfunction as measured by longer reaction times to particular stimuli and increased nonperception of visual stimuli, especially those in the visual field contralateral to the spike discharge. Thus, epileptiform activity occurring at critical times may substantially modify or â€œcolorâ€ the processing of sensory information.

Finally, there is now a substantial body of experimental evidence that activity-dependent behaviors of individual neurons, including those associated with seizures, rapidly initiate a cascade of changes in gene expression. These in turn may lead to further alterations in neuronal excitability within local areas or circuits, some of which are long lasting and associated with (although not yet proved to be causative of) structural remodeling. Some induced genes may relate to future seizure susceptibility, others to intrinsic protective or trophic mechanisms, and still others to plastic structural and functional changes that accompany recurrent seizures and that could, conceivably, produce changes in interictal neuropsychiatric behavior.

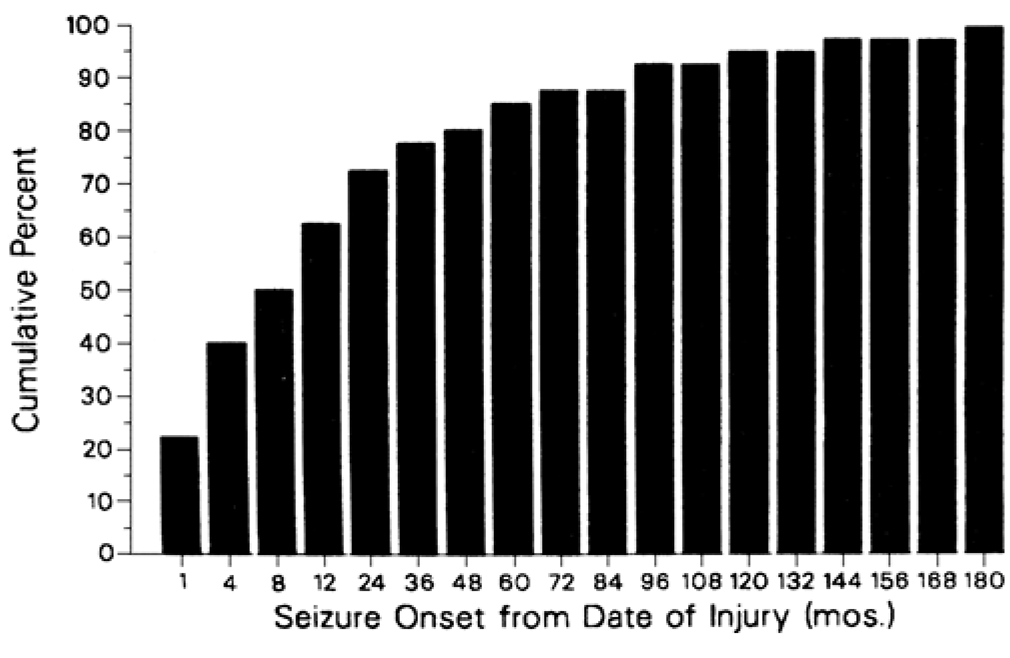

FIGURE 3. Latency of seizure onset in the Vietnam Head Injury Study. The *y axis* shows the cumulative percentage of patients (n = 197) with seizures by time after injury (*x axis*). Note that the time scale is expanded for the first year. (From Salazar AM, Jabbari B, Vance SC, et al. Epilepsy after penetrating head injury. I. Clinical correlates: report of the Vietnam Head Injury Study. *Neurology.* 1985;35:1406â€“1414, with permission.)

Epilepsy as a Discontinuous Process

Depending on the patient, seizures can occur frequently or infrequently, only at night or after awakening, in a cyclic pattern suggesting hormonal influences, only with highly specific triggers, in many other permutations, and, most commonly, without any apparent predictability. However, even patients with refractory seizures have attacks relatively infrequently compared with the total time available in their lives. The factors that precipitate seizure occurrence are still poorly understood, but clinical observations indicate that specific mechanisms must govern whether a patient is in an interictal or ictal state, and how the transition from the interictal to the ictal condition is made. Many environmental and physiologic factors modulate the probability of seizure occurrence: Fever, sleep deprivation, alcohol withdrawal, highly specific triggers in reflex epilepsy, hormonal fluctuations, and even nonspecific stress in some susceptible individuals. It is unknown, however, how these perturbations translate into increased epileptic susceptibility at the cellular or molecular level. In most patients, it is not possible to identify external or internal factors that explain why a

seizure happened at a particular time, rather than a week before or a few minutes later. Changes that alter neuronal excitability or the potential for synchronous interactions among neurons are undoubtedly important but remain to be specified in detail. As but one example, consider the disturbances that can occur in the extracellular microenvironment in epileptic brain regions and, in particular, the possibility that increased potassium concentration within extracellular spaces, which have perhaps been abnormally reduced because of gliosis, cell swelling, or other pathologic factors, may serve as a mechanism for increasing the excitability level of a population of neurons to a critical threshold for seizure generation. Equally mysterious is the fundamental nature of the inherent homeostatic forces in the brain that limit ictal spread after seizures have begun and that terminate them within seconds of their onset. Undoubtedly, the basic neuronal mechanisms underlying these processes are as diverse as those leading to seizure onset. As demonstrated by the condition of *epilepsia partialis continua*, the mechanisms mustered by the brain to limit ictal spread are different from those utilized to terminate the seizure discharge.

The Latent Interval

More than 125 years ago, Gowers[8] first recognized that there is almost always a seizure-free interval between a causative cerebral injury and onset of symptomatic epilepsy. The latency of occurrence of posttraumatic seizures is the clearest example of this point. Figure 3, taken from the Vietnam Head Injury Study,[19] shows the cumulative percentage of patients with posttraumatic seizures as a function of time after injury. Whereas seizures developed most often within the first 2 years of injury, more than 15% of veterans did not have their first seizure until 5 or more years later.

This latent period, which characterizes many (and perhaps all) cases of symptomatic epilepsy, raises important issues about the process of *epileptogenesis*. The clinical data suggest that this process is a dynamic and evolving one that progressively alters neuronal excitability, establishes critical interconnections, and perhaps requires critical structural changes before the first clinical seizure appears. A sequence that seems to be essential for at least one common form of epilepsy, mesial temporal lobe epilepsy with hippocampal sclerosis, involves an insult early in life that causes selective neuronal death, synaptic reorganization, and altered firing patterns within a defined neuronal population. Enhanced excitation and inhibition result in a propensity for hypersynchronization.[6] Recurrent hypersynchronous discharges recruit efferent structures into this epileptogenic process until a sufficient area of brain tissue is involved to manifest as clinical epileptic seizures. A genetic predisposition may influence the pattern of cell loss and synaptic reorganization, or the effect of these anatomic changes on local excitability, or the influence of these local excitability changes on projection areas and eventual manifestation of ictal events. Although this sequence of events has been developed from research on experimental animal models of mesial temporal lobe epilepsy, what is lacking in humans, of course, is evidence of a *subclinical* epileptogenic abnormality preceding the appearance of clinical seizures. Thus, if it were possible to have depth electrodes placed in the hippocampus from the time of the epileptogenic injury, it is likely that epileptiform changes would be detected long before any clinical hint of epilepsy. That a similar epileptogenic evolution in fact occurs in humans is suggested by the occasional observation of focal EEG spikes in patients with a brain tumor or vascular malformation, even in the absence of clinical seizures.

Because of the great variability in latent periods seen among patients, there must be both intrinsic and acquired modifying factors unique to each individual. One of these is undoubtedly genetic background, which is an inherent determinant of a person's susceptibility to seizures (â€œseizure thresholdâ€). Another factor is the location and spatial dimension of the injury, and a third is the severity of the injury, which may be expressed in terms of the effect a specific lesion has on adjacent or displaced brain tissue.

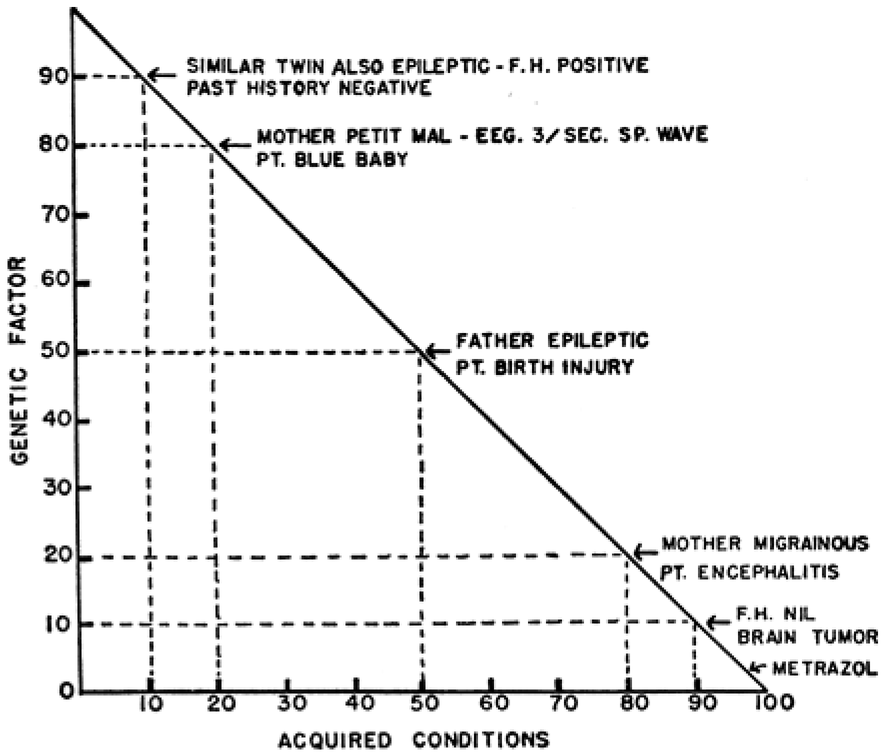

FIGURE 4. The interrelation of genetic and acquired factors in the development of seizures, as proposed by Lennox. (From Lennox WG. *Epilepsy and Related Disorders*. Boston: Little, Brown; 1960:532â€“574, with permission.)

The Era of Molecular Biology

This is the era of molecular genetics applied to human disease. Among the many individual epileptic syndromes described in humans, there are a number of idiopathic epilepsies that are considered to be familial and in which genetic determinants appear to be prominently involved. Twin studies[1,26] implicate strong genetic determinants in many types of seizures and seizure disorders, especially such ones as childhood absence epilepsy, juvenile myoclonic epilepsy, and idiopathic grand mal seizures. However, the role of genetic factors is not straightforward; to the contrary, it is quite complex. For example, seizures develop at increased rates in children of parents with

P.6

either idiopathic or symptomatic epilepsy, although the difference is greatest for children of parents with idiopathic generalized forms of epilepsy.[17] Thus, there may be some degree of shared genetic susceptibility present in both the idiopathic and symptomatic epilepsies. However, there are undoubtedly specific genetic determinants of the susceptibility of the brain to seizures and epilepsy following a particular injury, as well as other genetic factors that determine the occurrence of individual familial idiopathic epilepsy syndromes. Furthermore, some inherited disorders, such as tuberous sclerosis and neurofibromatosis, are associated with brain lesions that in turn give rise to symptomatic epilepsies. Whereas mutations in single genes account for some rare epilepsy syndromes and familial diseases that cause epileptic seizures, multiple genes must determine the various neuronal functions that alter seizure threshold and predispose to development of symptomatic epilepsy. For most epileptic disorders, it remains to be determined to what degree abnormalities of single genes, or concordance of key overlapping genes, determine the phenotypic expression of any given epileptic condition.

It is also important to underscore the importance of interactions between genetic predisposition and environmental factors in the manifestation of seizures and the particular expression of a given disorder. Lennox[13] was among the first to postulate a continuum between idiopathic and symptomatic epilepsies. He suggested that the occurrence of epileptic seizures derives from the complex interrelation of genetic factors and brain disease (Fig. 4). In any given patient, the *relative* contribution of genetic or acquired pathologic factors determines whether the epilepsy takes the form of an idiopathic disorder or a symptomatic one. Thus, although there is unequivocal evidence of hereditary factors in epilepsy, family studies do not clearly define a *pattern* of inheritance for the common forms of epilepsy. Furthermore, the data suggest a complex hereditary component in *all* forms of epilepsy, localization related and generalized, idiopathic and symptomatic.[17]

Animal models have allowed definition of a growing number of â€œepilepsy genesâ€ and their encoded proteins. Information obtained from animals with single gene mutations producing some aspect of an epileptic phenotype is permitting identification of protein products responsible for the molecular aberrations underlying the abnormal excitability and synchrony responsible for recurrent epileptic seizures. The genes and functional consequences identified in fortuitous mouse models are providing important tools for defining key sites of vulnerability in the brain's carefully regulated control of excitability.[16] Creation of transgenic animal models that overexpress particular genes on the one hand, or â€œknockoutâ€ selected genes on the other, has become a vitally important step in studying candidate genes and understanding the molecular basis of defects that result in epileptic excitability. At the same time, a growing number of specific genes and gene mutations are being isolated and cloned from cases of human epilepsy. A major problem facing investigators is that the population of genes that encode molecules contributing to regulation of cortical excitability through membrane and synaptic functions (and are therefore possible candidate genes in epilepsy) is very large. The complexity issue is further magnified if genes for various second messenger cascades, which indirectly regulate membrane proteins involved in signal transduction, are considered. Another daunting consideration is that genetic studies have identified both animal and human seizure phenotypes in which the genetic mutation and protein product have no previously known association with epileptogenesis (e.g., the LGI1 mutation in autosomal dominant temporal lobe epilepsy with auditory features[11] or cystatin B in Unverricht-Lundborg disease[18]). Finally, epilepsy may result from structural and functional changes occurring as a reaction to a transient genetic defect or a time-limited aberration that is present early in development but may have vanished by the time clinical seizures appear.

So what is the present status of the genetic basis of epilepsy? There can be no doubt about the importance of hereditary factors in epilepsy, in some syndromes more than others. But although specific gene mutations have been identified in a number of rare monogenic forms of idiopathic epilepsy and there is no lack of possible candidate genes for others, a *single* causative genetic mutation will not be found for most cases of epilepsy. Rather, there is considerable evidence that in the majority of cases, the genetic influence on risk of developing epilepsy is conferred by complex â€œsusceptibilityâ€ genes that

P.7

interact with other acquired or genetic disturbances, rather than cause epilepsy by themselves.[17] Generalized epilepsy with febrile seizures plus (GEFS+) may reflect this phenomenon.[20,27] For most patients, epilepsy is the consequence of diverse alterations in the complex interactions that occur within neuronal populations and circuits and in the multiple factors that modulate excitability within these circuits, all of which are ultimately under genetic control. And one must not forget that at the clinical level, epilepsy also comprises the neurologic, behavioral, psychological, and social consequences of the molecular, cellular, and network alterations that underlie seizures.

Summary and Conclusions

The answer to the question â€œWhat is epilepsy?â€ is not simple; it is many things at different times, and the patient's reply may be different from that of the physician. Answers are beginning to emerge, however, to both biologic and psychosocial aspects of the question. The diversity with which human epilepsy expresses itself indicates that it is not a unitary problem and that a single solution to any of its many facets is therefore unlikely. Nonetheless, the potential of new investigative tools, especially those of neuroimaging and molecular neurobiology, are providing unparalleled and heretofore unimagined insights into the mechanisms of epilepsy and epilepsy-related brain dysfunction, and are offering greater hope than ever before for prevention, effective treatment, and even cure.

This book was created in the belief that physicians today can be most effective when their practice has a sound scientific basis, and that the results of ongoing basic and clinical research increasingly affect patient management directly. That so much has been achieved is a tribute to past and present investigators; that there is still so much to do is a challenge to future ones. The conquest of epilepsy, as of any human disease, requires a sustained creative effort, with past, present, and future research representing an unbroken continuum of endeavor and achievement.

Chapter 2

Overview: Epidemiology, Pathology, and Genetics

W. Allen Hauser

Introduction

This is an exciting era for clinicians and investigators interested in the mechanisms of epileptogenesis. Advances in technology during the last three decades have made possible the detailed assessment of intracellular electrophysiologic changes, the determination of membrane responses to neurotransmitters, and even the identification and cloning of specific receptors and channels, some of which are mutated in inherited forms of epilepsy. Through these procedures, knowledge of the fundamental biology underlying cellular excitability and membrane stability has been acquired, sites of action and methods of modifying the function of various neurotransmitters have been determined, and our understanding of the manner in which neural networks enhance or impede seizure occurrence has greatly increased. These exciting developments in the laboratory sometimes result in a tendency to overlook important developments that have occurred within the same time period in the more clinically relevant areas of epidemiology, pathology, and genetics. As one peruses the chapters in this section, it becomes clear that these areas have been equally dynamic in terms of the development of new concepts and ideas. The substantial body of knowledge acquired in epidemiology, pathology, and genetics represents more than an addition to the assumptions that have been considered fact for the last three decades. Indeed, current concepts provided by recent studies in epidemiology and genetics contradict various ideas that were considered well established in the 1970s. The present state of our knowledge suggests various directions for future exploration, not only to students of these observational sciences, but also to those addressing basic neurophysiology.

Epidemiology

Through application of the techniques of descriptive and experimental epidemiology, our understanding of seizures and the epilepsies as these conditions affect humans has been expanded substantially, and this expansion parallels the explosion of discoveries in basic neurobiology. The discipline of epidemiology provides the rigor and broad scope of view that is lacking in clinical series and case reports, which are often viewed with relative skepticism by basic scientists. It is true that the study of real people is complex, but the study of mechanisms at the level of the single cell is equally difficult to integrate into broader concepts.

The development of sophisticated study designs and analytic methods for human investigations is not the only reason for recent advances in knowledge. An emerging classification for seizures and the epilepsies not only provides definitions of seizure type[1] and aggregation of symptoms,[2] but also deals with specifics of etiologic classification and case assignment,[3] thereby enabling the application of uniform definitions across studies. Although complex and in general relatively expensive, the studies of incidence performed during the last three decades have provided knowledge of the true frequency with which seizures and epilepsy occur in the general population and have also informed our understanding of the interpretive complexities involved in the much more readily available studies of prevalence. Although important in determining service needs, studies of prevalence provide no insight regarding the important areas of etiology, prognosis, and prevention. These discrepancies are elucidated in Chapter 5. The consistency of recent epidemiologic studies of incidence in terms of age of individuals affected and distribution of etiology and seizure type is impressive, and the now-well-accepted concept of epilepsy as a condition that affects the elderly as well as the very young, at least in Western countries, is clear.

The patterns of epilepsy in developing countries are explored thoroughly in Chapter 11. These studies are often difficult because of the lack of organized medical systems in many areas, and interpretations are blurred because of the lack of information derived from clinical and laboratory evaluations generally available in Western countries. Fortunately, incidence data from these areas allow a more accurate assessment of frequency and individuals at risk. It is clear that data from more economically developed countries cannot be directly applied to developing areas, but from many standpoints, epidemiologic patterns are similar. Additional clues are usually present that may allow hypotheses to account for any differences to be generated. For example, there is evidence for urbanâ€“rural differences in incidence. In rural areas of underdeveloped countries, many people with epilepsy have never been treated with antiepileptic drugs. Thus, a natural experiment can be undertaken to evaluate the effect of drugs on prognosis. Chapter 4 explores the sociocultural perceptions of epilepsy in such communities and further clarifies the reasons for the social consequences discussed in Chapter 11.

The exploitation of incidence and inception cohorts from industrialized countries (including but not limited to the United States, the United Kingdom, France, Iceland, Sweden, the Netherlands, and Japan) to identify antecedents has been a natural consequence of the identification of incidence cohorts. The results of the systematic evaluation of classic as well as novel risk factors are addressed in Chapter 6. The study of large birth cohorts[8,9] and cohorts with putative risk factors, such as stroke, head injury, infection, and degenerative disease of the nervous system, enable determination of the absolute risk for epilepsy and seizures, provide information regarding the impact of these putative risk factors that is more readily understandable and relevant to clinicians, and may lead to interventions. The role of factors such as adverse prenatal and perinatal events and febrile convulsions is being clarified, and questions regarding the influence of conditions not invariably associated with structural pathology of the brain, such as hypertension, cardiovascular disease, migraine, and such psychiatric disorders as depression and attention-deficit disorder, not only provide new insights into factors that have traditionally been considered

either consequences of epilepsy or only marginally related to epilepsy, but also supply the basis for possible new treatment strategies.[4,5,7]

Another consequence of the identification of incidence cohorts is the ability to determine more precisely the natural history of epilepsy through systematic follow-up of patients. Chapter 7 provides data regarding the prognostic measure closest to the hearts of clinicians, namely seizure control. This review of natural history and prognosis also provides information about other outcomes, including social integration, intellectual function, and comorbid conditions. Contrary to opinions held even into the last decade, epilepsy must now be considered a condition that, in the majority of cases, is relatively benign. Most patients with newly diagnosed epilepsy achieve complete freedom from seizures, and the majority of those who become seizure free can be expected to discontinue antiepileptic drugs without experiencing further seizures. The challenge to clinical investigators now is to clarify those factors associated with good and bad prognoses.

Most studies of cohorts with epilepsy have suggested that individuals with epilepsy are at increased risk for death. The reasons for this apparent increase in mortality, particularly among those with epilepsy of unknown cause, are obscure. In Chapter 10, the proportionate increases in overall mortality and cause-specific mortality are reviewed and compared with data from the general population. The minimally increased mortality in individuals with idiopathic or cryptogenic epilepsy is encouraging, but exploration of the factors that differ between these individuals and the general population is important. Certain conditions affect unique subgroups of people with epilepsy. Sudden death in people with intractable epilepsy is an example of a problem that is not well understood and needs to be addressed further. This specific topic is dealt with in a later section (Chapter 189).

Inducers and precipitants of seizures are discussed in Chapter 9. The distinctions among precipitants (e.g., sleep deprivation), triggers (stimulus-sensitive epilepsies), and modulators (stress, hormonal variation) are reviewed. The need for identification of these factors in developing an individualized approach to people with epilepsy seems clear. Patients with acute symptomatic seizures, reviewed in Chapter 8, represent a unique subset of individuals for whom, unlike people with epilepsy, there is little question regarding cause and effect. These individuals in general would not be expected to have seizures in the absence of a concurrent medical condition or particular set of circumstances. In general, the mortality of people with acute symptomatic seizures is high, and survivors have an increased risk for subsequent epilepsy. The identification of acute symptomatic seizures is important for presenting an accurate and comprehensive picture of seizures and epilepsy in industrially advanced countries and meaningfully assessing prognosis. It also makes possible a comparison with data from developing countries, where survivors of this class of seizures can seldom be distinguished accurately from those with epilepsy.

Pathology

Chapter 12 discusses the failure to identify structural or neurochemical features that might be causes of epilepsy and the difficulty of identifying specific pathology outside the hippocampus that may be associated with clinical seizures. This chapter also reviews the important issue of distinguishing pathologic changes that are the consequences of epileptic seizures from those that may be reasonably considered to be causative of them. Finally, the chapter discusses those brain lesions that are commonly associated with epilepsy, including neoplasms, inflammatory disorders, and brain injuries.

Changes in brain structure that may be attributable to epilepsy are also discussed. Chapter 13 reviews the unique pathology, electrophysiology, and molecular biology of hippocampal sclerosis. Hippocampal sclerosis is a consequence of an initial precipitating injury, which is not age specific and participates in the genesis of temporal lobe epilepsy. Recurrent seizures or status epilepticus modifies the pathology, but whether these are directly causal is controversial.

Our understanding of the neuropathology of epilepsy and epileptogenesis has been greatly modified in recent years. Chapter 14 discusses the role of cortical developmental malformations, which can now be readily identified in clinical practice by magnetic resonance imaging (MRI) brain scans and evaluated pathologically from surgical specimens. Such lesions are responsible for most of the identified structural pathology associated with epilepsy in children, and careful evaluation may provide clues to the timing and mechanisms of epileptogenesis. The single-gene disorders associated with developmental malformations also provide clues to underlying biologic behavior.

Genetics

The identification of a chromosomal locus for some epilepsy syndromes and the elucidation in a growing number of cases of the responsible genes have been important developments and the focus of considerable recent attention. The necessary groundwork for many of these genetic advances is provided by population genetic studies, and Chapter 15 discusses the importance of family studies. This chapter considers the complexities involved in interpreting such studies and stresses such factors as genetic heterogeneity, pleiotropy, and the role of geneâ€"environment interactions. The development of sophisticated mathematical models of inheritance patterns has been made possible by computer techniques.

Additional complexities entailed in family studies of epilepsy are addressed in the review of electroencephalographic (EEG) traits in Chapter 16. Many EEG patterns are clearly inherited, often as a single-gene trait. The relationship of these patterns to clinical epilepsy, however, is elusive. The failure to distinguish between familial aggregations of EEG patterns and familial aggregations of seizures or epilepsy continues to cause confusion and would appear to be an important area for further study.

Chapter 19 discusses the use of family data for patient counseling and the empirical risks for seizure and epilepsy within families. The important concept of presymptomatic detection of those at riskâ€"now possible for only a few of the convulsive disordersâ€"and its implications are also discussed. Although it is unlikely that such detection will play an important role in regard to the most frequently occurring types of epilepsy in the near future, investigators need to address the ethical considerations and approaches to such evaluation.

In a number of single-gene diseases, seizures are included in the constellation of symptomatology. Some of these are reviewed in Chapter 17. The review of the biochemical and structural bases of these syndromes can provide additional understanding of epileptogenic mechanisms. The question of why epilepsy develops in some individuals with a given genotype and not in others is the subject of active investigation.

Chapter 18 discusses genes specific for epilepsy. Those that have been identified most often involve channelopathies as the underlying primary mechanism.[10] In many situations, however, the genetic mechanisms remain obscure in both mice and humans.[6] An integrated effort by epidemiologists, molecular and population geneticists, and clinical and basic

neuroscientists is clearly needed to acquire a full understanding of specific genetic actions.

Summary and Conclusions

The rapidly growing pool of information regarding basic mechanisms of epileptogenesis emanating from modern laboratories has been paralleled by an increase in clinically relevant information. Both the laboratory and clinical approaches are important, and the results provided by each should be integrated to determine future research directions.

(The fact is that the cause of this affection is in the brain.)

Hippocrates: *On the Sacred Disease*[133]

Introduction

Among the diseases that have plagued humans over the centuries, few exhibit the brief, frightening manifestations of an epileptic attack and the relatively quick, seemingly miraculous recovery. Accounts of what may have been epileptic seizures can be found in several ancient scriptural accounts such as reference to the prophet Balaam falling down with the eyes open (Numbers, XXIV, 1) and to King Saul's fits of rage (Samuel I, 18, 10 and 19,9). While *naphal* and *nÃ´phÃªl* were Old Testament and Talmudic terms for epilepsy, Israelites also used *nikpheh* to refer to the disease.[201,204] Similarly, the prohibition against entering the temple by those *possessed by a malevolent power* in the ancient Egyptian text of Esra has also been thought to be a reference to epilepsy.[218] In contrast, the papyrus of Ebers, the oldest Egyptian medical book, has no mention of the condition. Initially, these ancient accounts of falling attacks attributed such â€œseizuresâ€ to an evil entity or punishment inflicted by a god or, later, to some natural cause. Not until Hippocrates was the origin of epilepsy placed in the brain. Temkin, in his book *The Falling Sickness,* describes a battle between rational, scientific thinking and magical beliefs that started with Hippocrates' connection of epilepsy to the brain and continued at least until Jackson's time.[232]

Sakkiku

The oldest medical reference to epilepsy consists of two clay tablets written in Assyrian-Babylonian, which are copies of portions of a comprehensive medical textbook known as *Sakkiku* that dates to the reign of King Adad-apla-iddina (1067â€“1046 BCE). The tablets were discovered during separate archaeologic expeditions in Turkey and Iraq (Fig. 1A, B); they were subsequently translated by Wilson and Reynolds.[248] Although written over 3,000 years ago, they provide remarkably accurate accounts of some characteristic clinical manifestations of the disease.

â€œIt is he again!â€ probably implies an aura. Descriptions of seizure phenomena include generalized convulsions; repetitive occurrence as in status epilepticus; partial motor seizures (â€œhis eyes roll to the side, a lip puckers, and his left hand, leg and trunk jerkâ€); adversive attacks and sensory symptoms, such as auditory hallucinations; and epigastric aura. Gelastic epilepsy was reported for the first time: â€œ[If at the] time of his epilepsy he laughs loudly for a long time, his legs (his hands and legs) being continuously flexed and extended.â€ The impressive astuteness of the clinical observations is matched by a detailed description of various demons that were considered responsible for each symptom. Interestingly, there is no discussion of treatment.

China

Epilepsy was apparently known in ancient China, but no chapter devoted to epilepsy is known to exist in the ancient Chinese medical literature. Lai and Lai[161] presented the information offered on epilepsy in *Huang Di Nei Jing* (The Yellow Emperor's Classic of Internal Medicine), a collective work of Chinese physicians that was compiled between 770 and 221 BC. In the *Ling Shu* volume the term *dian-kuang* was applied to a generalized attack preceded by behavioral alterations. At first, this term was used interchangeably for epilepsy and psychosis, but the two entities were differentiated around 200 BCE in the medical text *Nan Jing*.[161] Epilepsy was generally considered congenital, but other causes including phlegm and insufficiency of blood or kidney were mentioned. Treatment was focused on restoring the balance between the energies, the *yang* from the sun and the *yin* from the moon, or among the five elements *metal, wood, water, fire,* and *earth* that were considered disturbed during disease states.

India

The three ancient Indian medical systems of *Siddha, Ayurveda,* and *Unani* all recognized epilepsy.[226] The most elaborate descriptions are found in the *Ayurveda* (science of life), the oldest known medical system that evolved continuously from 4500 to 1500 BCE. The views on epilepsy are attributed to the physician Atreya (about 900 BCE). The compendium of Ayurvedic medicine known as *Charaka Samhita* (6th century BCE) used the term *apasmara* (*apa*, loss of; *smara*, consciousness or memory) for epilepsy.[19] Visual hallucinations; twitching of the tongue, eyes, and eyebrows; and jerking of the hands and feet accompanied by excessive salivation were some of the symptoms noted, as well as the observation of a patient awakening after the attack as if from sleep.[176] The term *Apasmara poorva roopa* was used for auras that included visual, auditory, and somatic symptoms, as well as behavioral disturbances.

The Ayurvedic system attempted to classify seizures into four types based on the defects in one the three *doshas* (humors). It also recognized external trigger factors such as high fever, internal bleeding, extreme mental agitation, and even excessive sexual intercourse. In addition to the traditional Ayurvedic approach to treat the whole body (physical, mental, and spiritual), cleansing through enemas, purgation, or emesis as well as medicinal preparations based on herbs were employed.

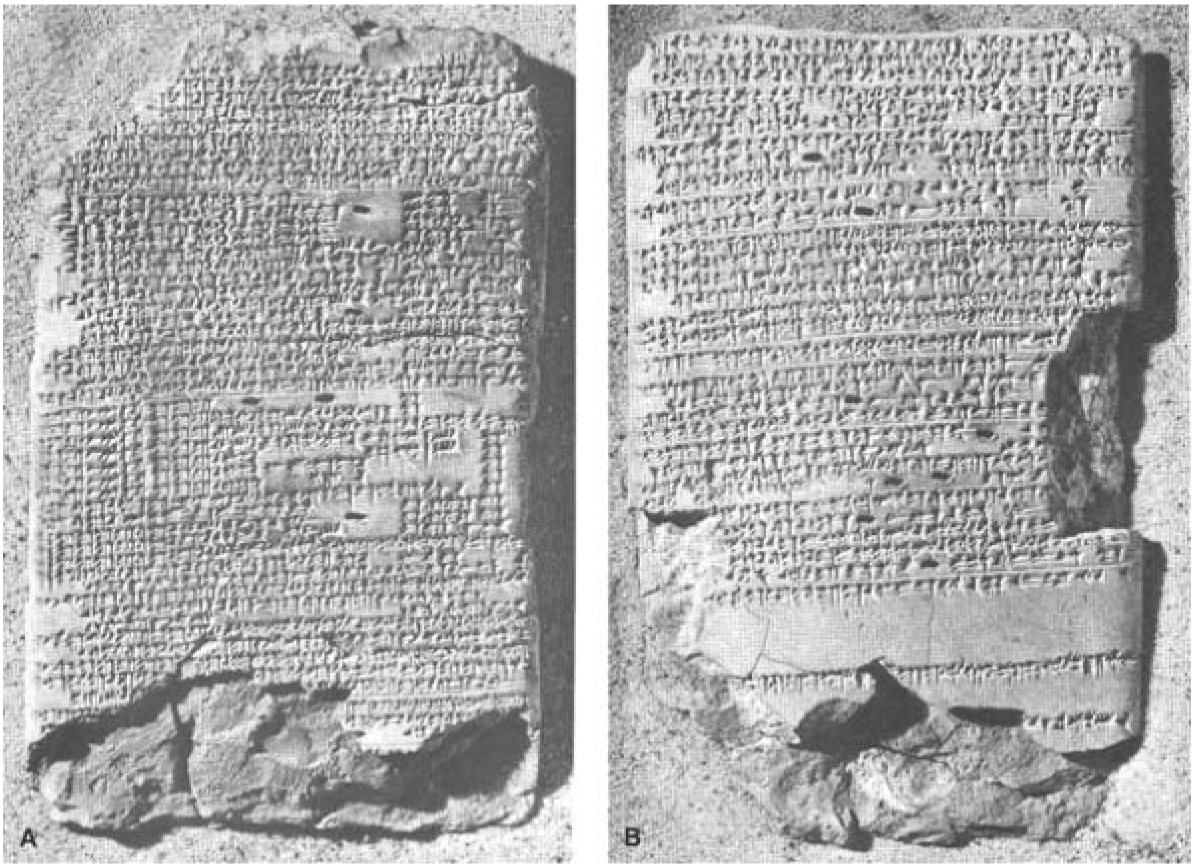

FIGURE 1. Tablet BM 47753, obverse **(A)** and reverse **(B).** (London, The British Museum, reproduced courtesy of the Trustees. Copyright British Museum.)

Hippocrates

The Hippocratic treatise *On the Sacred Disease*[133] is not a medical text; it was apparently written for the layperson. It begins with an attack against common popular superstitions

P.14

and all those who labeled epilepsy as â€œsacredâ€ to conceal their ignorance about its cause and justify their fraudulent practices. Contrary to the Babylonian text, the Hippocratic writings challenged the widespread beliefs of the time that epileptic seizures were caused by actions of demons or gods. The Babylonian text described in detail various epileptic symptoms, as caused by a particular demon, while Hippocrates (Fig. 2) attempted to disconnect the physical phenomena from supernatural forces. After a brief description of the generalized epileptic attack, the author recognized the hereditary nature of the disease and the greater frequency with which children were affected.

The fundamental difference, however, between Hippocrates' and other contemporary or older medical explanations (Assyrian, Indian, and Chinese) lies in the unequivocal statement about the origin of the disease: â€œthe factâ€¦that the cause of this affection (epilepsy)â€¦ is in the brain.â€ Hippocrates further recognized that all cognitive functions or emotional manifestations are related to the brain, emphasizing that â€œmen ought to know that from the brain, and from the brain only, arise our pleasures, joys, laughter and jests, as well as our sorrows, pains, grieves and tears. Through it, in particular we think, see, hear and distinguish the ugly from the beautiful, the bad from the good, the pleasant from the unpleasantâ€¦â€ Thus, Hippocrates importantly dissociated epilepsy from religion and magic, arguing forcibly and eloquently that epilepsy was properly a subject not for incantation but for medical investigation and study.

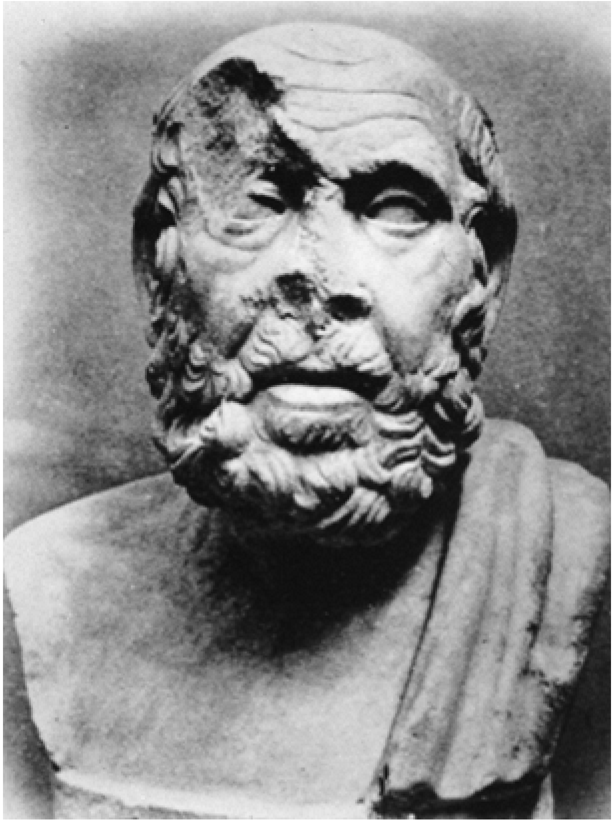

FIGURE 2. Hippocrates (c. 460â€“377 BCE), presumed author of the essay *On The Sacred Disease.* (Museo della Via Ostiense, Rome.)

His explanation that phlegm rushes into the cerebral vessels, preventing air from flowing into the brain, was the first attempt to explain the cause of epilepsy based on a physiologic process that affected the brain. Another important Hippocratic contribution to medicine was the introduction of prognosis. In the essay *On the Sacred Disease*, he commented on

P.15

the grave outcome of status epilepticus and the spontaneous remission of epilepsy in children as they mature. In *Wounds of the Head,* Hippocrates for the first time recognized laterality in brain function,[134] when he described trauma to the temple as producing spasm of the contralateral limbs. In his attempt to prove that there was nothing â€œsacredâ€ about epilepsy, Hippocrates stated that there was treatment for the disease, but no specific suggestions occur in his writings.

Post-Hippocratic Hellenistic and Roman Medicine

Attempts to define epilepsy started during Hellenistic times and continued during the time of the Roman Empire. The description of questionable authenticity,[232] attributed to the Alexandrian physician Erasistratus (3rd century BCE), â€œthat epilepsy is a convulsion of the body together with an impairment of the leading functionsâ€ emphasized two cardinal symptoms, convulsions and loss of consciousness. An interesting observation of that time was that sensory stimuli such as bad smell[133] or the sight of whirling wheels[5] were potentially epileptogenic. Greeks and Romans used this knowledge to evaluate the fitness of slaves being sold by having them face the sun while looking through a turning potter's wheel. Intermittent photic stimuli produced by his marching soldiers were reported to have triggered some of Julius Caesar's attacks.

Among those in the 1st and 2nd century CE whose writings have survived are Soranus of Ephesus and Celsus in Rome. Our knowledge of medical attitudes during the post-Hippocratic, pre-Christian era, from the 4th century BCE on, is limited to the information available from Soranus through Caelius Aurelianus.[47] None of Soranus' works in Greek have survived. It is believed, however, that the 5th-century CE physician, Caelius Aurelianus, preserved them in Latin translation. These writings contain an extensive list of symptoms that could precede epileptic attacks, including excessive sexual excitement accompanied by sexual acts (possibly seizures of frontal lobe origin), and they also discuss psychic causes, such as fright and anger, as precipitating factors. The seriousness of repetitive attacks was noted, and physicians were advised to warn relatives about their severity and lack of treatment to avoid possible repercussions after a patient's death. Consumption of wine was associated with seizures, and even drunkenness of the wet nurse was implicated as a cause of epileptic seizures in children. Soranus criticized Hippocrates' statement about the existence of treatment, when none was mentioned in the *Sacred Disease*. Soranus also attacked contemporary practices like Diocles' use of various substances in enemas, or the administration of animal or human excrements by Praxagoras, Asclepiades, and Serapion. Patients whose attacks had a predictable pattern of recurrence were bled in anticipation and purged with emetics (white hellebore) or cathartics (scammony or black hellebore). This type of â€œcatharsisâ€ was popular by Greek and Roman physicians from 300 BCE to 100 CE.[47]

Celsus in the *Comitialis, Book III, 23*[54] described both generalized convulsions and what were probably atonic and myoclonic attacks. He noted that epilepsy was more common among men and children but added that onset in childhood was associated with a better prognosis. He never discussed possible causes but advised dietary measures and avoidance of cold, heat, and wine, and opposed the practice of administering blood of dead gladiators.

In the 2nd century CE, the two main contributors to epileptology were Galen of Pergamon and Aretaeus of Cappadocia. Unlike Hippocrates, whose description of seizures in the essay *On the Sacred Disease* emphasized only major symptoms, Aretaeus provided a detailed narrative of generalized convulsions[6]:

â€œThe man lies unresponsive with the arms in spasm and the legs stiffened and then shaking; the head is twisted, either bent to the sternum or backwards as if pulled violently by the hair; the mouth is open with the tongue protruding at risk of being injured or cut; the eyes are turned upwards, while the lids blink; if they are not closed, the white of the eye shows; the face is distorted and changed, because the eyebrows frown or are pulled to the temples; the lips either protrude or are pulled to the side and shake; the initial redness of the face is replaced by paleness; the blood vessels of the neck dilate; the pulses are initially fast and then slow; towards the end there is loss of urine and feces or in some men ejaculation, while froth comes from the mouth.â€

Further recognizing the variety with which epilepsy could express itself, he stated: â€œEpilepsy is an illness of various shapes and horrible.â€ Without using the term, he described a visual auraâ€”â€œred or black lights or both together appear in arcs before the eyes, similar to the rainbowâ€â€”and gave a detailed list of auditory (ringing in the ears), olfactory (foul smell), and other sensory symptoms. Like Hippocrates, Aretaeus observed the greater frequency with which seizures occurred in children as compared to adults, as well as the spontaneous remission in old age: â€œIf it passes the peak of life, it co-ages and dies out.â€ Todd paralysis, first observed by Hippocrates, was termed â€œparetic handâ€ by Aretaeus.

Galen's descriptions of epileptic seizures[43,99,224,231] are scattered throughout his works and include â€œloss of consciousness and the leading functions,â€¦sudden fall,â€¦the presence of spasms, or sometimes (loss of consciousness) in the absence of them,â€¦secretion of froth from the mouth,â€¦loss of urine,â€¦ejaculation,â€¦changes in pulse rate.â€ He apparently did not restrict the diagnosis of epilepsy to generalized convulsions as he wrote â€œif there is not only convulsion, but also interruption of the leading functions, then this is called epilepsy.â€ Galen differentiated types of seizures based on their clinical features and the anatomic part involved in the aura. His classification of seizures as primary (originating in the brain) or sympathetic (arising either from the stomach or from other parts of the body) was the first and influenced the approach to epilepsy for centuries. Galen also noted the more frequent occurrence in childhood, a relation between seizures and the menstrual cycle, and the precipitation of seizures by prolonged starvation. Galen is credited with introducing the term *aura* (in Greek, sea breeze), which he described in a young man who reported the feeling of a â€œcool auraâ€ that started in his foot, marched upward, and heralded the onset of the attack.[100]

Treatment in the Hellenistic and Roman times was guided by the theories of three schools: The dogmaticâ€"Galen and Aretaeus (based on the pathology of the disease), the empiricâ€"Serapion, and the methodistâ€"Soranus, Themison, and Celsus. What was common to all three schools was the importance of dietary regimens, exercise, sleep, and â€œcatharsisâ€ through emetics, enemas, or bleeding. Various techniques of bleeding and cauterization of the arteries of the scalp, as well as trephination, were used. Both methodists, such as Theodorus Priscianus, and dogmatists, such as Aretaeus, recommended these methods. Soranus, however, and later the Galenist Alexander of Tralles, warned against them, â€œwhich to many become a punishment rather than a cure.â€[231] The use of drugs for epilepsy probably preceded the dietetic treatments that required time and money, and thus were affordable only by the rich. It is, therefore, not surprising that a large number of drugs were developed. Dioscurides (2nd century CE) in his *Materia Medica*[76] lists 45 antiepileptic substances. Temkin[231] divided them into three categories: 18 had no connection to magic and corresponded to contemporary pathologic theories; at least 13 were definitely based on superstition; and 14 had no apparent magical connotation, but the reason for their use was questionable.

P.16

Byzantine Medicine

The transfer of the capital of the Empire from Rome to Constantinople in 330 CE marked the transition from the Roman to the Byzantine Empire. The corresponding religious transformation led to significant changes in medical attitudes. While hospitals were built particularly for the care of the poor, religious views changed society's attitude toward medicine. In the case of epilepsy, the description of the miraculous cure of the â€œlunaticâ€ boy by Jesus in Matthew's Gospel (17:14â€"18) heralded a return to pre-Hippocratic beliefs of demonic possession. Origen, one of the early Fathers of the Church, stated, â€œPhysicians physiologize, as they do not consider it [epilepsy] to be a dirty spirit, but a somatic symptomâ€¦ This disease should be considered to be the influence of a dirty, speechless and evil spirit.â€[190] Supporters of this view included St. Athanasius, John Chrysostom, and Hieronymus in the West.[174] The â€œlunar influenceâ€ on epileptics, which was considered by ancient physicians to be the result of humoral changes of the brain, was explained as the devil's attempt to defame God by defaming his creation. In the Eastern Church it was not until several centuries later that the Alexandrine Stefanus of Athens and the 11th century Patriarch Photios in his *Amphilochia* settled this argument in favor of a naturalistic explanation.[173] Among physicians, however, a â€œbiologicâ€ approach to epilepsy based on the Hippocratic and Galenic tradition was retained throughout the thousand years of the Byzantine Empire. The Encyclopedists Oribasius, Aetius Amidenus, Alexander of Tralles, and Paul of Aegina preserved and organized the works of earlier Greek and Roman physicians.[83] Support for epilepsy as a natural disease is indicated by the comments of Leo (9th century CE) that â€œepilepsy occurs from obstruction of the ventricles of the brainâ€; Psellos (11th century CE) that â€œepilepsy is a spasm obstructing the exits for the psychic spirit. It may start at another part, like the hand or the foot as an aura that rises to the brainâ€; and Actuarius (14th century CE) that it is â€œa diseaseâ€¦due to a fine dyscrasia of the brain or the presence of bilious humor in its ventricles.â€[83,174]

Oribasius, physician to the last pagan emperor Julian the Apostate, attempted to challenge religious views on the influence of the moon on epilepsy by arguing â€œas the sunâ€¦warms the bodies, so the moon rather moistens themâ€¦ It makes the brains wetterâ€¦and triggers epilepsy.â€[83,189] Aetius Amidenus (6th century CE), chief physician to emperor Justinian, interpreted the fear that preceded the attacks: â€œthe so called terror is not a demon but intention and preface to epilepsy.â€[3,83] Influenced by Galen, Alexander of Tralles (6th century CE) classified epilepsy into â€œprimary, originating in the brain, one originating from the stomach and a third from other parts of the body, which subsequently reaches the brain.â€ He considered loss of consciousness as the main symptom of the attack but included complex partial seizures as â€œthey get wearied on the head, confused, hard of hearing and sense slowly before the attack.â€ He should be credited with the first description of reading epilepsy: â€œI observed a man falling while reading who sensed the attack from a cold aura starting in the tarsus and rising up to the brain.â€[4] Paulus Aegineta (7th century CE) defined epilepsy as â€œa spasm of the whole body with damage of all princely functions.â€ He explained the prodromal symptoms as â€œan unintentional tension of the soul [that] precedes the epileptic [attack], and dysthymia and oblivion of the future and tumultuous dream visions and headache and continuous head fullness, and irritability with paleness of the face and disorderly movements of the tongue.â€ Paulus noted the possible lethality of the attacks in childhood but also the occasional spontaneous remission after puberty. He recommended abstinence from alcohol â€œâ€¦particularly the old and heavy winesâ€ and sexual intercourse, because orgasm and epilepsy were considered equivalent.[194] Treatment of epilepsy included the use of various drugs and again â€œcatharsisâ€ through emetics, enemas, and venesection.[83]

Contributions from Islamic Medicine

The influence of earlier Persian, Indian, and particularly Greek (notably Hippocrates and Galen) practices set the foundations for Islamic medicine. A reference of a god telling Zoroaster to prohibit epileptics from offering sacrifices in his honor is probably the only mention of epilepsy from the ancient Persian religion. The translation of Greek words resulted in new Persian-Arabic medical terms such as *abilibsyÃ¢* (usually referring to the psychic symptoms) or *Sar* (connoting falling sickness).[240] Islamic medicine, like Byzantine, was strongly influenced by Galenic beliefs. The two main Islamic physicians who mostly influenced the West were Rhazes (865â€"925 CE) and Avicenna (980â€"1037 CE). Their opinions were based on personal observations of epileptic phenomena. Avicenna in his *Canon* deviated from Galenic opinions by not considering convulsions as essential. He defined epilepsy as a sickness that prevented animation of the members, the operation of the senses, movement, and standing erect.[243] Although he invoked the Galenic concept of ventricular obstruction, he differed in concluding that the lower (fourth) ventricle, and not the anterior ventricles, was the area of obstruction by an unhealthy humor, usually phlegm. He considered two possible mechanisms, one originating in the brain and the other in the nerves, proposing that a putrid vapor from the distal part rose to affect the brain. Rhazes used bleeding, emetics, and purgatives, while Avicenna used several traditional herbal and other pharmacologic agents.

Medieval Europe

The Middle Ages started earlier in the Western Roman world than in the East. Fragments of the works of Soranus and Caelius Aurelianus provided concise descriptions of epilepsy. Cassius Felix (5th century CE) recapitulated the old opinions that epilepsy was divided in two types: One accompanied by convulsions, the other by sleep. Like Galen, Cassius Felix believed that seizures originated in the brain due to influence of a melancholic humor or phlegm, the stomach, or any lower part of the body.[50] He used â€œepilepsyâ€ to refer to the idiopathic type originating in the brain, whereas â€œanalepsyâ€ was the type â€œascendingâ€ from the stomach, and â€œcataplexyâ€ the type arising from other parts. Cataplexy, however, was used differently in ancient writings to describe a condition with fever and mental obtundation.[11]

The translation of classical Greek and Arabic texts into Latin and the establishment of medical studies influenced the beliefs of medieval scholastic medicine. Based on older traditions and their own observations, physicians were quite familiar with convulsive epilepsy as well as some of the other forms. Bernard of Goddon (14th century CE)[165] described brief episodes of loss of consciousness and staring spells. The classification of epileptic symptoms was a matter of considerable discussion and description, with the main question centered on how to find the original lesion. Platearius (12th century CE) distinguished between â€œmajor and minor epilepsyâ€ in a way reminiscent of the later distinction between â€œgrand mal and petit malâ€ epilepsy.[231] Another division involved â€œtrueâ€ (Galen's â€œidiopathicâ€) versus â€œspuriousâ€ (originating from other parts) types of epilepsy. Arnold of Villanova (14th century CE) blamed phlegm for the â€œtrueâ€ and black bile mixed with phlegm for â€œspuriousâ€ epilepsy.[243] Gilbertus Anglicus[231] agreed on phlegm as the cause of â€œtrueâ€ epilepsy, but he suggested other humors as the cause of the â€œspuriousâ€ form. John

P.17

of Gaddesden[164] wrote of three forms: Minor or true (due to obstruction of the arteries to the brain), medium or truer (due to obstruction of the nerves), and major or truest epilepsy (due to obstruction of the ventricles). Significant disagreements existed among medieval authors about the type of humors involved in different forms of epilepsy based on arbitrary or even imaginary signs such as the viscosity of the saliva or the color of the urine. Medieval physicians recognized trauma as a cause of epilepsy probably based on the Hippocratic observation in the *Wounds of the Head.* AlÄ« ibn AbbÄs and Constantinus Africanus associated seizures with fractures of the skull and compression of the brain. Both early Arab and European physicians emphasized the hereditary nature of epilepsy as noted in the essay *On the Sacred Disease*.

During medieval times, Western European, Byzantine Greek, and Arab physicians did not significantly extend the boundaries of our understanding of epilepsy. At a time, however, of prevailing beliefs in falling evil and demonic possession, they deserve recognition for maintaining the tradition of understanding disease in terms of natural causes.[231]

Medieval China

Classification of seizures was published in Chinese medical books in the 7th century CE based on the Chinese philosophy of medicine and the belief of â€œyang and yinâ€ energy and disturbances of their balance. Nowhere was the brain mentioned as being involved in epilepsy. The goal of the treatment was to expel the wind and the phlegm, bring down the fever, activate blood circulation, and energize the kidneys and spleen. The therapy included herbs, acupuncture, *mai yao* (injection of herbs into acupuncture points), *mai xien* (inserting a piece of goat intestine into the acupuncture point), and massage.[161]

Pre-Colombian America

Although three major cultures, Inca, Aztec, and Mayan, flourished across the Atlantic, little documentation survived the colonization. The Inca term for epilepsy in the Quechua language (*sonko-nanay*) was rather erroneously translated by the Spanish chroniclers as â€œmal de corazon.â€ The term *sonko* means the center of the human body and mind located in the chest and upper abdomen and not heart (corazon), and *nanay* means disease. Variations of this term were used to describe different symptoms: *songo-piti* (pulling the heart) and *songo-chiriray* (getting frozen) for grand mal seizures, *nahuin-ampin* (darkening of vision) and *upayacurin* (behavioral arrest) for partial simple seizures, and *upakundiya* (*upa*, fool; *kontiyak*, volcanic) for complex seizures.[46] While the Incas considered epilepsy to be divine punishment, epileptics were considered closer to the supernatural forces. On the other hand, the Aztecs believed epilepsy was related to the influence of evil goddess Cihuapipiltin; children were not allowed to go out on the days of her descent to earth. As in the Greco-Roman world, slaves with epilepsy could not be sold.[84]

The American cultures used religious-magical means as well as the administration of products from plants, animals, or minerals to treat epilepsy. Both Aztecs and Incas employed removal of sin by washing and confession. The ritual of Bacabs (evil deities) was practiced by the Mayans, who invoked the help of good deities against them.[180] Constituents of magical means, such as hair from a corpse, a stag's horn, a dog's bile, or the brain of an ox or weasel, were part of the Aztec remedies. A large number of plants were used for epilepsy on an empirical basis but, unfortunately, none of them was included in a study that evaluated medicinal plants from Central and South America.[191]

The Renaissance

During the Renaissance the beliefs in supernatural or physical causes continued in their separate ways. Physicians believed that bilateral tonicâ€“clonic seizures, often associated with falling to the ground, were the sole manifestation of epilepsy. Nonetheless, there were occasional suggestions that epilepsy might include less dramatic events. Antonio Benivieni[15] described an obvious complex partial seizure without either falling or secondary convulsing and made it clear that he considered this a form of epilepsy that was probably unfamiliar to his contemporaries. In 1470, the Chinese author Fang Xian[161] wrote of olfactory auras and visual hallucinations preceding loss of consciousness without specifying that either falling or bilateral convulsing necessarily followed.

Paracelsus (1493â€“1541) discussed the falling sickness in his posthumously published *Diseases That Deprive Man of His Reason* that was written between 1520 and 1525.[242] He defined five varieties of epilepsy, beginning in the brain, liver, heart, intestine, and limbs, thus extending Galen's three. He tended to think in terms of alchemical processes and perceived resemblances between seizures and earthquakes. In the falling sickness the â€œvital spiritsâ€ of the body, like an earthquake, suddenly boiled up at the site of the apparent origin of the attack and then spread to other parts. Once they reached the brain, consciousness was lost. Such a concept, mounting to sudden spontaneous overactivity in some organs body, though highly fanciful, accurately conveyed the potential violence of the epileptic process. It reflected his belief that epilepsy had a natural rather than a supernatural origin. His disciple, van Helmont (1570â€“1644), further proposed that nearly all seizures originated in the stomach, where the local *Archeus* (the soul, or ruler of that organ) had become injured and angry.[192] This idea was subsequently abandoned, but Paracelsus' concept that seizures arose from abrupt overactivity in some parts of the body was adopted, refined, andâ€"a century laterâ€"restricted to the brain by Willis.

Paracelsus proposed new chemical remedies for epilepsy, many of them of mineral origin, including his allegedly efficacious green vitriolic oil. The chemical nature of these treatments remains obscure largely because the source material cannot be determined and, therefore, they cannot be reproduced. Both their claimed mechanisms of action and alleged efficacy appear highly speculative.

The Scientific Revolution

During the scientific revolution of the 16th and 17th centuries, some present-day authors have identified, though not fully convincingly, what could be regarded as the first descriptions of certain epileptic syndromes, such as benign Rolandic epilepsy by Martinus Rolandus in 1597,[238] focal motor (jacksonian) seizures by the philosopher John Locke in 1676,[194] and juvenile myoclonic epilepsy by Thomas Willis in 1667.[79]

Thomas Willis (1621â€"1675) was the main contributor to epileptology during this period. The evolution of his thinking about the subject can be traced in two separate publications: *Thomas Willis' Oxford Lectures*[75] preserved by Lower and Locke, who kept notes of his lectures between 1661 and 1664 that were published three centuries later, and *Pathologie Cerebri.*[247] Willis' account of hysteria contained descriptions of what would appear to be epileptic manifestations, including the paroxysmal events that befell his â€œvery noble lady of a most curious shape,â€ who may have suffered from juvenile myoclonic epilepsy. It is likely that generations of authors, perhaps going back to Plato himself, mistakenly attributed instances of a rising abdominal discomfort to hysteria, when in reality these

P.18

were the epigastric auras of temporal lobe epilepsy. Willis at least realized that hysteria could occur in men and concluded that it arose in the brain and not in the uterus. At autopsy his â€œvery noble ladyâ€ whose seizures were â€œhystericalâ€ had a macroscopically normal uterus, but Willis believed there were abnormalities in her brain.

Willis tended to diagnose epilepsy only when the sufferer was afflicted with â€œinsensibility, and horrid convulsions, and also with foam at the mouth.â€ He regarded preliminary symptoms, such as fits of â€œvertigo or giddinessâ€ associated with confusion, as precursors to, rather than as manifestations of, the seizure. His theories explain epilepsy as movement of the â€œanimal spirits,â€ an intangible entity whose existence had been invoked in the time of Galen as the psychic pneuma,[207] and which had been employed ever since to explain nervous system activity. In the period between 1661 and 1664, Willis suggested that epileptic seizures arose from contraction of meninges that squeezed the â€œanimal spiritsâ€ from the brain into the peripheral nerves, producing widespread muscle contractions. Later in his Oxford lectures, he spoke of a chemically induced boiling of these â€œanimal spiritsâ€ causing the postulated meningeal contraction. At that time he also suggested that the sensory aura produced the actual seizure through the centripetal movement of these spirits that started the aura and also activated a central epileptic explosive mechanism in the brain. By 1667, Willis abandoned the notion of meningeal contractions because he recognized that this was an anatomic improbability due to the dura's firm attachment to the skull. In his final explanation of seizure causation, he concluded that the decisive event was an explosion of animal spirits in the center of the brain. This explosion in the brain caused loss of consciousness, and its force set up a sequential series of chemically initiated explosions in the â€œanimal spiritsâ€ radiating centrifugally. When the explosions reached the origin of the peripheral nerves, it produced a tugging on the nerves that resulted in abrupt muscle contractions. Willis continued to believe that centripetal movement of â€œanimal spiritsâ€ associated with the experience of an epileptic aura could trigger an explosion in the center of the brain, producing a convulsive seizure. Alternatively, he also thought that local explosions near the origin of a peripheral nerve could be the cause of the aura itself, suggesting that a sensory aura might be of central and not peripheral origin.

Willis produced a â€œcomprehensiveâ€ hypothesis of the origin of epileptic seizures based on speculations of an intangible entity, â€œthe animal spirits,â€ whose physical existence had already been questioned by his contemporaries, Harvey,[127] Stensen,[228] and Glisson.[116] Ingenious though it was, Willis' line of thought was not developed further by his successors, though it contained the seeds of ideas that reappeared in the latter half of the 19th century. Through his theories of epilepsy causation, Willis reasoned his way to a rational approach to treating and preventing seizures. In practice, however, this approach justified the use of the multiple conventional antiepileptic remedies of his day, whose application in practice he described in detail in the *Pathologie Cerebri.*

FIGURE 3. Luigi Galvani (1737â€"1798), the discoverer of intrinsic animal electricity. This is an engraving made for the celebration of the 200th anniversary of his birth in 1937. (Courtesy of the National Library of Medicine, Bethesda, MD.)

The 18th Century

The period of the Enlightenment saw a gradual replacement of the notion of the â€œanimal spiritsâ€ as the explanation for neural activity, although it was still employed as late as 1770 by Tissot and 1779 by Morgagni. Concepts such as Cullen's brain â€œenergyâ€[70] or Haller's â€œirritabilityâ€[125] began to be used as the mechanism of neural function. A year after Galvani's discovery of electricity in 1780, Fontana began to write of the â€œelectrical fluidâ€ in nervous tissue.[36] However, the concept of an electrical component was not to be applied to ideas about epilepsy for some time.

During the 18th century, diagnosis of epilepsy generally required the presence of both loss of consciousness and bilateral convulsive activity. Cheyne,[56] however, seemed to imply that falling (presumably from loss of consciousness) might suffice for the diagnosis. Tissot[232] provided a reasonably convincing description of what Calmeil[48] later called absence seizures: â€œthese â€˜petitsâ€™ being accompanied at times by grande accÃ©s,â€ while Cullen in 1789[70] recognized the existence of partial convulsions involving only a localized part of the body with preservation of consciousness that distinguished them from epilepsy: â€œI might treat of particular convulsions, which are to be distinguished from epilepsy by their being more partial: That is, affecting certain parts of the body only; and by their not being attended with a loss of sense, nor ending in such a comatose state as epilepsy always does.â€ Heberden in his *Commentaries,*[129] perhaps following Tissot, wrote of brief minor depressions of consciousness in relation to epilepsy, as well as the familiar bilateral tonicâ€“clonic seizures. By then the clinical spectrum of epilepsy was beginning to widen. It was generally accepted that the origin of epilepsy was located in the brain, but there was little consideration of more precise localization. Boerhaave[27] wrote of â€œtoo great an action of the brainâ€ as the basis of the epileptic seizure, while Cullen[70] attributed it to an excess of brain energy, confessing that he was unable to be more specific. Curiously, Tissot,[232] in his thorough review of the earlier literature on epilepsy, reverted to Willis' notion that brain contraction expelled the â€œanimal spiritsâ€ and caused seizures.

The 18th century saw the development of interest in the pathologic basis of epilepsy. Morgagni,[183] using his experience in neuropathology, suggested that epileptic seizures arose from structural abnormalities of the brain such as hardening (gliosis) or abscess, which diverted the â€œanimal spiritsâ€ from their normal pathways through the brain substance or released an irritant that acted on these spirits to produce seizures. The growing interest in the neuropathologic basis of epilepsy was also reflected in attempts to classify the epilepsies according to the pathology.[27,70] Various structural pathologies as well as inheritance, strong emotions, and speculative chemical abnormalities were included in the causes. The details of these classifications are less important than the fact that etiology and structural pathology had become crucial in the attempt to understand the pathogenesis of epilepsy. Outside of the medical circles, however, beliefs of supernatural influences still persisted.

Gradually some of the more extreme, if not outrageous, remedies of the past began to disappear during the 18th century. Measures such as venesection continued to be used, and the antiepileptic pharmacopoeia became increasingly botanical in nature. Tissot reviewed these treatments[232] and commended valerian more highly than any of its numerous alternatives. Indeed, in appropriate types of seizures and at sufficient dosage, valerian may have had some chemical basis for genuine antiepileptic efficacy.[80]

Biologic Electricity

Luigi Galvani (Fig. 3) created the foundation for the field of electrophysiology and, ultimately, electroencephalography through his monumental discovery of animal electricity in 1791.[101] These fruits of his work would revolutionize the study of epilepsy in the 20th century. Galvani demonstrated that electrical charges produced by friction and stored in Leyden glass jars caused muscle contractions, whether the charge was applied to the muscle or the nerve (Fig. 4). For many years, Galvani's seminal observations had little scientific impact, in spite of confirmation of the phenomenon by Alessandro Volta (Fig. 5) and others. In fact, it was Volta, inventor of the first storage battery, who was largely responsible for the 50-year delay in the general acceptance of animal electricity because of his misinterpretation of Galvani's experimental findings. Volta

P.19

incorrectly and tenaciously ascribed all of Galvani's evidence of intrinsic nerve transmission to direct muscle stimulation from a battery effect due to the inadvertent use of two dissimilar metals.[241] Galvani, who opposed Napoleon, lost his position at the University of Bologna and the Institute of Sciences, while Volta, a supporter of Napoleon, received many honors, and by outliving Galvani by three decades, used his prestige to continue to deny the validity of his countryman's work. It was not until 1937, 200 years after Galvani's birth, that Bologna's Institute of Sciences celebrated his life and republished his treatise.

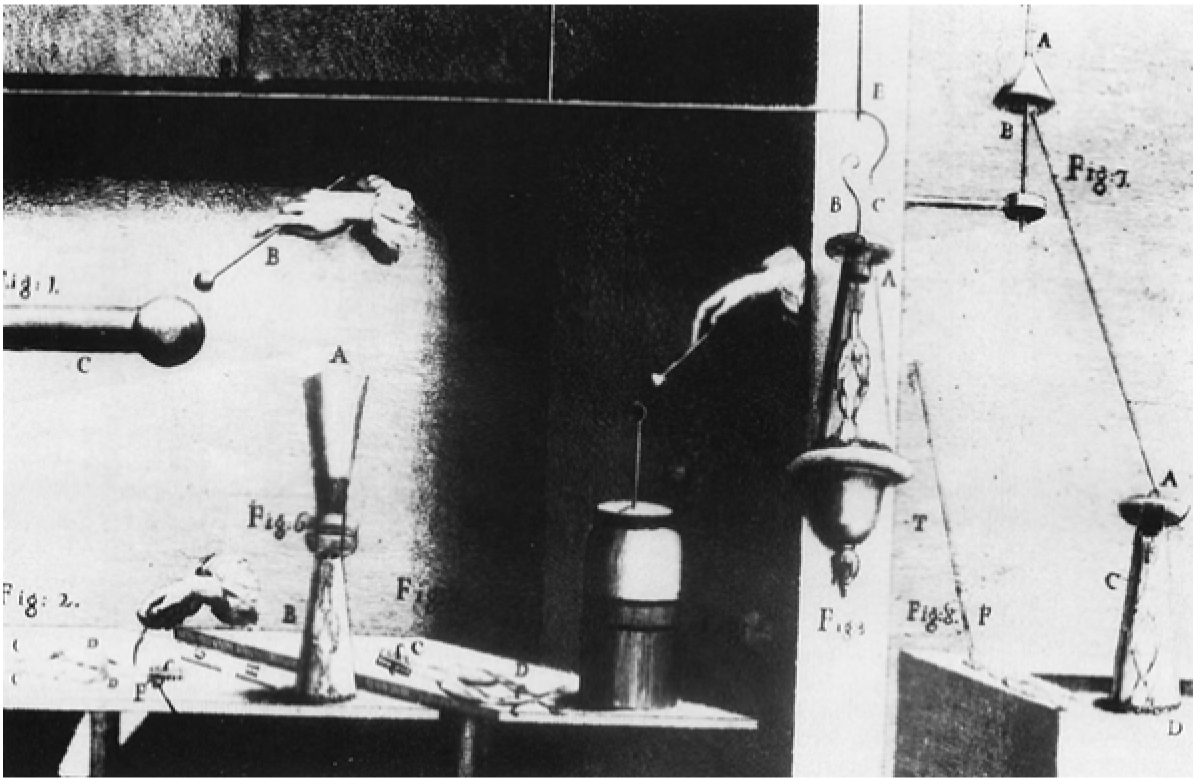

FIGURE 4. Galvani's laboratory in 1792. Sketch of three frog nerve-muscle preparations in insulated flasks, a Leyden jar, two hand-held metal wands to transfer charges, and metal wire suspended from the ceiling to collect and carry charge to the frog. FIGURE 5. Alessandro Volta (1745â€“1827) was an admirer of, and honored by, Napoleon, whose gesture he seems to have caught. **Right:** Original piles (batteries) invented by Volta (*above*) and his own sketch (*below*) of the experiment showing the pile making water alkaline in one arm and acid in the other. (From Brazier MAB. *A History of Neurophysiology in the 17th and 18th Centuries.* New York: Raven Press; 1984, with permission.)

The 19th Century

During the 19th century the acceptance of various clinical manifestations of epilepsy broadened considerably. New theories of the mechanisms underlying the origin of epileptic seizures emerged and provided the basis for today's evolving concepts of epileptogenesis. Supernatural ideas about the origin of epilepsy finally began to fade. Sieveking,[225] however, still cited and interpreted Moreau's statistical study in 1854, on perhaps not entirely justifiable grounds, as finally debunking the ancient belief in a lunar influence on epileptic seizures. And importantly, the first effective antiepileptic drug treatment appeared, almost incidentally, if not frankly, accidentally.

Epileptic Phenomena

In his 1823 review of previous knowledge concerning epilepsy, Cooke[67] continued to insist that loss of consciousness and bilateral tonicâ€“clonic seizures were required for diagnosis. From that time on, however, most authors, while still requiring transient loss of consciousness, have not emphasized bilateral convulsive behavior as a prerequisite for the diagnosis of epilepsy.[39,87,124,205,216,234] Thus, at the end of the 19th century, Beevor[14] could write that â€œepilepsy is the name given to sudden loss of consciousness with or without convulsions.â€

This change in diagnostic requirements triggered an increased interest in the minor manifestations of epilepsy such as the brief losses of consciousness that Tissot[232] had described, termed by Calmeil[48] as â€œabsencesâ€ and by Esquirol[87] as â€œpetit mal.â€ Prichard[205] had included these, along with superficially similar episodes characterized by a prodrome of which the patient was aware (i.e., simple partial seizures evolving into complex partial ones) in his subtype of â€œleiothymia,â€ a term that soon disappeared from use. He also described a tetanic type of epilepsy, probably the same or similar to present-day tonic seizures, and wrote of â€œpartial epilepsyâ€ largely in Cullen's[70] sense of epileptic manifestations appearing only in a part of the body without alteration of consciousness. New epileptic

syndromes were described: First Bravais[35] and later Bright[39] and Todd[234] reported focal motor seizures, before Jackson made them the subject of his special interest, and which Charcot later[55] associated with Jackson's name. Todd, and before him Bright, noted the temporary â€œepileptic hemiplegiaâ€ after such focal seizures and which later became known as *Todd paralysis*. West[245] described infantile spasms, sadly, in his own infant son, while Herpin[132] provided a detailed account of juvenile myoclonic epilepsy but did not regard it as a separate entity within the â€œcommotionsâ€ (i.e., myoclonic seizures). An increasing wealth of detail about the prodromes or auras became available in the literature, and Esquirol[87] recognized their occasional occurrence as isolated events without other manifestations of epilepsy. Herpin[132] considered the aura to be not a warning but rather the actual start of the seizure: â€œla premiÃ¨re manifestation de l'attaque.â€

At the same time that a diverse and expanded repertoire of epileptic seizures was being recognized, there was a growing effort to define and limit those phenomena that could legitimately be included under the rubric of epilepsy. This latter development arose from an increasing attempt to classify diseases on an etiologic basis. At the onset of the 19th century, Maisonneuve[174] and later Prichard[205] divided epilepsy into idiopathic and sympathetic types, with the latter further subdivided into gastric, intestinal, hysterical, and hypochondriacal subtypes, based on the part of the body where the first seizure manifestation was experienced. Esquirol[87] added a third type, a symptomatic form of epilepsy due to disease outside the central nervous system.

Delasiauve[73] utilized the same three main categories, but his idiopathic epilepsy was restricted to cases of cerebral origin without brain pathology, while his symptomatic type was characterized by detectable cerebral pathology. Shortly thereafter, Reynolds,[213] in his 1861 monograph on *Epilepsy: Its Symptoms, Treatment, and Relation to Other Chronic Convulsive Diseases*, defined an entity of â€œepilepsy proper,â€ which meant cases without obvious brain pathology. Seizures due to detectable cerebral, or extracerebral, pathology were termed *epileptiform* and not *epileptic*. Unfortunately, defining epilepsy as a disease whose cause was the absence of a detectable cause was virtually guaranteed not to have enduring validity as knowledge advanced. Two decades later, Gowers[121] extended this concept of epilepsy, almost surreptitiously, when he used the term *epilepsy* to refer to all seizures of cerebral origin without â€œactiveâ€ pathology. Contemporaneously, new hypotheses of epileptic mechanisms emerged. In the first third of the century, seizures were commonly ascribed to brain hyperemia or venous congestion.[67,87,205] while Mansford[175] postulated that cerebral plethora caused charged electrical fluid to accumulate in the brain until it could no longer be contained, thus triggering a brain discharge and an epileptic seizure. Romberg[216] accepted both brain plethora and brain anemia as being capable of producing seizures. As an outcome of his study of the neural mechanisms underlying the reflex arc, Hall[123] postulated that excessive activity in the afferent limb of the reflex arc (eccentric epilepsy) or in the central element (centric epilepsy) produced the excessive motor response comprising the convulsion. He proposed that the initial convulsive tightening of the muscles of the neck and larynx obstructed the cerebral venous return, causing brain congestion that led to loss of consciousness. Hall's interpretation did not account for epileptic auras and meant that bilateral convulsive movements began before consciousness was altered, contrary to the usual sequence of events in a seizure. Brown-SÃ©quard[45] overcame these difficulties by postulating that excessive afferent activity, which was sometimes also responsible for the aura, in the central nervous system ascended to structures as high as the medulla oblongata. Upon reaching the medulla it produced a discharge at the medullary vasomotor center, which caused immediate cerebral arterial spasm leading to loss of consciousness. Reynolds[213] combined elements of both Hall's and Brown-SÃ©quard's ideas, proposing that Brown-SÃ©quard's mechanisms initiated the seizure, while Hall's mechanism of venous obstruction mechanism perpetuated the unconscious state with the resultant hypercapnia from cessation of breathing converting the initial tonic convulsion into clonic jerking.

Gradually these postulated mechanisms had become acceptable in explaining convulsive seizures and placed the central events in the medulla oblongata. Van Sweiten' data[239] also settled on the medulla as the critical brain region involved in epileptogenesis, while Sauvages[219] and Nothnagel[187] had claimed the production of convulsions in animals by stimulating the medulla. Kussmaul and Tenner[160] reported convulsions in experimental animals after rapidly exsanguinating them and through sections at different levels of the central nervous system showed that an intact brainstem in continuity with the spinal cord was essential for such anoxic convulsions to occur.

In his animal experiments, Todd (1809â€"1860)[234] found that electrical stimulation of the spinal cord or the medulla produced tonic spasm of muscles and stimulation of the mesencephalon produced clonic convulsions, but stimulation of the cerebral hemispheres led only to slight facial twitching. On this basis he postulated that epileptic seizures arose in the cerebral hemispheres much like a discharge of static electricity from a condenser. If the discharge was restricted to the hemispheres, consciousness was lost but no motor symptoms occurred. If, however, the discharge reached the midbrain, clonic convulsive movements occurred in addition to loss of consciousness, but if it extended into the medulla and spinal cord, tonic components followed. Thus, Todd accounted for all of the elements of the convulsive epileptic seizure, except for the aura. He did not address epileptic unconsciousness without motor accompaniment. His ideas, however, did not attract a following among his contemporaries.

A STUDY OF CONVULSIONS.*

By J. Hughlings Jackson, M.D., F.R.C.P.

A convulsion is but a symptom, and implies only that there is an occasional, an excessive, and a disorderly discharge of nerve tissue on muscles. This discharge occurs in all degrees; it occurs with all sorts of conditions of ill health, at all ages, and under innumerable circumstances. But in this article I shall narrow my task to the description of one class of *chronic* convulsive seizures. The great majority of chronic convulsions may be arranged in two classes.

1. Those in which the spasm affects both sides of the body almost contemporaneously. In these cases there is either no warning, or a very general one, such as a sensation at or about the epigastrium, or an indescribable feeling in the head. These cases are usually called epileptic, and sometimes cases of "genuine" or "idiopathic" epilepsy.

2. Those in which the fit begins by deliberate spasm on one side of the body, and in which parts of the body are affected one after another.

It is with the second class only that I intend to deal in this article.

FIGURE 6. Left: John Hughlings Jackson (1835â€“1911), the neurologist who was physician to the London Hospital and the National Hospital, Queen Square. (Courtesy of the Archivist of the Royal London Hospital Trust.) **Right:** Jackson's publication in 1870, giving an accurate clinical-physiologic definition of epilepsy in the first paragraph and, in the next, a basic classification of seizures into generalized and focal (partial) that continues in use today. (From *Trans Saint Andrews Grad Assoc* 1870;3:162â€“204.)

In contrast to all of these concepts that were based on brain overactivity, Radcliffe[208] attempted to explain epileptic seizures as a manifestation of reduced neural activity. His ideas received a courteous reception, but were otherwise ignored and never developed further. Thus, by 1860, plausible explanations were available for the mechanisms underlying most aspects of epileptic phenomena, and a consensus had developed that the medulla oblongata was the critical brain region in the production of epileptic seizures. That state of knowledge formed the background against which John Hughlings Jackson's work over the next 40 years was carried out.

John Hughlings Jackson (1835â€“1911)

In the 1860s, Jackson[68] (Fig. 6) set out to analyze and then interpret the mechanisms underlying epileptic seizures. His numerous writings were compiled by Taylor.[230] Jackson, who initially attempted to study bilateral tonicâ€“clonic seizures, soon realized that these were too widespread, developed too rapidly to be followed reliably by the observer, and the patient, being unconscious, could contribute little information. He therefore decided to first try to study focal motor seizures, as events were more localized and easier to follow, and the patient could often describe the experience. Such seizures were sometimes followed by temporary hemiplegia similar to that due to lesions in the internal capsule rather than the brainstem. Spenser's psychology had prepared Jackson for the idea of localization of function within the cerebral hemisphere, although it had not yet been demonstrated. By the mid-1860s, Jackson had named focal motor seizures â€œcorpus striatum epilepsy,â€ as he had perceived that they probably began in neuronal cell bodies in the neighboring striatal gray matter, which had become functionally overactive.

By 1870, after considering Broca's[40,41,42] reports of aphasia from lesions in the posterior-inferior left frontal convolution, Jackson observed that temporary dysphasia occasionally coexisted with Todd paralysis after focal motor seizures involving the right face, and the association of focal motor seizures sometimes with syphilitic nodules in the meninges over the contralateral middle cerebral artery. Jackson[142] concluded that focal motor seizures involving the face or hand probably originated in the lower part of the perirolandic cortex of the opposite cerebral hemisphere. This radical departure from the conventional interpretation of the site of epileptogenesis received independent support within a comparatively short period from Fritsch and Hitzig's experimental studies of cortical stimulation and ablation in animals.[98] This work provided convincing evidence of localized representation of motor function within the cerebral cortex. During the next few years Jackson's concept of epilepsy became increasingly wide ranging:

â€œEpilepsy is not one particular grouping of symptoms occurring occasionally; it is a name for any sort of nervous symptom or group of symptoms occurring occasionally from local dischargeâ€¦ A paroxysm of â€˜subjectiveâ€™ sensation of smell is an epilepsy as much as is a paroxysm of convulsion; each is a result of sudden local discharge of grey matter.â€

Jackson's idea that all convulsions and epileptic manifestations were symptoms was at first criticized on the grounds that he had not studied â€œepilepsy proper,â€ but merely one variety of epileptiform seizure. His reaction to this criticism consisted of convoluted and rather repetitive writing, in which he continued to draw a distinction between focal motor seizures and â€œepilepsy properâ€ to make his ideas more acceptable to his peers, in spite of his private belief that they were manifestations of epilepsy and even occasionally saying so.

In the 1870s experimental physiologists, such as Ferrier,[90,91,92] began to map out aspects of localization of function in the animal cerebral cortex. At the same time Jackson started to pay attention to the minor, often paroxysmal, expressions of human epilepsy. He used the knowledge of the site of pathology in conjunction with the experimental animal findings to locate sites for the representation of various functions within the human cerebral cortex. He accumulated data suggesting that the foot was represented in the upper part of the perirolandic cortex,[145] and that the site responsible for auditory hallucinations and the so-called dreamy state or â€œintellectual auraâ€ was in the anterior part of the temporal lobe.[146,147] Jackson related visual hallucinations to the posterior half of the cerebral hemisphere without being able to more precisely localize the site of their origin. He deduced that consciousness depended on intact function of an extensive part of the prefrontal cortex of at least one hemisphere.[143] He attempted to explain the cortical origin of epileptic auras using these localizations and the belief that an epileptic discharge arose from a sudden release (at times he used the word â€œexplosionâ€) of local brain energy. If the localized discharge achieved sufficient intensity and extent of spread, the aura would progress to unconsciousness and even convulsing. Extensive involvement of the prefrontal cortex by the discharge caused loss of consciousness, while involvement

of the cortical motor areas produced contralateral convulsing. Jackson had originally thought[144] that unilateral motor cortex discharges might finally activate the uncrossed pyramidal pathway, and thus convert contralateral convulsing into bilateral convulsing. Later, following Horsley's experiments,[140] Jackson accepted the idea that the discharge must cross the corpus callosum and other brain commissures for bilateral convulsive movements to occur.

Thus, Jackson finally conceived, for the first time in the history of medicine, a single mechanism capable of explaining the full spectrum of epileptic phenomena: The aura, isolated or subsequent unconsciousness, contralateral and bilateral convulsive behavior. His concept is the basis of the modern understanding of epileptogenesis. Jackson's complete view was in place by 1890, after some 30 years of sustained intellectual endeavor. His ideas did not include primary generalized epilepsy, but in his time, before electroencephalography (EEG) became available, there was no way of knowing that such an entity existed.

Jackson's writing is often difficult to follow. He is often repetitive, using different wordings in different places for the same idea, leaving the reader uncertain if some subtle new insight was intended. It is sometimes further complicated by consequences of Jackson's stated intention to abandon his comprehensive early vision of epilepsy and restrict the word to its then contemporary conventional meaning. Thus, there is some justification for the view that Jackson's thought is more easily followed by reading his younger colleague

William Gowers.

William Gowers (1845â€“1915)

Gowers was probably the most important of Jackson's colleagues. In his monograph *Epilepsy and Other Chronic Convulsive Disorders,*[121] he discussed epileptogenesis. He used a reductionist approach weighing carefully clinicopathologic and experimental data to conclude the following:

â€œThe conclusion, then, is that all the phenomena of the fits of idiopathic epilepsy may be explained by a discharge of gray matter; that the hypothesis of vascular spasm is as unneeded as it is unproved; that there are no facts to warrant seeking the seat of the disease elsewhere than in the gray matter in which the discharge commences; that this is in most cases within the cerebral hemispheres, probably often in the cerebral cortex, although in some instances lower down even in the medulla oblongata; that epilepsy is thus a disease of the gray matter, and has not any uniform seat.â€

Unlike Jackson, who concentrated in one type, Gowers approached epilepsy as a whole. His interest actually included other disorders including hysterical attacks, which he tried to distinguish from real epileptic fits. In epilepsy the attacks tended to occur randomly and the limb movements did not resemble the pattern of voluntary movements, unlike the â€œquasi-purposive aspect and coordinated characterâ€ of the hysterical attacks. He preferred the terms â€œhysteroidâ€ and â€œco-ordinated convulsionsâ€ to avoid Charcot's confusing term â€œhystero-epilepsy.â€ In addressing the nature of Jackson's discharging lesion, Gowers used the term â€œsudden explosive discharge,â€ essentially the same words that caused Wills to be ridiculed two centuries before. He postulated the storage of latent energy in each neuron and a resistance to prevent its appropriate release. He also conceived that the frequent breaking of this resistance could produce repeated seizures as well as increase the nutritive capacity of nerve cells, leading to a facilitation of seizures.

Gower's espousal of Jackson's ideas, his critical consideration of alternative theories, and his concise statement in direct English made Jackson's ideas increasingly acceptable. Gowers almost inevitably tended to soften and harmonize Jackson's more extreme views when writing of them. To perceive, however, Gowers' book largely as a â€œtranslationâ€ of Jackson's thought is to ignore the significance of Gowers' original insights into matters such as the effect of â€œresistance,â€ a notion similar to that of present-day inhibition, in explaining epileptic phenomena.

Therapeutics

In addition to the more adequate interpretation of epileptic seizure mechanisms, in the first half of the 19th century an increasing disillusionment with the inadequacy of the available antiepileptic therapies had developed. Those who believed seizures arose from cerebral congestion continued to employ venesection and other measures to divert blood from the brain. Hall,[122] quite independent of his studies on epilepsy, had already indicated the potential hazards of diminishing the blood volume too quickly. The ancient method of applying a ligature proximal to the site of the appearance of an aura in a limb, itself a comparatively uncommon event, continued to have some demonstrable efficacy. Hall,[124] believing that laryngeal spasm contributed to the loss of consciousness during seizures, advocated and employed tracheostomy, but this approach never achieved any widespread use. Recommendations for certain remedies continued (e.g., oil of turpentine[205] and zinc oxide[131]). Esquirol[87] and Sieveking[225] made scathing comments about the vast array of ineffective antiepileptic drugs that had accumulated over the years: â€œIn fact, there is not a substance in the materia medica, there is scarcely a substance in the world, capable of passing through the gullet of man, that has not at one time or other enjoyed a reputation of being an anti-epileptic.â€[225]

FIGURE 7. Richard Caton (1842â€"1926), the discoverer of spontaneous electrical activity of the brain (EEG) and evoked potentials. (From Brazier MAB. *A History of Neurophysiology in the 17th and 18th Centuries.* New York: Raven Press; 1984, with permission.)

Into this scene of therapeutic destitute, one evening in 1857, came a totally unheralded event. At a meeting of the London Medico-Chirurgical Society following Sieveking's presentation of 52 patients with epilepsy, Sir Charles Locock, the president of the Society, remarked that he had treated 15 women with hysterical (i.e., menstrual) epilepsy with potassium bromide, and had stopped the seizures in all but one. Since potassium bromide could cause temporary impotence in males, he thought it might have useful effects in menstruating women. His observation was never published, but it was recorded in the reports of the meeting published in the *Lancet* and the *Medical Times and Gazette*. Radcliffe's[208] experience with it, however, in â€œhystericalâ€ epilepsy was even more encouraging, and he began to use it in all cases of epilepsy with generally good results. Gradually the use of potassium bromide became widespread, particularly after Wilks[246] rediscovered it. He had sought an alternative to potassium iodide in treating syphilis and, in ignorance of Locock's report, tried potassium bromide. He soon realized that its efficacy in controlling seizures due to cerebral syphilis was due to specific antiepileptic properties. Thus, the first reasonably effective antiepileptic agent came into use. By 1881 Gowers, after listing the numerous recommend antiepileptic therapies, wrote of potassium bromide:

â€œAnd the present generation has witnessed an advance in the treatment of these diseases equaled in perhaps no other branch of therapeutics. Thanks to the influence of one drug and its combinations, hundreds of epileptics have been cured, and thousands are leading useful lives who would otherwise have been incapacitated by the disease.â€[121]

In 1886 Horsley, a pioneering English neurosurgeon, performed the first operations intended to relieve focal motor epilepsy by removing the probable focus of seizure in the human cerebral cortex after locating its expected site by electrical stimulation. He continued this approach for some years,[137,138,139] as it seemed to provide at least short-term benefit in seizure control.

Spontaneous Electricity from the Animal Brain

In the mid-19th century, a renewed interest in the intrinsic electrical activity of muscle and nerve was sparked by Du Bois-Raymond's book *Untersuchungen Ã¼ber Thierische Elektricitat* (Investigations on Animal Electricity).[77] In the second volume, an illustrated description of recording muscle potentials from the surface of the skin of a man established the basis for clinical electromyography.

Inspired by this book, Caton (Fig. 7) at the Royal Infirmary School of Medicine in Liverpool used similar nonpolarizable electrodes and a mirror galvanometer to extend the work on animal nerve and muscle.[51] Based on Fritsch and Hitzig's demonstration of motor responses following electrical stimulation of various cortical areas in the dog,[98] Caton hypothesized that reversely peripheral stimulation might evoke local electrical responses in the brain. In his historic paper,[52] Caton was the first to demonstrate evoked cortical sensory responses in animals. Of much greater importance was that Caton is the first person to observe the continuous spontaneous electrical activity of the brain. He described â€œthe existence of electrical currentsâ€¦of the grey matterâ€ and noted that â€œfeeble currents of varying direction pass through the multiplier [amplifier] when the electrodes are placed on two points of the external surface, or one electrode on the grey matter, and one the surface of the skull.â€[53]

Caton's achievements are better appreciated considering the experimental conditions under which he worked, without electric lights, vacuum tubes, or electronic amplifiers, more than 25 years before the invention of the string galvanometer by Einthoven. The Thomson mirror galvanometer that Caton used had a high-frequency response of only 6 Hz. A stationary â€œoxyhydrogen lampâ€ shone on the galvanometer mirror whose tiny movements reflected the light upon â€œa distant wall with a graduated scale some eight or nine feet in length.â€ The distance between the mirror and its image on the wall was his amplifier (multiplier). There was no photographic method to capture and hold the fleeting data once it had disappeared from the wall. A candle flame was used for photic stimulation. More than 50 years, however, would elapse before the first report of spontaneous electrical activity from the human brain was recorded.

The 20th Century

By the end of the 19th century, there had been a marked quickening of the social conscience regarding care for the chronically ill and disabled. Indeed, for almost four decades, institutional care for people with refractory epilepsy had been gradually recognized as the duty of society. This in turn had generated organizations dedicated to establishing and running institutions thought appropriate for the care of disabled individuals. There was also increased interest in these institutions and in the latter half of the 19th century the Hospital for the Epileptic and Paralysed, Queen Square, London, and the Colony-Farm, Bethel, near Bielefeld in Germany, were founded.

Yet, it was early recognized that the clinical study of epilepsy in some hospitals and institutions had built-in logistical problems: Even in the National Hospital, Queen Square, an early hospital bylaw explicitly forbade bed occupation by long-term chronic patients, thus litigating against the study of epilepsy.[136] Indeed, Muskens,[186] who had studied there, complained that the Hospital for the Epileptic and Paralysed had â€œâ€¦ a tendency to pay too much attention to paralytic conditions.â€ The large number of colonies or colony farms for patients with refractory epilepsy provided ample opportunity for clinical studies.

With regard to the pathophysiologic understanding of the epilepsies, Jackson had elevated the cerebral cortex to play a prime role in the physiology of epilepsy, using the work of Fritsch and Hitzig[98] and Ferrier's ground-breaking findings summarized in *The Functions of the Brain.*[92] While Jackson's hypothesis that â€œcoarse pathologyâ€ such as tumors or infarcts was the cause of focal epilepsies, no such pathology could be seen in postmortem studies of many patients with epilepsy. Lacking such evidence of focal pathology, other lines of investigation focused on systemic-metabolic factors thought to excite the brain were pursued. Rapid advances in laboratory medicine were employed to analyze various relationships between chemical and metabolic parameters in the blood, cerebrospinal fluid, and urine. By the turn of the century, an air of cautious optimism pervaded medical thinking on epilepsy as expressed by Robertson[215]:

â€œThe subject of the pathology of epilepsy occupies at the moment a position of extreme interestâ€¦ For long it has almost completely baffled every sort of scientific investigation to discover its essential nature. But during the past five or six years investigations have been carried out whichâ€¦have so far advanced our knowledge of the subject that today we stand within measurable distance of one of the greatest triumphs of medical science. Already there is good reason to believe that this triumph will not be long delayed.â€

The modern reader would think that Robertson was referring to Hughlings Jackson's work. In fact, his opinion was based on laboratory data that were collected in an attempt to discover putative systemic metabolic causes of seizures. Indeed, enlightenment as to the true cortical pathology of seizure generation lay at least half a century and two world wars away, awaiting the development of undreamt of novel technologies.

The Organization of the Epilepsy Movement

Various organizations, both lay and professional, played an important role in improving the management of epileptics. Not only were the needs of the sufferers and their families recognized at last, but also professional attention was concentrated on their problems. The social burden that had been borne in silence by families either at home or in mental asylums was going to be hopefully relieved by the introduction of â€œcoloniesâ€ or â€œcolony farmsâ€ that offered a more caring and peaceful alternative. In Britain, the Charity Organisations Committee Report *The Epileptic and Crippled Child and Adult* in 1893, a historical landmark in social awareness, provided a clear picture of the needs of epileptics and the grave lack of available resources at that time to meet these needs. Early surveys of similar facilities in other countries were published in the early issues of *Epilepsia*.

The establishment of the International League Against Epilepsy (ILAE) in 1909 marked a major initiative worldwide to organize professional interest in epilepsy but also address scientific and social aspects. During the inaugural meeting in 1909, in Budapest, under the newly elected president, Prof A. Tamburini, ILAE adopted *Epilepsia* as the League's official periodical and outlined the aims of the organization. It continued as a quarterly periodical until 1915, when World War I forced its closure. The first volumes are a rich historical source of the status of epileptology and the international activity of the professional epilepsy movement in the first decade of the 20th century. The political chaos after World War I, combined with the Great Depression of 1929, delayed any resumption of the ILAE activity until the mid-1930s. Coinciding with the second International Neurology Congress in London in 1935, a number of interested physicians met at Lingfield Colony, Surrey, to reactivate the League.

The ILAE once again undertook an international survey of the services and facilities available in various countries. In volume 1 of the second series of *Epilepsia*, considerable data had been assembled before World War II prevented members from corresponding with its editor. Since 1941 the journal has been published in the United States to preserve continuity throughout the war years without interruption. The ILAE was also preserved and resumed its active role after the war, constituting the central spindle of the professional world epilepsy movement ever since. In 1961, the International Bureau for Epilepsy was established.

Two Damaging Diversions for Early 20th-century Epileptology

Over the centuries, the clinical problems of epilepsy have always attracted wayward theories about its cause and treatment. The early years of the 20th century saw the flowering of two such theories, both of which caused considerable difficulties for sufferers and retarded development of the management and the perception of epilepsy both in medical circles and the community.

The Autointoxication Theory of Epilepsy

The lack of neuropathologic evidence to underpin Jackson's concept of the role of the cortex in epilepsy had led even him to consider other causative factors such as a vascular mechanism.[142] For years, the concept of seizure generation by blood-borne chemical agents had been entertained in various forms,[79] and the knowledge of the epileptogenic proclivity of disorders like uremia and poisons such as lead helped bolster this concept.[233,234] The last decades of the 19th century and the first three decades of the 20th century saw the expenditure of an enormous amount of time and money in the quest for this unknown trigger in patients without obvious â€œcoarse pathology.â€ Bolten[28] and Turner[236] give a comprehensive summary of all the avenues hitherto explored. Indeed, the amassing of these data inspired the already mentioned Robertson's[215] sanguine statement at the century's turn.

Epilepsy was conceived by some as a metabolic disease, as presented by Munson at the National Association Meeting in 1906. Further, some senior neurologists in England held the concept of a â€œmetabolic dyscrasiaâ€ underpinning seizure causation until late into the second decade of the 20th century.[64] By the third decade of the 20th century, however, informed opinion was beginning to endow the brain and the brain alone with seizure generation and discharge.[135]

A byproduct of the autointoxication theory was the idea that the gastrointestinal tract was involved in seizures. From the time of Galen, involvement of the stomach in â€œanaleptic seizuresâ€ had held a prominent place in concepts of epilepsy. Based on Bouchard's writings,[30] autointoxication was also reckoned as the basis for epilepsy. This concept focused attention on the gut, this time as a site of stasis and bacterial growth or fermentation resulting in toxin production. The resultant absorption of bacteria or toxins, or both, was thought to give rise to the chemical triggers for seizure production, and accordingly strategies aimed at prevention of this cycle of events could possibly have a significant role in epilepsy management. Bra's work[32,33] in identifying bacteria in the blood of epileptic

P.26

patients was supported by Reed's[209,210,211] series; despite evidence to the contrary, surgical maneuvers to eliminate putative causes of intestinal stasis and blockage were undertaken on individual patients.[159]

The Epileptic Constitution and Psychoanalytic Concepts of Epilepsy

Refractory epilepsy had long been managed in mental asylums, and physicians working in them such as Esquirol[87] had made substantial contributions to epileptology. Berrios[18] has canvassed the association of epilepsy with insanity and pointed out that this only ceased early in the 20th century. Still the long-standing prejudicial opinion of â€œthe epileptic personality,â€ common in asylum medicine, was prevalent in almost every mental health system of the time.

Clinical opinion, however, derived from an entirely different avenue served to strengthen the impression of a link between epilepsy and psychiatry. Arising from the psychological trauma of World War I, the bizarre episodic events subsumed under the rubric â€œshell shockâ€ were thought of as closely resembling epilepsy or being frankly epileptic. Since the management of shell shock had been undertaken along psychoanalytic lines,[215] it was thought appropriate to extend this to epilepsy. Rows and Bond in their book *Epilepsy, A Functional Illness: It's Treatment*[217] established significant acceptance of this concept. Clark's earlier work at the Craig Colony (1914) had cemented the link of epilepsy with psychiatry. His controversial paper â€œA Personality Study of Epileptic Constitutionâ€ referred to psychoanalytic statements by Pilcz and Ferenczi, who â€œâ€¦made the clever suggestion that a fit represented a regression to the infantile period of wish fulfillment.â€[61] Clark's subsequent publication of a whole series of papers on this subject culminated in his article â€œA Psychological Interpretation of Essential Epilepsy.â€[62] This alternative psychoanalytic explanation held the potential for grave damage.[22] The addition of this psychoanalytic theory of the â€œepileptic constitutionâ€ to the already entrenched perception of the â€œepileptic personalityâ€ in fact constituted a disastrously negative perception of epilepsy by both the medical profession and the public.

Eventually, mainstream neurology overtook this misguided concept and Clark was subjected to public rejection at the October meeting of the New York Neurologic Society. Speaker after speaker commented upon the complete absence of any scientific data to underpin his concept.[62] Rejection was forthcoming from the other side of the Atlantic, too. Kinnier Wilson, in his chapter â€œThe Epilepsiesâ€ in Bumke and Foerster's

Handbuch,[254] summed it up concisely:

â€œDismissing the evidence for visceral, metabolic, humoral and other physical causation, some allege that relief from intolerable pressure of unconscious conflicts is sought in, and accomplished by the epileptic â€œflightâ€ into a fit; without stopping the enquire whether a â€˜flightâ€™ that lands the luckless sufferer in a fireplace or breaks his head open, is as convincing a proof of the validity of the theory as might have been wished.â€[254]

In addition, Wilson deprecated the term â€œessential epilepticâ€: â€œâ€¦the argument of the psychoanalytical school assigning him to an oral and erotic character, and egocentric and narcissistic personality can hardly apply, aside from the fact the conceptions are much too general to be of specific value in a matter of paroxysmal aetiology.â€ In retrospect, the modern reader is left with the question as to how all this could ever occur for, as Wilson implied, it simply defied common sense. By the middle of the 20th century the psychoanalytic theory of epilepsy had all but gone from mainstream neurology. Unfortunately, like the demonic possessions of the past, it took generations before it disappeared from community perception, and its echoes could be heard in psychiatry until quite late into the 1960s.

Important Figures in the Post-Jackson Era

W. Aldren Turner (1864â€“1945) contributed to the conceptual epileptology in the first three decades of the early 20th century[81] and also played an important role in establishing the ILAE as a researcher and contributor to *Epilepsia*. In keeping with the spirit of the times he espoused the cause of the social improvement of the sufferer. His first paper[235] actually discussed the advantages of epilepsy management in colonies, instancing the Chalfont Colony for Epileptics. He correctly judged the severity of both medical and community problems occasioned by epilepsy, and the dire need for radical reform of management policies.

Subsequent papers examined prognosis, nature, treatment, and associated mental conditions. All this culminated in his book *Epilepsy â€“ A Study of the Idiopathic Disease*[236] that was later summarized in his Morison Lectures.[237] They both provide an informed current status report of epileptology of the period. Turner's approach was descriptive and statistical, with large patient numbers derived from three admittedly disparate groups: Private practice, hospital consultancy, and the Chalfont Colony. While fully aware of selection bias by including the patients from Chalfont, he demonstrated that mental decline depended on seizure severity, duration of epilepsy, and age of onset. Although he mentioned â€œfacies epileptica,â€ he did not link it to the use of bromides.

His book[236] summarized his work and clearly depicted the innate problems of the concept of â€œidiopathic epilepsy.â€ Historically it provides a detailed summary of the pathologic processes currently thought significant in the genesis of epilepsy. He noted Ammon horn sclerosis but did not recognize its significance. The book contains the work on systemic body metabolism including examination of blood, sweat, urine, cerebrospinal fluid, and endocrine function during the ictus and interictally in an unsuccessful attempt to identify triggers for seizures. In spite of this failure, the concept of the â€œsystemic triggerâ€ for seizures remained popular as expressed in Collier's â€œmetabolic dyscrasiaâ€[64] and Brain's emphasis on metabolic factors in epilepsy.[34]

William Spratling (1862â€“1915) documented his vast experience as foundation director of the Craig Colony for Epileptics in New York in a textbook *Epilepsy and Its Treatment.*[227] Particularly, Clark and Prout's chapters on the neuropathology of epilepsy and status epilepticus, common conditions in epileptic colonies, was groundbreaking work.[23,59,60,223] Spratling's conclusions are also flawed by selection bias. His basic concepts of the nature and causes of epilepsy offer an informative view of that period: They feature toxic-metabolic causes combined with an â€œinherited seizure proclivityâ€ to explain the intermittent crises of refractory epilepsy. He hardly mentions jacksonian concepts, although it is clear from the text that he had personally discussed epilepsy with Jackson. Clark and Prout, on the other hand, emphasized the centrality of the cortex in seizure generation and in fact maintained that implication of its second layer (â€œa diseased state of the sensory elementsâ€) due to â€œactive nuclear poisonsâ€ underlaid seizure generation. Pathologic changes in Ammon horn were detailed, but their significance still remained uncertain. This well-documented text displayed the reigning conceptual confusion in epileptology at the turn of the century.

Hermann Oppenheimer (1858â€“1919), a prestigious German neurologist with numerous eponymous conditions named for him, offered a textbook that was the â€œgold standardâ€ of neurology. The section on epilepsy[188] demonstrates again the universal confusion in the epileptology of that era. Although he was fully accepting the jacksonian concepts on the role of the cortex, he also entertained possible implications of other brain sites and also felt that â€œtoxicopathicâ€ processes were involved

in seizure generation as suggested by the monumental amount of laboratory data.

L. J. J. Muskens (1872â€“1937), representing the younger generation of epileptologists at the turn of the century, came to be personally identified with the newly established journal *Epilepsia*, of which he became secretary to the editorial board, and then the newly founded ILAE, where he assumed the role of secretary general. Even more importantly, he was central to the revival of the League in 1935 and republication of *Epilepsia* again in 1937. The 1928 English edition of his book *Epilepsyâ€"Comparative Pathogenesis, Symptoms, Treatment*[186] (preceded by Dutch and German editions) offers a documentation of his experimental work on epilepsy and clinical and sociologic aspects of the disease.

In his experiments on myoclonic seizures in animals, he used a toxicologic approach. He thought that myoclonic activity was in fact reflex afterdischarge phenomena, and convulsive activity comprised an adaptive process designed to rid the body of toxic substances causing the seizures. He sited the seizure activity in brainstem structures, but accepted an additional cortical influence on these â€œmedullary convulsive centres.â€ His conceptualization of the type of experimental epilepsy he studied bears similarities to that of Prichard[205] emphasizing the role of reflexes in seizure generation. It is the final chapter of this book, where he discusses the global problem posed by epilepsy and describes his experience in the early days of the ILAE, that contains his main message to his colleagues working in this discipline. This message of advocacy for international cooperation for advancing both clinical enterprise and research in epileptology by a cooperative global effort has accorded him, though only recently, with his proper place in the history of epilepsy.[85]

Samuel Alexander Kinnier Wilson (1878â€“1937) can be considered Hughlings Jackson's direct heir. His early discovery, however, of hepatolenticular degeneration in 1912 delayed his entry into epileptology. His first communication on epilepsy was on â€œTemporo-sphenoidal forms of Idiopathic Epilepsy.â€[249] Jackson et al. had well documented that â€œcoarse pathologyâ€ (tumors, infarcts) occupying the temporal lobe could present with seizures, although seizures could also arise without any evident pathology. The dÃ©jÃ vu phenomenon, which seemed peculiar to temporal lobe epilepsy, could also occur totally unassociated with seizures. Wilson searched for an alternative etiology for these nonepileptic dÃ©jÃ vu episodes and pointed out that except for a few cases due to anoxic damage, most of them were simply inexplicable. Wilson also confronted Jackson's use of the concept of â€œdis-inhibitionâ€ to explain the evocation of the psychic symptoms in temporal lobe seizures. Eventually he reluctantly had to reject this altogether.[25,253]

His Harveian Lecture[250] emphasized the concept of the epilepsies, the absolute failure of the psychoanalytic approach, and the unity of pathophysiology of the many â€œepilepsiesâ€: An explosive hyperactivity of the brain and the primacy of the brain in seizure generation and all clinical manifestations. He took the jacksonian concept of â€œmany epilepsiesâ€ to embrace the potential for seizures to emanate from many areas of the brain, not just the cortex. By the same token, he felt that all epilepsy was manifestly not the same, and that the gloomy view of the condition that persisted in both lay and professional ranks should be abolished, for it handicapped the sufferer in many aspects of life, both medical and social.[252]

During the historical Royal Society's 1927 discussion on epilepsy, he studiously avoided any detailed consideration of metabolic factors in epilepsy, unlike most other speakers. He simply reiterated his concept of the â€œepilepsiesâ€ and then underlined the primacy of the brain alone in seizure generation: â€œâ€¦a fit was the discharge, the setting free, of accumulated nervous energy in healthy neuro-mechanisms.â€[251] In his *Modern Problems in Neurology,*[253] Wilson devoted the first four chapters to problems in epileptology, in which he revised concepts of temporal lobe epilepsy mechanisms, discussed the role of inhibition in epilepsy, emphasized the concept of the â€œepilepsies,â€ and finally offered his usually optimistic prognosis. The psychic symptoms of temporal lobe epilepsy, he decided, were simply a product of local epileptic irritation of that region of the brain, and he formally abandoned the jacksonian concept of disinhibition. He then widened his conceptual views of the overall condition of â€œepilepsyâ€ to embrace a broader range of clinical phenomena. The single most important tenet he emphasized above all was that epilepsy is always symptomatic and never a disease per se. He called for great patience in the study of epilepsy: â€œResearch will eventually disclose the cause of those conditions whose etiology currently eludes us.â€

In the last years of his life, Wilson was able to finish his two most important and almost identical chapters â€œThe Epilepsiesâ€ in Bumke and Foerster's *Handbuch der Neurologie*[254] and his own personal *Textbook of Neurology,* finally published posthumously in 1940,[255] edited by his brother-in-law Ninian Bruce. His immensely detailed grasp of the literature and documentation of the clinical aspects of epilepsy make it a very important resource in the history of the disease.[25] His overall concepts constituted a departure point for the new epileptology that would be ushered in by Lennox to the 1935 London Congress on the use of EEG in the study of epilepsy, an innovation that would change the concept of the condition forever.

W. A. Adie (1886â€“1935) introduced pyknolepsy to an English audience in his address to the Royal Society of Medicine.[1] Although this form of epilepsy had been reported by Friedmann[97] and Heilbronner,[130] Adie emphasized its uniqueness with its many, frequent short-duration attacks; occurrence in the early years of life; explosive onset; and excellent prognosis, and maintained that these features distinguished it from all other forms of epilepsy. In the discussion that followed it was reported that â€œhe was inclined to agree that the disease is only a variety of epilepsy, but its clinical characters are so distinct that it seems worthy of a separate name.â€ Adie introduced the concept of syndromology, with which epileptology continues now to be engaged in reformulating and revising. His work could only be matched by Herpin[132] and Janz and Mathes's early papers[148] that delineated juvenile myoclonic epilepsy.

By the 1930s, a variety of medical, social, and legal issues relating to the care of persons with epilepsy had led to the foundation of the ILAE; the foundation of a dedicated journal, *Epilepsia*; the formation of a number of charities, institutions, and colonies for persons with epilepsy; and an increasing interest in medical research by philanthropic individuals and organizations. Hughlings Jackson's concept of the discharging lesion certainly brought the cerebral cortex into focus as the structure most intimately involved with the production of â€œfits,â€ but the wide variation in the epilepsies, in their age of onset, semeiology, hereditary nature, and course, seemed to defy an explanation based largely on gross lesions of the cerebral hemispheres. These developments certainly produced a medical culture that fostered the study of the epilepsies that influenced epileptology during the 1930s and 1940s, particularly due to the rise of electroencephalography.

Electroencephalography and the Origins of Modern Epileptology

Experimental Electroencephalographic Recordings during Animal Seizures

Experimentally induced seizures were first recorded electroencephalographically by Kaufmann in 1912 in Russia.[158] After reading about spontaneous and evoked electrical activity in

the brain, he hypothesized that abnormal brain waves would be present during seizures. By curarizing his dogs and performing meticulous craniotomies, he was able to ascertain that abnormal waves seen during tonicâ€“clonic seizures originated in the cortex and were not injury potentials, movement artifacts, or evoked potentials. Like his predecessors, Kaufmann had no facilities to photograph his data. That same year, also in Russia, the first actual records of EEGs and evoked potentials in animals were preserved photographically and published by Pravdich-Neminski.[202] Two years later, Cybulski and Jelenska-Macieszyna[72] published the first photographs of paroxysms of abnormal cortical EEG activity during experimental seizures. The paroxysms were of very much higher voltage than with spontaneous activity, but their galvanometers were too sluggish to record EEG spikes.

The Human Electroencephalogram

The modern era of epilepsy might be dated to 1929, when Hans Berger (Fig. 8) in Jena, Germany, published his discovery that the brain's electrical activity could be recorded from humans using electrodes placed on the scalp.[16] Berger's eccentric research career, beginning with his studies of cerebral blood flow and culminating in his studies of the human EEG, has been detailed elsewhere.[37,118,183] Berger viewed the dynamic, psychophysical interaction between mind and brain in terms of thermodynamics, and he systematically attempted to measure the energy delivered to the brain and transformed into heat and electricity within the cerebral cortex. In this way, Berger hoped to arrive at a physical measurement of â€œpsychic energy,â€ the component of cerebral energy that was transformed into emotions, sensation, feeling, and rational thought. By 1931, he reported interictal EEG changes in epilepsy, and later that year he recorded human spike-and-wave activity. With funding from the Carl Weiss Foundation to construct a high-impedance vacuum tube amplifier with a high-frequency response of 125 Hz, he was able to produce a more faithful EEG recording. Berger's report in 1932[118] contains a series of four photographic segments showing progressive EEG changes following a generalized tonicâ€“clonic seizure as brain activity returned toward normal during an 11-minute period on a 53-year-old patient. A report in 1933[17] shows a segment of recording from an 18-year-old girl during a brief period of simple automatic activity â€œwith no other movement.â€ It appears to be very-high-voltage spike-and-wave complexes at about 3 Hz (Fig. 9). Berger cited the classic animal experiments of Caton in 1875,[51,52] as well

P.29

as later reports by Beck in 1890[12] and Beck and Cybulski in 1892[13] on desynchronization of spontaneous cortical activity in dogs and rabbits produced by light and other sensory stimuli.

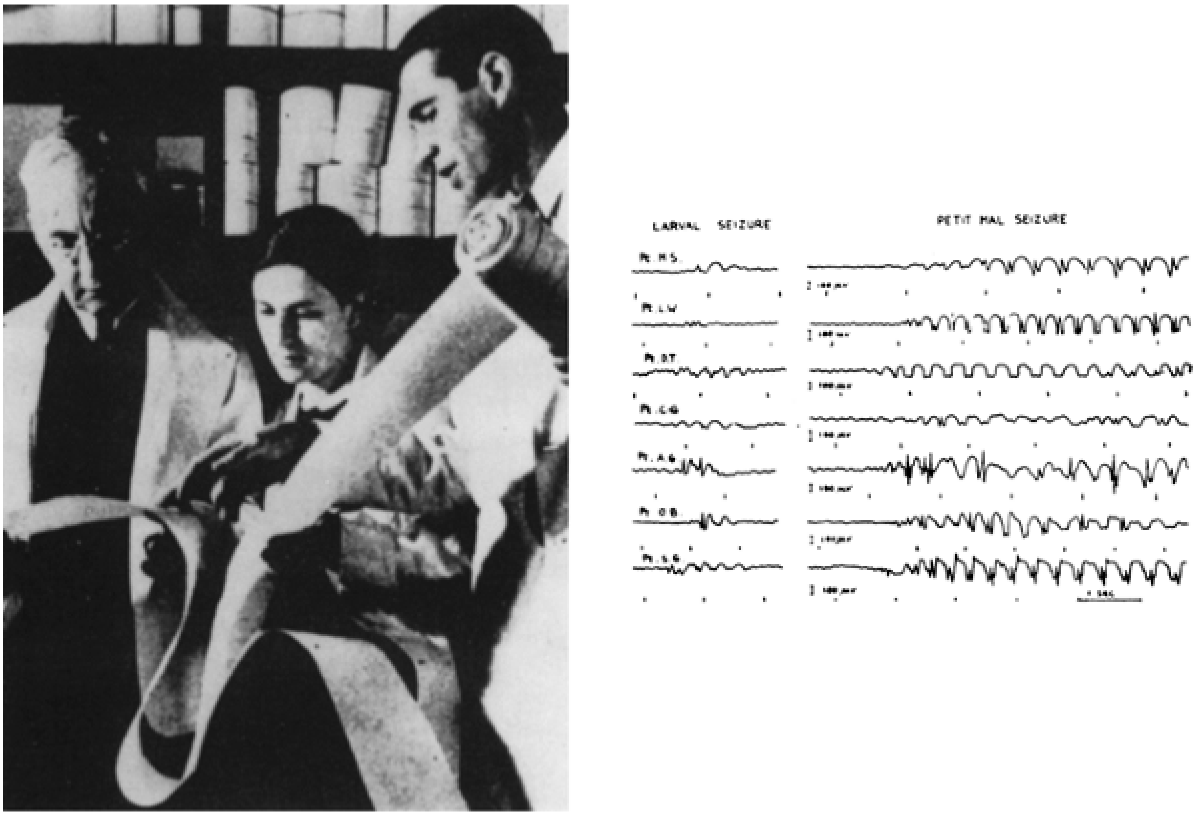

FIGURE 10. Left: William G. Lennox, Erna Gibbs, and Frederick Gibbs (left to right, about 1936) examining an electroencephalogram (EEG) in the Boston City Hospital laboratory. (Courtesy of Ellen Grass, personal collection.) **Right:** The first published recording of the EEG during epileptic attacks from nine of Lennox's petit mal patients by Gibbs, Davis, and Lennox in 1935. The continuous 3-Hz spike-and-wave complexes were associated with impaired consciousness. (From Gibbs FA, Davis H, Lennox WG. The electro-encephalogram in epilepsy and in conditions of impaired consciousness. *Arch Neurol Psychiatry.* 1935;34:1133â€"1148, with permission.)

Although Berger's early papers described his experiments in detail and were supported by numerous photographs of the electroencephalograms, the immediate reception to Berger's work at home was one of open hostility, while the unanimous reaction outside of Germany was one of disbelief. Indeed, most physiologists assumed that Berger had simply recorded some biologic or environmental artifact.[29,182] Berger's approach to understanding brain function was at odds with the main thrust of 1930s German neurophysiology, which had become intensely focused on the problems of cortical localization. Indeed, the leaders of German neurophysiology working at the Kaiser Wilhelm Institute for Brain Research in Berlin considered Berger a naÃ¯ve amateur who rejected the prevailing logic of cortical localization and ignored recent developments in electronic amplification.[156] As his opponents attempted to identify hundreds of different cortical areas in terms of their electrophysiologic profiles, they frequently defined their project in contradistinction to Berger's â€œholisticâ€ interpretation of the EEG, and resisted use of the term â€œelectroencephalogramâ€ due to its holistic connotation.[29,182]

Validation for Berger's work on the human EEG came in 1934, when the distinguished Cambridge physiologist

E.A. (later Lord) Adrian demonstrated *a* blocking in a recording made by Bryan Matthews and presented before the Physiological Society.[2] By this time, a number of research groups in North America had also turned their attention to the human EEG. The first recording of an EEG in North America was obtained in the winter of 1933â€“1934 in Hallowell Davis's physiology laboratory at Harvard University. Subsequent demonstrations in Davis's laboratory kindled the interest of three young researchers, William Lennox, Erna Gibbs (nee Leonhard), and Frederic Gibbs, who had been primarily focused on measuring blood gases in experimental animals and patients in order to test the prevailing vasomotor theory of ictogenesis.

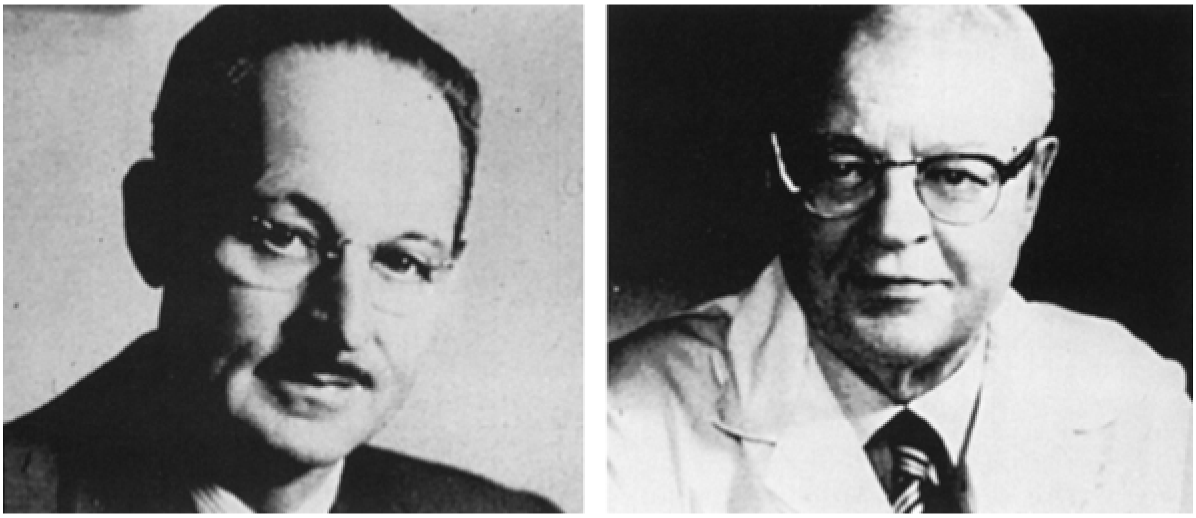

FIGURE 11. Tracy Putnam (1894â€“1975) **(left)** and H. Houston Merritt (1902â€“1978) **(right).** Their studies marked the end of using pure empiricism in finding new anticonvulsant drugs. Their imaginative approach and disciplined method identified phenytoin and instituted a method for evaluating potential anticonvulsants that remained in use for many years.

The Electroencephalographic Contributions to Epilepsy

A growing number investigators quickly transformed EEG from a scientific curiosity into a promising clinical tool. The first recording of the â€œegg and dartâ€ or â€œspike and domeâ€ pattern of petit mal seizures occurred in Davis's laboratory in December of 1934. This discovery ignited an explosion of EEG research in the Boston area. Using a single-channel vacuum tube amplifier and ink writer, Gibbs et al.[109] demonstrated that convulsive and absence seizures were accompanied by different EEG patterns and that â€œlarval seizuresâ€ (i.e., interictal discharges) frequently demonstrated the same morphology as the corresponding ictal rhythm. Over the following year, Gibbs et al. (Fig. 10) described EEG patterns that accompanied â€œpsychomotorâ€ seizures, the use of hyperventilation in provoking seizures, and the effects of phenobarbital and sodium bromide on the interictal EEG, and they performed the first invasive EEG recordings in a patient with intractable epilepsy.[110,163,167]

P.30

In 1936, Jasper[150] independently demonstrated focal spikes in localization-related epilepsy. At about the same time, Putnam and Merritt (Fig. 11) embarked on their systematic survey of potential anticonvulsant compounds in the neurologic research laboratory at Boston City Hospital. Putnam later recalled that it was Gibbs's belief that â€œevery true seizure is attended by an electrical â€˜stormâ€™ in the brainâ€ that led to the adoption of an electroconvulsive threshold model (in contrast, for example, to strychnine, camphor, or pentylenetetrazol models) for screening potential antiepileptic drugs.

By 1937, the Gibbses and their colleagues had redefined epilepsy in modern terms: â€œEpilepsy: A Paroxysmal Cerebral Dysrhythmiaâ€ clearly distinguished ictal EEG patterns for petit mal, grand mal, and â€œpsychomotorâ€ seizures; demonstrated the presence of subclinical seizures; and suggested a role for EEG analysis in seizure prediction.[111] That year, the first clinical department to formally perform and charge for EEG services in the United States was opened at Massachusetts General Hospital by Robert Schwab. Other hospital laboratories quickly followed. In an effort to establish valid EEG-clinical correlations, the Gibbs and Gibbs championed a â€œrough and readyâ€ approach, relying on Grass's early portable amplifier-ink writer systems that used a two- or three-channel referential montages to screen large numbers of patients. For most clinical EEG work, they advocated using a referential recording technique that seemed like epileptiform discharges, especially the 3-Hz spike-and-wave pattern of petit mal seizures. They also emphasized the visual art of pattern recognition in electroencephalography.[113] Tirelessly pursuing this streamlined approach to clinical EEG, Lennox and the Gibbses classified the epilepsies based on â€œpathognomonicâ€ or archetypal EEG patterns, proposed that one could render a diagnosis of epilepsy based on a clinical history of spells and â€œlarval seizuresâ€ captured in an interictal EEG, demonstrated the increased sensitivity of nonâ€"rapid eye movement (NREM) sleep for detection of epileptiform discharges, and enthusiasticallyâ€"if prematurelyâ€"advocated for the surgical treatment of epilepsy.

Like Frederic Gibbs, Herbert Jasper also became aware of Berger's publications on the human EEG in the early 1930s. Jasper's skepticism of Berger's work faded after he learned of Lord Adrian's EEG demonstration at the June 1934 meeting of the American Neurological Association (ANA). Jasper had recently become director of the psychology research laboratory at the Emma Pendleton Bradley Home near Brown University and, realizing the value of EEG work in understanding cerebral function, he asked Howard Andrews, an electronics engineer from the physics department, to design a suitable amplification and recording system. Jasper had worked mostly in peripheral neurophysiology, and did not want to rely on an ink writer system, because the friction of this apparatus might dampen high-frequency EEG activity. He also recognized the need to record the electrical activity of the brain and combined the high-frequency response of a fast Westinghouse mirror oscillograph with photographic equipment to record the mirror fluctuations. Jasper and Carmichael recorded their first EEG on July 9, 1934. Unaware of the work already under way in Boston, they briefly reported the results of their study of six normal subjects and two pathologic cases to *Science*, the first report on the human EEG from a North American laboratory.[149] Jasper emphasized the critical importance of instrumentation and recording technique in EEG above all else. His early emphasis on bipolar recordings, his insistence on carefully constructed electrodes and oscilloscope-camera or ink-writing systems to avoid artifact and accurately localize EEG abnormalities, and his opposition to using EEG for the classification of seizures and epilepsies resulted in continuing controversy with the Gibbses.

Jasper's early work focused on the physiologic basis of the human EEG, but he soon turned to clinical applications. Initially, he studied two overlapping populations: Patients with epilepsy referred by local physicians[151] and â€œbehavior problem childrenâ€ admitted to the Bradley Home.[71,152] While Jasper's study of children with attention disorders and behavioral problems established the value of routine EEG testing in this setting, it was his study of 55 epilepsy patients that led to the first set of criteria for identifying epileptogenic foci based on ictal and interictal discharges.[151] In 1937, Wilder Penfield visited Jasper's EEG laboratory, which consisted of a maze of chicken wire, and later recalled that inside â€œwas a young man, moving about like a bird in an aviaryâ€¦a rara avis, Herbert Jasper, a young man driven by one creative idea after another. He could, he said, localize the focus of an epileptic seizure by the disturbance of brain rhythms outside the skull. I doubted that but hoped it might be true.â€[199] Penfield finally was persuaded to operate on two of Jasper's subjects whose EEGs had demonstrated a focal

abnormality. With Jasper looking on from the observation room, the predicted lesion was found at surgery, and he invited Jasper to come to Montreal to continue his EEG studies on epilepsy patients.

After 6 months of weekly trips from Providence to Montreal, Jasper and Penfield organized a 4-year research program on the EEG in the epilepsies. Jasper's busy clinical neurophysiology laboratory opened in February 1939. While the Gibbses cast a wide net in their clinical EEG work, exploring EEG patterns in a variety of neurologic and medical conditions and functioning as consultant specialists in the emerging field of electroencephalography, Jasper had the demanding task of routinely predicting the location of a putative lesion during presurgical evaluation on the basis of the EEG findings. Within 2 years, Jasper had evaluated about 1,000 patients in the outpatient EEG department and performed dozens of intraoperative studies, recording the electrical activity of the cerebral cortex surface, subcortical structures, and epileptogenic lesions (in 1960). Penfield and Jasper provided the first descriptions of the focal and generalized seizures, distinguished the EEG correlates of tonic and clonic seizure activity, described the interictalâ€"ictal transition and the propagation of ictal rhythms across the cerebral cortex based on a series of electrocorticography studies, and concluded that persistent epileptiform discharges on electrocorticography after surgical resection had little prognostic value. Perhaps most importantly, Jasper and Penfield reported that using Jasper's bipolar EEG technique, scalp EEG recordings from patients being evaluated for surgery accurately predicted a surgical lesion within 2 to 3 cm in 85% of cases. These electrocorticography studies led Penfield and Jasper to distinguish the â€œseizure onset zoneâ€ from the â€œepileptogenic lesion,â€ which, at the time, was typically visualized on a pneumoencephalogram. It is difficult to clearly establish the impact of EEG on the success of epilepsy surgery during these early years of EEG, but one account describes a dramatic increase in surgical cases[168] and others suggest a precipitous decline in negative surgical explorations, from approximately 50% prior to introduction of routine presurgical EEG to <10% by 1940.[168,203]

As a result of these stunning breakthroughs in epileptology, dozens of investigators in North America, England, and Europe began using EEG in the late 1930s and 1940s. They used the EEG to explore a range of issues in epilepsy, including heritability, pathophysiology, localization, surgical treatment, and classification.

The Electroencephalogram and Seizure Classification

From the standpoint of classification, the EEG findings introduced a critical, physiologic axis for the taxonomy of seizures and epilepsy syndromes. Although phenomenologic distinctions between minor and major types of seizures had existed for centuries, etiologic or physiologic classification had been elusive. Indeed, Craig Colony president F. Peterson lamented in 1897 that such taxonomy â€œis not possibleâ€¦in light of the present knowledgeâ€¦[but] would be more scientific and valuableâ€ than existing systems. The physiologic basis of the EEG, along with the initial appearance of a clear relationship between â€œpathognomonicâ€ electrographic abnormality and seizure type, fostered early enthusiasm for a thoroughgoing revision of existing classification systems. Lennox's and the Gibbses' confidence in the paramount value of the EEG in all aspects of neurologic and psychiatric diseaseâ€”even supervening on clinical signs and symptomsâ€”was clearly evident by 1938:

â€œWe believe physicians should consider dysrhythmias of the electrical waves of the brain as primary and various clinical manifestations of dysfunction of the brain or of the mind as secondary. Abnormal cortical waves may not be demonstrable with the technique available but when they are present they should take precedent in classification, in nomenclature and possibly in treatment.â€[112]

Thus, after their initial descriptions in the mid-1930s of characteristic EEG patterns associated with petit mal, grand mal, and psychomotor seizures, Lennox and the Gibbses later described these EEG patterns in terms of their clinical semeiology. These enthusiastic generalizations were soon challenged by other investigators,[93,153] who failed to find a correlation between clinical seizure types and EEG patterns in larger populations of epilepsy patients. Jasper[153] was particularly critical of such correlations, pointing out that many clinical diagnoses were based on interictal EEGs and that particular EEG patterns were not predictive of clinical semeiology. Complaining that â€œonly confusion arises from the attempt to use clinical terms, grand mal, petit mal and psychomotor to describe types of electroencephalogram,â€ Jasper focused instead on organizing epileptiform EEG abnormalities based on localization (localized, diffuse, or bilateral) and frequency. Despite such early precautions, however, the EEG quickly became a critical tool in the classification of seizures, providing physiologic evidence for the distinction between â€œfocalâ€ and â€œcentrencephalicâ€ seizures by Penfield and Jasper,[197,198] and for the characterization of temporal lobe epilepsy by Gastaut.[102]

Simultaneous Video-electroencephalographic Recordings

The first investigator to design a laboratory for the simultaneous recording of EEG and motion pictures actually had nothing to do with the study of seizures or epilepsy! In 1935, Alfred Loomis, a Wall Street investment banker turned private scientist, had independently discovered the alpha rhythm in his efforts to improve electrocardiography recordings with additional electrodes. Loomis had been fascinated by hypnotism since childhood and the discovery of â€œbrain rhythmsâ€ led him to the study of the EEG changes during hypnosis and sleep. Without any apparent limitations on time, money, or space, Loomis's EEG lab at his Tuxedo Park home contained a bedroom for subjects to sleep and for the first amplification stage; an amplifier room containing two additional stages as well as electrocardiographic and respiration monitors; and a control room located 66 feet away to house the system of three independent sets of high-speed ink writers *and* cathode ray oscilloscopes with cameras for photographic recording of the EEG oscillograph trace.[170,171] As subjects were expected to achieve normal sleep during the experiments, the sleeping room was dressed with heavy drapes. Loomis also equipped the rooms with motion cameras with the fastest lenses available. Infrared film had been specially manufactured by the Eastman-Kodak company and was flown in daily from Rochester on dry ice, and the film was developed in two professional-quality darkrooms in the laboratory.[65]

Around this time, Robert Schwab designed a system using two 16-mm cameras to record clinical seizures and corresponding EEG. Both films had special synchronizing marks that were matched and processed into a composite duplicate, which was shown in 1938 at the 96th meeting of the American Psychiatric Association. Hunter and Jasper later reported a method of simultaneously recording the EEG and clinical seizures with a single camera.[141] The camera was directed at a full-length mirror hanging above the patient and received the image of the patient and the reflected image from the EEG tracing simultaneously through a system of mirrors mounted at angles above the moving EEG paper.

The use of television in the 1950s made the process less cumbersome. The first use of closed-circuit television (CCTV) for simultaneous recording of the EEG and seizures was reported

P.32

in 1966 by Goldensohn.[119] At first, the combined split-screen TV images and sound were transferred from the TV to movie film (kinescopes) and later directly to video cassettes.[74,119] Vacuum tube amplifiers in EEG machines were replaced in the 1960s by transistors invented in 1947 by Bardeen, Bratain, and Shockley. The advent of the transistor improved the quality of the routine ink-written EEG record, but it was of much greater importance for the ongoing revolution in computerized handling of all aspects of EEG information related to epilepsy.

The Epileptogenic Electroencephalographic Spike

Much research in neurophysiology has focused on understanding the cellular electrical activities that generate seizures. Although vacuum tube amplifier technology that could reproduce electrical signals from single neurons had been available since 1906, most laboratories generally took a long time to abandon galvanometers. The Boston physiologist Alexander Forbes was the main contributor to the early development and application of vacuum tube amplification to neurophysiologic research,[94] as described in an appreciation by Eccles.[82]

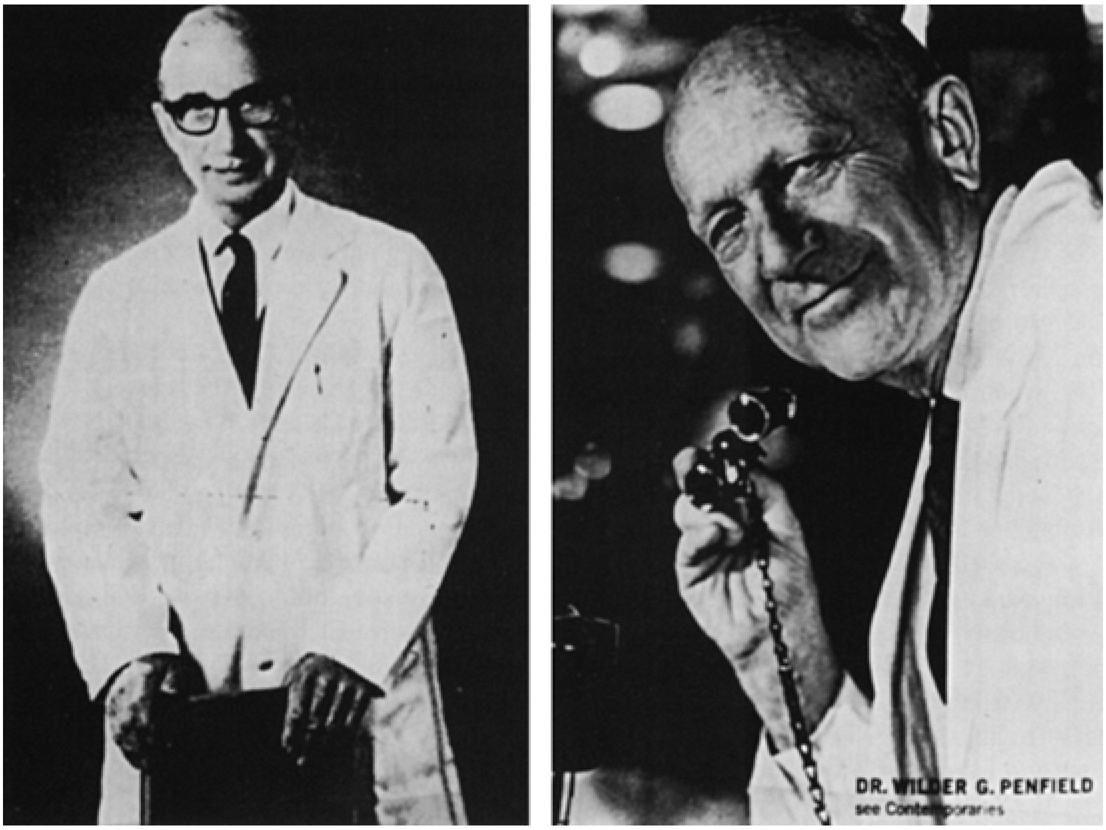

FIGURE 12. Neurophysiologist Herbert Jasper (b. 1906), **(left)** and neurosurgeon Wilder Penfield (1891â€“1976) **(right).** Together, for more than a quarter of a century, they were consistently leaders in applying multidisciplinary scientific and applied advances to the surgical treatment of epilepsy. (Courtesy of the National Library of Medicine, Bethesda, MD.)

At first, most investigators believed that action potentials of axons and cell bodies summated to form EEG waves. Later, the idea emerged that the relatively slow EEG wave might not consist of â€œall or noneâ€ 0.5- to 1.0-msec action potentials, but rather of graded, slower potentials originating at the synapse. Renshaw et al.[212] used extracellular microelectrodes that touched single-cell membranes to show probable relationships between slow potentials of single cells that resembled EEG waves. Li and Jasper,[169] also using extracellular microelectrodes, were able to prevent single-cell action potentials from occurring while slower synaptic potentials temporally related to EEG waves persisted, demonstrating that synaptic potentials, but not action potentials, contributed to the generation of EEG waves. Bishop and Clare[20,57] ascribed surface electrical activity to nonpropagated dendritic potentials, and the concept that brain waves were mainly postsynaptic potentials gathered further impetus. Using high-impedance intracellular electrodes for recording in hippocampal neurons, Kandel and Spencer[157] demonstrated temporal relationships between EEG afterdischarges and transmembrane potentials. With the use of intracellular microelectrodes, Goldensohn and Purpura in 1963 were the first to demonstrate the synaptic origin of interictal EEG spikes in the neocortex.[120] The EEG spikes at the brain surface were found to be summations of depolarizing (excitatory) and hyperpolarizing (inhibitory) postsynaptic potentials (EPSPs and IPSPs) with extreme depolarizations sufficient to prevent firing of the cell. Matsumoto and Ajmone-Marsan in 1964[177,178] described intracellular activity during both ictal and interictal periods and showed that the extreme depolarizationsâ€”paroxysmal depolarization shifts (PDSs)â€”are an essential feature of the spike focus.

Postwar Epileptology: Conceptual Advances

Lennox, in summing up the year's literature for 1944 in *Epilepsia*, remarked: â€œWar the consumer, has drawn the attention of men from the medical problems of epilepsy in the civilian population, and epilepsy as an aftermath of war has not yet had time to assert itselfâ€¦â€

Indeed, this hugely expensive and exhausting war had slowed advances in many areas of medicine to a crawl. Nevertheless, in some areas there had been progress and some special centers had made significant advances.

Wilder Penfield (1891â€“1976) and the Montreal Neurological Institute

For more than a decade and a half, Penfield and his team had been working on the surgical treatment of epilepsy as part of a wider program based on investigating the role of the cerebral cortex of man.[168,200] Penfield and Jasper (Fig. 12) had become experts in applying EEG methods to epilepsy research and practice. Their concept of the centrencephalic system and its role in the mechanisms of what today would be called primary generalized epilepsy[197,198] played a major role in subsequent attempts at seizure classification. In fact, Penfield and Erickson[196] had already made one of the earlier attempts at establishing a framework for classification of specific phenomena[196] based on data obtained from documenting the localized function of various cortical areas. In spite of its obvious limitations, this served to promote further attempts to organize epileptic phenomena with the intention of advancing research.[179]

Penfield's pioneering work attempted to examine the cerebral cortex under direct observation and following stimulation in the operating room. It stands as the first really significant effort to understand the problems posed by abnormal cortical areas involved in epileptic seizures. In a field that has blossomed with the development of modern neuroimaging techniques, the pioneering work in the electrophysiology of the cerebral cortex and the mechanisms of epilepsy of Jasper and Gloor provided an important window into a largely unexplored area.[117,198] The Montreal program, founded by Penfield et al., carried out by a team of exceptional clinicians and scientists, represents a major milestone in mid-20th century epileptology.[115]

Henri Gastaut (1915â€“1995) and the Marseille School

Postwar European epileptology was notable for the early contributions of the Marseille school led by Henri Gastaut (Fig. 13). His program produced a steady stream of publications on many aspects of epilepsy. Through his skills in organizing and financing important meetings that focused on selected aspects of epilepsy, Gastaut initiated a new wave of international interest and cooperation.

Gastaut et al. organized the important third and fourth meetings of the now legendary Colloques de Marseille series, which introduced temporal lobe epilepsy to an international audience. Gastaut's paper on the â€œSo-called â€˜Psychomotorâ€™ and â€˜Temporalâ€™ Epilepsy: A Critical Studyâ€ was presented as a preliminary report to the Scientific Session of the ILAE meeting in Lisbon in 1953. In this he produced a well-documented, wide-ranging study of this topic and included an extended discussion of the subject by a number of international experts who had attended. The fourth Colloque de Marseille in 1954 discussed the pathologic anatomy of temporal lobe epilepsy and it was followed 3 years later by a meeting in Bethesda, Maryland, in which a large number of international experts covered many aspects of the topic. By now a substantial number of centers in several countries had begun resective surgery programs for this type of epilepsy. Gastaut and the Marseille school had played a significant role in arousing international interest in temporal lobe epilepsy.[9,44,102,104]

His 1954 book *Epilepsy: Electro-Clinical Correlations*[103] attempted to present a current account of the mechanisms of epileptic seizure generation in the different forms of epilepsy. Synthesizing the rapidly increasing information on neurophysiologic data from his extensive clinical investigation of patients with various forms of epilepsy, Gastaut introduced new and provocative concepts to explain both partial and generalized seizure forms. His ideas pertaining to the generalized epilepsies

were particularly novel. Eight years later, Gastaut collaborated with Roger Broughton[108] to revise the work in light of more recent data. He then initiated the task of encouraging international neurology to attempt to classify seizures, a work that has continued to progress since that time.

Gastaut's work with Fischer-Williams established the essential electrical and clinical differences between syncope and epilepsy, a problem that had dogged clinical studies in this area for centuries.[105] This contribution was followed by his description of what eventually became known as the Lennox-Gastaut syndrome.[106] Finally, his 1969 classification of epileptic seizures on clinical and EEG criteria (with his dismissal of the concept of â€œidiopathic epilepsyâ€) stands as one of the early attempts to marry the clinical and technologic data to form an organized system of epileptology.[107] Gastaut's unit constituted a powerhouse of European epileptology in the immediate postwar period. His introduction of novel concepts and his research into many facets of this discipline formed the basis for important advances.

Bancaud and Talairach and L'HÃ´pital St. Anne in Paris

Bancaud (1921â€"1994) and his neurosurgical colleague, Talairach, at the L' HÃ´pital St. Anne used specially designed stereotactically implanted electrode arrays to record and plot the paths of various seizure patterns, thus introducing stereoelectroencephalography. With this technique, they demonstrated that seemingly focal seizures could in fact originate from a focus distant from the area of final expression. Bancaud's concepts regarding the spread of the process of focal epilepsy allowed extensive broadening of current thinking about the origin and spread of focal epileptic seizures.[10]

Medical Treatment of Epilepsy: 20th-century Developments

Though some of the older antiepileptic remedies of dubious efficacy had not been completely abandoned, by the beginning of the 20th century, the various bromide salts, particularly potassium bromide, had become the mainstay of the drug therapy of epilepsy. The next effective antiepileptic agent to be recognized was phenobarbital (phenobarbitone). In 1912, Hauptmann,[128] while using it to tranquilize patients, realized it had suppressed the seizures of those who also happened to suffer from epilepsy. Subsequently, two of its congeners, mephobarbital (*N*-methylphenobarbitone)[26] and primidone (desoxy-phenobarbitone),[126] were found effective in treating epilepsy.

Up to this point in time, effective antiepileptic drugs had been discovered by chance during their administration to humans for other purposes, or had been tried in the treatment of epilepsy because of chemical structural analogy with antiepileptic molecules. In the late 1930s, however, Putnam and Merritt began to systematically study in experimental animals molecules with structural resemblances to phenobarbital to find new antiepileptic agents. They tested several hydantoin derivatives (in which the central heterocyclic ring of the molecule lacked one of the carbon atoms of the barbiturate ring) and found that phenytoin (diphenylhydantoin) had an apparently promising balance between sedative and antiepileptic properties. It proved to be effective when tried in human epilepsy[181] and thereafter came into increasingly widespread use. Friedlander[95] has recorded in detail the story of its discovery. Other hydantoin derivatives, such as mephenytoin, were later developed and used in humans, but all proved unsatisfactory for reasons of lesser efficacy or toxicity.

The success of the Putnam-Merritt approach led to further experimental animal studies attempting to find other small

heterocyclic molecules with potential antiepileptic properties. Beginning with troxidone (trimethadione),[166] various oxazolidinedione derivatives were shown effective in controlling absence seizures in which barbiturate and hydantoin derivatives were ineffective. Subsequently, succinimide derivatives, in which an oxygen atom replaced one carbon atom in the oxazolidinedione ring, were tested and proved more satisfactory than the oxazolidinediones.[256] Carbamazepine, a dibenzazepine derivative and a congener of the antidepressant imipramine, was tested for antiepileptic activity by the pharmaceutical firm Geigy Ltd. in the 1950s and came into increasing use in humans during the following decade.[221] The next antiepileptic agent, valproate (used as free acid or sodium or hemisodium salt), was discovered by chance. Initially used in 1961 as a solvent for possible antiepileptic agents in experimental animal studies, it became clear that the solvent, and not the putative agents, was the effective antiepileptic substance.[222] Other agents with some effectiveness against seizures (e.g., sulthiame, clonazepam, and other benzodiazepine derivatives) were discovered and came into some use during the 1960s and 1970s. Additional antiepileptic drugs have since been discovered as the outcome of strategies based on several approaches,[220] random screening of numerous molecules with a wide range of chemical structures (e.g., felbamate), testing structural analogs of known antiepileptic agents (e.g., oxcarbazepine, levetiracetam), and rational attempts to modify known factors believed to facilitate epileptic activity (e.g., vigabatrin, lamotrigine, tiagabine, gabapentin). Reminiscent of ancient dietary recommendations, the ketogenic diet has been used since 1922 with some success in controlling seizures, mainly in children with drug-resistant epilepsy.[66]

Seizure Surgery in the 20th Century: Early Days

Surgery for epilepsy has a history dating back to antiquity, although not always confined to the skull and brain. Trepanation (opening the skull) for seizure relief dates back to antiquity and pre-Columbian times.[69] In addition, Cooke[67] had documented surgery for the removal of peripheral lesions thought to cause local irritation, in turn triggering seizures in the area of focal fits. Since seizures were considered equivalent to the orgasm, and onanism or genital irritation were linked by Tissot to seizures, surgery on both male and female genitalia was practiced at various times, particularly after the 18th century.[21,78] Bacon[7] recommended castration as an extreme method of seizure prevention. Gowers,[121] however, condemned it with authoritative brevity: â€œCastration has been proposed as a remedial measure, and this has been performed without effect.â€

Jackson's famous footnote[146] to his article on â€œA Particular Variety of Epilepsyâ€â€”â€œI have suggested that the radical cure of fits in such cases is for the surgeon to cut out that discharging lesion, as well as the tumor, if there be one, producing itâ€â€”was the first suggestion of a potential surgical cure.

Surgery for intracranial lesions, guided solely by clinical localization alone, had been practiced early in the final quarter of the 19th century,[42] and by the time of Jackson's writing Macewen in Glasgow and Horsley in London had been performing resections of symptomatic lesions.[137,138,139,156,172,229] Macewen had targeted tumors presenting with seizures, while Horsley was assisted by Hughlings Jackson in the selection of the operative site to remove posttraumatic lesions producing

focal fits. Most importantly, Jackson's footnote showed his realization of two important principles: The allocation of this special type of seizure to the temporal lobe and the need to remove not only the tumor, but also the epileptogenic cortex.

Early in the 20th century a small number of specialized, mainly European, neurosurgeons were engaged in seizure surgery,[86] such as Krause in Berlin. Epilepsy surgery, however, began to flourish during the interwar era, the second and third decades. Foerster of Breslau is known as an early pioneer, because of his mentoring relationship with Penfield during the Penfield's study visit in 1928. Surgery was directed to remove lesions discovered at operative exploration and actual extirpation was achieved by encompassing all visibly abnormal tissue. In 1934, Penfield at the Montreal Neurological Institute introduced the development of a special team to investigate all aspects of preoperative diagnosis, identification and localization of the epileptic focus. In the postwar years, the introduction of comprehensive management programs to care for the patient with epilepsy in all aspects, both medical and social, constituted a major advance in the overall treatment of epilepsy.[87,88]

The Electroencephalogram, Refractory Epilepsy, and Seizure Surgery

The tremendous impact of EEG on epileptology has been described above, and the impact of this new technique on epilepsy surgery cannot be underestimated. Particularly in North America, which was spared from the destructive effects of World War II, electronics technology saw tremendous advances during the 1940s. These developments allowed the United States and Canada to gain an advantage in applying this novel and productive technology for the investigation of patients with epilepsy surgery by the end of the war.

Evidence for a common pathologic-anatomic substrate for medication-refractory epilepsy, namely, sclerosis of the mesial temporal structures, had been known from postmortem studies since the early 19th century. Yet, the significance of what is now known as â€œhippocampal sclerosisâ€ and its association with epilepsy was much debated.[31,185,255] Consequently, mesial temporal sclerosis had not been of much neurosurgical interest until the advent of the EEG revealed the central role of this condition in temporal lobe epilepsy and introduced newer concepts in its surgical treatment.[89] The first major development in the treatment of refractory epilepsy was the discovery by Gibbs et al.[114] that EEG recordings of patients with so-called â€œpsychomotor epilepsyâ€ revealed a spike focus over the anterior temporal lobe. This discovery was soon followed by the publication of a series of temporal lobectomies for intractable epilepsy based on EEG findings.[8] A small series consisting of five patients subjected to anterior temporal lobectomy without the use of EEG was published by Morris,[184] who correctly emphasized the necessity to remove all the medial temporal structures for effective surgery.[24,89] A larger series of temporal lobectomies for intractable epilepsy was published by Penfield and Flanagan[196] that same year. This nearly simultaneous publication of several surgical series, some of which were guided by EEG data, has led to subsequent controversy about the historical priority. It is also unclear whether Jasper believed that the EEG findings were not specific for a localized epileptogenic zone within the temporal lobe as Gastaut[102] has suggested, or whether Penfield, despite Jasper's opinion, was not convinced of the specificity of the EEG activity to a temporal origin.[153] In any case, it is clear that the first significant series of temporal resections for intractable temporal lobe epilepsy, guided by EEG both preoperatively and intraoperatively, was produced by Bailey and Gibbs,[8] who deserve recognition for this important contribution.[86]

Thus, less than a century after Hughlings Jackson had floated the concept of radical neurosurgery â€œto cut out the discharging lesion,â€ surgery was proven feasible and was set to take its place in routine epilepsy management. Temporal lobectomy for refractory epilepsy was performed in many centers and interest in this very common form of epilepsy and its surgical treatment intensified. The Marseille Colloquia in 1952 and 1953 generated a great deal of international enthusiasm for temporal lobe epilepsy[104] by delineating this syndrome. In the Bethesda, Maryland, meeting in 1957, a large number of contributors from all over the world presented their data.[9] As Bailey remarked, Lennox had â€œâ€¦called the psychomotor epilepsies a crossroads, a meeting ground for various disciplines and research-minded men.â€ It has produced a stream of significant data on the operative treatment of temporal lobe epilepsy, but also on the pathologic etiology and innovative approaches to pre- and postoperative effects of the epilepsy and the surgery.[24] Falconer's concepts of temporal lobe epilepsy and mesial temporal sclerosis[89] and Taylor's introduction of the concepts of cortical dysplasias[229] had constituted significant milestones.

Since then, several epilepsy programs have been established in many countries.[86] The introduction of informative neuroimaging modalities and the use of modern technologies to monitor and record seizures would not only effect radical change in the diagnosis and surgery of epilepsy of focal origin, but along with the radical advances in the genetics of epilepsy, also effect changes in conceptual epileptology at the beginning of the 21st century, seemingly unbelievable to Ford Robertson and his optimistic opinion in the year 1900.

Summary and Conclusions

Over the centuries attempts to understand and explain epilepsy have been plagued by religious, social, and even â€œscientificâ€ explanations. Demonic possessions, the â€œvital spirits,â€ â€œmetabolicâ€ causes, psychoanalytic explanations, or even personal dislikes as well as political oppression were among the factors that had to be fought against to allow progress.

Nevertheless, any advice in our understanding of epilepsy has followed a philosophic or scientific progress or major technologic discovery. By explaining natural phenomena as physical forces and not divine acts, the philosophers of Ionia probably paved the way for Hippocrates' disconnection of epilepsy from the supernatural and connection to the brain. Similarly, the progress in anatomy and physiology, and in particular the observations and experiments in cortical localization of specific functions, influenced Jackson's innovative concepts. The discovery by Galvani and others of nerve and muscle electricity led eventually to Berger's invention of EEG, which revolutionized modern epilepsy. The subsequent development of imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) as well as functional imaging such as single photon emission computed tomography (SPECT), positron emission tomography (PET), and functional MRI gave new insights into our understanding of epilepsy.

The current explosion in molecular biology and genetics has been opening new horizons in the study of specific epileptic syndromes and will hopefully lead to the discovery of new specific antiepileptic drugs to control or even prevent the occurrence of seizures.

Chapter 4

Sociocultural Perspectives

Leon Eisenberg

Introduction

The clinical course of epilepsy is the result of two vectors: The pathophysiology of the disease process and the social context in which the patient lives. The objective of this chapter is to outline the sociocultural factors. A century ago, when there were no effective treatments, clinical course was primarily a function of the underlying biology of the disease. Today, the very successes of medicine and surgery in seizure control[2,9,28] have made the sociocultural factors that govern access to care major determinants of illness trajectory.

In respect to health and illness, the term *sociocultural* focuses on three aspects of social life: First, the set of beliefs by which the members of a community understand the workings of the world they inhabit (and, in particular, the theories they hold about the cause and cure of disease); second, the methods, the techniques, and the organizational means by which care is provided to those who are judged to be sick; and third, the class structure of the community, which governs the likelihood of becoming ill, as well as the probability of receiving care. The world over, those with the fewest resources (in both industrialized and developing countries) are at the greatest risk of becoming ill and are the least likely to receive health care, a phenomenon that the British physician Julian Tudor Hart[14] has termed â€œthe Inverse Care Law.â€

When Western physicians think of culture, they are likely to associate it with the exotic: The beliefs held and the practices observed among peoples remote in space or time from modern Western â€œcivilization,â€ which is assumed to be â€œrationalâ€ and â€œscientific.â€ This cultural chauvinism is a major handicap in analyzing health problems in developing countries. It overlooks the problematic nature of the â€œculturalâ€ beliefs of our own Western medical community; some of what we take to be true is firmly evidence based; much of it is based on no more than the oral tradition physicians call â€œclinical experience.â€ Attributing â€œbeliefâ€ to the â€œnativesâ€ and â€œrationalityâ€ to the â€œdoctorsâ€ is a source of grievous error. Misused, the concept of â€œcultureâ€ can obscure our recognition of the financial and organizational barriers to care and can tend to blame the victims for their own misfortune.

A particularly tragic instance has been described in eloquent language by Anne Fadiman.[10] The book's title, *The Spirit Catches You and You Fall Down*, is an approximate translation of the term for epilepsy among the Hmong peoples, who attribute the disorder to spirit possession and believe it should be treated with animal sacrifices. The Hmong parents, recent refugees from Laos, had no understanding of Western medicine; the doctors in California had no knowledge of Hmong culture. Misunderstanding between physicians and the parents and conflicts between the physicians and the Hmong shaman the parents consulted resulted in brain death even though all of those involved acted from humane intentions.

Medical understanding is always incomplete; it changes as new paradigms arise. Not so long ago, doctors shared the prevailing pessimism about epilepsy and employed desperate, though unavailing, remedies. As recently as 1968, Rodin wrote that four-fifths of all patients with epilepsy are likely to go on to a chronic seizure disorder, as cited by Reynolds.[20] He was echoing Gowers's[13] view that â€œthe spontaneous cessation of the disease was an event too rare to be reasonably expected.â€ Recent studies reveal completely reversed odds. Population-based data reveal that no more than 20% to 30%, rather than 80%, of newly diagnosed patients develop chronic epilepsy. The National General Practice Study of Epilepsy[4] reported that 3-year remission rates were 87% and 5-year rates 71% for idiopathic epilepsy.

Doctors have done far worse than cast a gloomy prognosis. Nineteenth-century physicians dosed patients with bromides, opium, and snake venom extract; they drilled holes in the skull and removed ovaries. As these radical ministrations failed, physicians invoked hereditary explanations that focused on degeneracy and made epileptics into moral lepers.[8] Epilepsy was equated with madness and criminality. Those medical opinions lent credence to early 20th-century immigration laws that restricted the entrance of epileptics into the United Statesâ€"laws not changed until 1965. By the late 19th century, discouraged and frustrated by the failure of even desperate treatment measures, the medical community concluded that epileptics would be â€œbest offâ€ in isolated, out-of-sight communities where, in the euphemistic language of the day, they would receive â€œthe best possible care and treatment.â€ One of the first such institutions, Craig Colony for Epileptics, opened in southwestern New York state in 1896; it did not change its name until 1967.[8] This history is not cited to judge our predecessors with the wisdom of hindsight but to remind us of how widespread ignorance and superstition were in our Western medical culture until phenobarbital and phenytoin revolutionized care in the second third of this century.

Historical Belief about Epilepsy

Epilepsy is an ancient disease that has been â€œexplainedâ€ for as long as it has been perceived. Its manifestations invite arcane theories of its causes and its meanings. Seizures are dramatic, public, and frightening. They occur with unpredictable frequency in unexpected places. The forced cry, the loss of consciousness, the fall, the twitching, and the foaming at the mouth suggest possession by a spirit. The antiquity of the recognition of the disease is attested to by an Akkadian text from the second millennium BC. It describes someone whose neck turns left, whose hands and feet become tense, whose eyes stare wide open, whose mouth froths, and who loses consciousness.[25]

P.42

A Babylonian text dated from the middle of the first millennium BC deals with epilepsy, â€œthe falling disease.â€ Its manifestations were attributed to the work of demons and ghosts that â€œpossessedâ€ the victim during the seizure.[31]

Epilepsy was the subject of the first monograph on a single disease.[25] The Hippocratic text *On the Sacred Disease* was written about 400 BC. It records the struggle between â€œscientificâ€ and â€œmagicâ€ interpretations of epilepsy. Epilepsy, the author asserts, is no more divine than are other diseases. The book attacks magicians, wizards, and charlatans, who called the disease â€œsacred.â€ The alleged divine character, the author insists, is nothing more than a blindfold to conceal ignorant and fraudulent practices.

Although belief that the patient is possessed by an evil demon has been the common response, seizures can also be interpreted as divine possession, particularly if they are heralded by auras of ecstasy, such as those that enrapture Myshkin in *The Idiot*[7]:

> â€œSuddenly in the midst of sadness, spiritual darkness and oppression, there seemed at moments a flash of light in his brain, and with extraordinary impetus all his vital fores suddenly began working at their highest tension. The sense of life, the consciousness of self, were multiplied 10 times at these moments which passed like a flash of lightning. His mind and his heart were flooded with extraordinary light; all his uneasiness, all his doubts, all his anxieties were relieved at once; they were all merged in a lofty calm, full of serene, harmonious joy and hope. But these moments, these flashes, were only the prelude of that final second â€¦ with which the fit began. That second was, of course, unendurableâ€¦. â€œWhat if it is a disease?â€ he decided at last. â€œWhat does it matter that it is an abnormal intensity, if the result, if the minute of sensation, remembered and analyzed afterward in health, turns out to be the acme of harmony and beauty, and gives a feeling, unknown and not divined until then, of completeness, of proportion, of reconciliation, and of ecstatic devotional merging in the â€œhighest synthesis of life?â€â€¦ That it really was â€œbeauty and worship,â€ that it really was the â€œhighest synthesis of lifeâ€ he could not doubtâ€¦. At the very last conscious moment, he had time to say to himself clearly and consciously, â€œYes, for this

moment, one might give one's whole life!â€

Beliefs about Epilepsy in Traditional Societies

Belief in supernatural causes is widespread in traditional societies today: The revenge of aggrieved ancestors; visitation by the devil; ghosts; or the evil eye, witchcraft, and bewitchment. Sorcery is a way of trying to explain the relationship between experienced misfortune and the envy, conflict, hatred, and malice in the community.[27] In Ethiopia, patients may be treated as lepers and banished.[12] Among the Navaho, epileptics were suspected of having committed incest.[19] Informants in Kenya and Ecuador reported that they would not let their children play with known epileptics, nor would they let their children marry into such families.[24] Because of the frequency with which burns follow seizures in cooking areas, epilepsy is known as â€œthe burn diseaseâ€ in some societies.[29]

Where epilepsy is considered to be infectious, patients are shunned. Ideas of pollution and contamination create enormous difficulties for patients and families. What is the origin of the belief in the infectious and toxic nature of the epileptic's saliva? Jilek[15] suggests that it stems from a conflation of epilepsy with rabies, given that rabies manifests itself by agitation, spasms, and terminal generalized convulsions with frothing and foaming. The saliva of rabid patients is indeed infectious. The hypothesis that the confusion between epilepsy and rabies accounts for the belief in contagion is supported by the correlation in Africa between the regions where rabies is endemic and those where belief in the infectiousness of epilepsy is prominent.

There have been two recent studies of public attitudes toward epilepsy in developing societies, one in Tanzania and one in China. Whyte[30] examined beliefs about epilepsy in three rural villages and in one urban community in each of two regions of Tanzania. The most common attribution for the cause of the disorder was supernatural powers: Sorcery by others who were jealous or envious of the victim or his or her parents, spirits, ghosts of departed ancestors, or curses put on children by their parents. Accusations of possession and witchcraft as well as actual social deprivation and ostracism were frequent, as were negative attitudes about marriage, sharing accommodations, schooling, and even physical contact. The label *epileptic* carries so strong a stigma that some families employed elaborate rationalizations to pretend to themselves that their children did not have epilepsy. Four out of five of the patients were not in school, either because the school insisted the child stay at home or because the parents were worried about the possibility of self-injury at school.

Lai et al.[18] studied popular attitudes in Henan province, China. More than 90% of the respondents had heard of epilepsy, and three quarters knew at least one patient with the disorder. Nonetheless, more than half the sample stated that they would object to having their children associate in school with epileptics or play with them. More than half believed epileptics should not be employed in jobs alongside ordinary workers. Almost 90%, whether they were poorly educated or well educated, objected to the idea of having their children marry an epileptic.

Beliefs in witchcraft may flourish where medical care is unavailable, but patients remain concerned about confidentiality, even in industrialized countries where legislation formally protects their rights. In a UK study of patients with a recent diagnosis of epilepsy,[3] 70% of the patients feared that knowledge of their illness might jeopardize their employability. Stigma is still alive and well in the West.

Epilepsy and the Family

Kleinman et al.[17] undertook an ethnographic study of families with epileptic members in two poor and fairly remote regions of interior Chinaâ€"not the China of Beijing and Shanghai. They uncovered extensive emotional, financial, and marital burdens. Stigma, loss of face, and diminished self-esteem were widespread. Ideas that attribute the cause of epilepsy to bad fate, heredity, negative geomantic forces, and the malign influences of gods, ghosts, or ancestors are all accusations about moral status. Moral blame is not applied to the patient alone but extends to the entire family. Patients with seizures routinely experience discrimination in school, the workplace, and the community. The emphasis on social control rather than patient rights in China means that pupils with epilepsy may be excluded from the classroom, workers may not be permitted to carry on with their jobs, and work units may discriminate against patients and families who request more resources for treatment.

Families feel a powerful need to protect the child with epilepsy. They are afraid the child will get no help if a seizure does occur in public because of the general fear of contamination. This results in isolating the patient at home. Overprotection of sufferersâ€"a form of intrafamilial social control aimed at preventing epileptic family members from being shamed and from harming themselves if they have a seizure in a public placeâ€"unfortunately often becomes the chief constraint on the patient's life chances.

The financial consequences of epilepsy can be ruinous. The economic constraints often mean the difference between receiving treatment and not, between remission and relapse. For Chinese parents, a child disabled by sickness means that they are both legally and morally responsible for care until

they or the child die or until the child marries. With marriage, the responsibility for care is shifted to the spouse; thus, there is great pressure to conceal the epilepsy and to arrange a marriage. The illness transforms the economic conditions of everyday life, using up limited resources, deepening debt, and forcing families into humiliating negotiations with creditors.

Help-seeking Behavior

Help seeking, in both rural and urban areas of China, relies on consulting traditional Chinese doctors and various folk healers, herbalists, and religious healers.[17,18] Traditional healers are sought after to counteract witchcraft and sorcery by others. Alert and entrepreneurial healers take full advantage of popular suspicions. The most costly treatments were those administered by healers who were frequently consulted even where free government medical services were nominally available. Patients and families do not actually avoid biomedical treatment; too often they are unaware of it. When they do attend Western-style dispensaries, they complain that they are not given a diagnosis. This is rare among those who consult healers. Healers â€œexplainâ€ the disorder in terms that fit with the culture, explanations that â€œmake senseâ€ of the problem, even if the remedies fail to work.

Adherence to Treatment

Although controlled trials leave physicians in no doubt that anticonvulsants control seizures, their effectiveness is much less clear to individual patients and families. Families come seeking cure rather than suppression of seizures; the notion that continuous treatment is needed to prevent recurrence or that partial suppression is worthwhile when total control is not possible is alien. Patients with epilepsy know from their own experience that seizures may continue in spite of treatment and there may be no seizures during periods of no treatment. In the Kleinman[17] study, more than one in four of the respondents had stopped their treatment altogether because of its perceived ineffectiveness, troublesome side effects, or costs. However, that phenomenon is not limited to â€œtraditionalâ€ cultures.

In U.S. studies, noncompliance with drug treatment averages 30% to 40%, with a range from 20% to 70%.[5] Many patients attempt to regulate their own medication. In their lexicon, they are not â€œnoncompliantâ€; they are â€œmanagingâ€ the control of their own illness on the basis of experience. They take extra medication when they anticipate â€œstressful circumstancesâ€ or sense that a seizure is coming on; they reduce dosage when they are feeling â€œflattened outâ€ and anticipate a special need for alertness. Others suspend medication periodically to see if they still â€œneedâ€ it. If seizures return, they go back on drugs. They resent their dependence on medication and want to see if they can get on without them. Regulating medication is an attempt to assert control over a chronic disorder for which there is no cure.[26]

Does â€œCultureâ€ Bar Modern Treatment?

In traditional communities, resort to more than one type of care is common. The available range of explanations includes somatic, psychosocial, hereditary, and supernatural causes. As Whyte[30] points out: â€œ[This] means that elements of neurologic and psychiatric medicine can be accepted without â€¦ excluding other possible explanations.â€ Western and traditional medicine can coexist peacefully, so long as neither asserts a claim to exclusivity. If the patient takes the medication regularly, it will control the fits. If patient and family choose also to participate in healing rituals, the ceremonies may offer psychologic comfort and repair social rifts without impairing drug action.

Reports from Kenya and Malawi document the success of treatment programs employing a limited pharmacopeia but enjoying strong community support because of the provision of responsive services. At both sites, seizures were fully controlled in about half the patients and reduced in another quarter. The Kenya protocol[11] was carried out by primary health workers backed up by a physician. Outcome was similar to that in industrialized countries where about 70% of patients with newly diagnosed epilepsy can be controlled with a modest dose of a single antiepileptic drug.[2] The Malawi study[29] recruited a remarkably large clientele: More than 3,000 patients attending 45 clinical units distributed throughout the country. The medical officer enlisted the enthusiastic support of area chiefs and village representatives. Patients and families were given an explanation of disease pathogenesis (â€œa scar on the brainâ€) that justified the need for continuous treatment (â€œit takes a long time for the scar to healâ€). Program success was based on communication channels appropriate for the culture, educating health care staff as well as patients, a simple treatment regimen, mobile clinics to make care more accessible, ensuring an adequate supply of drugs, treating without charge, and holding monthly clinics, with the patient seen by the same staff member each time.

Patient education for families in rural areas should stress safety in such simple daily tasks as drawing water from a well, cooking on an open fire, fishing, and other mundane activities. Education for the general public must address stigma and institutional discrimination. To succeed, it must enlist local opinion leaders in a continuing campaign to overcome prejudice and reintegrate patients into school, work, and community life.

Gretchen Birbeck and Roy Baskind[1] held focus group discussions to develop working relationships with ten traditional healers in Zambia. The healers (N'Ganga) recognize epilepsy by means of much of the same symptoms neurologists employ, but they believe witchcraft plays a central role in provoking seizures. Treatment incorporates plant and animal products; if it fails, the healer may refer to other â€œmore powerfulâ€ N'Ganga. If there is evidence of associated systemic illness (brain injury, malaria, high fever), they will refer patients to the hospital for Western treatment. The discussion led to an informal agreement for hospital staff to make periodic visits to the villages to see patients referred by traditional healers and for the healers to be welcome observers on the ward.

Magnitude of the Problem

Is epilepsy an important public health problem? The World Health Organization (WHO)[33] estimates that there are some 50 million people with epilepsy worldwide, more than half not treated properly or not treated at all. Each year, there are some 2 million new cases, half preventable. According to World Bank estimates, epilepsy causes about 9% of the total burden resulting from mental and neurologic disease; among children from 5 to 14 years of age, it is the eighth leading cause of morbidity.[32] The incidence and prevalence of epilepsy are probably several times higher in developing than in industrialized countries, particularly in regions where parasitic infections, notably neurocysticercosis, abound.[23] The treatment gapâ€"the percentage of patients with active epilepsy who are not in treatmentâ€"estimated by the WHO to be 50% the world over, is more than 90% in Paki-stan and the Philippines, and more than 80% in Ecuador.[24] Applying today's methods for prevention and treatment

P.44

could reduce the worldwide illness burden from epilepsy by 75%.

The Outcome of Untreated Epilepsy

There is a striking discrepancy between incidence and prevalence rates in low-income countries. As noted, prevalence is higher than in industrialized societies, but it is clearly not as high as incidence rates would predict, given that untreated epilepsy is a chronic disease. The reason for the failure of prevalence to rise to expected levels in view of the treatment gap could lie either in unexpectedly high remission rates, which seems unlikely,[21] or in differential mortality, that is, death rates for epileptics considerably greater than those in the general population.[22] Is there any evidence for high mortality?

When Dr. Louise Jilek-Aall[16] returned to the Ulanga district of Tanzania, where she had established a successful treatment program from 1963 to 1971, she discovered that her former patients had been without medication for the two decades since her departure. She was able to obtain information on 164 of the more than 200 patients she had treated 30 years earlier. Two thirds were dead! Where the causes of death could be ascertained, half were due to the epilepsy itself: Status epilepticus, death during a seizure, drowning, or burns. The mortality rate among the former patients was far greater than that for the rural population of the area. In contrast, in industrialized countries, where care is widely available, the mortality rate among epileptic patients is only slightly higher than that of the general population. In the light of the â€œtreatment gap,â€ these outcome data reveal a public health problem of serious magnitude.

Summary and Conclusions

Belief that epilepsy has supernatural causes is widespread among the world's peoples. The disorder may be interpreted as the revenge of aggrieved ancestors, as punishment for sinful past behavior by the patient or the family, or as witchcraft cast upon the family by its enemies. Patients may be banished from the classroom, the playground, and the workplace, lest the disease infect others; they will be rejected as future marital partners, lest epilepsy be passed on within the family. Families may so fear public rejection that they keep their child out of view by isolating him or her at home. The financial consequences of epilepsy can be ruinous; treatments from traditional healers are often very costly.

What allows stigma to persist is the treatment gap: The 80% to 90% of patients in low-income populations who are not in care. When treatment is made accessible, and when it respects patient and family needs, is affordable in cost, and is consistent in its application, seizures can be fully controlled in half the patients and reduced in another quarter of patients in low-income societies. The integrated application of modern methods of prevention and treatment can reduce the illness burden from epilepsy worldwide by three quarters.

The *World Mental Health* report[6] proposes a new structure for a UN World Mental Health Program. The report is designed to persuade the Consultative Committee for Management (the interagency coordinating committee) to undertake epilepsy control as a major project. It is up to health professionals to make certain that epilepsy gets a high priority on the international public health agenda.

Chapter 5

Incidence and Prevalence

Poonam Nina Banerjee

W. Allen Hauser

Introduction

To develop optimal approaches to the treatment of epilepsy, to evaluate the effectiveness of treatment strategies, and more importantly, to identify interventions that may prevent the development of epilepsy, valid information regarding the frequency, cause, and natural history of the condition is necessary. Such information is provided by descriptive and hypothesis-testing epidemiologic studies. Early reports of the prevalence of epilepsy, which used information from selective service records, provided data similar to those of contemporary studies undertaken in industrialized countries, such as the United States, for the same age groups.[27] Approaches to the study of the epidemiology of epilepsy have become increasingly sophisticated; current epidemiologic studies provide a much more comprehensive picture of the characteristics of persons with epilepsy, which has led to considerable improvement in understanding epidemiologic features of the seizure disorders in general and epilepsy in particular. These improved methods include the development of clear definitions of the condition being studied; use of data provided by incidence studies of the convulsive disorders; and use of these incidence cases and other inception cohorts to determine natural history and identify risk factors. Unfortunately, incidence studies are expensive and difficult to do. Therefore, there are relatively few reports dealing with total populations. Relying on less expensive and relatively less complex studies of prevalence to gain epidemiologic insights can be compared to an epileptologist performing epilepsy surgery based on clinical history alone. One may have some of the pieces, and a correct decision may be made, but in many cases, an inappropriate procedure will be undertaken.

The following discussion reviews data regarding the incidence of seizure disorders and epilepsy, and the risk factors for epilepsy as suggested by these studies. In addition, potential insights provided by prevalence studies are highlighted. Definitions are important in epidemiologic studies. In the present discussion, the term *epilepsy* represents a condition characterized by two or more unprovoked seizures. For other definitions, the reader is referred to the report of the Commission on Epidemiology and Prognosis of the International League Against Epilepsy (ILAE).[46]

Incidence of Epilepsy

Total Population Studies

There are relatively few studies of incidence of epilepsy in total populations. In developed countries, the age-adjusted incidence of epilepsy (recurrent unprovoked seizures) ranges from 24 to 53 per 100,000 person-years.[6,30,44,50,57,58,59,60,72,95,100] Total population studies reporting the incidence of a first diagnosis of unprovoked seizures (differing from incidence of epilepsy by the inclusion of persons with a single unprovoked seizure as well as those with recurrent unprovoked seizures) provides estimates of incidence ranging from 26 to 70 per 100,000 person-years[37,51,57,60,72,90,112] (see Table 1). Given methodologic differences, the incidence in studies of predominantly Western, industrialized countries seems remarkably consistent across geographic areas. This seems particularly true of reports for the last two decades (1986 to 2005).

Several recent studies provide incidence from developing countries. An incidence of epilepsy that is considerably higher than that reported in industrialized countries (114 per 100,000 person-years) has been reported from a rural area of Chile.[66] A study in Tanzania[106] reported the incidence of epilepsy to be 77 per 100,000. These are two to three times the incidence reported in industrialized countries in which similar definitions have been used. A study in Ethiopia reported an incidence of 64, but this fell to 46 after age adjustment, underscoring the importance of age adjustment if comparisons are to be made. A large population-based survey in Ecuador[97] identified all individuals with a history of seizures. Included were all persons with newly occurring nonfebrile seizures (including acute symptomatic seizures) and some children with multiple febrile seizures. Based on the number of people seen with seizures in the year preceding the survey, incidence was higher than that of most other reports (190 per 100,000), although incidence for neurologically confirmed cases was about 30% lower. In studies in France[72] and Rochester, Minnesota,[50] about half of newly occurring afebrile seizures do not fulfill criteria for epilepsy.

Because of the broader case-inclusion criteria in the study from Ecuador and uncertainty regarding age-specific distribution and cause of acute symptomatic seizures, there is no way to compare these incidence studies. Nonetheless, the incidence of epilepsy may likely be higher in developing countries than in industrialized countries.

[a] All unprovoked seizures.

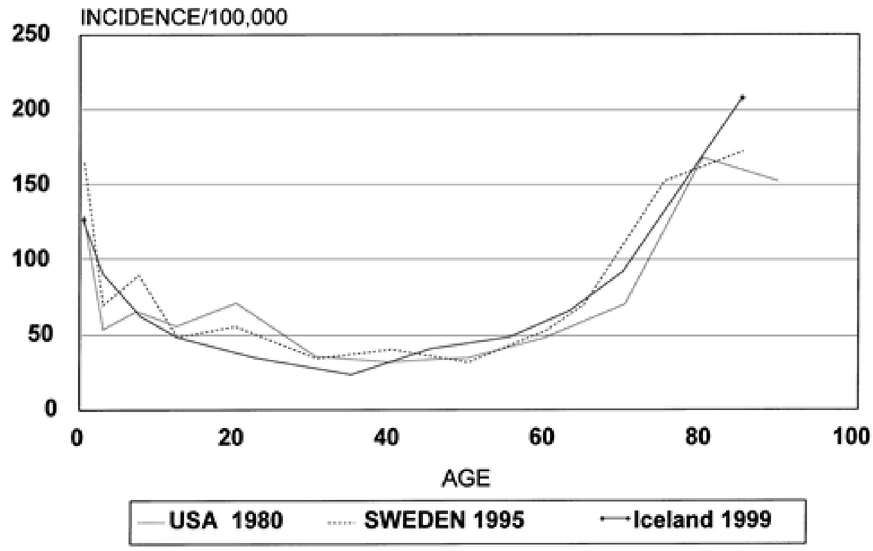

FIGURE 1. Age-specific incidence of epilepsy in industrialized countries.

Studies in Selected Age Groups

A number of studies report the incidence of epilepsy in specific age groups. These include studies of child-ren,[14,15,20,22,24,33,36,38,84,102,111,112,117] adults,[37,50,64,90,95] and the elderly.[71,76,105,115] Evaluation of these studies again requires consideration of definitions used, but in general, information is complementary to and consistent with incidence in total-population studies when age-specific rates are evaluated. For example, the more comprehensive studies limited to children[111,117] include children with neonatal seizures and children with a single unprovoked seizure as incidence cases of epilepsy. Taking this into account, incidence in the youngest

P.46

age group in studies limited to children are, in general, similar to those reported in total population studies.

Age-specific Incidence

Contrary to popular belief, epilepsy is a disease with onset at the extremes of life (Fig. 1), at least in industrialized countries. Where provided, age-specific incidence is consistently high in the youngest age groups, with highest incidence occurring during the first few months of life. Incidence falls dramatically after the first year of life, seems relatively stable through the first decade of life, and falls again during adolescence.[22,51,90]

In virtually all studies conducted in industrialized countries, age-specific incidence is lowest during the adult years. Contemporary incidence studies, most of which are in Western countries, show an increasing incidenceâ€”at times dramaticâ€”in the elderly.[37,50,71,88] In Western countries, the incidence of epilepsy is higher after the age of 70 years than during the first 10 years of life. Only about 50% of cases of epilepsy start in childhood or adolescence.[50,90] A British general practice survey reported that almost 25% of all newly identified seizures (not epilepsy) occurred in persons aged 60 years and older.[108]

The reported patterns of age-specific incidence are quite different in developing countries. In studies from Africa and South America, the peak incidence of epilepsy occurs in young adults, and the dramatic increase in incidence in the elderly has not been identified (Fig. 2).[66,106,116] It is likely that patterns of incidence, and therefore risks for epilepsy, are different in these populations.

P.47

Sex

In most total population studies, incidence of epilepsy or of unprovoked seizures is higher in males than in females. This seems true even after the higher incidence in males of definitive risk factors for epilepsy (i.e., head injury, stroke, central nervous system infection) is taken into account. One exception is the study from Ecuador,[97] in which the male-to-female ratio is 0.8, although this study cannot be used for comparison as it included persons with acute symptomatic as well as unprovoked seizures. The other exception is the study of incidence in children in Sweden (male-to-female ratio of 0.7).[112] For most but not all incidence studies, sex-specific differences in incidence are not statistically significant. The consistency of the male-to-female difference across studies suggests that males are at higher risk than females for unprovoked seizures and epilepsy.

Seizure Type

Seizure-specific incidence or proportions of cases with a specific seizure type based on the International Classification of Epileptic Seizures[100] are provided in several contemporary incidence studies (Table 2). A detailed distribution from the Iceland study[90] is provided in Figure 3. In studies in Rochester, Minnesota,[50] the Faeroe Islands,[59] and Chile,[66] slightly more than 50% of incidence cases were classified as partial seizures. Partial seizures are also the predominant seizure type in Sweden in adults after information from the separate studies of adults and children is combined.[37,112]

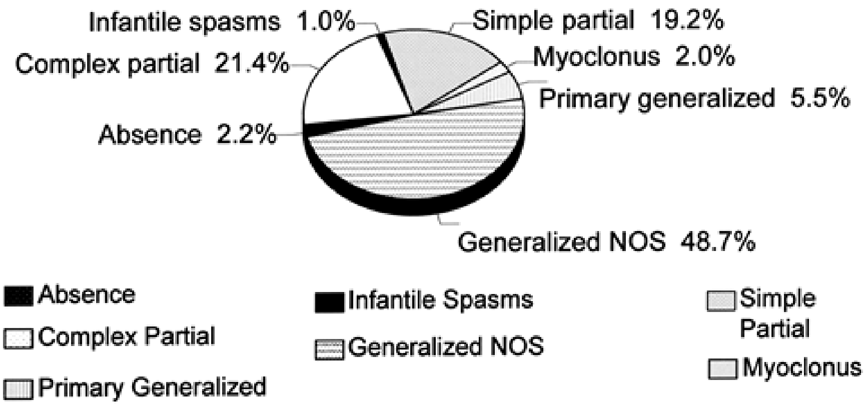

FIGURE 3. Distribution of seizure type in Iceland incidence cases, 1995â€“1999. NOS, not otherwise specified.

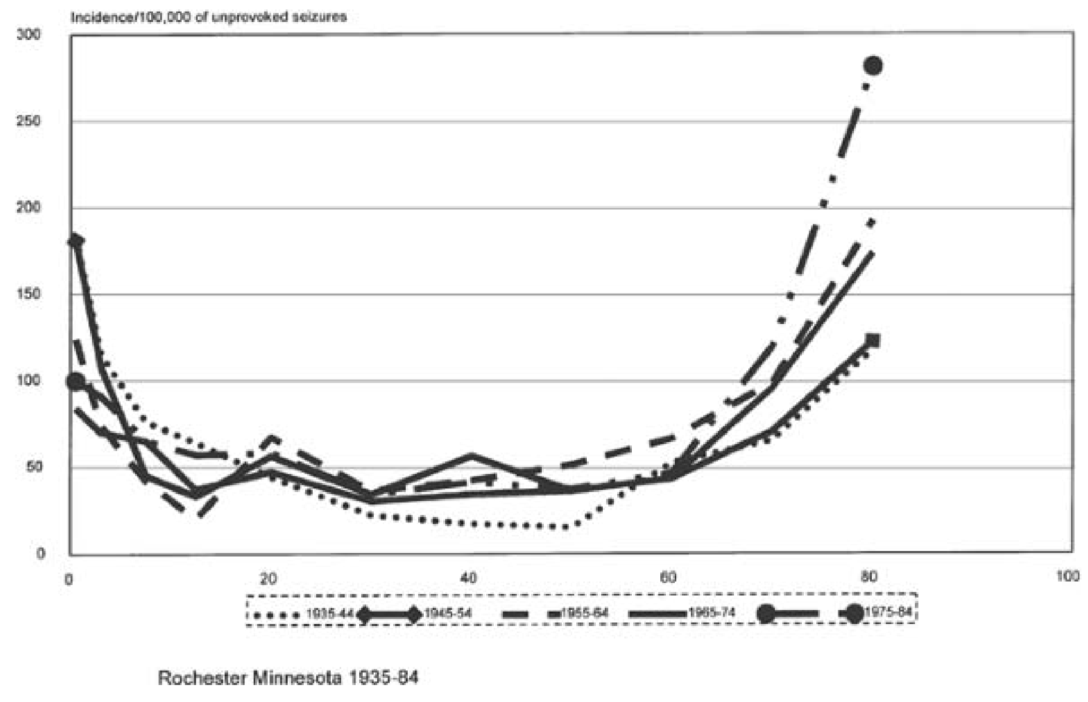

FIGURE 4. Time trends in Rochester, Minnesota, 1935â€"1984.

Race

Most total population incidence studies have been performed in white populations of European extraction. Even in

P.48

studies of incidence in Asian or African populations, study groups have been homogeneous. Racial differences have been examined only in incidence or cohort studies in children. In the National Collaborative Perinatal Project,[83] incidence of afebrile seizures did not differ across racial groups through the age of 7 years. In studies of Japanese children in Tokyo[117] and Caucasian children in Rochester, Minnesota,[50] age-specific incidence and incidence by seizure type through the age of 14 years were virtually identical. Definitions of epilepsy were similar in these two studies, although methodology was different. A study of children in New Haven, Connecticut,[111] reported incidence of epilepsy through age 15 years to be 1.7 times greater in blacks than in whites, although the definition of epilepsy was quite different from those used in many of the studies mentioned above. This study also made an ecologic comparison based on mean neighborhood socioeconomic level. After controlling for race, incidence of epilepsy was significantly higher in lower socioeconomic classes.

Time Trends

Information on time trends of incidence is provided in the studies from Copparo, Italy,[44] and Rochester, Minnesota.[50] In the Italian study, the incidence of epilepsy decreased over three time intervals from 1964 to 1978, although this may be related to methodologic issues (Fig. 4). The Minnesota study reports a more than 50% decrease in the incidence of epilepsy in those under the age of 10 years from 1935 to 1984. During these same years, there was an increase in incidence in those over age 60 years, causing the age-adjusted incidence in this community over the entire 50-year interval to show little change.

P.49

The fall in the middle decades of this century is largely unexplained, but the increase after 1975 may be related to increased survivorship of very-low-birth-weight infants. The findings of this study underscore the potential pitfalls in relying on total incidence of epilepsy in children.

In the studies of a British general practice that included all afebrile seizures, incidence under age 20 was 172 per 100,000 between 1964 and 1973, 152 per 100,000 between 1974 and 1983, and significantly lower (61 per 100,000) from 1984 to 1993.[26] This difference may be explained partially by inclusion in the earlier period of nonepileptic episodes, but even cautious interpretation of these data suggest dramatic reductions in the incidence of childhood-onset epilepsy in industrialized countries. The reduction in incidence over time in children is not readily explained by current epidemiologic or clinical data and deserves further investigation.

It appears that the incidence of epilepsy in the elderly is increasingâ€"at least in the United States. This may be related, at least in part, to an increase in the proportion of the population with a history of stroke.[4] Although the incidence of stroke is decreasing, the prevalence is increasing as more people are surviving strokes.

Epileptic Syndromes

There are few total population incidence studies that present the distribution of epilepsy syndromes such as the study conducted in Bordeaux,[72] studies from Rochester,[50] and studies from Iceland.[90] Some studies provide the distribution of epilepsy syndromes among newly diagnosed cases of epilepsy.[63,72,78,112,121]

In Bordeaux, the incidence of idiopathic localization-related epilepsy was 1.7 per 100,000 (7% of all cases). An additional 13.6 per 100,000 (56%) had symptomatic localization-related epilepsy. Thus, if the same criteria are used as in most other contemporary incidence studies, about 60% of cases can be classified as partial seizures. Each of the following syndromes accounted for about 1% of new cases: Juvenile myoclonic epilepsy, awakening grand mal, and West syndrome. About 2% had pyknolepsy. These proportions are similar to those provided by the Rochester, Minnesota, studies.[9] Crude incidence for all epilepsy (about 24.5 per 100,000) was about half that reported in studies in industrialized countries.[37,44,59,89,90] A few reports of incidence of specific epileptic syndromes in other total population studies provide data consistent with the above figures.[37,59,90]

The incidence of nonfebrile situation-related epilepsy in the French study was about 30 per 100,000.[72] Incidence for this class of seizure in Rochester, Minnesota, was about 40 per 100,000.[85] Isolated unprovoked seizures occurred in 18 per 100,000 population in the French study, which is similar to that in Rochester[50] and considerably less than that reported from Iceland.[90]

There are some reports of the incidence of specific syndromes. West syndrome has been studied in different geographic areas,[48,75,90] with an incidence ranging from 2 to 7 per 10,000 live births. Benign rolandic epilepsy is thought to be among the more frequently occurring childhood epileptic syndromes; one Italian study[24] reported this to account for 24% of incidence cases in children with epilepsy between the ages of 4 and 15 years. In Sweden, the incidence of benign rolandic epilepsy in children under 15 years of age was 10.7, accounting for about 14% of childhood epilepsies.[112] In Iceland, benign rolandic epilepsy accounted for 5% all newly diagnosed cases.[90] The incidence of juvenile myoclonic epilepsy in the Faeroe Islands was 1.1 per 100,000 per year, or about 2.5% of cases.[59] In Sweden, five children under the age of 15 years had a diagnosis of juvenile myoclonic epilepsy, making the incidence 6 per 100,000,[112] and in Iceland, juvenile myoclonic epilepsy occurred in 1% of patients,[90] providing an incidence of 0.7 per 100,000 person-years. Data from the Rochester cohort studies suggest that the incidence of juvenile myoclonic epilepsy is about 1 per 100,000 per year.[50] These data seem to be reasonably consistent and suggest a lower frequency of juvenile myoclonic epilepsy than has been suggested in recent clinical studies. Lastly, childhood absence epilepsy occurred in seven patients in Iceland (1%; incidence of 0.8 per 100,000 person-years).[90]

Etiology of Epilepsy in Incidence Cohorts

Most of the population-based incidence studies provide information regarding presumed etiology (Table 3). Rarely have definitions for inclusion been provided, but the proportion of cases with an identified antecedent (remote symptomatic epilepsy) is relatively consistent, ranging from 23% to 39%[50](Fig. 5). In children, epilepsy associated with neurologic deficits from birth seems to be the most important single etiologic relationship, whereas cerebrovascular disease is the most commonly identified cause among adults.

Classic Risk Factors

Most physicians have preconceived notions about postnatal antecedents of epilepsy. Head (brain) trauma, stroke, central nervous system infection, and degenerative brain disease are frequently identified.[5,7,9,107] Specific causes of epilepsy may differ across geographic areas, but whether incidence studies are undertaken in developing countries or in developed countries, a definitive etiology has been identified in only about one third of all newly diagnosed cases. In industrialized countries, cerebrovascular disease is the most frequently identified â€œcauseâ€ of epilepsy, accounting for about 12% of all new cases and about one third of cases with an identified cause (Fig. 6).[50,90] In South America, the most frequently identified cause is infection of the central nervous system. In developing and developed countries, cerebral palsy is associated with a large proportion of cases, particularly in children. In incidence studies in endemic areas, neurocysticercosis accounts for about 10% of newly diagnosed cases of epilepsy, confirming the importance of this factor.[23]

Risk Factors Identified in Epidemiologic Studies

Epidemiologic studies have not only confirmed the importance of postnatal insults, but also qualified the risk. As shown in Figure 7, a risk ratio of 1 implies no increase in risk, a risk ratio of â‰¤1 suggests a protective effect, and a risk ratio of >1 suggests an increase in risk. The risk for epilepsy among persons with penetrating head injuries acquired during military service is more than 500 times that expected in the general population.[107] In contrast, individuals who have had brain injury associated with loss of consciousness or amnesia of â‰¤30 minutes' duration have no increase in risk.[5] Studies have also identified other factors (drug and alcohol abuse, depressive illness, suicidality, migraine with aura, hypertension, and risk factors for stroke) that increase the risk for epilepsyâ€"at times as much as or more than the classic risk factors.[2,52,54,55,70,74,85,86,109]

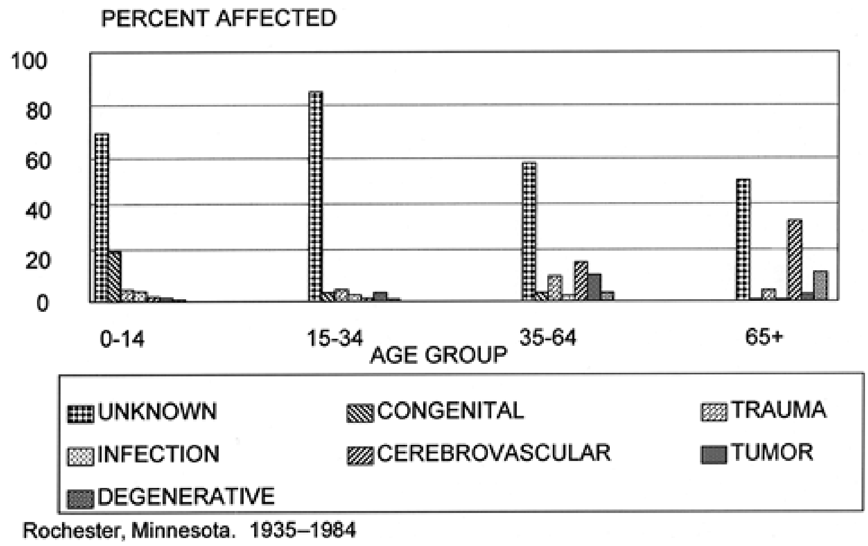

FIGURE 5. Age of onset attributable to various antecedents.

There is a continued belief that adverse prenatal and perinatal events are associated with an increased risk for epilepsy (Fig. 8). Although at times these may be risk factors for cerebral palsy, they have not yet been demonstrated, at least in

developed countries, to be risk factors for epilepsy in the absence of overt neurologic handicap. Separate or together, pre- or perinatal factors pose little increase in risk, and for most of these factors the differences are not significant. Epidemiologic evidence does not support a causal association between febrile convulsions and epilepsy.

Family History as Risk Factors

A small proportion of cases of epilepsy may be attributable to single-gene disorders. In two syndromes with mendelian inheritance patterns, a chromosomal localization has been achieved. Benign familial neonatal convulsions with a dominant inheritance pattern was initially localized to chromosome 20,[67] but genetic heterogeneity has been demonstrated by a more recent localization to chromosome 8.[68] A gene for progressive myoclonic epilepsy has been localized to chromosome 21.[35] A gene for partial epilepsy with auditory features has been localized to chromosome 10, and several sodium and potassium channelopathies have been identified in association with Dravet syndrome and generalized epileptic seizures plus (GES+) syndromes.[17,119] Although the mode of inheritance is obscure, a localization for juvenile myoclonic epilepsy and other juvenile-onset disorders has been proposed.[35,45] Others question this finding.[120] Localizations for several other epilepsy syndromes have been identified.

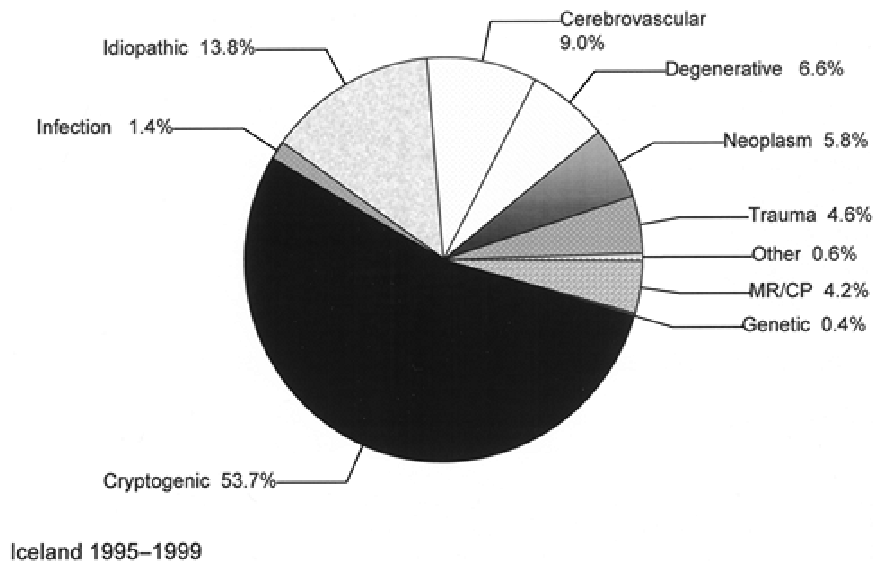

FIGURE 6. Classic risk factors.

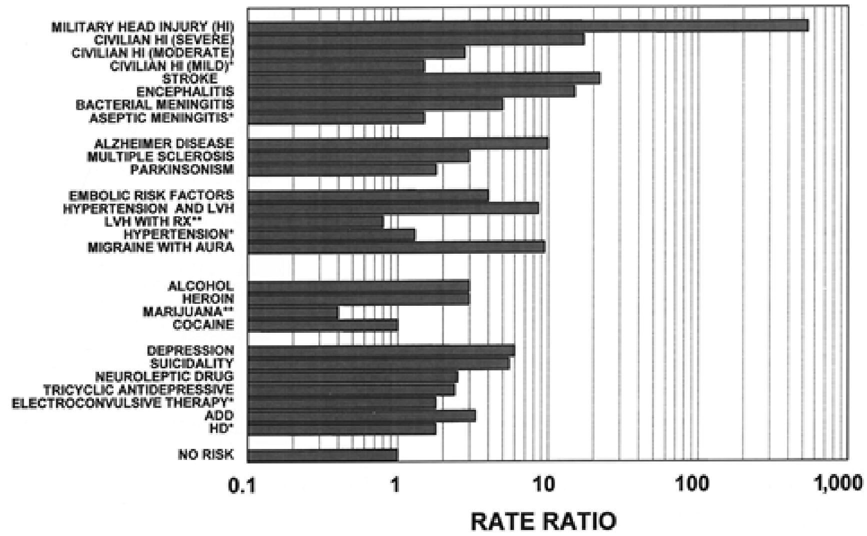

*Not significant. **Protective.

FIGURE 7. Change in risk for epilepsy in association with specific antecedents. ADD, attention deficit disorder; HD, hyperactivity disorder; LVH, left ventricular hypertrophy.

Even though a small proportion of cases follow mendelian inheritance patterns, in epidemiologic terms family history may be considered an important risk factor for epilepsy. In the absence of other information, epilepsy in a first-degree relative increases the risk threefold.[8] The absolute increase is modified by which first-degree relative is affected (sibling, mother, father), the seizure type and etiology of epilepsy in the affected relative, and the electroencephalographic pattern in the relative or individual in question.

P.51

Cumulative Incidence

Cumulative incidence is the summation of age incidence. Given the modest alteration mortality among people with epilepsy, cumulative incidence provides an estimate of the proportion of the total population that has been affected with epilepsy by a specific age. Estimates of cumulative incidence of epilepsy have been provided in four total population studies.[50,60,89,90] In Denmark, the risk for having epilepsy by the age of 80 years was 1.3%,[60] a substantially lower number than the cumulative incidence of epilepsy for the same age in Rochester, Minnesota (4% for epilepsy and more than 5% for all unprovoked seizures)[50] or the rate of 5.4% for all unprovoked seizures to age 85 from the Iceland study.[90] This difference can be explained by the considerably higher incidence in the elderly in the Minnesota study. As would be expected from age-specific incidence rates, cumulative incidences of epilepsy through childhood are almost identical in Japan and Rochester.[50,117] In Rochester, the cumulative incidence for epilepsy and unprovoked seizures is significantly greater for males than females.

Incidence of All Afebrile Seizures

There are a few studies that include all afebrile seizures in their definitions of epilepsy, and this definition is consistent with some recent recommendations of the ILAE.[57,58,97] Table 4 includes studies from which incidence using this definition have been provided. The incidence is substantially increased in Ecuador,[97] although it is not clear if this is due to a methodologic approach or reflects differences in the burden of epilepsy between developed and developing countries.

Prevalence of Epilepsy

Because it is easier to obtain information about prevalence than about incidence, many prevalence studies of epilepsy from diverse populations have been reported.[1,10,11,13,16,18,19,25,31,32,34,39,40,41,42,43,47,53,61,62,69,73,79,80,81,87,92,94,96,101,103,104,110,113,114] Prevalence is a measure of the interaction of obvious factors such as incidence, death, and remission of illness, and except for

geographic isolates such as Iceland, prevalence is also affected by factors such as migration or access to multiple sources of medical care. Prevalence is more a reflection of survival and severity or chronicity of illness than of frequency of illness. Little reliable information regarding etiology or prognosis can be derived from prevalence studies, although they can provide intriguing clues to guide hypotheses that can be tested in properly designed studies. Prevalence data are primarily of value in planning for health care.

There are some well-known difficulties in interpreting prevalence data, related to difficulties in interpreting mortality and remission. Other difficulties stem from inconsistencies in definitions or in the fact that only crude prevalence is reported. Age-specific prevalence in developed and developing countries is difficult to compare, given the dramatic differences in age structure of the populations and the wide variation in age-specific prevalence. Age standardization should be used if any comparisons are to be made, as wide variations in apparent prevalence are demonstrated even in studies of contiguous populations.

Age-Adjusted Prevalence

Age-adjusted prevalence per 1,000 population varies widelyâ€"from 2.7 to more than 40, although most studies show a range from four to eight.[49] Even when the same investigators have used similar protocols, definitions of epilepsy, and methodologies, the prevalence of â€œactiveâ€ epilepsy ranges from 3.6 to 41.3.[18,93] Somewhat higher prevalence (ranging from 14 to 57 per 1,000) has been reported in pilot studies using a standardized World Health Organization (WHO) protocol in Panama,[43] Ecuador,[97] and Colombia.[99] However, the same protocol used in large-scale population surveys yielded low prevalence in India[18,65] and China.[69]

The high prevalence of epilepsy reported in Central and South America by those using the WHO protocol may be a reflection of methodology. One study[97] using the International Community Based Epilepsy Research Group (ICBERG) protocol in rural Ecuador found the prevalence to be considerably lower (8 per 1,000) than that reported in a pilot study[29] by investigators using the WHO protocol in the same region (18.5 per 1,000). The difference may be related to more stringent case verification in the ICBERG study, but this cannot account for all the differences. A recent population survey in a village in rural Mexico, which was age adjusted to the 1980 U.S. population, revealed a prevalence of active epilepsy of 5.9 per 1,000.[53,94] The prevalence in Pakistan is about 10 per 1,000,[12] and in rural Ethiopia about 5 per 1,000.[116]

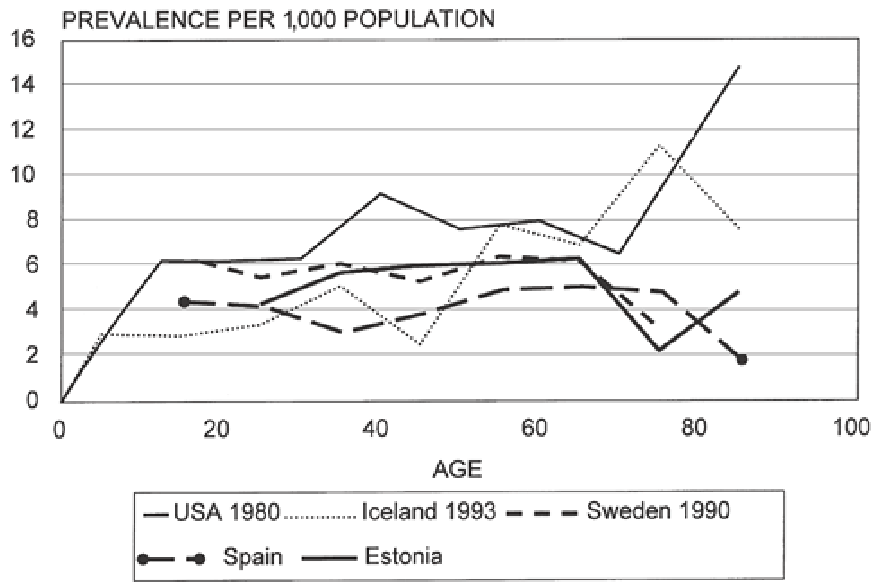

FIGURE 9. Prevalence of epilepsy in industrialized countries.

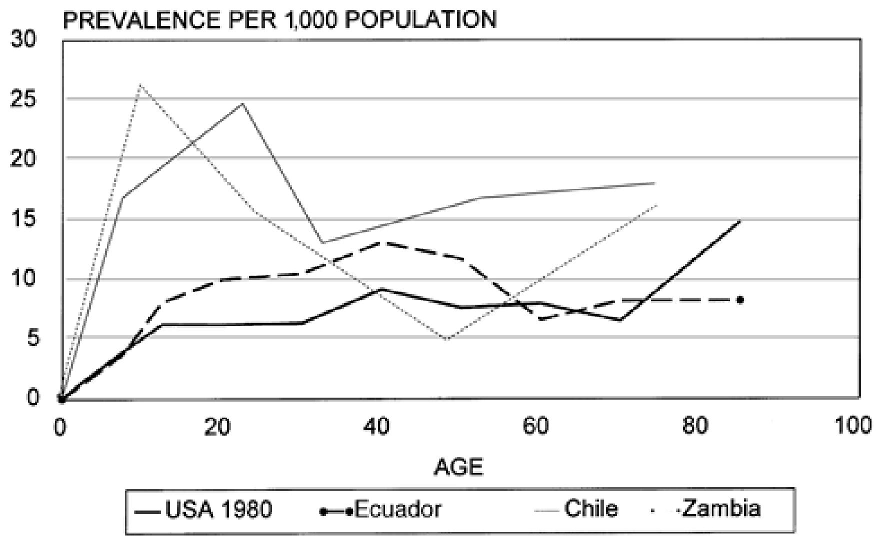

FIGURE 10. Prevalence of epilepsy in developing countries.

Age-Specific Prevalence

Although epilepsy is a disease acquired throughout life, the reported patterns of age-specific prevalence seldom reflect

P.53

this. This is particularly striking, as many of the prevalence studies provide data for lifetime prevalence (which should approximate cumulative incidence) rather than for active prevalence (which measures current seizures or current use of antiepileptic drugs). In the studies of prevalence from Rochester, Minnesota,[49] and from Iceland,[91] there is a pattern of active prevalence increasing in each subsequent age group, with the highest prevalence occurring in the elderly (Fig. 9). Studies from other European countries[64,118] and the Faroe Islands[59] report a relatively constant prevalence in adults. In many cases, age-specific estimates are unstable because of small numbers within age groups. Most studies, particularly those from developing countries, report the highest prevalence in the second and third decades of life, with lower prevalence in the elderly[29,53] (Fig. 10).

Gender

As is the case with incidence studies, most studies of prevalence report a higher prevalence in males than in females.

Etiology

For all total population studies providing information, the majority of cases, typically between 55% and 89% (Fig. 11), even in developing countries, have no identified cause.[1,10,11,13,16,18,19,25,31,32,34,39,40,41,42,43,49,53,61,62,65,73,81,87,92,93,94,99,101,103,104,113]

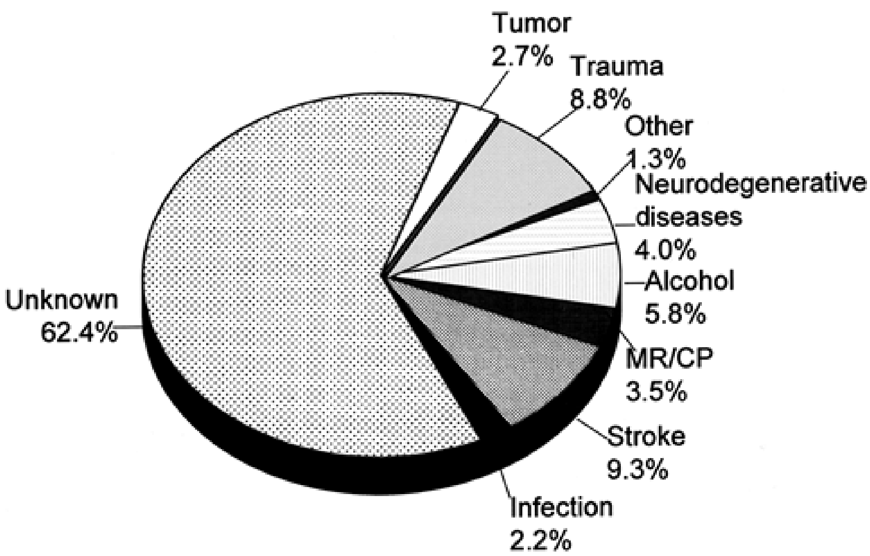

FIGURE 11. Distribution of etiology of epilepsy cases. CP, cerebral palsy; MR, mental retardation.

Race

Race seems more of an issue in the United States than in most other countries, and most studies addressing race or ethnic issues are from this geographic area. There are few studies that provide data on the prevalence of epilepsy in underrepresented populations in the United States.[49] Most studies provide data on prevalence in African-Americans. When comparable data were available, all report a higher prevalence than in the white population, although as usual, definitions cause difficulties in comparison. In Copiah County, Mississippi, the entire population was screened and follow-up evaluations were scheduled with symptoms of seizures or epilepsy to determine the

P.54

prevalence of epilepsy.[3,47] Definitions used in this study would include some people now categorized as acute symptomatic epilepsy in other studies such as those in Rochester, Minnesota. The age-adjusted active prevalence in blacks defined as recent seizures or current medication use was 8 per 1,000. This was about 60% greater than the age-adjusted prevalence in the white population in the same county.

A study in a rural Alabama county reported a lifetime prevalence of epilepsy of about 12 per 1,000 in the 2,200 black residents based upon clinic record review. This was almost double the prevalence in whites determined in a similar fashion.[56]

There are reports of prevalence of epilepsy limited to children that include information regarding the prevalence in minorities. The prevalence of epilepsy was determined in three counties in Oklahoma using multiple sources for case identification.[28] The active prevalence in black children of 5.7 per 1,000 compared to 4.2 per 1,000 in white children. The overall prevalence in â€œothers,â€ including Native American and Hispanic children, was 4.5 per 1,000. Prevalence was higher in males than in females for all ethnic groups. The excess in black children seemed attributable to a higher prevalence of generalized seizures and was present for all age groups. No further information is provided for the â€œotherâ€ group.

In Atlanta, multiple sources were used to identify potential cases that were screened to identify children with epilepsy. The lifetime prevalence of epilepsy in black children at age 10 was 6.4 per 1,000, not significantly higher than the prevalence in white children (5.7 per 1,000).[82] The prevalence of generalized seizures was significantly greater in black children than in white children.

Studies of prevalence in minority populations are inexorably confounded by socioeconomic status. Few studies attempt to address the relationship of socioeconomic status and the prevalence of epilepsy. In Ecuador, prevalence was inversely correlated with community ranking by socioeconomic class.[97,98] The prevalence of epilepsy in Pakistan has been reported to be greater in rural than in urban areas.

Summary and Conclusions

As more insight is gained into the epidemiologic characteristics of the epilepsies, apparent discrepancies between epidemiologic and clinical studies will be resolved. In addition, more pointed questions will be asked, and the prime epidemiologic goal of preventing epilepsy and its consequences will be addressed.

Chapter 6

Risk Factors

Dale C. Hesdorffer

Introduction

Well-established risk factors for unprovoked seizures include head trauma, central nervous system (CNS) infection, Alzheimer disease, clinically detected stroke, febrile seizures, cerebral palsy, and mental retardation. Each of these increases the risk for unprovoked seizures at least 10-fold. Several other risk factors for unprovoked seizures are less well described; these include consumption of alcohol, use of heroin or marijuana, low socioeconomic status, attention deficit hyperactivity disorder, major depression, multiple sclerosis, dementia other than Alzheimer disease, and risk factors for stroke in the absence of clinically detected stroke. Additionally, current diuretic use has been shown to protect against the development of a first unprovoked seizure.

Epidemiologic Study Designs

Epidemiologic studies of risk factors for epilepsy or unprovoked seizures employ one of three study designs: Case control, retrospective cohort, or prospective cohort. These study designs are reviewed briefly before the discussion of risk factors for epilepsy in children and adults.

In case-control studies, potential predisposing factors are compared between patients with epilepsy and control patients without epilepsy. The odds ratio (OR) derived from these studies indicates the extent to which a given factor increases or decreases the risk for epilepsy. Case-control studies are best done with new-onset cases of epilepsy; identification of factors preceding the occurrence of seizures that might increase the risk for developing seizures supersedes investigation of factors that are a consequence of seizures. Population-based case-control studies have advantages over hospital-based studies because they include all cases of epilepsy in a population rather than the select group of patients who seek care at a particular hospital.

Both retrospective and prospective cohort studies begin with people who do not have epilepsy. These people are categorized according to whether or not they were exposed to a factor thought to predispose to epilepsy. Exposed and unexposed people are then followed chronologically to determine risk for epilepsy among people exposed to the predisposing factor relative to the risk among unexposed people. The measure that quantifies this risk is called the relative risk (the risk for disease in exposed subjects compared with the risk for disease in unexposed subjects).

The stronger the association is between a risk factor and a disease, the less likely the association can be explained by another, potentially confounding, factor. For example, it is harder to explain away a relative risk or of 10 than of 2. Associations of 10 or greater are strong enough to be considered clinically detectable by most physicians who see patients with epilepsy. Examples of these include, but are not limited to, head injury and clinically detected stroke.

Risk Factors for Childhood Epilepsy

The risk factors for childhood epilepsy are different from those for epilepsy later in life.[1] Inherited epilepsy is discussed elsewhere (see Chapters 15,16,17,18,19); consequently, this discussion is limited to nongenetic factors. The risk for epilepsy beginning in childhood is increased by febrile seizures, head trauma, CNS infection, mental retardation, cerebral palsy, and attention deficit hyperactivity disorder. Age itself seems to be a risk factor independent of other factors.[23] Adverse events during the prenatal and perinatal period do not influence seizure risk when children with mental retardation and cerebral palsy are excluded. Pertussis vaccination does not appear to alter the risk for unprovoked seizures; nor does low socioeconomic status.

Febrile Seizures

Febrile seizures can be regarded as distinct from childhood epilepsy (Chapter 57). Berg[9] summarizes the epidemiologic evidence for this assertion as follows: The risk of recurrent febrile seizures is far greater than the risk of unprovoked seizures after a febrile seizure; and risk factors for recurrent febrile seizures differ from risk factors for subsequent unprovoked seizures. Large cohort studies demonstrate that following a first febrile seizure, 2% to 4% of children experience a subsequent unprovoked seizure,[6,52,76] a risk four times the risk for unprovoked seizure in the general population. The increased risk for unprovoked seizures after febrile seizure is substantially greater among children with neurologic abnormalities present from birth than among children without such abnormalities. For most children with febrile seizures (i.e., those with simple febrile seizures), the risk of unprovoked seizure is only increased slightly.

Risk factors for unprovoked seizures following a first febrile seizure include a family history of epilepsy, complex features of the febrile seizure (i.e., multiple or focal and lasting longer than 15 minutes), and the presence of neurodevelopmental abnormalities present from birth.[6,10,52,76] Increasing duration of fever prior to the first febrile seizure and high temperature are associated with a reduced risk of developing subsequent unprovoked seizures,[10] suggesting that some children may have a low overall seizure threshold.

The type of febrile seizure influences the type of unprovoked seizure that may develop.[6,47] Repeated simple febrile seizures increase the risk for generalized-onset unprovoked seizures. Additionally, there is an association between complex febrile seizures and partial-onset unprovoked seizures. The suggestion of an underlying brain pathology common to both complex febrile seizure and partial-onset unprovoked seizure has led to the question of whether some febrile seizures lead to the development of mesial temporal sclerosis and subsequent intractable temporal lobe epilepsy. One study of 107 patients with drug-resistant epilepsy[46] showed that 45 (42%) had

P.58

focal or diffuse hippocampal volume loss on high-resolution volumetric magnetic resonance imaging (MRI) and most of these had a history of febrile seizures during childhood. If febrile seizures do predispose to some cases of hippocampal sclerosis, this cannot be the only mechanism involved, as 64% of the patients[46] with hippocampal volume loss had no history of febrile seizures. Further insight into this potential association comes from a prospective study[75] in which MRI examinations were performed within days of a prolonged febrile seizure. Among 15 children with focal prolonged febrile seizures, two had chronic hippocampal abnormalities and four had increased T2-weighted signal intensity and increased hippocampal volume associated with a mean seizure duration of 41 minutes: Two of the four with acute injury developed hippocampal atrophy on the follow-up MRI. In contrast, none of the 12 children with generalized prolonged febrile seizures had a definite abnormality on MRI. These data suggest that extremely prolonged focal febrile seizures can cause acute hippocampal injury, leading to later atrophy. Still unanswered is whether or not this atrophy is associated with the development of temporal lobe epilepsy.

Prenatal and Perinatal Risk Factors

Prenatal and perinatal adverse events do not appear to be associated with the occurrence of childhood epilepsy when children with cerebral palsy and mental retardation are excluded. In an early case-control study,[15] 100 children with epilepsy born in four hospitals in a large town in Germany were compared with 100 healthy children of the same age who had been born â€œat virtually the same time.â€ The study indicates that higher age of the mother at birth, toxemia of pregnancy, premature birth, and heavy birth weight were associated with later epilepsy; many other factors were not. This study had methodologic weaknesses: Medical records were reviewed retrospectively, a select group of patients was studied, and children with cerebral palsy and mental retardation were included. It is therefore interesting to compare the results with other, better designed studies.

In a review of large studies of defined populations, including the National Collaborative Perinatal Project (NCPP) cohort, Nelson and Ellenberg[53] concluded that among the hundreds of prenatal and perinatal factors studied, the main predictors of childhood seizure disorders were congenital malformations of the fetus (cerebral and noncerebral), family history of certain neurologic disorders, and neonatal seizures. In agreement with the British National Child Development Study,[67] labor and delivery factors in the NCPP did not appear to contribute to childhood seizure disorders. It seems that maldevelopment, rather than damage at birth to an intact nervous system, is the more common mechanism. In a prospective 1-year birth cohort study performed in northern Finland[61] that included 12,058 children, 208 had epilepsy. Of these children, 8.7% had a prenatal risk factor, 18.2% a perinatal risk factor, 15.9% a postnatal risk factor, and 57.2% no identifiable risk factor. This study included seizures in the neonatal period; some cohort studies, such as the British Child Health and Education Study (CHES),[77] have not included neonatal seizures.

Postnatal Causes

The British CHES cohort[77] has demonstrated that the causes of epilepsy in children, when known or suspected, are heterogeneous. No single cause predominates.

Traumatic Brain Injury

Jennett[42] found that the incidence of posttraumatic epilepsy in children was not markedly different from that in adults (Chapter 253). The risk for later epilepsy after depressed fractures ranged from <30% to 70%. Jennett also drew attention to â€œearlyâ€ epilepsy after head injury; in about 5% of all patients admitted to the hospital, seizures occurred within a week of the head injury. The incidence in children <5 years of age was almost double this. First-week seizures were quite distinct, occurring 30 times more frequently in the first week than the average of any of the 7 succeeding weeks. Fewer than a third of the patients with one or more seizures in the first week had any further epilepsy in the next 4 years.

Vaccination

It is unlikely that a relationship exists between vaccination, in particular pertussis immunization, and serious acute neurologic illness in children[2]; however, diphtheria-tetanus-pertussis (DPT) vaccination appears to increase the risk for fever, resulting in an earlier onset of febrile seizures among children predisposed to such seizures.[37,70] The possibility of an association between DPT vaccination and afebrile seizures was addressed in Great Britain by the National Childhood Encephalopathy Study.[50] In a review of the relationship between pertussis immunization and seizures,[8] Bellman suggested that pertussis vaccination was not associated with a convulsive disorder and instead might act as a nonspecific trigger for the onset of symptoms in children who were already predisposed to the development of infantile spasms. The one study to address this question[20] found no statistically significant increased risk in young children for any type of afebrile seizure in the 7 days after DPT vaccine exposure. Thus, it appears that the only adverse neurologic consequence significantly associated with DPT vaccination is febrile seizure in children who are already predisposed to such seizures.

Attention Deficit Hyperactivity Disorder

Clinically, there is a perception that attention deficit hyperactivity disorder (ADHD) is more common among children with epilepsy, due to the seizure disorder or its treatment.[7,16] When time order is examined, ADHD is associated with increased risk for developing epilepsy. This has been shown in case-control studies of children with epilepsy[7,16,34] and in cohort studies of select populations of children with ADHD.[28,40,41,79] In two prior case-control studies of children with incident unprovoked seizure,[7,16] behavioral disturbances before the onset of first seizure were more frequent than among controls. In one study of 148 children with first unprovoked seizure and 89 seizure-free sibling controls, attention problems as assessed by the Child Behavior Checklist were 2.4-fold more common prior to identification of the first seizure (8.1%) than in controls (3.4%).[7] In a population-based case-control study conducted among Icelandic children,[34] children with incident unprovoked seizure were 2.5-fold more likely than age- and gender-matched controls to have a history of ADHD (95% confidence interval [CI] = 1.1 to 5.5), meeting *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-IV criteria prior to seizure onset. The association was restricted to ADHD-predominantly inattentive type (OR =

3.7; 95% CI = 1.1 to 13). When the occurrence of new-onset seizures is examined in selected samples with ADHD,[28,40,41,79] the percentage of children who develop unprovoked seizures (0.2% to 2%) is greater than the expected rate, because the average annual incidence of seizures is approximately 0.0470 per year in children aged 5 to 16 years.[24] Thus, there is an increased risk for developing seizures in children with ADHD, and the reported increased risk is smaller in case-control studies than in cohort studies, which were limited by small numbers of ensuing unprovoked seizures during short follow-up periods in selected populations. This is consistent

with the 23.1% prevalence of learning disorders reported in an unselected sample of children in Finland.[72]

Other Neurologic Problems

Mental retardation and cerebral palsy both predispose to the development of epilepsy (see Chapter 263). In a cohort of 221 children identified with mental retardation and born between 1951 and 1955 in Aberdeen, Scotland,[21] the cumulative risk for epilepsy was 15% by 22 years of age. In children with mental retardation and no associated disabilities, the cumulative risk at 22 years of age was 5%; in those with mental retardation and cerebral palsy, it was 38%; and in those with a postnatal injury associated with mental retardation, cumulative risk 15 years after the injury was 66%. Interestingly, epilepsy often remitted in mentally retarded individuals. In Rochester, Minnesota, neurologic deficits from birth, mental retardation, and/or cerebral palsy were important antecedents of epilepsy.[24] Thus, in the absence of associated disability or postnatal injury, the incidence of epilepsy in those with mental retardation alone was more than three times that of the general population of Rochester, Minnesota. Additionally, there appears to be an interaction between mental retardation and cerebral palsy on the risk for epilepsy.

Association of Different Risk Factors with Different Types of Epilepsy

Most published works examine risk factors for epilepsy as if epilepsy were a single condition rather than a heterogeneous group of seizure types and syndromes. Rocca et al.[63,64,65] addressed this issue in several articles, using the Rochester data to identify risk factors for different types of epilepsy. The risk for absence seizures was significantly increased by a history of febrile convulsions.[63] For generalized tonicâ€“clonic seizures, the following were significantly more common in cases than controls: A history of epilepsy or febrile seizures in the mother, febrile convulsions, and a history of head trauma.[64] For complex partial seizures, the following were significantly more common in cases than controls: A history of epilepsy or febrile convulsions in the mother, febrile convulsions, neonatal convulsions, cerebral palsy, head trauma, and viral encephalitis.[65] This work emphasizes the importance of accurately identifying seizure types and epilepsy syndromes when considering etiology.

Risk Factors for Epilepsy in Adults

There are several established risk factors for epilepsy in adults: Head trauma, CNS infections, CNS malignancies, occlusive cerebrovascular disease, and Alzheimer disease (Fig. 1). Several other factors have been associated with epilepsy but await confirmation in future studies. These potential risk factors include multiple sclerosis, hypertension, left ventricular hypertrophy, risk factors for embolic stroke, dementia other than Alzheimer disease, major depression, alcohol abuse, use of illicit drugs, and low socioeconomic status (Fig. 1). Acute symptomatic seizures also appear to increase the risk for subsequent epilepsy. There is evidence that diuretic therapy may be protective for the development of epilepsy.

Head Injury

Head injury increases the risk for later unprovoked seizure, with the greatest risk occurring among survivors of severe injury (Chapter 253). Analogous to seizures after penetrating head injuries, unprovoked seizures may be a consequence of neurosurgical procedures to the head.

In a study of Vietnam veterans who survived penetrating head wounds caused by missile injury, risk for remote symptomatic seizures increased 580-fold during the first 12 months after the injury and 25-fold after 10 to 15 years.[11,68] Among those veterans with epilepsy, persistence of epilepsy was associated with features related to the wound and not to functional consequences of the injury.

Penetrating head injuries sustained during war are more severe than all but 17% of cases of head trauma accompanied by loss of consciousness or posttraumatic amnesia in nonmilitary populations.[3] In civilian populations, case-control studies[64,65] and retrospective cohort studies[3] report an increased risk for unprovoked seizure after head trauma. In a retrospective cohort study from Rochester, Minnesota, that excluded people with seizures before head injury, the increased risk for subsequent unprovoked seizure was related to the severity of the injury.[3] Among residents of Rochester with mild injury, defined as unconsciousness or posttraumatic amnesia of less than 30 minutes' duration, risk for unprovoked seizure was increased 1.5-fold, which was not statistically significant. The risk for unprovoked seizure was increased fourfold for residents with moderate injury, defined as skull fracture or 30 minutes to 24 hours of unconsciousness or posttraumatic amnesia. Similar to the risk for seizures among Vietnam veterans 10 to 15 years after head injury, the risk for unprovoked seizure was increased 29-fold after severe injury, defined as more than 24 hours of unconsciousness or posttraumatic amnesia, brain contusion, or intracerebral hematoma. Severity of head injury may be a proxy for the amount of permanent epileptogenic damage inflicted by the injury.

Studies of unprovoked seizures after neurosurgery are complicated by the nature of the underlying disease, the presence of seizures before surgery, and the select nature of the populations studied. In one study, the risk for unprovoked seizures after surgery increased with increasing severity of preoperative neurologic deficit,[43] providing evidence that preoperative neurologic function alters postoperative seizure risk. Data also suggest an increased risk for seizure from the neurosurgical procedure itself. Using life table methodology[18] to study 877 consecutive neurosurgical patients, unprovoked seizures developed in 17% within 5 years of surgery. This cumulative incidence far exceeds the risk for seizures in the general population.[24] Further large and carefully designed studies are needed to untangle the effects of preoperative conditions and neurosurgical procedures in increasing the risk for seizures.

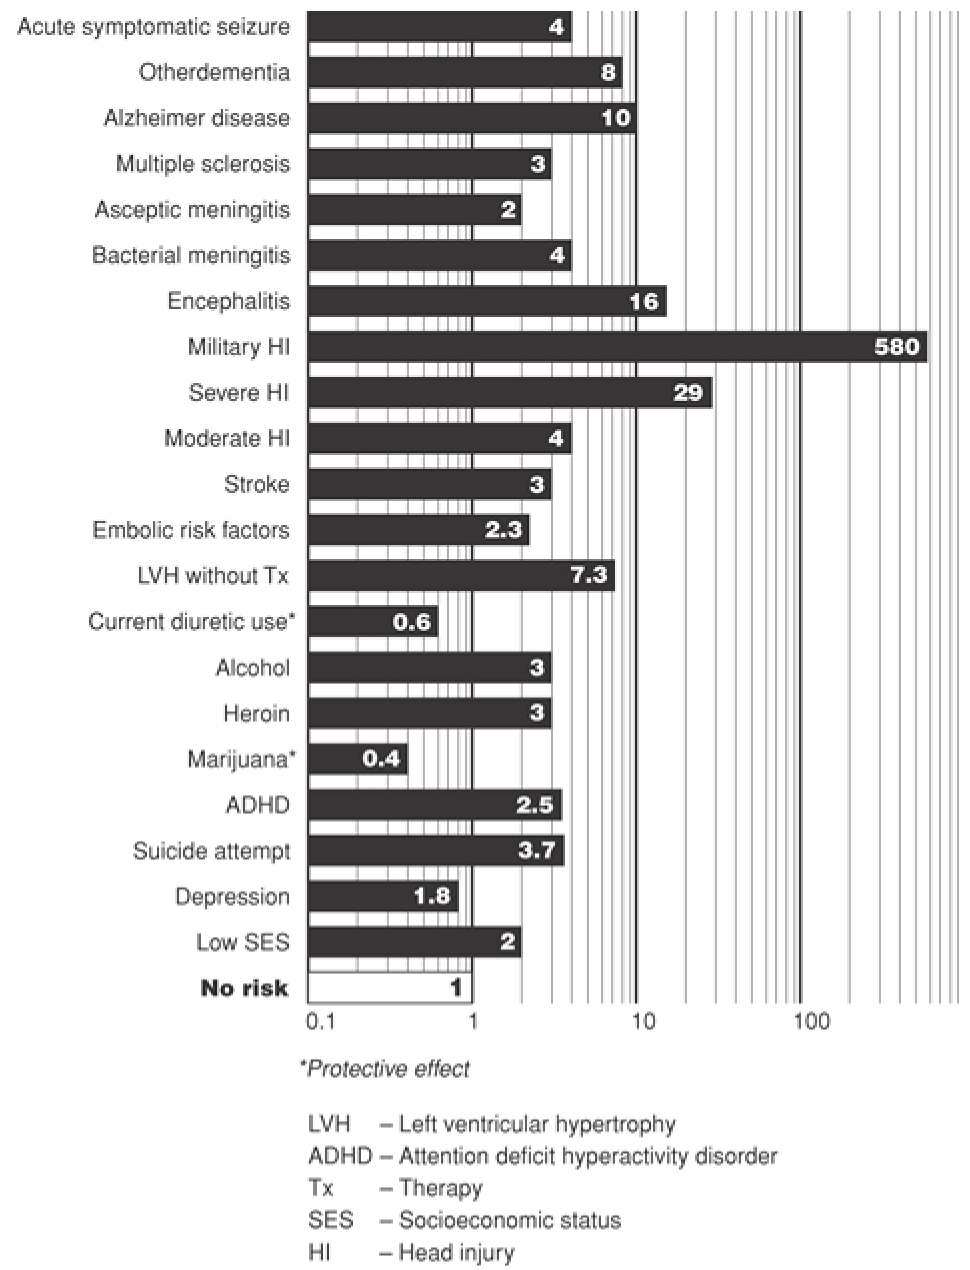

FIGURE 1. Risk factors for seizures in adults.

Central Nervous System Infection

Infections of the CNSâ€"encephalitis and meningitisâ€"are associated with an increased risk for subsequent unprovoked seizures. Among children with complex partial seizures, there is a 31-fold increased risk associated with viral encephalitis.[65] In a retrospective cohort study from Rochester, Minnesota, that followed people of all ages for the development of unprovoked seizure, CNS infections increased seizure risk 11-fold.[4] The risk for seizures varied by type of CNS infection. A 16-fold increased risk was associated with encephalitis, a fourfold increased risk with bacterial meningitis, and a twofold increased risk with aseptic meningitis. Almost all unprovoked seizures occurred during the first 5 years after infection (see Chapter 265 for further discussion).

Central Nervous System Malignancies

Case series have been used to evaluate the risk for epilepsy among patients with brain tumors or the prevalence of brain

tumors in newly diagnosed cases of epilepsy. Series of the former type report that 28% of patients undergoing surgery for brain tumors have seizures,[18,19] a risk far exceeding the incidence in Rochester, Minnesota.[24] Series of the latter type reveal that 12% to 16.3% of adults with newly diagnosed epilepsy have brain tumors[13,49,62]; indeed, seizures are often the first sign of brain tumors (see Chapter 264 for further discussion).

Occlusive Cerebrovascular Disease

A chronic epileptogenic lesion at the stroke site may account for unprovoked seizures that occur more than 1 to 2 weeks after a clinical stroke.[14] Such unprovoked seizures occur after a clinically detected stroke in 2.7% to 35% of patients.[26,38,45,51,59,78] This variability can be attributed to several factors in study design: Variation in length of follow-up, inclusion of only patients with computed tomographic confirmation of stroke, or inclusion of patients with subarachnoid hemorrhage only if they survived long enough to have surgery. Regardless of the selection factors or length of follow-up, the risk for unprovoked seizure after stroke is at least three times that expected based on the incidence among adults in Rochester, Minnesota.[24]

Because stroke produces a focal brain injury that serves as a substrate focus for seizure development, it has been hypothesized that only unprovoked partial seizures should occur after stroke. Generalized seizures are, however, not uncommon after stroke, although some investigators include secondary generalized seizures in this category.[22] Researchers who distinguish primary from secondary generalized seizures find that primary generalized seizures account for 4% to 69% of all unprovoked seizures after stroke.[38,39,45,48,59,74] Undetected onset of partial seizures may account for this variability. Nonetheless, true primary generalized seizures do occur after stroke, perhaps as a result of persistent global alterations in neurotransmitter function after stroke or of factors that alter cerebral autoregulation in people with risk factors for stroke.

Seizure prevalence is greater than expected *before* the occurrence of a first clinical stroke. In a case-control study of acute cerebrovascular accidents,[71] the prevalence of epilepsy preceding stroke was 4.55%, compared with 0.6% among controls selected from patients hospitalized for routine surgery and matched to cases by age, race, and sex. Potential controls were

excluded if they had a history of undefined cerebrovascular disease or if their surgery was related to disseminated carcinoma or alcohol excess, not formally defined abuse. These results have recently been replicated using the UK General Practice Research Database.[12] The cumulative risk for stroke was 10.0% in people with seizures compared with 4.4% in those without seizures (p <0.0001).

This increased prevalence of epilepsy before a first clinically detected stroke has led to the study of risk factors for stroke in the absence of stroke as risk factors for unprovoked seizures. Data from three studies suggest that if hypertension, measured by a physician's diagnosis or blood pressure reading, increases seizure risk, the magnitude of the increased risk is small (OR ranging from 1.0 to 1.7).[29,56,69] Additionally, left ventricular hypertrophy untreated with diuretics is associated with a sevenfold increased risk for developing unprovoked seizures[29] with a 20-fold increased risk for generalized-onset seizures and a threefold increased risk for partial-onset seizures. Thus, risk factors for stroke may increase the risk for unprovoked seizures.

Dementia

The underlying pathology of Alzheimer disease may be associated with an increased susceptibility for seizures. In patients in whom Alzheimer disease was later confirmed by autopsy,[25] there was a 10-fold increased risk for unprovoked seizures compared with the expected risk derived from data from Rochester, Minnesota. In a comparison of the risk for unprovoked seizures in patients with mild probable Alzheimer disease to the risk in cognitively normal controls over a 7.5-year follow-up period,[66] new-onset seizures developed in 16% of patients with probable Alzheimer disease after they became severely demented; no control developed seizures. All seizures in this study were generalized tonicâ€"clonic seizures. In a population-based case-control study[30] there was a sixfold increased risk for unprovoked seizure associated with Alzheimer disease. In contrast with an earlier study,[66] which may have missed partial-onset seizures, this population-based study found an increased risk for both generalized- and partial-onset seizures.

Hesdorffer et al.[30] also evaluated the risk for seizures associated with dementia other than Alzheimer disease determined by ad hoc criteria based on DSM-III. They found that dementia increased the risk for unprovoked seizure eightfold overall; risk was increased for both generalized- and partial-onset seizure. This result suggests that any disease sufficiently severe to result in a dementing process may increase seizure risk.

Multiple Sclerosis

Several studies now suggest that multiple sclerosis is associated with an increased risk for epilepsy,[44,57,60,73] suggesting an epileptogenic role for white matter lesions. In these retrospective cohort studies of people with multiple sclerosis, 1.8% to 4.8% had seizures at the time of diagnosis or developed seizures after diagnosis. Across studies, this risk is more than three times the risk for unprovoked seizures over a similar time period.

Depression and Treatment for Depression

Depression diagnosed according to DSM-III-R criteria, treatment with tricyclic antidepressants, and use of phenothiazine and electroconvulsive shock therapy were studied as risk factors for unprovoked seizures in a population-based case-control study.[31] Only depression increased the risk for seizures after controlling for the other risk factors (OR = 3.7). Additionally, attempted suicide has been shown to increase the risk for first unprovoked seizure,[32] adjusting for depression, alcohol consumption, age, and gender. These associations may be caused by disturbances in neurotransmitter function common to depression, suicide attempt, and seizures (see Chapter 205 for further discussion).

Alcohol

Alcohol intake appears to be associated with seizure occurrence (Chapter 268). A case-control study in Harlem in New York City compared individuals admitted for a first seizure with controls admitted for the first time for an acute surgical procedure.[54] Controls were excluded if they had a condition related to alcohol abuse or had experienced a seizure. Controlling for age, sex, history of hypertension, history of head injury, history of stroke, and heroin use for more than 6 months, there was a dose response between alcohol consumption and the risk for seizure, particularly among male patients (OR = 1.3 to 19.5, depending on the amount of alcohol consumed). Seizure occurrence was not associated with time since last drink. A case-control study from Nigeria also associated alcohol consumption with seizures; however, these authors did not define alcohol use.[58]

Illicit Drugs

The association between heroin and marijuana use and seizures was investigated in the Harlem case-control study.[55] Controlling for age, history of head trauma, history of stroke, and alcohol use, these investigators found that heroin increased the risk for unprovoked seizures threefold and the risk for provoked seizures fourfold. Marijuana use conferred 82% protection against provoked seizures and 64% protection against unprovoked seizures. These interesting results require confirmation in other studies (see Chapter 268 for further discussion).

Acute Symptomatic Seizures

Acute symptomatic seizures typically occur within the first week of an insult known to predispose to seizures (e.g., head trauma) and are not regarded as epilepsy (Chapter 8). In Rochester, Minnesota, the cumulative incidence of acute symptomatic seizures in patients up to 80 years of age is 3.7%.[5] Across many causes of acute symptomatic seizures, studies suggest that such seizures increase the risk for later epilepsy at least threefold, perhaps because their occurrence is a marker for severity of brain injury.[36]

Among Rochester adults with moderate or severe head trauma, early seizures increased the risk for later unprovoked seizures ninefold[3]; children with early seizures were not at increased risk for unprovoked seizures. In military populations with penetrating missile wounds to the head, 50% of men with early seizures experienced later unprovoked seizures.[11] Early postoperative seizures are associated with unprovoked seizures.[18] The magnitude of this increased risk appears related to the underlying disease requiring surgery; patients with vascular or ventricular disease before surgery have the greatest risk (increased fourfold) for unprovoked seizure. Among stroke patients without early seizures, the risk for unprovoked seizure is 19%; for those with early seizures, the risk is even greater.[26] If early seizures occur, the risk for unprovoked seizures after encephalitis is increased threefold, and after bacterial meningitis fourfold.[4]

The Protective Effect of Diuretics

Current diuretic use has been shown to be protective for the development of idiopathic/cryptogenic unprovoked seizures in a population-based case-control study in the elderly.[33] The protective effect was 46% for thiazide use and 39% for furosemide; Aldactazide was not associated with a protective effect for seizure development.

Socioeconomic Status

Indices of low socioeconomic status (SES) are associated with many established risk factors for epilepsy, including cerebrovascular disease, head trauma, congenital malformations, central nervous system infection (meningitis, encephalitis), alcohol intake or abuse, brain neoplasms, and Alzheimer disease. This complicates studies designed to examine the association between low socioeconomic status and the development of epilepsy.

Two studies now show that low socioeconomic status is associated with an increased risk for developing epilepsy,[27,35] and one study fails to find an association.[17] These studies are either community based or population based. A prospective study in England,[27] using a composite measure of SES, concluded that low SES is a risk factor for the development of epilepsy. A case-control study in Iceland[35] found that low education increased the risk for unprovoked seizure twofold, whereas home ownership was protective. When analyses were repeated by seizure etiology, the association persisted only in the idiopathic/cryptogenic group even after adjusting for cumulative alcohol intake. Interestingly, there was no effect of low SES in children, suggesting that there is a cumulative effect of social deprivation associated with the development of epilepsy.

Future Research

Much is known about factors that appear to increase the risk for unprovoked seizures, particularly for risk factors that produce clear structural brain damage. Recently, studies have suggested associations between factors that are not known to lead to such brain damage (e.g., major depression) and unprovoked seizures. Thus, the challenge for future studies of unprovoked seizures is to elucidate risk factors that increase risk in people whose seizures have no established cause. Such studies have the potential to identify novel mechanisms for seizure occurrence or to identify shared genetic susceptibility between a risk factor and unprovoked seizures.

Few studies exist concerning risk factors for seizures in older adults, in whom the incidence of seizures is increased. New studies elucidating novel factors associated with seizures in this population and confirming those already suggested are needed.

Summary and Conclusions

Studies suggest that febrile seizures, mental retardation, and cerebral palsy are risk factors for epilepsy unique to children. Prenatal and perinatal adverse events are not associated with the occurrence of epilepsy when investigators exclude children with mental retardation and cerebral palsy. Among children and adults, established risk factors for epilepsy include CNS infection, head injury, and CNS malignancies. Attention deficit hyperactivity disorder also increases seizure risk in children. In adult populations, cerebrovascular disease and Alzheimer disease are established risk factors for epilepsy. Multiple sclerosis, risk factors for stroke, major depression, alcohol intake, illicit drug use, and low socioeconomic status appear to increase the risk for epilepsy, but further studies are needed to confirm these findings.

Chapter 7

The Natural History and Prognosis of Epilepsy

Ettore Beghi

Josemir W. Sander

Introduction

For the majority of people with epilepsy, the condition is treatable and the term *prognosis* generally refers to the probability of attaining seizure freedom after treatment has been started, during treatment, and after drug withdrawal. Little is known about the natural history of the untreated condition as most patients, particularly in industrialized countries, are treated. There are only a few reports, mostly from resource-poor countries, on the prognosis of untreated epilepsy.

Methodologic Issues

As with most other chronic conditions, the prognosis of epilepsy depends on the characteristics of the population concerned, the case definition, the spectrum of severity of the condition, the duration of follow-up, and the choice of prognostic predictors, including treatment. More specifically, the design of an ideal study on the prognosis of epilepsy should include the following:

1. Well-defined criteria for the inclusion of patients.
2. Standard (homogeneous) definitions of the prognostic predictors and outcome measures.
3. Adequate duration of follow-up and proper statistical methods to adjust for those lost to follow-up and limited periods of observation.

Ideally, patients should be enrolled at a similar point in the course of the disease (e.g., the time of diagnosis or the time of the index event) and should be representative of the general population of people with epilepsy. Many patients do not seek medical advice until seizures have recurred; using these people as the population under study will exclude those who have had only one seizure and may well influence the prognosis. Additionally, most studies of the prognosis of epilepsy have been carried out in specialized services, generally including predominantly people with complex, difficult to control epilepsy; thus, selection bias may well affect the prognosis of epilepsy.

Homogeneous (preferably standard) definitions for the most common prognostic indicators should be encouraged. For example, there are inconsistent reports that a family history of epilepsy increases the risk of seizure recurrence; this may be explained by the fact that family history is difficult to ascertain and may be unreliable. Details should also be given of *all* the putative prognostic predictors considered, to provide a comprehensive overview of the prognosis of the disease and to give the best explanation of the results after controlling for the known prognostic indicators. Prolonged follow-up is required and attempts should be made to obtain information on the outcome in *all* patients. Outcome measures should be clearly defined and, where possible, reliable indicators should be used. Proper statistical methods (including multivariate analysis models) should be employed to assess the independent role of each prognostic predictor. Most of the differences among studies on the prognosis of epilepsy can be explained by the different methodology, with particular reference to the study design (retrospective or prospective; community based or specialized clinic based), the target population (children and/or adults), the timing of enrollment (interval between first seizure and enrollment), the type of seizure (generalized tonic and/or clonic, partial, and other), the length of follow-up, and the use of antiepileptic drugs.

Overall Prognosis of Epilepsy

The overall prognosis of epilepsy is favorable in the majority of patients. There are several pieces of evidence that support this conclusion. First, reports from several resource-poor countries (where people with epilepsy are largely untreated) give prevalence rates that tend to be broadly similar to those of industrialized countries.[3,7,8,21,22,28,31,48,50,52,59,64,65,69,71] Prevalence rates for active epilepsy are usually between 4 and 10 per 1,000 in both settings. In most resource-poor countries the incidence of epilepsy is higher than that in industrialized countries.[27,30,36,42,43,48,50] Incidence rates in developed countries tend to fall within the range of 30 to 60 cases per 100,000, while most reports from resource-poor countries give figures in excess of 70 per 100,000. The increased mortality of epilepsy in resource-poor countries explains only part of the difference between incidence and prevalence. The most likely explanation for the similarity of the prevalence rates, therefore, is spontaneous remission in some people. Additionally, contrary to old reports,[49] studies done in newly diagnosed patients have consistently shown that 55% to 68% of cases achieve prolonged seizure remission (Table 1).[35]

Table 1 Population-based Studies on the Prognosis of Epilepsy

Country	Population	% (Duration) remission	Source	Follow-up (yr)	Notes
United States	All ages	55% (10-y) at 20 y	Records linkage	33	Included isolated seizures
United Kingdom	All ages	69% (5-y) at 9 y	General practitioners	9	Included isolated seizures
Sweden	Adults	58% (5-y) at 11 y	Multiple	10	Included isolated seizures
France	All ages	62% (complete) at 5 y	Neurologists	5	Included isolated seizures
Switzerland	All ages	68% (complete) at 10 y	Neurologists	10	Included isolated seizures
Ecuador	All ages	21% (complete) at 4 y	Hospitals	4	Only two or more seizures

Holland	Children	62% (2-y) at 5 y	Hospitals	5	Included isolated seizures
Canada	Children	55% (complete) at 7 y (average)	Child neurologists	>20	Included isolated seizures
Finland	Children	68% (5-y) at 30 y	Multiple	>30	Only two or more seizures

Early Prognosis of Unprovoked Seizures and Epilepsy

Prognosis after the First Unprovoked Seizure

The risk of relapse after a first unprovoked seizure has been reported to range from 23% to 71%[5] and from 14% to 68% when actuarial methods are used. The rates at 2 and 5 years are 21% to 69% and 34% to â‰¥71%, respectively. Population-based studies[2,29] provide more homogeneous relapse rates at 1 (36% to 37%) and 2 years (43% to 45%). In a systematic review of 16 reports,[11] the average overall recurrence risk was 51% (95% confidence interval [CI], 49% to 53%). By 2 years, the recurrence risk was 36% and 47% in prospective and retrospective studies, respectively. After a first unprovoked seizure, the probability of a relapse decreases with time; about

P.66

50% of recurrences occur within 6 months of the initial seizure and 76% to 96% within 2 years.[11]

Risk Factors for Relapse of a First Unprovoked Seizure

The two most consistent predictors of recurrence are a documented etiology of the seizure (as opposed to idiopathic or cryptogenic seizures) and an abnormal (epileptiform and/or slow) electroencephalogram (EEG) pattern.[11] The pooled recurrence risk in patients with an idiopathic or cryptogenic first seizure is 32% (95% CI, 28% to 35%), compared with 57% (95% CI, 51% to 63%) for a remote symptomatic seizure (i.e., a seizure with an underlying, nonacute brain problem). The recurrence risk ranges from 27% (95% CI, 21% to 33%) with a normal EEG tracing to 58% (95% CI, 49% to 66%) with an EEG showing epileptiform abnormalities. Epileptiform abnormalities tend to be associated with a higher risk of seizure recurrence than do nonepileptiform abnormalities. The pooled 2-year recurrence risk is lowest for an idiopathic or a cryptogenic first seizure with a normal EEG (24%; 95% CI, 19% to 29%), intermediate for a remote symptomatic seizure (48%; 95% CI, 34% to 62%) with normal EEG *or* an idiopathic/cryptogenic seizure with an abnormal EEG (48%; 95% CI, 40% to 55%), and highest with a remote symptomatic seizure with an abnormal EEG (65%; 95% CI, 55% to 76%). Seizures occurring during sleep tend to be associated with a higher risk of recurrence in both children and adults.[34,57,68] Partial seizures, which are usually associated with a documented brain injury, are also correlated with a higher risk of recurrent seizures, even after controlling for etiology and EEG abnormalities.[2,15] A positive correlation between seizure relapse and family history of seizures has only been confirmed in patients with idiopathic or cryptogenic first seizures in one study.[33] A history of prior acute symptomatic seizures has occasionally been found to increase the risk of relapse, while evidence is inconclusive or lacking for sex, age, and presentation with status epilepticus.[11]

Treatment, Risk of Recurrence, and Long-term Prognosis of a First Seizure

There are at least five published randomized studies assessing the effects of treatment of the first unprovoked seizure.[16,20,23,25,44,46] The results of these studies consistently show that treatment of the first seizure seems to reduce the risk of short-term relapse but is apparently ineffective on the chance of long-term seizure remission. A large multicenter Italian trial[23] (the FIRST study) of 397 children and adults was conducted to assess the effectiveness of treatment of the first seizure on the risk of relapse and the long-term prognosis of epilepsy. Patients seen within 7 days after a first witnessed unprovoked tonicâ€"clonic seizure with or without partial onset were randomized to be treated or to be left untreated until the time of a second seizure. The mean period of observation was 274 days in patients given immediate treatment and 309 days in patients who did not receive treatment. Overall, 36 of 204 treated patients and 75 of 193 untreated patients were referred for seizure relapse. In this trial, the cumulative time-dependent risk of recurrence in treated patients was 17% at 12 months and 25% at 24 months, and in untreated patients was 41% and 51%, respectively. The differences tended to disappear, however, when the end-point was the chance of initiating a 2-year remission. The cumulative probability of long-term remission in the two treatment groups tended to be similar from the second year of follow-up until 15 years after randomization.[41a] The results of this study were confirmed by an even larger pragmatic randomized European trial (the MESS study) comparing immediate and deferred treatment for early epilepsy and single seizures.[44] Patients aged at least 1 month were randomized if both the clinician and the patient were uncertain whether to proceed with treatment. In this trial, 722 patients were randomized to immediate treatment and 721 to deferred treatment. Of these, 404 and 408, respectively, had a single seizure at randomization. Immediate treatment prolonged the time to the first relapse (risk ratio [RR] 1.5; 95% CI, 1.2 to 1.8) and increased the proportion of patients achieving immediate 2-year remission (64% vs. 52%) (p = 0.023). However, at the 2-year follow-up, 32% of those with immediate treatment had had a recurrence compared with 39% of those with deferred treatment. In addition, 92% versus 92% patients achieved 2-year remission at 5 years and 95% versus 96% at 8 years, respectively. The results of these trials tend to confirm several observational reports that the long-term prognosis of the first seizure is substantially unaffected by immediate treatment. However, the comparative effects of the treatment of the first seizure and treatment only on relapse on the chance of long-term remission (without drugs) have not yet been assessed.

Prognosis of Untreated Epilepsy

With one exception,[37] the prognosis of untreated epilepsy has been assessed only in resource-poor countries where epilepsy is

P.67

largely untreated (treatment gap ranging from 70% to 94%). In a population-based study conducted in Ecuador,[48] the cumulative annual incidence rate was 190 per 100,000 and the prevalence rate of active epilepsy was 7 per 1,000, which implies a remission rate of at least 50%. Similar prevalence rates of active epilepsy (5 per 1,000) were found in Nigeria,[47] where only 4% of patients were treated at the time of the survey, and in Ethiopia.[65] In a smaller study conducted in Malawi,[70] duration of active epilepsy was similar to that of industrialized countries. All these findings lend support to the hypothesis that spontaneous remission of untreated epilepsy is a common event. In a field study conducted in Warsaw in the 1970s, almost one third of those who had never been treated, including some who had previously had frequent generalized seizures, had been free of seizures for more than 5 years.[72] A small study in Finland, conducted in those with untreated epilepsy, found the probability of remission to be 42% by 10 years after the onset of epilepsy.[37]

Prognosis of Newly Diagnosed Epilepsy

In industrialized countries treatment of epilepsy is generally started at the time of diagnosis, which is not usually made until at least two unprovoked seizures have occurred. In fact, after a second unprovoked seizure the risk of a third seizure has been estimated as 73%, and after a third seizure the risk of a fourth seizure has been estimated as 76%.[32] Population-based studies on the long-term prognosis of treated epilepsy report a 58%

to 65% cumulative 5-year remission rate at 10 years.[1,18] This number rises to about 70% by 20 years following seizure onset.[1] The 5-year remission rate at 10 years is 61% in adults[41] and the 3- to 5-year remission rate at 12 to 30 years in children is 74% to 78%.[24] In a Finnish cohort of patients with childhood-onset epilepsy, after over 30 years of follow-up 64% of cases were in 5-year terminal remission, of whom 74% were off medications.[60]

Principal Prognostic Predictors

The etiology of the epilepsy is by far the strongest prognostic predictor for seizure recurrence. In general, idiopathic epilepsy has a better chance of seizure remission than symptomatic or cryptogenic epilepsy. In the population-based study from Rochester, Minnesota, people with symptomatic epilepsies were found to have a significantly lower chance of 5-year remission than those with idiopathic epilepsies (30% vs. 42% at 15 years).[1] Within the group of those with symptomatic epilepsies, patients with neurologic dysfunction present at birth had the lower chance of remission (46% and 30% off drugs at 20 years). Lower, albeit less significant, remission rates in patients with symptomatic epilepsies were also found in the United Kingdom, Sweden (adults), and Finland (children).[35] A documented etiology of epilepsy has also been found to be a significant predictor of seizure intractability in childhood-onset epilepsy.[62] In the Connecticut study of childhood-onset epilepsy, early predictors of intractability included known etiology, high initial seizure frequency, and focal EEG slowing.[9] Other prognostic indicators of 5-year remission in the Rochester, Minnesota, population included absence of EEG epileptiform abnormalities (odds ratio [OR] 1.6) and absence of generalized tonicâ€"clonic seizures.[55] In the UK National General Practice Study of Epilepsy (NGPSE), the only independent predictor of 1-year and 2-year remission was the number of seizures experienced by the patient in the 6 months after the first seizure.[18,43] When other prognostic predictors are taken into consideration, there is no evidence that age at onset of seizures affects seizure outcome. With the exception of epilepsies associated with rare inherited sex-linked disorders, sex has not been indicated as a significant prognostic predictor.

Prognosis of Epilepsy Syndromes

An epileptic syndrome is a symptom complex that is characterized by a fairly uniform clinical and electrographic picture. In addition to seizure type, defining features of epileptic syndromes also include family history, age at onset, presumed etiology, and EEG and neuroimaging findings.[19] To some extent, particularly in children, different epileptic syndromes have various and sometimes distinct outcomes and responses to treatment. It has been suggested[52] that epilepsy syndromes can be classified into four prognostic groups:

1. Excellent prognosis (about 20% to 30% of the total) with high probability of spontaneous remission: These include neonatal seizures, benign partial epilepsies, benign myoclonic epilepsy in infancy, and epilepsies provoked by specific modes of activation.
2. Good prognosis (about 30% to 40%) with easy pharmacologic control and possibility of spontaneous remission: These include infantile absence epilepsy, epilepsies with generalized tonicâ€"clonic seizures secondary to specific conditions, and some partial epilepsies.
3. Antiepileptic drugâ€"dependent prognosis (about 10% to 20%), which may respond to drugs, but tend to relapse after treatment withdrawal: These include juvenile myoclonic epilepsy and most partial epilepsies (symptomatic or cryptogenic).
4. Guarded prognosis (about 20%) in which seizures tend to recur despite intensive treatment: These include epilepsies associated with congenital neurologic defects, progressive neurologic disorders, and some symptomatic or cryptogenic partial epilepsies.

The prognosis of specific epilepsy syndromes may be significantly different and reflects, at least in children, the inherent severity of epilepsy more than the quality of the therapeutic approach.[58]

Antiepileptic Drugs and Seizure Outcome

Antiepileptic drugs (AEDs) are often successful in suppressing seizures, but they do not seem to alter the long-term prognosis of epilepsy. In addition, in the FIRST and MESS studies[44,46] there was evidence of less than optimal outcome of seizures in about 20% of patients with newly diagnosed epilepsy.

There are virtually no reports on the comparative efficacy of old and new AEDs on the long-term outcome of epilepsy, and there is no evidence to suggest that the newer medications are more efficacious.[4,40] Although individuals seem to present differing responses to the available drugs, all first-line AEDs seem to be equally effective at a community level. In a single-center hospital-based study of 470 patients diagnosed, treated, and followed for a mean period of 5.6 years, 47% of cases became seizure free with the first prescribed drug.[39] There was no significant difference in the proportion of cases with inadequate seizure control among those treated with carbamazepine, valproate, or lamotrigine. The majority of seizure-free patients required only a moderate daily dose of AED.

Prognosis of Epilepsy after Treatment Withdrawal

A long-term population-based study has shown that 5-year terminal remission of epilepsy (without drugs) is 61%.[1]

Discontinuation of drug treatment is thus a valuable option in patients with epilepsy who are seizure free for 2 years or longer. In a critical review of 28 studies accounting for 4,615 cases, most of whom had at least 2 years of seizure remission, the proportion of patients with relapses during or after treatment withdrawal ranged from 12% to 66%.[63] Using life-table analysis, the cumulative probability of remaining seizure free in children was 66% to 96% at 1 year and 61% to 91% at 2 years. The corresponding values in adults were 39% to 74% and 35% to 57%, respectively. The relapse rate was highest in the first 12 months (especially in the first 6 months) and tended to decrease thereafter. In a meta-analysis of 25 studies, the pooled relapse risk was 25% (95% CI, 21% to 30%) at 1 year and 29% (95% CI, 24% to 34%) at 2 years.[10]

In the only randomized trial on the effects of AED withdrawal on seizure relapse, 22% of patients randomized to continued treatment had relapsed by 2 years, while 41% of patients randomized to slow drug withdrawal had relapsed.[45] This differential risk of relapse was maximal between 1 and 2 years and declined thereafter. After 2 years, the risk of subsequent relapse was the same for both treatment groups. The risk of recurrence was also similar in patients who relapsed after withdrawal of AEDs and in those who relapsed while remaining on treatment.[17]

Factors Predicting Seizure Relapse after Treatment Withdrawal

A number of factors have been associated with favorable or unfavorable seizure outcome after treatment discontinuation. Factors consistently indicating a higher-than-average risk of seizure relapse include adolescent-onset epilepsy, partial seizures, presence of an underlying neurologic condition, and abnormal EEG findings (in children). Factors associated with a lower-than-average risk were childhood-onset epilepsy, idiopathic generalized epilepsy, and (in children) normal EEG. Selected epilepsy syndromes (e.g., benign epilepsy with centrotemporal spikes and juvenile myoclonic epilepsy) may be associated with significantly different outcomes after treatment withdrawal.[63] In the Medical Research Council AED withdrawal study, independent predictors of relapse included history of partial seizures, primarily or secondarily generalized tonicâ€"clonic seizures, or myoclonic seizures; use of more than one AED; seizures after treatment start; and a shorter seizure-free period at randomization.[45] In a meta-analysis of 25 studies, those with adolescent age at onset of seizures had a 1.34-fold increased risk of relapse (95% CI, 1.00 to 1.81) compared with those with adult age at onset.[10] Patients with remote symptomatic seizures had a 1.55-fold increased risk of relapse (95% CI, 1.21 to 1.98). An abnormal EEG prior to drug discontinuation was associated with a 1.45-fold increased risk of relapse (95% CI, 1.18 to 1.79). In the same review, prognosis following drug withdrawal was similar whether a 2-year or a 4-year seizure-free interval was considered. Additionally, a randomized trial comparing a 6-week taper with a 9-month taper after 2-year seizure remission in children with epilepsy showed no difference in recurrence risk at 2 years.[66]

Psychosocial Outcome

People with epilepsy are more likely to be unemployed than people in the general population, with unemployment rates ranging from 24% to 36%.[51] In a population-based study of adults who had childhood-onset epilepsy, independent predictors of low socioeconomic status included poor fine-motor performance (OR 14.8), poor short-term outcome after treatment (OR 9.8), and presence of psychoneurotic symptoms (OR 3.2).[61] In that study, 15% required little assistance in daily living activities and about 50% were socially disabled, of whom 60% had moderate to severe handicap. School achievement in children and adolescents with epilepsy is lower than that in the general population. Low achievement may occur even when epilepsy is not associated with other neurologic sources of impairment.[41] A lower intellectual level is the most likely explanation for underachieving at school. Learning disabilities and cognitive dysfunction are commonly reported in children with epilepsy.[13] Factors associated with underachieving at school include epilepsy, use of AEDs, and psychosocial factors. The strongest independent predictors of underachieving at school include early onset of seizures and cumulative number of seizures.[54] Alteration of cognition might reflect a chronic adverse effect of AEDs, but the negative effects of the drugs are only one of several factors that may influence cognition. In addition, subjective complaints of cognitive deficits (e.g., memory problems or attention) may also reflect aspects of adverse effects other than those concerning specific cognitive functions (e.g., mood and anxiety).[14] Although intuitive, the correlation between underachieving at school and psychosocial factors is not supported by studies with robust methodology.

Lower rates of marriage and fertility (even after adjustment for marriage) have also been reported in people with epilepsy when compared with the general population.[53] Several sociocultural limitations may explain the lower likelihood of marriage in the presence of epilepsy. Although adverse treatment effects may be implicated, the cause of decreased fertility remains unclear.

In the absence of seizures (with or without treatment), the risk of accidents and injuries is clearly decreased compared with those with ongoing seizures, and tends to be close to that of the general population.[38,67] In a multicenter cohort study conducted in six western European countries (Italy, Germany, England, Holland, Spain, and Portugal) and three eastern European countries (Russia, Estonia, and Slovenia), 951 children and adults with early idiopathic, cryptogenic, or remote symptomatic epilepsy and 909 matched controls were followed prospectively for 17,484 and 17,206 person-months, respectively.[6,67] Two hundred and seventy accidents were reported by 199 people with epilepsy (21%) compared with 149 accidents reported by 124 controls (13%). About one quarter of accidents in people with epilepsy were seizure related. The most common accidents in people with epilepsy were, in decreasing order of frequency, contusions, wounds, fractures, abrasions, and brain concussions. Contusions followed by wounds and sprains or strains predominated in the controls. In people with epilepsy, about one third of brain concussions, contusions, and fractures were seizure related compared with one fifth of burns and less than one sixth of wounds. Most accidents occurred at home, followed by traffic, sports and other leisure activities, work, and school. About one half of domestic accidents were seizure related. About one third of school accidents and one quarter of traffic accidents were seizure related. Apart from brain concussions, accidents occurring both in patients with epilepsy and in nonepileptic controls were mostly trivial. The proportion of road accidents attributable to seizures in people with active epilepsy is extremely low, ranging from 0.02% to 0.2%.[12,56]

Summary and Conclusions

In the past, studies from tertiary referral centers offered a picture of epilepsy as a chronic, progressive, unremitting disorder.[26,49] Epidemiologic evidence indicates that the poor prognosis observed in earlier studies was largely the result of selection bias. More recently, the results of epidemiologic studies and randomized clinical trials have greatly changed our

understanding of the nature and natural history of seizures and of epilepsy. On this basis, one can assume that epilepsy is a fairly benign condition in the majority of cases, with a good prognosis for seizure control and, ultimately, discontinuation of AEDs. However, epilepsy is a heterogeneous clinical condition and many different syndromes have been recognized. The outcome is determined to some extent by the type of epilepsy. Factors influencing the prognosis of epilepsy include etiology, EEG abnormalities, presence of generalized tonicâ€"clonic seizures, the number of seizures experienced after the onset of treatment, and the syndromic pattern. Antiepileptic drugs are successful in suppressing seizures, but do not alter the long-term prognosis of epilepsy. The available compounds seem to be equally effective, about 50% of patients being satisfactorily controlled by the first drug, given as monotherapy. In contrast to the medical prognosis, the psychosocial prognosis of epilepsy is at best fair, reflecting the negative aspects of the disease on the daily living activities and the quality of the patient's life. The heterogeneous spectrum of the disease, the adverse treatment effects, and stigma may all concur in affecting the psychosocial outcome of epilepsy.

Chapter 8

Epidemiology of Acute Symptomatic Seizures

W. Allen Hauser

Introduction

What condition looks like epilepsy, is frequently called â€œepilepsy,â€ is frequently counted as epilepsy in epidemiologic studies, but in general has a different basis from that of epilepsy and is seldom treated as epilepsy? The answer is *acute symptomatic seizures,* also referred to as *reactive seizures, provoked seizures,* or *situation-related seizures.* Acute symptomatic seizures are seizures that occur at the time of a systemic insult or in close temporal association with a documented brain insult.[7,8,16] This class of seizure falls into the category of situation-related seizures in the Revised Classification of Epilepsies and Epileptic syndromes suggested by the International League Against Epilepsy.[7]

Acute symptomatic seizures differ from epilepsy in several important aspects: First, unlike epilepsy, these seizures have a clearly identifiable proximate cause, to the extent that one can never be certain of a causal association. When one considers the temporal sequence of acute symptomatic seizures (e.g., uremia, head injury, or stroke immediately preceding a seizure), the biologic plausibility (acute disruption of brain integrity or metabolic homeostasis) and in many cases the dose effect (severity of injury correlated with the risk for seizures) all quite compellingly indicate causation. Although a risk ratio for the immediate association between cause and effect has not been calculated, it must be enormous. Second, unlike epilepsy, acute symptomatic seizures are not characterized by a tendency to recur. The risk for subsequent epilepsy may be increased in individuals experiencing such insults; in general, one does not expect seizures to recur unless the underlying condition recurs. As a corollary, such individuals usually do not need to be treated with antiseizure medication on a long-term basis, although such treatment may be warranted on a short-term basis until the acute condition is resolved.[34]

Few epidemiologic studies report the frequency of acute symptomatic seizures. This may be caused in part by the difficulties involved in identification. Such seizures are seldom indexed as acute symptomatic seizures; rather, the underlying condition is likely to be diagnosed and coded. This makes a study design relying on medical record review inefficient and probably leads to gross underenumeration. Individuals with acute symptomatic seizures are seldom referred to neurologists for long-term follow-up, and given the acute nature of the condition, an electroencephalographic evaluation may not be warranted or appropriate. These important sources of patient identification are thus eliminated. In studies relying on field surveys, a moderate amount of sophistication is necessary to distinguish acute symptomatic seizures from unprovoked seizures. Thus, even though causation and prognosis of acute symptomatic seizures are quite different from those of epilepsy, some recent epidemiologic studies have categorized individuals with such seizures as having â€œepilepsy,â€[31] have failed to distinguish between unprovoked and acute symptomatic seizures,[28] or have not provided detailed information on cause, age, or gender.[13,20,21] To study acute symptomatic seizures properly, it is more efficient to study the associated conditions, such as head injury or stroke. This procedure is not usually undertaken by most epileptologists, and seizures are not a major interest to specialists treating underlying conditions such as stroke or hyponatremia. Nonetheless, in aggregate, acute symptomatic seizures account for more than half, and in some geographic areas as much as 80%, of all newly occurring seizures. Failure to consider these conditions separately will greatly modify the apparent epidemiologic characteristics of what is called â€œepilepsy.â€ In addition to greatly increasing the apparent incidence of â€œepilepsyâ€

mortality, age and gender structure of those affected is quite different if such cases were included as epilepsy, as has been suggested by some.[14,18,27] At present, acute symptomatic seizures continue to be a useful concept for classification and prognosis, and the suggestions by some that the term (and presumably the concept) be abolished seems inappropriate.

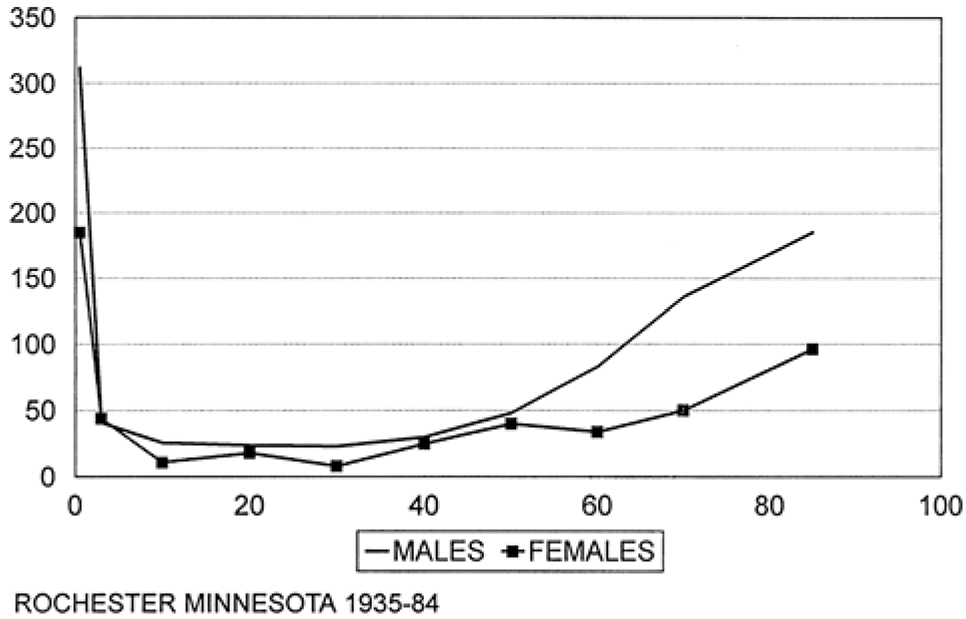

FIGURE 1. Age-specific incidence of acute symptomatic seizures (excludes childhood febrile seizures). CVD, cerebrovascular disease.

A major difficulty with acute symptomatic seizures remains their definition. For conditions such as stroke or brain trauma, seizures occurring in the first week of an insult have generally been classified as acute symptomatic. This is clearly an artificial cut-point of convenience and would better include all seizures occurring until the point of clinical stabilization. For metabolic conditions, it is frequently unclear for systemic metabolic derangements how severe a derangement must be or for what duration it must persist. For some conditions (e.g., neurocysticercosis), the acute insult may persist for weeks or months, defying a strict temporal definition.[11] This chapter reviews the incidence of acute symptomatic seizures and the incidence of seizures in conditions associated with acute symptomatic seizures. Although febrile seizures in childhood are by definition acute symptomatic seizures, they differ from other acute symptomatic seizures in their unique age specificity, high frequency in the population (up to 9%), and universality of exposure. It therefore seems appropriate that they be discussed separately.

Incidence of Acute Symptomatic Seizures

Overall Incidence

Only two studies provide detailed information regarding the incidence of acute symptomatic seizures.[5,24,26] The incidence of seizures occurring at the time of systemic metabolic insults or temporally associated with an insult to the central nervous system (CNS) was determined for the residents of Rochester, Minnesota. The age-adjusted incidence rates for 1955 to 1984, the period of most complete case ascertainment, was 39 per

P.72

100,000 person-years (U.S. 1970 population). This represents about 40% of all cases of afebrile seizures identified in the community during the study period and underscores the overall importance of this class of seizure disorder in population-based incidence surveys.

This rate is somewhat higher than that reported in Gironde, Bordeaux, France, which was 29 per 100,000 person-years. In this community-based study, acute symptomatic seizures also accounted for about 40% of all newly identified cases of afebrile seizures. The difference in absolute incidence of acute symptomatic seizures in these two communities may reflect a difference in the completeness of case ascertainment or a difference in the frequency of underlying conditions rather than any true difference in the epidemiologic characteristics. In any case, the similarities in the patterns and causes reported in the two studies are considerable.

Other studies provide some concept of frequency, but do not provide additional detail about age, etiology, or gender. In Switzerland, incidence was 25.2 per 100,000, accounting for 35% of all new cases of unprovoked seizures (Jallon). In Martinique, the incidence was 17 per 100,000, accounting for about 20% of all incident cases; in a study in children in Tunis, about 10% of all new cases were acute symptomatic. Although not specifically population based, a study from a British general practice survey[33] reported 21% of newly occurring seizures to fall into the category of acute symptomatic seizures.

Gender

From what we know about the conditions associated with acute symptomatic seizures, men seem to be at higher risk than women. In both the French study and the U.S. study, the age-adjusted incidence in men was considerably higher than that in women. Sex-specific incidence in the French study, adjusted to the U.S. 1970 population, was 33 for men and 17 for women. In contrast, the adjusted incidence in the United States during a similar time interval was 56 for men and 33 for women. These differences would seem to reflect gender-related differences in incidence of underlying conditions associated with acute asymptomatic seizures rather than any specific biologic phenomena.

Age

The age-specific incidence of acute asymptomatic seizures in the U.S. study was by far the highest during the first year of life (Fig. 1). This is attributable to the high incidence of acute symptomatic seizures associated with metabolic, infectious, and encephalopathic causes during the neonatal period. Incidence declined in childhood and the early adult years and reached a nadir of 15 per 100,000 person-years among those 25 to 34 years of age. After 35 years of age, the incidence increased progressively, and reached 123 per 100,000 among those older than 75 years of age. Cerebrovascular disease accounted for about half of all acute symptomatic seizures in persons older than 65 years of age.

As mentioned previously, age-adjusted incidence is considerably higher in men than women. The sex difference was greatest at the extremes of age. Between the ages of 15 and 44, there were few differences among all causes of acute symptomatic seizures. Seizures associated with eclampsia in women of childbearing age offset a lower incidence of seizures among women associated with other causes.

The age-specific incidence rates of acute symptomatic seizures in the French and U.S. studies were similar in middle-aged men, but the U.S. rates were higher in children younger than 15 years of age and in the elderly. Because incidence rates by etiologic groups were not provided in the French study, it is not possible to contrast the rates by etiology or to judge whether the differences in overall incidence might be attributable to differing distributions of the underlying insults associated with acute asymptomatic seizures.

Causes of Acute Symptomatic Seizures

The major causes of acute symptomatic seizures in both the French and U.S. studies were traumatic brain injury, cerebrovascular disease, drug withdrawal, and CNS infection. The underlying causes of the seizures are reflected in patterns of age, sex, and time period. Although the overall proportional distribution by cause was similar in the United States and France, no age- or etiology-specific data are available for the latter study. Cause-specific data from the U.S. study are presented in FIGURE 2.

P.73

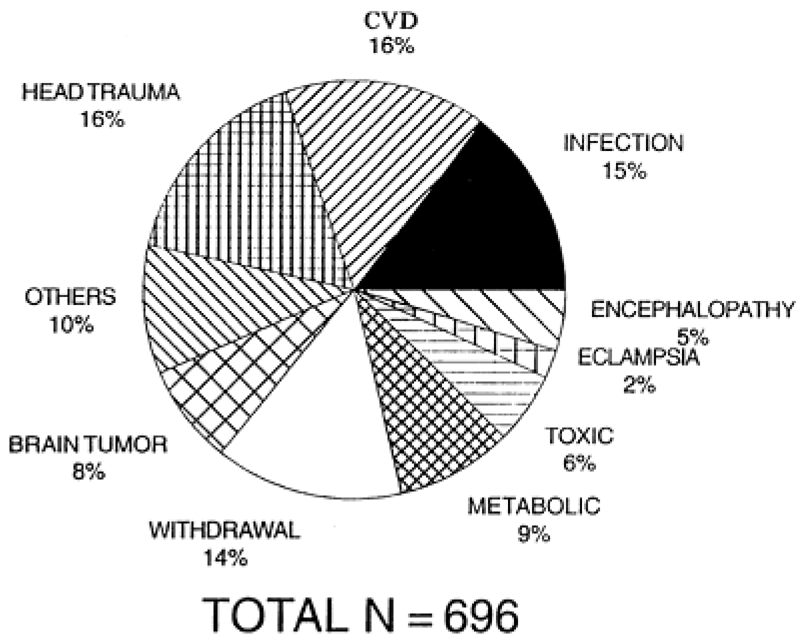

FIGURE 2. Acute symptomatic seizure precipitating causes.

Acute Symptomatic Seizures Associated with Primary Brain Insults

Central Nervous System Infection

Acute symptomatic seizures in infections of the central nervous system are those occurring during the acute phase of infection. About 5% of people with CNS infection can be expected to experience an acute symptomatic seizure.[4] Infections of the CNS accounted for about 15% of all acute symptomatic seizures in both Bordeaux, France, and Rochester, Minnesota. In the latter study, the age-specific trends of acute symptomatic seizures associated with CNS infection followed the pattern of incidence of CNS infection.[29] The highest incidence was during the first year of life and in children younger than 15 years of age; the incidence was lower in adults. The age-adjusted incidence of 5.2 per 100,000 person-years has been relatively constant over time. Overall, the age-adjusted incidence in men is twice that in women.

Neurocysticercosis (NC) represents a special category of CNS infection and also a special category of acute symptomatic seizures. Seizures are second only to headache as a presenting symptom of NC. It is assumed that most of these seizures are acute symptomatic and are associated with the response to the acute inflammatory response associated with transitional cyst degeneration.[10] Unlike most time-delimited insults associated with acute symptomatic seizures, the inflammatory response may last from weeks to months, thus requiring a modification of some of the usual concepts of acute symptomatic seizures.[11]

Brain Trauma

Seizures occurring within the first week of a traumatic brain injury are generally assumed to be acute symptomatic. Seizures occurring after that time are generally considered late or unprovoked, although it would certainly be more appropriate to include the concept of stabilization in such definitions. In civilian studies of traumatic brain injuries, about 6% of all cases are associated with acute symptomatic seizures.[2,32] The frequency of early seizures increases with severity of injury and probably represents a surrogate for severity. Acute symptomatic seizures associated with head trauma accounted for about 15% of all acute symptomatic seizures occurring in Rochester and only about 5% of all cases in Bordeaux. The higher frequency in Rochester reflects the fact that all cases of head injury in the community were reviewed, whereas the

French study depended on identification of only those people with seizures. Traumatic acute symptomatic seizures in Rochester were more common in men (age-adjusted rate, 8.6) than in women (age-adjusted rate, 4.8) at all ages. The age-specific incidence of head trauma is trimodal.[3,9] Given similar levels of severity of injury, children are at higher risk for acute symptomatic seizures than adults.[2]

Cerebrovascular Disease

Following the example of brain injury, acute symptomatic seizures associated with cerebrovascular disease are generally limited to seizures occurring within 1 week of the acute ictus. Between 5% and 10% of individuals with a cerebrovascular insult experience a seizure at the time of stroke.[22,30,35] The frequency varies with the nature of the insult and is probably highest in those with intracerebral hemorrhage. In Bordeaux, cerebrovascular disease accounted for about one third of all cases of acute symptomatic seizures, compared with only 15% of all cases in Rochester.

Paralleling the incidence of cerebrovascular disease,[6] acute symptomatic seizures associated with stroke are rare in persons younger than 55 years of age; the incidence rises rapidly with increasing age, reaching 54.6 per 100,000 among persons older than 75 years of age. The age-adjusted incidence of acute symptomatic seizures is higher in men than in women (9.4 vs. 4.7 per 100,000 cases).[6] The sex-specific difference is particularly dramatic in those 65 to 74 years of age: 55.1 per 100,000 in men versus 15.5 per 100,000 in women.

In Rochester, the age-specific incidence of acute symptomatic seizures associated with cerebrovascular disease was stable from 1945 through 1974 but fell in the final decade along with the incidence of stroke.[6] The age-adjusted incidence fell through the years from 8.6 in the decade 1955 to 1964 to 6.5 in the decade 1964 to 1974 to 5.1 in the decade 1975 to 1984.

Brain Tumor

There is debate about how to classify seizures associated with brain tumors. A high proportion of individuals with brain tumors may experience acute symptomatic seizures.[15] In Rochester, acute symptomatic seizures associated with primary or secondary brain tumors occurred at all ages but were rare in persons younger than 45 years of age. The age-specific incidence rates in persons older than 45 years of age were constant at 6 to 8 per 100,000 person-years. Unlike most other acute symptomatic seizures, seizures associated with neoplasm were equally common in men and women.

Acute Symptomatic Seizures Associated with Systemic Disturbances

Seizures occurring in association with systemic insults are easy to identify, although strict operational definitions are elusive. The severity of a systemic insult or the timing of the seizures from the start of the insult is seldom specified.[12] Nonetheless, this category accounts for a substantial proportion of all acute symptomatic seizures.

Eclampsia

In the Rochester studies, 15 women had seizures attributed to eclampsia during a 50-year period; this accounted for about 3% of acute symptomatic seizures in women, an incidence of 2.8 per 100,000 women ages 15 to 44 years. The incidence of eclampsia may more appropriately be expressed as a proportion of deliveries. The risk per 1,000 deliveries was 1.1 in the decade 1934 to 1944, 0.6 during 1945 to 1954, 0.4 during 1955 to 1964, 0.2 during 1965 to 1974, and 0.1 during 1975

to 1984. Because a higher proportion of deliveries occurred at home during the 1930s and 1940s, cases of eclampsia have been missed during this period, leading to an underestimation in the true decline in incidence in this community. The progressive decline of the incidence of eclampsia since 1935 probably reflects better management of toxemia in pregnancy.

Socioeconomic factors probably play a role in incidence rates of eclampsia. In Houston, Texas, the incidence of eclampsia in two inner-city hospitals from 1982 to 1992 was 0.7 per 1,000 deliveries,[1] a frequency similar to that in Rochester, Minnesota, in the 1940s. Seizures associated with eclampsia were not separately reported in the Bordeaux study.

Toxic Insults

Seizures may occur in association with a variety of toxic insults (e.g., carbon monoxide poisoning or acetylsalicylic acid overdose). Toxic insults accounted for about 5% of all acute symptomatic seizures in Rochester, but only a small proportion of cases in Bordeaux. This may be a consequence of differences between these two studies in inclusion criteria for this category. In Rochester, the overall incidence of acute symptomatic seizures associated with toxic insults was 2.2 per 100,000 cases, with the highest incidence in the elderly (older than 75 years of age).

Drug Withdrawal

Most drug withdrawal seizures are associated with abuse of ethanol and, less frequently, barbiturates or other substances. This category of acute symptomatic seizures accounted for about 15% of cases in Rochester and about one third of cases in Bordeaux. Incidence for this group of acute symptomatic seizures peaked in the 35- to 54-year-old age group, and the age-adjusted incidence was considerably higher in men than women (10.5 per 100,000 person-years vs. 3.4 per 100,000 person-years). Withdrawal seizures were the primary cause of acute symptomatic seizures for those 25 to 55 years of age. The incidence of seizures attributed to this cause progressively increased during the study period. Seizures associated with alcohol or drug abuse or withdrawal may be less completely ascertained than seizures associated with other causes because, unlike evaluations of stroke, head trauma, CNS infection, and brain tumors, each alcohol-related patient evaluation is not systematically reviewed for seizures.

Metabolic Insults

Systemic metabolic illness accounted for about 10% of all acute symptomatic seizures in Rochester and about 15% of cases in Bordeaux. In Rochester, the incidence of acute symptomatic seizures attributed to metabolic insults was highest during the first year of life. This was largely caused by hypocalcemia or hypoglycemia in newborns. These cases were identified primarily before 1960; they are virtually nonexistent at the present time in this community, although it is conceivable that they continue to account for a substantial proportion of newborn cases in less medically sophisticated areas. Seizures associated with metabolic disturbances were rare between the second week of life and 55 years of age. There was a slight rise in incidence after this age. The incidence of seizures attributed to metabolic causes among newborns fell from 105 per 100,000 cases during the decade 1945 to 1954 to 50 per 100,000 in the decade 1975 to 1984.

Cumulative Incidence of Acute Symptomatic Seizures

In Rochester, the risk for experiencing an acute symptomatic seizure during an 80-year life span is 3.6%; this approaches the risk for epilepsy. The risk for any type of acute symptomatic seizure from birth through 80 years of age is almost 5% in men and a little more than 2.5% in women. The prevalence of history of acute symptomatic seizures is somewhat lower than the cumulative incidence because of the high mortality rate associated with many of the causes of acute symptomatic seizures.

Prognosis of Acute Symptomatic Seizures

In general, acute symptomatic seizures are a reflection of disease severity and, as such, are associated with a relatively high mortality rate.[18,23,27] However, prognosis obviously varies with the underlying condition. No studies address the influence of acute symptomatic seizures on risk for mortality within given conditions, so it is impossible to assess the contribution of seizures per se on mortality. In survivors of neurologic insults, those with acute symptomatic seizures seem to be consistently at increased risk for subsequent epilepsy compared with those without acute symptomatic seizures.[2,4,19] This is probably not related to a kindling phenomenon but rather to the increased severity of initial insult in those with acute symptomatic seizures. Acute symptomatic seizures associated with metabolic insults are not associated with a similar increase in risk for subsequent epilepsy. None of the cases of eclampsia in the Rochester cohort had subsequent seizures. There has been no systemic study of the risk for epilepsy in people with other metabolic conditions.

Summary and Conclusions

Acute symptomatic seizures account for a substantial proportion of all newly occurring seizures, even when febrile seizures are excluded. Acute symptomatic seizures continue to be a useful concept for classification and prognosis, and the suggestions by some that the term (and presumably the concept) be abolished seems inappropriate. The causes and prognosis of acute symptomatic seizures require further systematic study and greater consideration when the total picture of the epilepsies is considered.

Chapter 9

Seizure Precipitants

Pierre Jallon

Benjamin G. Zifkin

Introduction

Seizures occur in patients with and without epilepsy. In patients *without* epilepsy, provoked seizures may arise from an underlying systemic disorder or be caused by direct cerebral insult. These provoked seizures, called *acute symptomatic seizures* (Commission) or *situation-related seizures*, are considered extensively in Chapter 8. Although epilepsy is defined as a condition characterized by recurrent, unprovoked seizures, it has long been recognized that even if most seizures appear to occur spontaneously, they may be provoked or the occurrence modulated by a variety of endogenous and environmental phenomena. Seizure precipitants are â€œthose circumstances that precede the onset of an epileptic attack and are considered by both patient and neurologist to be a possible explanation for why the seizure happened when it did, and not earlier or later.â€[4] These precipitants include both seizure-inducing and seizure-triggering factors. Seizure-inducing factors are of environmental or endogenous origin and produce transient lowering of the seizure threshold.[1] More than 40 precipitating factors have been reported in the literature.[1] Seizures may be triggered by *specific* stimuli. The terms *reflex seizures* and *reflex epilepsies* have been proposed and this nosographic group will be developed in Chapter 257.

Knowledge of seizure precipitants has practical implications in patient treatment and counseling. Some 53% to 92% of patients reported one or more seizure precipitants.[6,19,24,26] Precipitants are much more frequent in patients with active and/or intractable epilepsy and in some epileptic syndromes such as idiopathic generalized epilepsies with myoclonic seizures.[3,6,10] Patients often mention several factors. It is often difficult for a patient and/or the doctor to determine exactly which specific precipitant may have facilitated or triggered a seizure or to discern the relative importance of the individual factors.

Common Reported Seizure Precipitants

Emotional Stress

Although difficult to quantify, emotional stress is the most common factor (30% to 66%) identified by patients, mostly by women.[6,19,24,27] Since the time of Hughlings Jackson and Gowers, attention has been paid to the role of the emotions in the precipitation of epileptic seizures. Many reports provide evidence of an association between stressful life events or tension states and seizures.[7,10,18,19,26] In one study,[18] 58% of patients reported emotional stress, such as worry, anxiety, frustration, and anger, as the second most frequent precipitating or modulating factor for seizures. Another study[7] examined the psychologic factors confronting psychiatric patients with epilepsy before the onset of epilepsy. No fewer than 20 of 51 patients had experienced a severe emotional disturbance shortly before the first attack, caused, for example, by a mother-in-law's serious illness, the death of a mother, arrest by the Gestapo, a husband's heart attack, retirement after 45 years with the same firm, severe financial difficulties, and frequent unemployment. In patients subjected to a stress interview with electroencephalogram (EEG) recordings, neuronal instability increases during procedures, as evidenced by a seizure or emergence or increase in epileptiform activity. The mechanisms whereby emotional factors may elicit seizures have yet to be determined. An activation of specific networks has been involved.

Patients with generalized seizures and those with partial seizures seemed to be equally sensitive to emotional stress.[19] However, patients with temporal lobe epilepsy would be expected to be more vulnerable to emotional activation of seizures than patients with complex partial seizures because the anatomic structures involved during complex partial seizures are those that handle normal emotional responses. In one study,[10] stress represented 30% of seizure precipitants. Patients with temporal lobe epilepsy were the most likely to identify stress (46%) and patients with cryptogenic epilepsies were the least (15%). However, multiple factors may converge. Emotional disturbance may lead to sleep deprivation, noncompliance, excessive drinking, and even hyperventilation. Stress may be present during a period of time ranging from minutes to days, weeks, or years. Relaxation was the most commonly used technique for aborting seizures by 53.7% of the patients, which is consistent with the fact that 53% of the patients who could identify seizure precipitants reported that stress or tension could trigger their seizures.[25]

Sleep and Sleep Deprivation

Many patients have seizures only at night. In the 1950s, some neurologists erroneously considered sleep (â€œmorpheicâ€) epilepsy as an entity. In several epileptic syndromes, such as idiopathic epilepsies, benign partial epilepsy of childhood with centrotemporal sharp waves, and symptomatic or cryptogenic frontal and temporal lobe epilepsies, seizures appear preferentially during sleep. Sleep deprivation is the second most often reported seizure precipitant in four studies.[3,6,10,19,22,26] As sleep deprivation usually occurs during periods of overactivity or tension often associated with the use of stimulants and overhydration, its role is not always clinically clear.[1] Patients with idiopathic epilepsies frequently reported sleep deprivation as a significant precipitant.[10] There is no gender distribution. Sleep deprivation is a common precipitant of seizures in juvenile myoclonic epilepsy (JME).[6] In the adolescent and young adult population affected by JME, late nights of studying or socializing frequently result in myoclonic jerks and generalized tonicâ€“clonic seizures (GTCSs). Sleep deprivation as an activator of EEG epileptiform discharges is commonly used as a diagnostic aid in epilepsy[9] but has been recently reported as not affecting seizure frequency during video EEG monitoring[17] (see Chapter 188). Sudden awakening is a major precipitant of JME. Provoked awakenings are more dangerous than spontaneous ones.

P.77

The effect is more noticeable when sleep is interrupted during unstable phases, such as rapid eye movement (REM) sleep during the early part of the night and phase 2 sleep at the end of the night.

Fatigue and Exercise

Reports on the effects of fatigue and exercise on seizure frequency have been controversial. In Nakken's study, which compared seizure precipitants in three twin registries (Norway, Denmark, and United States), tiredness is the third most frequently reported seizure precipitant.[19] Physical activity was given as a precipitant factor by 6% of the Norwegian sample but accounted for only 0.3% and 0.7% of the reported precipitants by Danish and American populations, respectively. Some studies[7] have suggested that aerobic exercise raises seizure thresholds, thereby conferring a protective effect. Hyperventilation in the resting patient is very different from that in response to exercise and rarely provokes seizures. This is a consequence of metabolic acidosis that occurs during exercise. Seizures induced by exercise are actually seizures occurring shortly after exercise. The risk is greater after continuous exercise than after intermittent exercise. The lower the pH and base excess values are after exercise and during the recovery phase, the greater the number is of EEG epileptiform abnormalities. Sustained hypoxia or hypoglycemia after vigorous physical exercise is probably also involved. Physical activity such as running or jumping is reported by 7% of the patients as a technique for aborting seizures.[24]

Alcohol

The interactions between alcohol and epilepsy are complex. Chronic and acute effects of alcohol on the central nervous system are quite different and, sometimes, even opposite to one another.[2] These interactions are discussed more thoroughly in Chapter 268. It is commonly perceived that alcoholic beverages are a frequent cause of seizures in adult patients with epilepsy. Alcohol consumption was the fourth most frequent precipitant (5.7%) reported in one study.[19] Given the usual reluctance to admit alcohol use, this proportion is clearly underestimated. Alcohol abuse is often associated with poor compliance and sleep deprivation. However, there is little experimental evidence that moderate ingestion of alcohol influences seizure occurrence.[13] In fact, one study[18] found that moderate alcohol intake does not trigger seizures and can even decrease EEG epileptiform abnormalities! Alcohol abuse may be accompanied by seizures in two situations.[2] On the one hand, chronically alcoholic patients with or without epilepsy experience attacks during bouts of heavy drinking but more frequently on withdrawal. On the other hand, seizures may be precipitated in nonalcoholic patients with epilepsy after excessive drinking. Seizures occur during the period of rapidly falling alcohol blood levels, especially when excessive alcohol intake is associated with insufficient sleep.[18]

Missed Antiepileptic Medication

Penetrating insights on compliance with antiepileptic drugs (AEDs) have been published.[23] It is generally accepted that about one third to one half of people receiving long-term therapy take their medication in ways that differ from the clinical prescription. In a small series involving 40 patients admitted with seizures, noncompliance was the most common potentially preventable precipitating factor (45%),[26] and patients with subtherapeutic AED levels despite good compliance was the second most common precipitating factor. Noncompliance is probably underestimated and the degree of compliance varies considerably, as does the motivation for the consequences of poor compliance. Despite some patients' beliefs, occasional omission of one or two doses can be harmless. Because of a longer drug-free period, however, a greater risk exists when patients decide for themselves that they are cured and stop taking their medication. Two mechanisms explain the occurrence of seizures in such situations. First, a seizure can reflect the natural course of pharmaco-dependent disease. Seizures occur with different lag times, which vary according to the severity of epilepsy and with the drug (lag times are short with most AEDs but longer with valproate, probably because of a carry-over effect). Usually, a single seizure is observed, at least in moderate epilepsies, when AEDs are withdrawn, but status epilepticus is possible in severe epilepsies. Second, withdrawal seizures may also occur when barbiturates or benzodiazepines are stopped, as is observed in persons without epilepsy. These are generalized seizures, and they occur shortly after drug withdrawal.

Drugs Lowering Seizure Threshold

Many classes of pharmacologic agents prescribed at therapeutic dosages have been implicated in lowering the seizure threshold: Antidepressants, antipsychotics, central nervous system (CNS) stimulants, hypoglycemic agents, antimicrobial agents, aminophylline, antihistaminics, ephedrine, steroids, and a wide variety of other drugs.[11,15,16,29]

Metabolic Factors

Significant metabolic derangements can result from diarrhea, constipation, acute infections, liver and renal failure, and diuretic intake, especially in the very young and very old. Hypernatremia or hyponatremia, hypocalcemia, and hypoglycemia can provoke seizures in patients with or without epilepsy. In patients with diabetes, seizures frequently occur with overdose of insulin or sulfonamides, and perhaps during hypoglycemia following a large meal.[1]

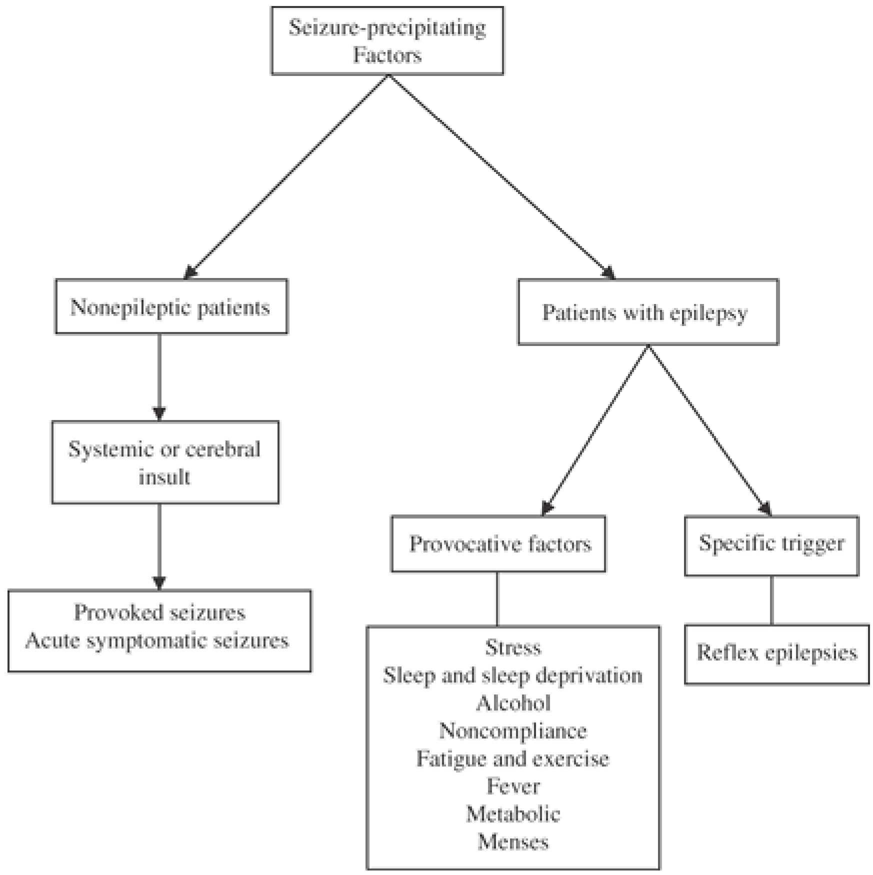

FIGURE 1. Seizure-precipitating factors.

Hyperventilation

Hyperventilation produces a respiratory alkalosis that causes central vasoconstriction and, if sufficiently marked, can modify the level of cerebral oxygen and glucose. Excessive breathing incommensurate with or without physical effort may eventually induce seizures in some patients.[5] Hyperventilation easily elicits absence seizures in children and, less commonly, other types of seizures.[12] Involuntary hyperventilation may occur in the course of a patient's daily activities due to anxiety, sobbing, or sexual activity.

Fever

Febrile convulsions are a special syndrome, characterized by seizures caused by a sudden rise in body temperature (see Chapter 57). They are seen only in children <5 years of age, usually <3 years of age. At any age, but mainly in the elderly, an acute febrile infection may provoke a seizure in the susceptible patient. Nevertheless, fever is often reported by patients as a precipitant factor of their seizures.[10,19]

Hormones

Catamenial epilepsy is defined as the occurrence of at least 75% of seizures per month within a period including the 3 days

P.78

preceding and the 4 days following menstruation.[20] While this is an uncommon condition, seizure frequency is reported to be affected by the menstrual cycle in 10% to 70% of women with epilepsy.[21] Many women report an increase in seizure frequency around the time of their menses. Herzog described three distinct patterns of catamenial epilepsy: Perimenstrual, periovulatory, and inadequate luteal-phase catamenial seizures.[14] Cyclic changes of ovarian hormonesâ€”estrogens (proconvulsivant) and progesterone (anticonvulsivant)â€”seem to play an essential role in the occurrence of catamenial seizures, as do possible variations in AED levels during the menstrual cycle. Natural progesterone therapy has proven to be effective and the use of neurosteroids in the future has to be explored.

Pregnancy has relatively little influence on seizure frequency. Altered disposition of AEDs and noncompliance seem to be the major reasons for increased seizure frequency (see Chapter 198).

Diagnosis

Clinicians must be aware of possible seizure precipitants (Fig. 1) and look for them. Skilled questioning and history taking based on knowledge of seizure-inducing mechanisms are essential.[1] The results of studies about seizure precipitants are quite different when the patients report the different factors spontaneously versus when a list of the factors is proposed.[24] In some cases it may be difficult or impossible to discern the relative importance of one or several factors. Too often, patients and family members give what appears to them a logical explanation for their seizures. Patients can use these factors to simplify the explanation for their seizures or to hide noncompliance. Some skepticism is necessary. Although a seizure precipitant is identified in association with a seizure, this does not necessarily prove a causal relationship between the two. However, the body evidence supporting an association is a major argument for addressing patients and their families in education. Tan et al.[26] reported that, in their small cohort, despite the frequent occurrence of noncompliance as a precipitating factor only 5% of patients were aware that neglecting their medication was the precipitant for their seizures.

There are few studies about the distribution of seizure precipitants among epilepsy syndromes. Generalized epilepsiesâ€”and particularly idiopathic generalized epilepsiesâ€”are more sensitive to stress, sleep deprivation, and menstruation.[3,6]

In the subjects who have recognized their seizure precipitants, 60% reported that they use this information to control their epilepsy by avoiding high-risk situations; however, 6% reported deliberately seeking this high-risk situation to have seizure.[24,25]

Summary and Conclusions

Common treatment measures are indicated for common seizure precipitants. These include educational interventions, wherein patients are counseled regarding situations that must be avoided or countermeasures that must be employed (e.g., detailed and repeated explanations on the necessity of sufficient sleep, proper dietary intake, and adherence to prescribed regimens of drugs).

Identification of modulators of seizure occurrence offers the possibility of improved control in some patients through alternative interventions. Emotional and tense states are among the most difficult of the inducing factors to manage. Nonpharmacologic (i.e., psychologic) methods of seizure control may be helpful as an adjunct to AED therapy. Numerous articles and several excellent reviews concerning behavioral methods of seizure control are available in print.[28] The issues and results of these are discussed in more detail in Chapter 132. Treatment with psychotropic drugs such as neuroleptics, lithium, or tricyclic antidepressants and other antidepressants is sometimes necessary. Seizure frequency in most patients is not increased when psychotropic medications are used in low to moderate

P.79

doses and introduced progressively. However, it is safer to preferentially employ medications that minimally affects seizure threshold.[16]

Introduction

The majority of patients with epilepsy have a good prognosis that allows them long periods of seizure freedom.[9,10,43] Despite this, it is known that the mortality rate in epilepsy is raised to two to three times that of the general population[8,19,28,29,32,39,53] and life expectancy in some of these patients is reduced.[17] Studies in the last two decades have thrown considerable light on the various factors that influence mortality and also on the various causes of mortality in epilepsy in the developed world.[8,19,28,29,32,39,53] However, there are no large-scale studies of mortality in epilepsy from resource-poor countries.[7]

There are many problems inherent to the study of mortality in epilepsy, including the problems of case ascertainment. Death certificates have been found to be an unreliable source of case ascertainment,[3] and prospective studies of cohorts of people with epilepsy are more likely to provide accurate data on mortality.

Several aspects of epilepsy may affect mortality:

1. Seizures themselves can be a cause of death, either directly as in prolonged status epilepticus or indirectly because of increased risk of accidental death, especially drowning.
2. Some of the risk factors for epilepsy (e.g., brain tumors, cerebrovascular disease, traumatic brain injury) are associated with increased mortality whether or not epilepsy is present.
3. There is an increased risk for sudden unexpected death in epilepsy (SUDEP).
4. The long-term use of antiepileptic drugs (AEDs) has been thought to increase the incidence of malignant neoplasia and osteoporosis, thereby potentially affecting long-term mortality rates in persons with epilepsy, especially in younger adults (ages 15 to 49 years). Although rare, other adverse effects of idiosyncratic type can also occasionally be fatal.

The objectives of this chapter are to review the evidence for, and patterns of, mortality in persons with epilepsy and to evaluate the current understanding of these factors.

Overall Mortality

The most often used and preferred statistical measure of epilepsy mortality is the standardized mortality ratio (SMR). This is the ratio of the number of observed deaths in a study population to the expected number of deaths in the age- and sex-matched general population in that time period. Older studies utilize the proportional mortality ratio (PMR), which expresses mortality as a ratio of the number of observed deaths due to a particular cause in a study population to the total number of deaths in that study population. This method is subject to more bias, depending on the kind of cohort studied, where deaths due to any one cause may be overrepresented, and is not a measure of the mortality rate in epilepsy versus the general population. SMRs among people with epilepsy have been evaluated in several population-based studies (Table 1) and vary from

1.6 to 8.8. Although these studies span several decades and countries, follow incidence or prevalence cases, and vary in terms of the age composition and characteristics of the patients studied, most are consistent in reporting a twofold to threefold increased mortality rate for people with epilepsy. Similarities between the population-based epidemiologic studies and the more selective hospital-based studies are not truly consistent with each other but probably the result of compensating biases. It should also be noted that the overall relative increased premature mortality of twofold to threefold should not be applied to all people with epilepsy; this is a summary measure that masks very important differences among those with epilepsy. The most important of these are the etiology of epilepsy, age, duration, and type of epilepsy.

Etiology of Epilepsy

The increased mortality rates of epilepsy reflect both the effects of epilepsy and also the effects of central nervous system (CNS) insults, such as brain tumors, cerebrovascular disease, and head trauma, which are the presumed cause of approximately one third of all epilepsy cases.[33] In epidemiologic studies, seizure disorders have often been classified into four broad groups according to presumed etiology:

1. Idiopathic (or cryptogenic) epilepsy.
2. Remote symptomatic epilepsy, related to CNS lesions acquired postnatally from trauma, brain tumors, cerebrovascular disease, infection, or chronic degeneration.
3. Acute symptomatic seizures, related to CNS insults where seizures manifest within a week of the acute insult (e.g., head injury, cerebral hemorrhage, or infarction).
4. Major neurologic dysfunction of uncertain cause but presumed to have been present at birth and manifested by gross neurologic deficit (spasticity, hemiparesis), or mental retardation (IQ <70).

SMR = Observed deaths/expected deaths.

Table 2 Standardized Mortality Ratios (with 95% Confidence

Intervals) According to Etiology

Country	Idiopathic	Remote symptomatic	Acute symptomatic	Neurodeficit
United States 1980[19]	1.8 (1.4â€“2.3)	2.2 (1.8â€“2.7)		11.0 (6.9â€“16.4)
United Kingdom 1994[8]	1.6 (1.0â€“2.4)	4.3 (3.3â€“5.5)		50.0 (10â€“146)
France 1999[32]	1.5 (0.4â€“3.9)	6.5 (3.8â€“10.5)		
Sweden 2000[29]	1.1 (0.5â€“2.4)	3.3 (2.4â€“4.5)		
United Kingdom 2001[28]	1.3 (0.9â€“1.9)	3.7 (2.9â€“4.6)	3.0 (2.0â€“4.3)	25 (5.1â€“73.1)
United States 2004[4]	1.43 (0.36â€“5.73)	33.46 (18.53â€“60.43)		

NBâ€”idiopathic, idiopathic or cryptogenic or nonsymptomatic.

The level of increased premature mortality appears greatest in patients with epilepsy in association with a neurologic deficit present from birth. Such patients had a considerably high SMR of 7.0 (95% confidence interval [CI], 4.6 to 10.2) in the Rochester, Minnesota, study[19] and of 25 (95% CI, 5.1 to 73.1) in the UK General Practice Study (although this latter SMR was based on only a few deaths).[28] The extremely high SMR in the neurologic deficit group reflects the large number of observed deaths at relatively young ages, when few deaths are expected. Mortality is also high in individuals with symptomatic epilepsy compared to those in other groups. In the Rochester study,[19] persons with epilepsy as a result of postnatal CNS insults had an SMR of 2.76 (95% CI, 2.3 to 3.4). In the UK study, the SMR for postnatally acquired epilepsy was 3.7 (95% CI, 2.9 to 4.6).[28] The higher relative mortality in the British study may

P.82

be a consequence of the comparatively shorter mean follow-up period, as SMRs decline with duration.

Studies that present SMRs for all patients and separate SMRs for persons with idiopathic (or cryptogenic) epilepsy (epilepsy without a presumed cause) show considerably lower SMRs for patients with idiopathic epilepsy than for all patients with epilepsy. The mortality rates among those with idiopathic epilepsy from Rochester,[19] Sweden,[29] and the UK General Practice Study[28] are still raised above those of the general population, but only by 50% to 60% and not significantly so in the latter two studies (Table 2). The UK General Practice Study also studied patients with acute symptomatic seizures as a separate category as defined above and found an SMR of 3.0 (95% CI, 2.0 to 4.3) in this group.[28]

Age

The population-based studies that present age-specific SMRs are shown in Table 3. Mortality rates are increased at all ages among persons with epilepsy, but the increase is not uniform across age groups. There is a sharp decline in SMRs with age in these study populations. The higher SMRs in persons under 50 years of age are caused in part by the extremely high relative death rates for patients with epilepsy in association with neurologic deficits and the low expected mortality in these age groups. However, in the UK General Practice Study, the 50- to 59-year age group had higher mortality rates than all other age groups, and this may be explained by the high incidence of brain tumors in this population.[28] Head trauma in younger patients may be another contributory factor. Another factor is the increased risk for sudden death in younger adults with epilepsy; it is uncertain whether this increased risk persists among elderly patients with epilepsy. Although the SMRs decrease with age, the death rates among the elderly (>65 years of age) with epilepsy are still 50% to 60% above the rates in the general population and remain significantly elevated even in patients over the age of 80 years.[19]

Table 5 Causes and Categories of Death in Epilepsy

Epilepsy-related deaths

Directly related
- SUDEP
- Status epilepticus

Indirectly related
- Accidents as a consequence of seizures
- Aspiration pneumonia after seizures
- Iatrogenic; drug toxicity and idiosyncratic reactions
- Suicides

Underlying disease related deaths

Primary and secondary CNS neoplasia
Cerebrovascular disease

CNS infections
Inherited neurodegenerative disorders

Unrelated deaths

Non-CNS neoplasia
Ischemic heart disease
Pneumonia
Accidents unrelated to seizures

CNS, central nervous system; SUDEP, sudden unexpected death in epilepsy.

Duration of Epilepsy

Due to a high proportion of so-called â€œagonalâ€ seizures in patients with newly diagnosed epilepsy who have serious underlying brain pathologies such as brain tumors and cerebrovascular disease, mortality is highest in the first few years

following diagnosis. This is well illustrated by the UK General Practice Study where the highest SMR of 6.6 (95% CI, 4.8 to 8.7) was reported in the first year compared to an SMR of 1.5 (95% CI, 1.0 to 2.1) at 4 to 9 years (Table 4).[28] The Swedish study reported a similar trend with an SMR of 7.3 (95% CI, 4.4 to 12.1) in the first year and no elevation of SMR at 6 years after diagnosis.[29] In the Rochester study,[19] persons with idiopathic epilepsy had significantly increased mortality rates (SMR 1.9) during the first 10 years after the diagnosis of epilepsy but only slightly increased rates thereafter. Persons with epilepsy caused by a postnatal neurologic insult had a threefold increased death rate during the first decade after diagnosis and a twofold increased rate after 10 years. Those with epilepsy in association with a neurologic deficit

had high mortality rates throughout follow-up. A late increase in mortality, thought to be directly caused by epilepsy, occurred in the third decade.[19] It is an interesting observation, since the influence of underlying pathologies on mortality could be expected to be much less than at diagnosis, and mortality due to status epilepticus and SUDEP in those with refractory seizures may conceivably become more prominent. This remains speculative at the current time. A small but similar late rise in mortality occurred after 9 years in the UK study, but with only three direct epilepsy-related deaths in this cohort during this time, this rise is not easily explained.[28] The Swedish study also reported a late increase in mortality after 9 to 11 years.[29]

Table 6 Cause-specific Mortality in Epilepsy (SMRs with 95% Confidence Intervals)

	Study		
Cause	United States[19]	United Kingdom[28]	Sweden[29]
Cerebrovascular	2.6 (1.8â€“3.6)	3.7 (2.3â€“5.5)	5.3 (4.9â€“5.8)

Heart disease	1.1 (0.8â€“1.5)[a]		
Ischemic heart disease		1.1 (0.6â€“1.7)	2.5 (2.3â€“2.7)
Myocardial insufficiency			
Other circulatory	7.1 (3.4-13)		
Neoplasms	2.9 (2.1â€“3.9)	3.5 (2.6â€“4.6)	2.6 (2.4â€“2.8)
Neoplasms excluding brain tumors	1.8 (1.1â€“2.6)	2.4 (1.7â€“3.4)	2.0 (1.9â€“2.2)
Pneumonia	3.5 (1.6â€“6.6)	7.3 (4.8â€“10.6)	4.2 (3.6â€“4.8)
Accidents	2.4 (1.3â€“3.7)		4.7

SMR, standardized mortality ratio; CI, confidence interval.
[a]Significant increases in ages 25â€“44 years (SMR 5.7 [95% CI 1.8â€“13.3]) and 45â€“64 years (SMR 2.5 [95% CI 1.4â€“4.1]).

Cause-specific Mortality in Patients with Epilepsy

Causes of death (Table 5) vary in both epilepsy-related and -unrelated mortality according to the populations studied. The commonest causes of death in community-based analyses are usually pneumonia, cerebrovascular disease, and CNS-related, as well as nonâ€“CNS-related, neoplasia, whereas the hospital-based analyses have larger representations of sudden unexpected deaths and epilepsy-related mortality. Table 6 shows the SMRs of cause-specific mortality in these studies.

Sudden Unexpected Death in Epilepsy

SUDEP is defined as a sudden, unexpected, witnessed or unwitnessed, nontraumatic, and nondrowning death in patients with epilepsy, with or without evidence of a seizure having occurred, excluding documented status epilepticus, in which postmortem analysis does not reveal an anatomic or toxicologic cause of death.[33] Studies in the United Kingdom suggest that there are approximately 500 deaths per year attributable to SUDEP.[18] Several studies have attempted to examine the incidence of SUDEP and these are represented in Table 7. Their results reflect the varying case ascertainment methods and study populations used.

Population-based studies, with less selection bias, provide lower figures for SUDEP incidence (0.09 to 2.7 per 1,000) than do selected cohorts that constitute large numbers of patients with refractory epilepsy (0.2 to 9.3 per 1,000). In one comprehensive and often quoted population-based study, the estimated incidence of SUDEP was 0.35 per 1,000 person-years, occurring in 8.6% of recorded deaths in people aged 15 to 44 years.[16] The SMR for sudden death in the 20- to 40-year age group was 23.7, suggesting a large increased risk for sudden death in patients with epilepsy compared to that of sudden death in the general population. Although fairly uncommon in population-based incidence cohorts, SUDEP may be the leading cause of death in patients with refractory epilepsy.[51]

The mechanisms that underlie SUDEP are unknown, but there is mounting evidence that it is a seizure-related

phenomenon. Risk factors for SUDEP have been analyzed in case-control studies.[51] These and the hypothetic mechanisms behind SUDEP are discussed in more detail in a separate chapter (Chapter 189).

AED, antiepileptic drug; SUDEP, sudden unexpected death in epilepsy.
[a]Estimates based on assumed epilepsy prevalence data.

Status Epilepticus

The incidence of status epilepticus (SE) in population-based studies varies from 9.9 in Switzerland[11] to 57 per 100,000 in a nonwhite population in Richmond, Virginia.[13] Case fatality rates similarly vary from 7.6% in the same Swiss study to 31% in a study from Bologna in Italy.[52] The etiology of SE is the most important determinant of mortality, and most deaths in the first 30 days are due to acute symptomatic causes such as anoxic brain damage, CNS infections, brain trauma, and cerebrovascular events. In one large study, no deaths were found in those cases with SE due to idiopathic causes, whereas almost 90% belonged to the acute symptomatic group.[31]

Accident-related Deaths

The risk of death due to injury in patients with epilepsy is estimated at 2.68 per 100,000 persons per year.[21] Other studies quote up to 16% of deaths in epilepsy patients arising as a consequence of accidents, and SMRs for accidents are thus significantly increased at 2.4 to 10.4.[19,38,44] These most often occur in water or as a result of burns or trauma. In one Canadian study, 5% of all drownings were attributable to seizures, 60% of which occurred in bathtubs.[42] Fatalities in motor vehicle accidents due to seizures were found to be uncommon in an American study where only 0.2% of over 44,000 deaths were attributable to seizures.[45] In the UK General Practice Study,

there were three accidental deaths (a bathtub drowning, a fall resulting in a cervical fracture, and severe burns) in over 11,400 person-years of follow-up, suggesting that accidental deaths in community-based populations may be rare.[28]

Suicides

The risk of suicide is said to be higher in patients with epilepsy, and most studies that have attempted to address this issue have been of selected cohorts, reporting up to a fivefold elevation in suicide rates compared to that of the general population. However, community-based studies such as the Rochester study and the UK General Practice Study have found no increased risk. The attendant psychiatric comorbidity in many patients with refractory epilepsy may be an important factor that explains this disparity. Depression may occur in up to 62% of patients with epilepsy. A recent case-control study from Sweden identified 49 epilepsy patients who had committed suicide (26 definite and 23 possible) and found that there was a ninefold increase in suicide risk with concurrent mental illness and a 10-fold increase with the use of antipsychotic drugs. A softer association of increased risk was found with high seizure frequency and antiepileptic drug polytherapy.[36]

Neoplasia

Increased mortality due to primary and secondary brain tumors in patients with epilepsy is to be expected and so is consistently reported by many studies. High SMRs due to non-CNS neoplasia, particularly lung cancer, in patients with epilepsy have been noted in several studies, although the design and interpretation of many of these studies are easy to criticize. A carcinogenic effect of antiepileptic drugs has been postulated, although this has not really been substantiated and indeed, most neoplasia related deaths occur soon after diagnosis, rendering this association unlikely.[8,28,46] Some studies show a trend toward an increased incidence of lymphatic malignancies,[22,40,46] although this is not significant and has not been confirmed in larger studies. In animal studies, phenobarbital has been shown to be associated with liver and thyroid malignancies, phenytoin with liver and lymphoid malignancies, valproate with uterine adenocarcinoma, carbamazepine with hepatic and testicular tumors, and gabapentin with pancreatic tumors. In humans, only phenobarbital and phenytoin are considered possibly carcinogenic by the International Agency for Research on Cancer.[47]

Pneumonia

Pneumonia is a frequent cause of death in epilepsy (SMR 3.5 to 7.2) in community-based studies[8,19,43] as well as in hospital-based studies.[22,23,38,53] This is a common terminal event in the elderly, and the mean age of patients who died of pneumonia in the UK General Practice Study was 81.3 years.[8,28] The consistently raised SMRs that reflect this may represent an increased tendency in elderly patients with epilepsy to hospitalization in comparison to those of a similar age without epilepsy in the general population.

Vascular Disease

As with CNS neoplasia, the significantly increased mortality due to cerebrovascular disease in epilepsy in community-based studies (SMR 2.5 to 3.7[8,19,28]) as well as in hospital-based studies (2.5 to 5.3[38,44]) reflects mainly on the increased mortality associated with the underlying pathology. Ischemic heart disease, however, does not appear to be a significant cause of mortality in epilepsy, and in both the Rochester study[19] and the UK General Practice Study,[8,28] SMRs did not reach significance. This was similarly true of hospital-based studies.[44] Other studies have found elevated SMRs, especially in patients under the age of 65 years, although these may reflect methodology rather than a true increase in mortality.[2,38]

Summary and Conclusions

Individuals with epilepsy have mortality rates in the order of two to three times that of the general population. However, much of this increase is due to the causes of acquired epilepsy-brain tumors, cerebrovascular disease, traumatic brain injuryrather than epilepsy itself. Increased mortality is not consistently associated with idiopathic epilepsy. The relative mortality of individuals with epilepsy is influenced by age, as the younger ages have higher relative mortality rates than older individuals with epilepsy. In addition to the excess mortality associated with the causes of acquired epilepsy, the major contributors to increased mortality among individuals with epilepsy are deaths associated with accidents and those attributed to SUDEP.

Chapter 11

Epidemiology in Developing Countries

Nadir E. Bharucha

Arturo Carpio

Amadou Gallo Diop

Introduction

The term *developing* is taken usually to mean economically developing from poverty toward affluence. Geographically, most such countries are found in Asia, Africa, and Central and South America. However, several countries or parts of countries in these areas are considered quite affluent and correspondingly, some parts of developed countries are economically developing, namely, Eastern Europe.

Although there are no inherent differences between developing and developed countries regarding the biologic and clinical aspects of epilepsy, differences are found in incidence, etiology, social and cultural factors, and systems of health care delivery and treatment.

Developing countries often do not have an organized health care system. Record keeping is generally poor and research minimal. Neuroimaging and drug monitoring facilities may be available, but patients are often too poor to afford what can be obtained. Antiepileptic drugs (AEDs) also may not be available and for various reasons may not be taken. As a result, a large proportion of people with epilepsy do not get treatment. In addition, little accurate scientific data have come from developing countries. In view of this paucity of information, it is easy to assume that the experience of developed countries in treating epilepsy can be applied without modification to developing countries. The purpose of this chapter is to highlight differences in the epidemiology of epilepsy between developed and developing countries, so that such experience can be meaningfully and profitably applied for the benefit of patients.

Incidence and Prevalence

The evaluation of published vital statistics in epilepsy is often complicated by methodologic problems that have not been fully addressed.[91,93] Problems that bedevil studies of incidence and prevalence in developing countries include diagnosis, case ascertainment, and definitions of seizures and epilepsy. The early pioneer studies particularly exhibited these weaknesses, although they did provide approximate statistics upon which later investigations could build.

Methodology

Diagnosis

Accurate diagnosis is essential, both at presentation and during treatment. It is mainly clinical, depending on history and examination. Electroencephalography (EEG) contributes to, but does not always confirm, the diagnosis. Accuracy of diagnosis is vitiated by lack of an eyewitness account. A therapeutic trial of antiepileptic drugs is never warranted. Even in developed countries in patients referred with a diagnosis of refractory epilepsy, the rate of misdiagnosis may be as high as 26.1%.[103] The most common misdiagnoses are psychogenic, nonepileptic seizures and syncope. In two Indian population-based studies, syncope was frequent in one and psychogenic seizures in another.[9,52] Such information is invaluable to a clinician working in India.

Case Ascertainment

In developing countries, concealment of epilepsy for social reasons is common. People also may be genuinely unaware of seizures that present differently from tonicâ€"clonic seizures. Accurate case ascertainment requires a community-based door-to-door survey using a locally validated questionnaire in order to screen the population, with the informed consent of the individuals concerned, the family, and community leaders. If key informants and local medical workers are used, including traditional healers, then case ascertainment will be much better. The capture-recapture method also uses information from different sources to obtain a prevalence ratio that is higher than that obtained from using a door-to-door survey alone.[27] Another way of enhancing the yield of a door-to-door survey is to examine a random sample of those people who in the door-to-door survey had been found not to have epilepsy. This enables calculation of the rate of false negatives.[86]

Definition of Seizures and Epilepsy

In 1993, the International Commission of Epidemiology and Prognosis of the International League against Epilepsy (ILAE) published guidelines for epidemiologic studies.[45] These guidelines give definitions of seizures and epilepsy, a classification, risk factors, and recommended measurement indices. These are particularly useful for field studies in developing countries, where facilities for investigation are unavailable. Unfortunately, these guidelines are not always followed.

It should be remembered that acute symptomatic seizures, although not considered epilepsy, are common. Such patients do not need long-term treatment for seizures, but they do need treatment for the acute seizure and for the underlying condition, which, in developing countries, most commonly is neurocysticercosis.[75] In addition, the terms *idiopathic* and *cryptogenic epilepsy* should not be confused. In a developing country without investigations, making the distinction is not always possible in a field study. Studies should mention the amount of active epilepsy (i.e., those who have had at least one seizure within the past 5 years). These people are important from the point of view of public health.

Incidence is defined as the rate of occurrence of new cases in a specified population per unit time, usually 1 year. The numerator is the number of new cases. The denominator is the number of persons at risk, although usually the total population is used. Prevalence is defined as the proportion of a specified population with the disease at a specified time. Point prevalence is this proportion on a particular day.

Both incidence and prevalence studies are useful for health service providers, especially in developing countries with few neurologists and 80% of the burden of epilepsy. Incidence studies give clues to risk factors and information about prognosis, but there are few studies from developing countries because they are difficult to carry out.

Incidence

In developed countries, the age-adjusted incidence of epilepsy, defined as recurrent unprovoked seizures, ranges from 28.9 to 53.1 per 100,000 person-years, with most studies falling toward the higher end of this range.[42] If single unprovoked seizures are included, higher figures, up to 70 per 100,000 person-years, are obtained. The few available studies in developing countries, none of which is prospective (Table 1), give a range from 35 to 190 per 100,000 person-years. The Ecuadorian study, in which the incidence range was 122 to 190 per 100,000 person-years, includes single seizures and acute symptomatic seizures.[86] The incidence of epilepsy in five sub-Saharan African studies ranges from 63 to 158 per 100,000 person-years.[87] Comparisons of rates are valid only when age-adjusted to the same population. This has been done for the Americas[22] and is given in Table 2. The higher incidence in developing countries may be a consequence of the fact that populations in the developing world are younger and have poorer medical facilities, poorer general health, and a lower standard of living. Specifically, there are more infections of the central nervous system (CNS), especially with cysticercosis, tuberculosis (TB), and human immunodeficiency virus (HIV). Perinatal morbidity, head injuries, and consanguinity are also more common. The relative importance of these factors is unknown.

The graph of age-specific incidence of epilepsy in developed countries is a U-shaped curve, with the highest incidences in those <1 year old and >60 years old. It rises sharply after age 60. In developing countries, the peak incidence occurs in young and middle-aged adults[10,56] (Fig. 1). The different age-specific incidence rates in developed and developing countries have two implications. One is that the risk factors may differ. In developing countries infections and parasitic diseases are endemic. The second is the difficulty of comparing studies from countries with differing stages of development and age distribution of the population without age adjustment to a common population as the denominator.

The age-specific incidence of epilepsy in developed countries has been changing over time. There has been a decrease in childhood epilepsy due to better perinatal care, as well as an increase in epilepsy among the elderly because of rising cerebrovascular disease. Such data are not available for developing countries, but that from developed countries suggests the possibility of reducing the present burden by improving obstetric and perinatal care and diminishing future burden by early attention to prevention of cardiovascular disease.

Incidence throughout the world is slightly higher in males than females. The Ecuadorian study found a preponderance of females. Many studies have found no difference. When found a difference, it was slight.

Seizure Type

In general, partial seizures are more common in developed countries than other seizure types, accounting for just over 50%. In developing countries, where symptomatic epilepsy is more common, one would expect partial seizures to predominate. However, in differing circumstances, generalized tonicâ€“clonic seizures tend to be more commonly noted for the following reasons, none of which seems to apply to all situations:

1. The partial onset of a seizure that rapidly generalizes will be missed by the patient or the field worker.
2. Untreated partial seizures may become generalized more rapidly.
3. A questionnaire may not be designed to pick up anything apart from generalized tonicâ€“clonic seizures.
4. There is a lack of the EEG to pick up a focal onset.

There are no population-based incidence studies of epilepsy syndromes from developing countries.

Prevalence

There have been many more studies of the prevalence of epilepsy than of incidence because they are much more easily carried out. Although methodologic differences among these

P.91

studies make comparisons difficult, it seems clear that, unlike incidence, the prevalence of active epilepsy remains within the range of 4 to 10 per 1,000 population throughout the world.[46] Higher prevalences have been reported from sub-Saharan African countries (e.g., 35.1 per 1,000 in Benin using the capture-recapture method[27] and the prevalence of 49 per 1,000 in Grand Bassa county in Liberia[36]). A rate of 20 per 1,000 was found among the Wapogoro in Tanzania.[50] In South and Central America, a rate of 57 per 1,000 has been found among the Guaymi Indians of Panama.[34] In areas with a high prevalence, there is often a strong family history of both epilepsy and consanguinity, possibly as a result of social stigma forcing intermarriage. A large number of studies in India and China suggest a prevalence of active epilepsy of between 4 and 6 per 1,000, similar to that in developed countries.[9,54,104,111]

As with incidence, rates that are age-adjusted to a common denominator for the Americas allow more meaningful comparisons (Table 3).[22]

Age-specific Prevalence

Age-specific prevalence rates for epilepsy vary in different studies and are difficult to interpret, possibly because of small numbers and methodologic differences. FIGURE 2 shows age-specific prevalence of epilepsy in the Americas. This is more fully discussed by Hauser in Chapter 5.

Sex

As with incidence, there is a predominance of males, with some exceptions in Africa,[89] South America,[79] and one study in Pakistan.[5]

Seizure Type

As is the case with incidence studies and for the same reasons, generalized seizures are more common than partial seizures in developing countries. There are exceptions. In the Ecuadorian study, 49% had partial seizures, which may reflect the input of the specialist medical team. The Parsis had 54.5% partial seizures, a figure possibly resulting from the medical input and the community's higher level of education. When EEG is used in addition, the proportion of partial seizures increases. In a Ugandan study it rose from 24% to 42%[51] and in a Bolivian study from 34% to 53%.[78]

Socioeconomic Factors

Studies in developed countries have suggested that socioeconomic deprivation increases the risk of epilepsy.[33,44,60,73] Studies in Ecuador, Pakistan, and Turkey showed the prevalence of epilepsy to be higher in rural areas, but the reverse was shown in the meta-analysis of the Indian studies.[4,5,86,104] In India, poverty is greater in rural areas where it is more difficult to conceal epilepsy. The whole relationship of socioeconomic factors to epilepsy needs further exploration.

Incidence-prevalence â€œGapâ€

The term *incidence-prevalence gap* refers to the higher incidence of epilepsy in developing countries than in developed countries, whereas prevalence values are similar throughout the world.[11,16,57,70,78,86,89] Possible explanations are differences in methodology, namely, inclusion of acute symptomatic seizures as incidence cases in developing countries; the higher mortality rate in developing countries[10,15]; and higher rates of remission, which would imply a more benign prognosis. There are no answers yet to these speculations, nor will there be until there are

P.92

well-conducted incidence studies and population-based outcome studies from developing countries. Certainly, there need be no further prevalence studies, unless they are designed to look at specific epilepsy syndromes or health status.

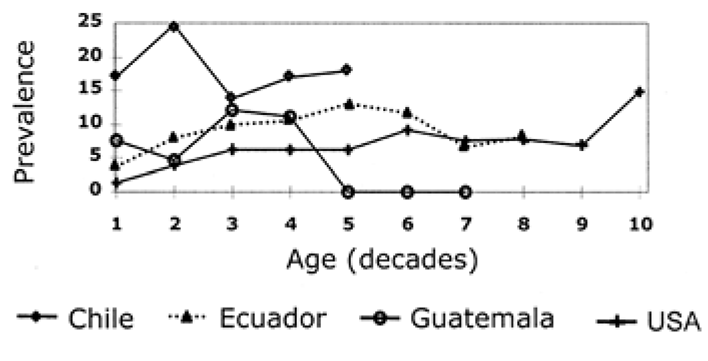

FIGURE 2. Age-specific prevalence of epilepsy in the Americas. (From Carpio A. Perfil de la epilepsia en el Ecuador. *Revista Ecuatoriana de Neurologia.* 2001;10:20â€"26.)

Prognosis

The prognosis of epilepsy is defined by Hauser and Hesdorffer[39] as the risk of recurrence following a first seizure or more seizures; the probability of remission, both spontaneous and with treatment; the risk of relapse following drug withdrawal; and the mortality of epilepsy. It has been suggested that in these countries, the prognosis of epilepsy is different, but few studies of natural history allow comparisons.[1,12,16] Methodologic shortcomings have contributed to the uncertainties.[39,90]

Recurrence after a First Unprovoked Seizure

In developed countries, prognosis for full seizure control is very good. More than 70% of patients achieve long-term remission, most within 5 years of diagnosis.[40,61,101] In developing countries, after a first unprovoked seizure, the risk of recurrence is 33% to 37%, similar to that from developed countries.[18,26,53,94] Studies from developing countries show that patients with epilepsy secondary to underlying structural causes and with an abnormal EEG have the worst prognosis.[18,53,94] The type of seizure and drug treatment used seem not to affect prognosis. Developing countries have produced no published studies of the prognosis of epileptic syndromes.

Recurrence in Newly Diagnosed Epilepsy (or Probability of Remission)

In developed countries, most studies of seizure prognosis or epilepsy prognosis in adults[23,40,61,62,96] and children[3,99,101] have examined the risk of recurrence following a first unprovoked seizure, but according to ILAE definitions, a single unprovoked seizure does not constitute epilepsy. Very few studies have reported the risk of recurrence after a second seizure.[41,100] Hauser et al.,[41] in the United States, reported that the risk of a third unprovoked seizure was 73% after 4 years of follow-up. The study by Shinnar and Pellock,[100] in the United States, showed that the cumulative risk of a third seizure was 71% at 5 years. Carpio et al.,[18] in Ecuador, found that in 340 newly diagnosed epilepsy patients with one recurrent unprovoked seizure, the risk of a third unprovoked seizure was 79% after 4 years of follow-up. Etiology was an independent predictor of recurrence. Patients with idiopathic cryptogenic epilepsy had less risk of recurrence than patients with symptomatic epilepsy (38% vs. 52%, p <0.05). FIGURE 3 shows the probability of seizure recurrence. Multivariate analysis showed no significant differences in recurrence risk due to sex, age, family history of epilepsy, EEG results, or the type of seizure.

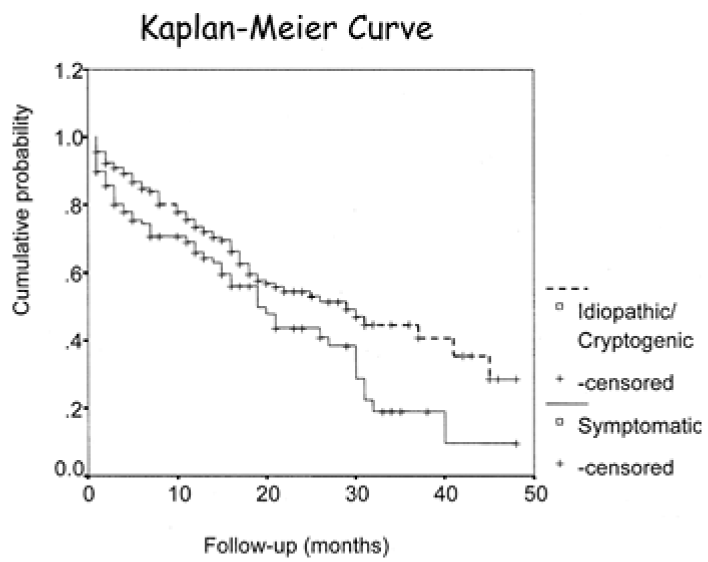

FIGURE 3. Probability of seizure recurrence in 289 patients with epilepsy as a function of etiology. (From Carpio A, Hauser WA, Lisanti N, et al. Prognosis of epilepsy in Ecuador: a preliminary report.

Epilepsia. 1999;40[Suppl 2]:110.)

Prognosis for Seizure Recurrence in Patients with Neurocysticercosis

Very few studies estimate the prognosis of acute symptomatic seizures. Seizures due to neurocysticercosis (NC) demonstrate prognosis well. In a prospective, cohort study in Ecuador, Carpio and Hauser[19] found that 40% of patients had a recurrence. Multivariate analysis showed that the only predictor of recurrence was a change in appearance on the computed tomography (CT) scan. Twenty-two percent of patients in whom cysts disappeared had no further seizures, but 56% of those with persistent cysts had a recurrence (p <0.05). The authors' conclusion that seizure recurrence is high following a first acute symptomatic seizure due to NC, therefore, seems related to persistence of active brain lesions. However, when the NC lesion clears up, the recurrence risk is low and in keeping with the risk following other brain insults leading to a static encephalopathy. There was no correlation between treatment with antihelminthic agents and seizure recurrence.

Spontaneous Remission and Effect of Treatment on Prognosis

Some patients spontaneously enter remission.[57] In a retrospective survey of 460 previously untreated patients attending newly established epilepsy clinics in Malawi, Watts[112] indirectly demonstrated spontaneous remission. The study found that as the duration of epilepsy increased, the number of patients with active epilepsy decreased. Thus, remission without therapy is common. This finding is substantiated by an Ecuadoran survey in which 28% of all identified cases entered remission without treatment[84] and by Mani et al.[66] in a rural community in south India, from which he reported a remission rate of 50% of untreated patients.

Antiepileptic drug trials[30,31,85] reported from Nakuru, Kenya, and Ecuador show a generally excellent response to standard therapy. These studies also show that in patients who had not previously received antiepileptic drug (AED)

treatment, neither the duration of the disease nor the number of seizures before treatment are predictors of outcome. This was corroborated by a more recent study from Yelandur, India.[64] Therefore, failing to treat seizures at the earliest possible opportunity does not increase the likelihood of chronicity and agrees with findings from developed countries that for most patients, the chance of remission is not improved by early treatment.[68,76] Treatment reduces the rate of recurrence of seizures but does not affect the natural history of epilepsy. There is some conflicting evidence from a hospital-based study in Glasgow, which showed that those who had had 20 or more seizures before starting treatment were more likely to have refractory epilepsy.[55] The authors concluded that there was some underlying abnormality of the brain, which rendered the epilepsy refractory from its inception (i.e., frequent seizures could be an indicator of refractoriness rather than cause). The study from Yelandur in India also suggested that those with a lifetime total of more than 30 seizures had less chance of entering remission. More outcome studies are needed from developing countries with populations whose epilepsy is still largely untreated.

Risk of Relapse following Drug Withdrawal

There have been no studies from developing countries.

Epilepsy Mortality

In developed countries, the overall mortality associated with epilepsy is two to three times that of the general population from other causes.[7,14,32,49,59,88] In developing countries, it is almost impossible to ascertain the number of deaths due to epilepsy because incidence studies are difficult, death certificates are unreliable, autopsies are not easy to obtain, and the cause of death is not usually known with certainty.[10,15] The overall autopsy rate is probably <5% in public hospitals and almost zero in private hospitals. There are few reliable coroners' reports, and if available, they are incomplete. Migration makes large, prospective, population-based mortality studies of epilepsy very difficult to carry out.

Two Indian population studies of mortality among the Parsis in Bombay and a semiurban community in Vasai[10,15] appear to suggest that epilepsy may confer a protective effect against mortality in Parsis, who form a small, urbanized, literate community of higher socioeconomic status than the general Indian population. Comparing these two results is misleading because Parsis with epilepsy probably take better care of their health than those without it, and cases studied were mainly prevalent, so the result was biased in favor of survivors whose epilepsy was less active than that of the patients in Vasai. The methodologic advantages of the Parsi study are that it is a population study in which the diagnosis of epilepsy was made by a neurologist and follow-up is virtually complete. Comparison of the Vasai and Parsi studies suggests that the poorer, rural population with epilepsy has a much higher mortality rate than the urban one. Factors possibly responsible for this are being explored elsewhere.

In Ecuador, a prospective cohort study of 412 patients with newly diagnosed epilepsy gave a crude standardized mortality ratio (SMR) from all causes of 6.3.[15] The age-specific SMR at entry is summarized in Table 4. The overall mortality of epilepsy in Ecuador is higher than reported in the general population of a developed country. Present cohort studies of sudden unexpected or unexplained deaths in epilepsy (SUDEP) have produced rates varying from 1.5 to 9 per 1,000 patient-years.[32,49,59,88] Rates depend on the methods used and the population studied. The Ecuadorian SUDEP rate of 2.6 per 1,000 patient-years was nearly ten times that of 0.3 per 1,000 patient-years in an incidence study from Rochester, Minnesota,[43] and as high as those reported in patients with severe epilepsy. Mortality rates may be high because only the severe cases were picked up.

Table 4 All-cause Mortality in Patients with Epilepsy In Ecuador

Age	Patients with epilepsy	Expected deaths[a]	Observed deaths	SMR[b]
0â€“19	268	0.56	4	7.7
20â€“59	102	0.31	2	7.1
>60	9	0.41	1	3.2
Total	379	1.28	7	6.3

SMR, standardized mortality ratio.

[a]Calculated by multiplying the number of person-years with epilepsy with the corresponding mortality rate of the Ecuadorian general population divided by 100.

[b]Observed number of deaths divided by expected number of deaths.

Source: Carpio A, Bharucha NE, Jallon P, et al. Mortality of epilepsy in developing countries. *Epilepsia.* 2005;46(Suppl 11):28â€“32.

It is also possible that the risk of death was overestimated because the less severe, new-onset cases of epilepsy were not ascertained at hospitals. This affects the distribution of cause of deathâ€"those patients lost to follow-up may have had different causes of death from those who were followed. Also, small numbers prevent comparison of SUDEP rates by seizure type, etiology, age, or sex. As expected, only one patient had an autopsy. On the other hand, in cohort studies the diagnosis of epilepsy is well documented and definitions and analytic procedures are current.

In Martinique in the Caribbean, death certificates were used to follow a cohort for 1 year.[15,49] The mortality rate was 5.73 per 100,000 population and the SMR was 4.25. There were no data concerning cause of death or the exact relationship of epilepsy with the death.

In summary, it seems that mortality of epilepsy in developing countries is generally higher than the mortality reported in developed countries. The SMR ranges broadly from 0.76 in a population study of a select community in India to 6.3 in a prospective cohort study in Ecuador. It is incorrect to generalize from such selected populations.

Etiology and Risk Factors

In developing countries, analytic epidemiology designed to establish associations and determinants of epilepsy has been scarce. Comparing results of studies of etiology is difficult because of differences in definitions and lack of diagnostic criteria.[16] Most studies lack information on the latency between the first acute symptomatic seizure and the first unprovoked seizure, and the age at onset of seizures and age at diagnosis.

In studying etiology, it is necessary to use incident cases and not prevalent cases, because one cannot assess the importance of potential etiologic factors that preceded the onset of epilepsy from those which occurred after the disease developed. Cause and effect become confused.[20]

In children, the proportion of patients with generalized idiopathic epilepsy is fairly similar in studies from Ecuador (29%), the United States (21%), and Finland (22%).[6,17,102] However, symptomatic localization-related epilepsies are a group of more diverse syndromes, probably due to different risk factors for epilepsy in developed and developing countries.

Tables 5 and 6 show the reported frequencies in all age groups of localization-related epilepsies in the series from

P.94

developing countries: 58% in Ecuador, 63% in India, and 73% in Sri Lanka.[22,74,97] Differences are probably due to methodologic differences. The Ecuadorian study included only newly diagnosed patients, whereas the Indian and Sri Lankan studies used prevalent cases. The frequency of localization-related epilepsies in newly diagnosed epilepsy in developed countries is lower: 42% in England and 47% in Switzerland.[48,63] In childhood, localization-related epilepsies account for 55% in India in newly diagnosed unprovoked seizures, similar to the reported frequencies in the United States of 58% and Finland of 61%.[6,98,102]

Symptomatic localization-related epilepsy in all age groups was 39% in India, much higher than the reported frequency of 13.5% from Switzerland and 29% from Italy.[47,48,74] However, the frequency of 27% in the Ecuadorian study and 27% in another Indian study[17,98] are similar to those from developed countries.

Generalized epilepsies and epilepsy syndromes accounted for 12% of epilepsy in India and 30% in Ecuador, probably related to the patient populations studied. However, in Indian children, generalized epilepsies and epilepsy syndromes accounted for 35% of all epilepsy.[74] Idiopathic epilepsy accounted for 24% of epilepsy in Ecuador, similar to the 27% in Switzerland and 18.5% in Italy.[17,47,48]

The diagnostic categories for age-related partial and generalized idiopathic epilepsies apply to all countries. The overall frequency of symptomatic and cryptogenic, localization-related epilepsies is similar, but there are differences within the symptomatic group because of differing risk factors.

Despite etiologic differences in developed and developing countries, the ratio of idiopathic/cryptogenic to symptomatic epilepsy remains fairly constant throughout the world. In Rochester, 65.5% of newly diagnosed cases of epilepsy were idiopathic.[38] Developing countries show a similar proportion

P.95

of idiopathic cryptogenic (60% to 70%) and symptomatic epilepsy (30% to 40%),[20] but the causes of the symptomatic group are different. In developed countries, cerebrovascular diseases account for a significant proportion of symptomatic epilepsy,[38] whereas perinatal brain damage, neurocysticercosis, CNS infections, and traumatic brain damage are the most frequent risk factors in developing countries.[1,12,16]

Etiology and risk factors for epilepsy vary with age and geographic location. Congenital, developmental, and genetic conditions are mostly associated with epilepsy in childhood, adolescence, and early adulthood. Head trauma, CNS infections, and tumors may occur at any age and may lead to epilepsy, although tumors are more likely over age 40. Cerebrovascular disease (CVD) is the most common risk factor for epilepsy in people over 60 years of age. In some parts of developing countries, endemic infections, such as malaria, neurocysticercosis, paragonimiasis, and toxocariasis, are associated with epilepsy.[8,71,81,87,89]

Few case-control designs have been applied in developing countries. These studies found febrile seizures to be a significant risk factor. Some studies from India also suggested that head injury, development delay, and family history of epilepsy were significant risk factors.[9,83,92]

Prenatal and Perinatal Pathology

Poor prenatal or perinatal care resulting in brain damage is often claimed to be a reason for the high prevalence of epilepsy in the tropics,[1,81,97] but few tropical studies define inclusion criteria for this category. In developed countries, the presence of prenatal and perinatal events does not appear to be associated with the occurrence of childhood epilepsy when children with cerebral palsy and mental retardation are excluded.[39]

The American Collaborative Perinatal Project,[77] which prospectively followed a large population, found that 14% of children who had nonfebrile seizures also had cerebral palsy to some degree. Conversely, 21% of children with cerebral palsy had had at least one nonfebrile seizure by the age of 7 years. However, seizure disorders in children of low birth weight without cerebral palsy were not found to be significantly more frequent. Of the late pregnancy and birth conditions evaluated, including conditions considered to be associated with anoxia and markers of fetal distress, none was found to be an important antecedent of seizure disorders in children without motor handicap. Among factors observable in the neonatal period, delay of the first cry by 3 minutes or longer, abnormality of tone, and neonatal seizures or meningitis were leading predictors of later seizures.

We cannot extrapolate these findings to the situation in developing countries, where health care systems are quite different. In developing countries, most deliveries in rural areas are conducted by traditional birth attendants, families are large, and the frequency of preterm deliveries is at least twice as high as in developed countries.[1,12] Many mothers are malnourished and exposed to a variety of infections that may affect the baby in utero or at the time of delivery. These factors need further study to evaluate their contribution to perinatal brain damage. In developing countries perinatal brain damage accounts for 13% to 14% of later epilepsy in children.[24] In a hospital-based study from south India, static encephalopathy related to perinatal brain damage accounted for 9% of all later epilepsy and 13.5% of remote symptomatic epilepsies.[74]

Infections of the Central Nervous System

Infectious and parasitic diseases are the most common causes cited for the higher incidence of seizures in developing countries. Acute infections of the CNS are significant risk factors for both acute symptomatic seizures and epilepsy. In a retrospective cohort study from Rochester, Minnesota, CNS infections increased the risk for the development of unprovoked seizures by 11-fold.[38] In Ecuador, infectious diseases, mostly TB plus bacterial meningitis, preceded development of epilepsy in 4.5% of cases.[17] Epilepsy followed tuberculous meningitis in 8%.[16,20] Seizures are also common manifestations of intracranial tuberculomas. There are no reliable data available on long-term sequelae of bacterial meningitis, endemic or epidemic.

CNS toxoplasmosis is common in patients with acquired immunodeficiency syndrome (AIDS).[12] As AIDS incidence increases in tropical countries, toxoplasmosis may become a more important cause of epilepsy. Epilepsy is a well-recognized consequence of toxoplasmosis in about 25% of affected people.[1,12] Mental retardation and seizures follow brain damage associated with congenital toxoplasmosis. In an institution for mentally handicapped children, 6.8% of patients with epilepsy had congenital toxoplasmosis.[20]

Neurocysticercosis

Studies of selected hospital patients with seizures or epilepsy in some developing countries report NC as its cause in 30% to 50% of patients.[1,12] A prospective multicenter study in Ecuador[17] found that NC was a risk factor in 8.3% of newly diagnosed patients with epilepsy. Other studies, where acute symptomatic seizures were excluded, found only 5.3% to 11% of patients with epilepsy had NC.[2,67] Most have acute symptomatic seizures that do not develop into epilepsy. This high incidence probably occurred because of failure to differentiate between epilepsy and seizures.[19] Although it is one of the most frequent antecedents among the symptomatic group, NC is not the main cause of epilepsy.

Surprisingly, the proportion of epilepsy associated with cysticercosis discovered using immunologic tests is considerably lower than that found using CT. Only 12% of patients with epilepsy attending an outpatient clinic in Peru had serologic evidence of *Taenia solium* by enzyme-linked immunotransfer blot (EITB) test.[21] There are also clinical inconsistencies in the link between epilepsy and NC. Parasite location may be remote from the apparent epileptogenic region.[67] There is no correlation between the burden of cysticercal lesions and the severity of epilepsy. Patients with severe refractory seizures may have only one calcified lesion, whereas other patients may have multiple cysts or calcifications but no epilepsy. Since NC and epilepsy are common diseases in most developing countries, a causal as well as fortuitous relationship between the two conditions might exist independently.[21,67,81,106]

Recent new studies have not modified this position. A report from Brazil[94] concluded that the presence of calcifications on CT does not increase the risk of seizure recurrence. A Brazilian study[106] confirms the good prognosis of parenchymal NC. The authors point out that, if it is assumed that NC can be an incidental finding in a considerable number of patients with epilepsy in endemic regions, inflammatory processes related to parasitic infection, death, degeneration, and calcifications in the brain of the host do not significantly aggravate the cognitive deficits observed in medically refractory mesial temporal lobe epilepsy. A study in rural Ecuador[28] affirms that NC is associated with one in three cases of epilepsy and is possibly the cause of the excessive proportion of epilepsy in that population. However, results were not statistically significant and only 3 (8%) of 24 patients with epilepsy had â€œdefinitiveâ€ NC. A community survey[72] concluded that brain CT abnormalities compatible with NC were more frequent in individuals with seizures and in those with positive immunoserologic assay (EITB) for cysticercosis. Most of the patients who were diagnosed with NC in this study had only calcifications (half of them had just one calcification); however, it is well known

P.96

that brain calcifications do not necessarily mean that a patient has NC.

The small numbers of the above studies do not allow generalizations. So far, there are no case-control or prospective studies in which CT scan has been used for providing information on the proportion of NC patients or seropositive individuals that will develop seizures. In addition, some authors have reported an association between seizures and NC, based on positive serum antibodies to *T. solium*/cysticercosis; unfortunately, the presence of antibodies may indicate only previous exposure to or infection with the parasite, but not necessarily brain infection.[35]

Cerebrovascular Diseases

Cerebrovascular disease in developed countries is the most commonly identified cause of epilepsy, accounting for about 11% of all new cases and about one third of cases with any identifiable cause.[39] However, in Ecuador, cerebrovascular diseases accounted for only 4.4% of new cases.[17] In developing countries, cerebrovascular diseases are thought to account for only a small proportion of epilepsy.[12]

Other Tropical Diseases

Malaria is endemic in tropical America, Africa, and some Asian countries. Acute cerebral malaria encephalopathy,[71] despite appropriate treatment, still carries a mortality of 22%.[108] Epilepsy has long been recognized as a late sequela of cerebral malaria.[97] Pathologic examination of the brain in fatal cases has shown severe vasculopathy with hemorrhages, and granuloma of DÃ¼rck formed by astroglial reaction.[108] The lesions may act as epileptogenic foci in those who survive, giving rise to chronic epileptic seizures. A special relationship has been described between cerebral malaria and febrile convulsions. Together they are responsible for 5% of pediatric emergency consultations in endemic areas in central Africa and the Amazon forest.[12,20] However, it is difficult to ascertain whether these convulsions are in fact febrile seizures or secondary to cerebral malaria.

In *schistosomiasis*, seizures occur frequently during the acute meningoencephalitic phase, but only 2.4% to 3.8% of patients with confirmed cerebral deposition of ova have seizures during the chronic phase.[12] In *paragonimiasis*, another trematode infection prevalent in South America, the lung is the primary site of infection, but the brain is often involved. Seizures, usually focal motor, are the most common manifestation of cerebral paragonimiasis.[12,16]

American trypanosomiasis or *Chagas disease* is a public health problem in rural areas of Central and South America.[79] CNS involvement is secondary to cerebral embolization from cardiac blood clots. Immunologic reactions probably underlie the pathology of the disease, including diffuse meningoencephalitis with edema and arachnoiditis. These may cause late-onset epilepsy, with a high frequency of partial seizures.[12,16]

Approximately one in three patients with cerebral *hydatid cysts* develops epilepsy.[98] Signs of focal cerebral involvement or of raised intracranial pressure are found at the onset of epilepsy in all patients. Seizures secondary to cerebral *amoebiasis* and cerebral *toxocariasis* have also been described,[20] but their contributions to the etiology of epilepsy require further study.

Principles of Evaluation

Principles of evaluation and treatment of a patient with epilepsy are the same the world over. In developing countries, however, where investigatory facilities are minimal, a diagnosis of epilepsy is essentially clinical. A first-hand, eyewitness account from the time of onset of symptoms is necessary. Often, description alone may be inadequate and it may be more helpful if the witness is able to act out the movements and sounds of the seizure. (It should be carefully considered whether the patient is to be present during this act, as it may be embarrassing.) Pseudoseizures, hyperventilation, and other nonepileptiform disorders should be excluded. Careful enquiry both from the patient and observer about symptoms and signs at the onset will help to identify more partial seizures than are usually diagnosed in developing countries. If available, EEG should be used judiciously when the onset of the seizure occurs during sleep, when the seizure appears to be primarily generalized, and to differentiate petit mal or absence seizures from complex partial seizures in children.

The indications for neuroimaging are generally the same throughout the world. Neuroimaging is done primarily when a focal lesion is suspected. If the suspected lesion is nonprogressive or not amenable to definitive treatment, as with cerebral palsy and mental retardation, neuroimaging should be withheld. It will not alter management. In developing countries, there are exceptions to this policy because parasitoses can appear at any age, often with a primarily generalized seizure, so neuroimaging should be done more often to identify these infections. Other investigations for parasitoses include examination of urine, stool, and blood; tissue biopsy to look for the parasite by microscopy; skin tests; serologic methods; demonstration of antigen by chemical methods; and DNA or RNA probes. The main problems with serologic tests are that their accuracy or validity may not be known in a given location and they may not distinguish between past and present infection. Because parasites are often confined to the CNS, examination of cerebrospinal fluid may also be necessary.

Treatment

The major issues relevant to treatment and prevention in developing countries are discussed in the section on Providing Health Care later in this chapter (see Section XII).

Pharmacologic Methods

To ensure compliance from their patients, allopathic doctors must be aware of traditional cultural beliefs and practices in their areas and give simple accounts of the illness and what patients may reasonably expect from drug treatment. The choice of drug depends on availability and cost. Phenobarbital and phenytoin are commonly available and inexpensive and are the drugs used most often in developing countries. A community-based trial of phenytoin versus phenobarbitone in children in rural India found both drugs to be equally acceptable.[82] Both have associated problems, however. Phenobarbital is sedative in adults and induces hyperactivity in children. If stopped suddenly for any reason, it produces more withdrawal seizures than other AEDs. In many places, it is unavailable without prescription and only a few stores stock it. In developing countries, the main problem with phenytoin is that it is usually available only in 100-mg tablets, so adjusting the dose for children is neither easy nor accurate. Drug-level assays are needed for all AEDs but are most necessary for phenytoin, because of the pharmacokinetics of its metabolism. Chronic phenytoin intoxication may lead to cerebellar atrophy, encephalopathy, or both. Gingival hyperplasia is a problem in people who already have poor oral hygiene.

Widely available but more expensive choices than phenobarbital and phenytoin are carbamazepine and sodium valproate.

If used, they too entail problems. Use of sodium valproate requires liver function tests and serum ammonia estimation, particularly in children who are mentally retarded. Rarely, carbamazepine therapy can depress one or all of the three blood elements and cause hepatic dysfunction. If suggestive symptoms should arise, patients are asked to seek immediate medical attention and have a blood cell count. Anemia and hepatitis are already common problems in developing countries. Especially in rural areas where laboratory facilities are unavailable, it may be impossible to differentiate problems of AEDs from concurrent illnesses.

Dosages of AEDs in developing countries follow the milligram per kilogram of body weight scale used in developed countries. In general, however, because high doses often are not tolerated, the initial dose is lower and increased gradually if necessary. Malabsorption syndromes, malnutrition with hypoproteinemia, and hepatic dysfunction may interfere with the pharmacokinetics of AEDs. Calcium and vitamin D supplementation are desirable for all patients taking phenytoin and other drugs capable of inducing hepatic enzymes.[80] In those susceptible to rickets or osteomalacia, they are essential. Folic acid supplementation is particularly important for young women likely to become pregnant. Ideally, this should be given with vitamin B_{12} to prevent precipitating subacute combined degeneration in a B_{12}-deficient vegetarian community, such as in India. Patients are often unwilling to take so many tablets for a long period of time.

The newer AEDs clobazam, oxcarbazepine, lamotrigine, gabapentin, topiramate, levetiracetam, and pregabalin are available, and indeed locally manufactured, and sold in countries with a developed pharmaceutical industry, as in India. Many are still unaffordable to most of the population, so cost should always be considered before prescribing them, particularly since expenses will have to be borne out of pocket and parents will always make sacrifices for their children.

Nonpharmacologic Methods

Epilepsy surgery, vagus nerve stimulation, and a ketogenic diet are alternatives to pharmacologic treatment. Vagus nerve stimulation is no more effective than medical treatment and is very expensive, and the device requires maintenance. A ketogenic diet is difficult to sustain. Epilepsy surgery, in appropriately selected patients, renders the patient seizure free in 70% to 80% of cases. It should be considered early to decrease medical and psychosocial consequences of repeated seizures and ultimately to diminish the cost of continued expensive medication.[107]

Pregnancy Register

Pregnant women with epilepsy, whether on or off treatment, should be entered in a national pregnancy register, which should conform to the methodology of established registries in developed countries. The aim of this is to assess the risk of major congenital malformations, and it will allow optimal treatment of pregnant women with epilepsy under differing local circumstances, with due consideration to both mother and baby.

Compliance

Ensuring compliance is a difficult matter in any country. Pregnant women, and sometimes their doctors, may fear that AED treatment will harm the fetus. Parents may fear that AEDs will retard their child's development.

Students may be made sleepy from the AEDs, preventing them from studying at night. Newly married women may have concealed their epilepsy from their husbands and fear being caught taking medication. In developing countries people believe that allopathic medicine produces unacceptable side effects and they fear that they will become dependent on their drugs. If the drugs do not fulfill expectations, the patient may change doctors and treatment, or turn to traditional healers. If the patient wishes to go to a traditional healer while receiving allopathic medicine, this should not be discouraged, unless traditional methods require taking oral medicines that may contain unknown quantities of anticonvulsant. In addition, some traditional medicines have their own side effects, which the patient may attribute to allopathic medicines. Conversely, if benefits occur with allopathic therapy, the patient may attribute any improvement to the traditional methods of treatment and stop taking the allopathic drugs alto-gether.

As in developed countries, compliance can be assessed by interviewing the patient and by taking pill counts. Techniques to monitor AED blood levels are not always available and not always standardized.

Prevention, Safety, and First Aid

In addition to compliance, other general measures that will help patients live with epilepsy should be explained and emphasized. These include getting adequate rest and avoiding alcohol, fasting, and stress. In developing countries, religious fasts are common and often prolonged. Lack of food alone may provoke seizures during these times and the patient may also omit taking medication. Activities that may endanger the patient or others, such as cooking beside an open fire, standing in the doorway of a train, or driving, should be avoided as much as possible. Alternatives should be worked out with the patient.

The family of the patient needs to be made aware of first-aid measures. During a seizure, the patient should be turned on the side in a semiprone position, head down if possible, to allow drainage of secretions and vomitus. Nothing should be put in the mouth, as this obstructs the airway and might result in injury to the patient's teeth or tongue. If there is status epilepticus, the patient should be hospitalized as soon as possible. Rectal diazepam or buccal midazolam may be used at home.[95]

Treating the Cause of Epilepsy

Finally, the cause of the epilepsy needs to be treated. In developing countries, this mainly involves treating the chronic parasitoses and tuberculomas. The management of neurocysticercosis in particular remains difficult. Treatment depends on the number and location of the cysts and whether they are vesicular, degenerating, or calcified.

Diagnosis of the cause is mainly by neuroimaging with some help from serology. The treatment armamentarium consists of antiepileptic drugs, cysticidal agents, steroids, and surgery. The choice of treatment is a delicate and controversial matter.[35]

Prevention

Epidemiology has contributed less to our knowledge of etiology and prevention of epilepsy than it has to that of lung cancer and stroke. In over half the cases of epilepsy in developing and developed countries, no cause can be found. If all cases of known cause were prevented, more than half the total number of cases would still occur. When the etiology is known, seizures can be prevented by combining treatment of known risk factors in the community with prophylactic AED therapy.

P.98

Providing Health Care

Health Care Delivery

Epilepsy is treatable with relatively cheap medication, but the treatment gap in developing countries is still very high, up to 80% to 90%. Epilepsy has not only medical, but also psychologic, sociologic, economic, and cultural dimensions. Of particular importance in developing countries is symptomatic epilepsy related to endemic parasitic and infectious diseases, head trauma, and poor perinatal care. Levels of education, ability of health care workers and patients to communicate, and lack of availability of resources for the health care system influence the management of epilepsy and related problems. Few developing countries have established programs and institutions to deal with these problems.

Costs

The cost of providing care in developing countries is a major issue. Phenobarbital and phenytoin are the cheapest drugs, although the latter is available only in some countries. One of these two drugs is prescribed in 65% to 85% of treated patients with epilepsy,[29] and the drugs are available at most health centers and/or community pharmacies. The annual cost of phenobarbital, at 100 mg/day, ranges from $4 to $16, compared with $3 to $30 for phenytoin. Other less widely prescribed drugs including carbamazepine (CBZ), valproate (VPA), and injectable diazepam (DZP) are 6- to 12-fold more costly.[113]

Sub-Saharan Africa is the home of 11% of the world population, but it benefits from only 1.3% of world income. In 2001, the mean Gross Domestic Product per capita in the sub-Saharan countries was $1,690, ranging from $12,508 (Seychelles) to $490 (Sierra Leone), versus $24,973 in the developed world. Among the 40 least wealthy countries in the world, 32, or 80%, are in Africa.[110]

The provision of AEDs through government-funded schemes is therefore impossible in some cases. Not only do governments lack resources, but also people are unable to pay for AEDs from their own incomes. Between 61% and 72.8% of the population in the poorest countries of the world live on less than $1 per day.[110]

Phenobarbital will remain the only treatment until drug companies bring down their prices and make their products affordable to small health centers in the developing world.

Treatment Gap

Treatment gap has been defined by the International League Against Epilepsy as â€œthe difference between the number of people with active epilepsy and the number whose seizures are being appropriately treated in a given population at a given point in time, expressed as a percentage.â€ This is estimated at between 80% and 90% in developing countries. While cost is a major issue, other factors such as inadequate planning at government level, poor infrastructure, insufficient availability of drugs, and scarcity of trained medical personnel, particularly in rural areas, are also significant. Cultural factors also play a major part.

Cultural Influences and Traditional Medicine

In many developing countries, epilepsy is perceived as a manifestation of supernatural forces, caused by ancestral spirits or attributed to possession by evil spirits. People with epilepsy are often stigmatized. Stigma generates a hidden burden, which discourages patients from seeking another diagnosis and the care they need and deserve. Furthermore, discrimination against people who have seizures excludes them from adequate employment. In some societies, fear of â€œcontaminationâ€ by the breath, blood, sperm, and genital secretion of people with epilepsy produces unacceptable responses such as ignoring or avoiding a person having a seizure, which may lead to death, drowning, burns, and other injuries. Children with untreated epilepsy often face discrimination and isolation at school, resulting in low self-esteem and underachieve-ment.

Sociocultural factors, and in particular what the person believes is the cause of his or her epilepsy,[69] can explain why patients often first seek advice from the many traditional therapists and healers.[25] In developing countries, traditional healing is usually the first treatment sought. Sometimes between 6.5 and 13.4 years elapse before the patient receives allopathic treatment.[25,29,109,112] Traditional healing should not be completely discredited, since often patients obtain secondary benefits such as reassurance and emotional support. It should be integrated with Western methods to provide full support and care for the patient and his or her family.[31] Sharing information with and offering training to traditional healers has shown that working in close connection with traditional healers and community and religious leaders promotes acceptance of the primary health care worker by the community and enables him or her to modify certain harmful practices. The challenge is how to marry the differing convictions that determine traditional and scientific treatment concepts.

Role of Physician and Paraprofessionals

In those developing countries that have specialists in the neurosciences, there is a very low doctor-to-population ratio. In Europe there is one neurologist for 100,000 people, but in developing countries the ratio is one neurologist for up to 6 million people. The World Health Organization (WHO) recommends one neurologist for 50,000 people. In developing countries, everyone qualified should be actively involved in health care delivery. In addition, diagnostic centers are very few and mostly located in capital cities. Such a shortage of professionals makes the role of paramedical staff essential, prevention of epilepsy paramount, and coordination of government programs imperative.

Since complications in the peripartum period are the leading cause of future epilepsy in developing countries, the epilepsy program should be included in plans for primary health care at both government and community levels. It should also be coordinated with other public health programs, such as antenatal and postnatal care and pediatric health in the first 10 years of life, including immunization programs. Prevention of head trauma and alcohol and drug abuse should also be priorities.

Early detection and appropriate treatment will reduce disabilities caused by epilepsy. Publicizing, preventing, and managing those infectious diseases that affect the brain and prevention of consanguineous marriages should also be considered priorities for public health. Eradication of neurocysticercosis should receive special attention.

The following goals are essential:

- To ensure availability of phenobarbitone to patients.
- To promote the use of generic drugs and carry out quality control checks from time to time.
- To continue to permit use of traditional medicine that is not dangerous, but ensure that the patient keeps on taking AEDs.

P.99

- To establish drug banks: An agreement between ILAE/International Bureau for Epilepsy (IBE) national chapters and drug suppliers could ensure availability and supply of cheap AEDs; such a system could employ its own funding mechanism and become sustainable and relatively autonomous.
- To establish specialized investigatory facilities with an EEG machine, a CT scanner, and a drug monitoring laboratory.

Public and Private Agencies

To deal with the gradual decline in the provision of health care services as a result of poverty in African states, the WHO resolved to revitalize district health systems by establishing community-based management centers and employing only essential drugs to combat major public health problems. This was called the Bamako Initiative. Phenobarbital for epilepsy is on the list of essential drugs. As it is cheap and taken only once a day, its use should be explained and it should be prescribed to most patients with epilepsy. Fifteen years down the line, much progress has been made, but much is yet to be done. There are operational problems caused by poverty, lack of human resources, demographic pressure, sociocultural differences, and recurring emergency situations. The next step will be to include a larger number of drugs, particularly those that are in generic form, with effective, sustainable quality control. Public and private sectors need to cooperate to expand drug coverage.

Community-based Epilepsy Programs

The treatment of epilepsy in developing countries is not only a medical, but also a political issue. Widespread poverty, stigma, and discrimination in employment and education against people with epilepsy obstruct the effective delivery of services and treatment of patients. These wider issues need to be addressed at both the individual and the societal level.

Summary and Conclusions

The essential components of an effective strategy for addressing epilepsy in developing countries are as follows:

1. Adequate financing.
2. Changing laws and community attitudes.
3. Making people with epilepsy and their families aware of their rights and what treatment should be available to them.
4. Actively providing psychosocial rehabilitation, educational opportunities, and income generating projects, including incorporation of traditional with allopathic approaches to treatment.
5. A public education program to ensure that awareness of and sensitivity to the needs of people with epilepsy permeate education, employment, health, and the legal system.
6. Adopting a multidisciplinary approach involving patients and their families interacting with health and social workers; this would be promoted by government and delivered through a range of agencies to include community leaders, pharmaceutical companies, nongovernmental organizations (NGOs), and international groups.

However, these issues also need to be tackled at the global level. The Global Campaign Against Epilepsyâ€"Epilepsy out of the Shadows is an international and collaborative initiative set up by the IBE, ILAE, and WHO. With the support of governments, interested UN agencies, international institutions, NGOs, and the pharmaceutical industry, the ultimate aim of the Global Campaign is to free every person in the world who has epilepsy from the burden of any preventable or manageable epileptic disorder. This two-part strategy consists of the provision of a platform for international awareness and assisting health departments to develop national epilepsy programs.

By comparison with developed countries, epilepsy in developing countries presents unique problems due to differences in incidence, etiology, cultural, and socioeconomic factors. In addition, the health care delivery systems in these countries are often inadequate, poorly organized, excessively bureaucratic, and underfinanced. Although there are no significant differences in most parameters of epilepsy prognosis, mortality seems to be higher than in developed countries. Developing countries need more incidence studies, prospective studies on large cohorts with recent-onset epilepsy to determine mortality, and analytic case-control studies on incidence cohorts. Prevention of cerebral infections by immunization and control of parasitic diseases through improved sanitation, hygiene, and elimination of the responsible vectors together with prevention of head injuries will reduce the incidence of new symptomatic cases, as will good maternal and child care. A major impediment to raising the standard of medical care is the unavailability of physicians or other trained personnel and the lack of modern diagnostic and treatment facilities, especially in rural areas. A multidisciplinary approach involving public and private agencies, professionals, paraprofessionals, and even traditional healers is required in many developing countries. Community-based epilepsy programs should be incorporated in national health care programs. Finally, a continuing challenge is the treatment gap, which is estimated to be 80% to 90% at any one time in some countries. It needs to be addressed by measures such as the Global Campaign, which increase awareness of epilepsy and strengthen national epilepsy programs.

Acknowledgments

The authors gratefully acknowledge Dr. Roberta Harrison Raven for considerable help in editing this chapter and Dr. W. Allen Hauser for reviewing parts of this chapter.

Harry V. Vinters

Introduction

The history of the study of structural brain changes in patients with intractable epilepsy is characterized by continuing debate concerning the primacy of neuropathologic abnormalities in seizure genesis in temporal lobe epilepsy (TLE) (see Chapter 13), and intractable seizure disorders in infants and children,[4,156,157] and subtle cortical cytoarchitectural alterations in primary generalized epilepsy.[113,119] This chapter will focus on neocortical pathologic abnormalities and will rely for the most part on studies using human tissue. Specific structural alterations in brain tissue, which may serve as a final common pathway for the development of many diverse epilepsy-associated conditions, are discussed. Neuropathologic changes that may be attributed to epilepsy, including the neuropathologic consequences of status epilepticus (SE), are also discussed. Characteristic neuropathologic conditions that result in epilepsy syndromes (excluding developmental malformations but including epilepsy-associated neoplasms) are described.

Are There Unique Morphologic Substrates That Subserve Intrinsic Epileptogenicity in Human Neocortex?

Advances in epilepsy neuroimaging[53,54,144,158] have created new challenges for the diagnostic neuropathologist, but also provide a unique opportunity to better characterize the nature of the epileptogenic lesion. A key issue in the investigation of patients with lesional epilepsy is to determine the relative contribution of the lesion and of the surrounding perilesional brain tissue to seizure genesis. Virtually all epilepsy-associated lesions may also occur in the absence of epilepsy. What, then, distinguishes the lesion that has caused epilepsy from the one that has not? Is there an underlying genetic basis for epilepsy susceptibility in such patients, and/or are there unique structural changes present in the perilesional brain tissue that provide the pathologic substrate for seizure generation? There is good evidence that some lesions are of themselves intrinsically epileptogenic; in this regard dysplastic cortical tissue is hyperexcitable.[34,110] However, hyperexcitability alone is insufficient for seizure genesis. None of the epilepsy lesions has ever been shown to demonstrate spontaneous depolarization using current patch clamp techniques in an in vitro environment. Furthermore, it is clear that some lesions such as cavernous angiomas cannot be intrinsically epileptogenic, and in such cases alterations in the surrounding cortex will almost certainly provide the key to understanding seizure genesis.[178]

It is useful to consider a number of definitions that relate to the epileptogenic lesion and surrounding brain tissue. The lesion itself may or may not contain functionally active neural tissue. The epileptogenic zone is the area located immediately adjacent to the lesion, which is essential for seizure genesis and whose removal is generally considered to be essential for improved seizure control.[17] Usually, but not always, the epileptogenic zone includes the seizure onset zone. Ideally, the functional deficit zone, which by modern neuroimaging techniques is shown to have functional abnormalities during seizure development, overlaps with the epileptogenic zone, though again this may not always be the case. Ictal symptoms result when an area of cortex is activated during epileptiform discharge and is referred to as the symptomatogenic zone. Interictal spikes utilized in the past for localization purposes reflect activity in an irritative zone, which may or may not be included within the epileptogenic zone. Finally, there is a defined area from which the seizure typically begins, referred to as the seizure onset zone. Ideally, the area in the immediate vicinity of the epileptogenic lesion would include all of the above zones, though seldom does this occur in practice. Spectacular advances in neuroimaging have led to a situation whereby the pathologist in receipt of tissue originating from epilepsy surgery can now be more certain that the resected material includes the epileptogenic zone. Additional techniques such as magnetoencephalography (MEG) have been used to map the extent of the epileptogenic zone surrounding relatively inert epilepsy-inducing lesions such as cavernomas.[92,124]

In attempting to determine if there is a specific pathologic change in the epileptogenic zone, immediate difficulties are encountered in terms of procuring adequate control tissue. Comparison of perilesional tissue from patients without epilepsy with the perilesional epileptogenic zone from patients with epilepsy, both having similar underlying lesions, would go a long way toward resolving the nature of any epilepsy-induced brain changes. Rarely has this been achieved. Nevertheless, new developments in molecular and pathologic techniques have provided a unique opportunity to answer questions regarding specific structural changes in the epileptogenic zone.[40,41,118,121,182] Standard immunocytochemical techniques have now been supplemented with a bewildering array of sophisticated analytic techniques capable of probing the genetic and neurochemical profile of individual neurons within an epileptogenic zone. Laser capture microscopy facilitates analysis of individual neurons both in terms of neurochemical profile and surface receptor expression. Coupled with microarray studies of gene expression, it is now possible to build a very accurate genetic profile of individual neurons arising within the epileptogenic zone.[27] Additionally, in vitro slice current-clamp recordings have been obtained from neurons in dysplastic brain tissue.[139]

Any morphologic approach to the study of the epileptogenic zone must go some way to explaining the key neurophysiologic

P.104

events in seizure genesis, namely, the recruitment and repetitive and sustained synchronous discharge of groups of neurons. Since the first Golgi studies, there has been awareness that epileptogenesis is associated with altered synaptic morphology in groups of neurons. More recently, the concept of an intrinsic deficit in neuronal function has been confirmed by the demonstration of genetically determined alterations in structural and functional properties of neuronal ion channels.[64,170]

Decreased Inhibitionâ€“Increased Excitation

Morphologic studies to date have focused on the demonstration of decreased inhibition or increased excitation in the epileptogenic zone. At the very least the concept of decreased inhibition (Î³-aminobutyric acid [GABA]-ergic) is simplistic and does little to elucidate the sequential change that undoubtedly take place in the epileptogenic zone as seizures become more chronic, more prolonged, and generally more severe. Attempts to determine the severity of loss of inhibitory interneurones[108,120] coupled with the extent of increased excitation, resulting perhaps from axonal sprouting leading to new facilitated excitatory pathways,[135] is perhaps beyond the resolution of even the sophisticated neuropathology techniques outlined above. Probing more deeply, it is difficult to see how alterations in receptor density expression on individual neurons might be used to define the origin of an epileptic focus, especially as evidence for the existence of intrinsically epileptic neurons is still not completely convincing.[76,93,111,126,149] In an individual epileptogenic zone it may well be that very subtle alterations in inhibition combined with reorganization of excitatory circuits (glutamatergic) will be sufficient to result in epileptogenesis. The complexity of the decreased inhibitionâ€“increased excitation concept is illustrated by studies on chandelier cells and other cortical inhibitory interneurons in epileptogenic brain tissue, in which there is considerable variation of results within and between individual cases.[6,48,49,71,88]

The Neocortex in Temporal Lobe Epilepsy

Human neocortical neurons can, in response to stimulation, generate bursts of action potentials, which are caused by activation of *N*-methyl-D-aspartate (NMDA) receptors.[13,14,65] Neurons adjacent to cavernous angiomas show spontaneous excitatory and inhibitory synaptic events and, following stimulation, demonstrate multiple action potentials.[178] Spontaneous inhibitory potentials related to GABA receptor activation may also be demonstrated in human brain slices.[12,15,165] Pharmacologic manipulation of receptors can lead to generation of epileptiform activity in resected neocortex, but receptor blockade or stimulation in isolation is often insufficientâ€"the addition of an electrical stimulus being required to generate epileptiform discharges.[52] Nevertheless, there is increasing evidence that synchronization, a key element in the generation of epileptiform discharges, is in part mediated by GABA receptorâ€"mediated potentials in epileptogenic neocortex.[43]

Cortical Dysplasia (CD)

The spectrum of cortical dysplasia (CD)[128] almost certainly extends beyond the classic description of Taylor et al., in which a combination of balloon cells and large malorientated neurons with coarse Nissl substance were the defining pathologic features.[166] Detailed morphometric studies of human temporal neocortex obtained from patients undergoing resective surgery for TLE has shown a significant increase in mean neuronal somal volume in neocortical and ectopic white matter neurons.[26] This subtle form of CD is not recognizable without recourse to morphometry. It is reasonable to assume that the neurophysiologic properties of classic â€œTaylor typeâ€ CD might also be present in subtle CD.[126] For many years it has been recognized that CD tissue shows a general decrease in density of inhibitory neurons and an increase in excitatory neurons. However, detailed quantitative analysis of CD demonstrates considerable variation in the distribution and severity of GABAergic system alterations both within and between cases.[3,30,64,159,167] Additionally, these studies have demonstrated considerable variation in the number of synapses per neuron both between different cases and within individual cases. The difficulty with all of these studies is a determination of the contribution of the epileptic activity itself to alterations in synaptic density, especially in terms of functional reorganization that might contribute to new synapse formation.

Intracellular recordings from the giant neurons of CD (but not from the balloon cells) show evidence of hyperexcitability when depolarized, in contrast to the balloon cells, which are essentially inert.[34] Additionally, these large neurons have larger voltage-gated currents than normal-appearing neurons. Furthermore, the large neurons have increased immunoreactivity for glutamergic receptor subunits such as NMDA and also show alterations in the composition of NMDA subunits when compared with normal-appearing neurons from nonepileptic tissue.[33] Intriguingly, some but not all â€œnormalâ€ neurons from CD tissue show similar consistent variations in NMDA subunit expression. However, in spite of all the excellent work that utilizes human epileptic tissue in vitro, it has not been possible, to date, to demonstrate intrinsic spontaneous epileptiform activity.

A Role for Glial Cells in Epileptogenesis

More recently, the contribution of the astrocytic component in any epileptogenic zone has received attention.[42,68] Astrocytes are functionally active and express ion channels and neurotransmitter receptors similar to neurons. Astrocytes play a key role in modulating the neuronal extracellular environment. Long believed to be a relatively inert cell type, it is now widely recognized that astrocytes, through their ability to buffer potassium, may contribute to neuronal hyperexcitability.[160] In virtually all structural lesions associated with epilepsy there are increased numbers of astrocytes either within or surrounding the lesion. Astrocytes possess voltage-activated potassium [K^+] channels through an inwardly rectifying K^+ channel (K_{IR}), which have a critical role in buffering potassium levels.[10,78,82,151] Fluctuations in extracellular calcium and potassium levels might well be the ionic basis for conversion of regular firing neurons into burst firing neurons capable of functioning as pacemaker neurons having the ability to recruit other neurons. There is recent evidence that genetic alterations in K_{IR} channel subunits may contribute to the development of epilepsy susceptibility.[68,163] Such alterations in potassium channel function might also be due to environmental factors. Impaired clearance of extracellular potassium could result in neuronal hyperexcitability. What is required now is a comparative study of glial cell functional properties in epileptic and nonepileptic brain tissue.

In summary, although there have been spectacular advances in neuroimaging and in the array of molecular techniques available to study the epileptogenic zone, the evidence, to date, for common underlying epilepsy-specific pathologic abnormalities that distinguish the epileptogenic zone surrounding an inert epileptic lesion from nonepileptogenic tissue surrounding a similar lesion is difficult to delineate.

Common Neuropathologic Changes That Result From Epilepsy

The effects of recurrent and prolonged seizures on the developing brain and also on the fully formed adult brain require careful consideration. Before discussing whether or not specific neuropathologic changes develop as a consequence of recurrent and prolonged seizures, it is necessary to examine whether or not there are recognizable clinical deficits that occur as a consequence of seizure activity. Intuitively, all clinicians involved in the care of patients with epilepsy suspect that frequent and/or prolonged seizures amounting to status epilepticus (SE) are harmful to the developing and mature brain. Gradual decline in school performance and behavior is frequently attributed to the effects of recurrent seizure activity in children. However, a careful examination of the literature reveals a paucity of detailed long-term prospective studies that attempt to correlate seizure frequency over many years with objective measures of cognitive function. Nevertheless, in a critical review of the studies to date (however imperfect), a statistically significant relationship was confirmed between the number of seizures or the presence of SE and decreased scores on cognitive performance.[50] The effect on cognitive performance was greater for patients having uncontrolled seizures of the generalized tonicâ€"clonic type. A similar effect was not seen with partial epilepsy. When neuroimaging findings are included, it has been shown that brain atrophy in temporal lobe epilepsy as measured by quantitative magnetic resonance imaging (MRI) is the primary mediator of the effect of epilepsy duration on neuropsychological morbidity.[127]

In relation to the specific issue of intellectual decline following SE in adult patients, the problem is more difficult to resolve. Significant memory impairment may occur as a result of SE, though in the majority of instances this is not permanent. Frequently SE is a reflection of underlying cerebrovascular or other serious systemic disease, the presence of which more likely determines the patient's subsequent intellectual and cognitive performance. In a series of 1,685 patients with epilepsy who underwent comprehensive neuropsychological testing, comparison of IQs and Wechsler Adult Intelligence Scale (WAIS) scores between those who experience SE and a control group who did not, failed to demonstrate any significant intellectual decline following SE.[1] Although the study may be criticized on the suitability of the WAIS-R test for measuring all cognitive functions, particularly amnesia and memory, it was not possible to demonstrate any long-lasting intellectual dysfunction.

Neuroimaging Studies

Before attempting to determine if epilepsy causes seizure-induced (recurrent unprovoked or SE) permanent neuronal injury, several confounding factors must be considered, including the neurotoxicity of antiepileptic drugs, the neuropathologic consequences of any systemic illness associated with epilepsy, any brain injury sustained during seizure episodes, and the initial precipitating event such as a prolonged febrile seizure, together with the nature of the underlying process that may have caused the epilepsy to develop in the first place. It is immediately obvious that human pathologic studies are unlikely to be able to tease out these interdependent variables. Longitudinal prospective imaging studies can readily detect alterations in the volumes of specific regions such as the hippocampus and the neocortical ribbon. Surprisingly, and although in their infancy, such studies have shown that progressive brain atrophy is not an inevitable accompaniment of epilepsy and that when volume loss does occur, it does so independently of seizure frequency and antiepileptic drug usage.[101] In fact, it is felt that any developing atrophy is more likely to be due to a combination effect of normal aging and the underlying disease process that caused the epilepsy to occur in the first place. It must be stressed that such studies are difficult to execute and will require large numbers and several years of follow-up.

Patients with temporal lobe epilepsy demonstrate mean reductions of from 4% to 6.6% in cerebellar volume when compared with nonepileptic control patients; in general, a longer duration of TLE with an increased lifetime number of generalized tonicâ€"clonic seizures were present in those with cerebellar atrophy. Furthermore, the cerebellar atrophy appeared to occur independently of cerebral cortical atrophy.[75]

Recent neuroimaging studies, especially those which measure water diffusion through the brain, have demonstrated alterations in diffusivity after both prolonged seizure activity and single seizures. Single seizures may be followed by focal changes in diffusion-weighted imaging (DWI), which invariably return to interictal levels within a few hours.[147] The pathologic correlate of the altered DWI is as yet unknown, though it is likely that transient edema may occur. Alterations in DWI that have developed following prolonged seizure or SE[79] have gradually returned to interictal levels, though in a few instances the changes in DWI have been followed by brain atrophy.[96] SE with minor or no motor disturbance (i.e., nonconvulsive SE), either generalized or focal, may be associated with MRI changes.[37] Thus, although the neuroimaging evidence for seizure-induced neuronal injury is beginning to accumulate, currently it is difficult to be certain of the long-term significance of these changes in terms of clinically apparent brain injury.

Human Pathologic Studies

In a few well-documented human pathologic studies, it has been possible to demonstrate neuronal injury that has clearly occurred as a direct result of seizure activity. In a detailed imaging and autopsy study, a 28-year-old man was shownâ€"during 5 months of idiopathic convulsive SEâ€"to develop evolution of generalized cerebral cortical atrophy with severe neuronal loss and gliosis. The patient had not become hypoxic or hypotensive in the course of the illness.[132] In another report, a 9-year-old girl with refractory focal SE developed progressive generalized brain atrophy over a 3-year period during which the MRI showed progression from normal through increased focal T2 signal to generalized atrophy. Brain biopsy demonstrated neuronal loss and gliosis.[51] Again, there was no evidence of any confounding variable such as hypotension or hypoxia. Crossed cerebellar atrophy has been demonstrated by MRI,[94,116] positron emission tomography (PET),[85] and pathologically[97,164] in the cerebellar hemisphere contralateral to the cerebral hemisphere from which unilateral persistent seizure activity arose, thereby providing good evidence for enhanced neuronal activity, transmitted via corticocerebellar pathways, as the likely explanation for neuronal injury.

Although the neuropathologic consequences of SE in humans have not been extensively studied in recent years,[154,175] there is good evidence from autopsy examinations that widespread neuronal necrosis with varying degrees of gliomes-odermal proliferation may occur,[103] though not invariably so, after SE.[38] There is general agreement that the severity of such neuronal injury is less in children than in adults.[70] The hippocampus shows the most striking changes, with widespread neuronal necrosis. Similar changes may be present in the thal-amus and in a patchy distribution throughout the neocortex. The extent of any associated astrogliosis or microglial cell proliferation depends, to a large extent, on the duration of a given patient's survival following SE. Repeated episodes of SE could result in sufficiently severe degrees of neuronal loss to eventually lead to cortical atrophy.

Controversy has arisen in relation to watershed/borderzone ischemic lesions occurring in SE. In a review of the neuropathologic consequences of SE,[28] which cited the classic work of

Corsellis and Bruton, it was suggested that watershed distribution necrosis is feature of SE. In subsequent correspondence, Bruton[29] explicitly stated that such lesions were not described in his original publication. In reply, the editors cited incorrect referencing, declaring that the description of watershed lesions in SE should have been credited to the classic work of Norman,[123] originally published in 1966 and reprinted in 1987. Unfortunately, however, a very careful scrutiny of the original 1966 work and of the subsequent 1987 reprint has failed to locate any reference whatsoever to watershed lesions in the brains of patients dying of SE. It is our belief that neuronal necrosis having a watershed distribution cannot be attributed to SE alone and that some other contributory factor, such as profound hypotension, should be sought, either as the cause of or a complication of SE.

Common Brain Lesions Associated with Epilepsy

In this section, selected features of several characteristic neuropathologic entities associated with seizure disorders are described. Structural features of these lesions (and their relationship to epilepsy) will be emphasized and selectively illustrated. Especially in patients with temporal lobe epilepsy, â€œdual pathologyâ€ (e.g., mesial temporal/hippocampal sclerosis *together with* cortical dysplasia or a cortical neoplasm) is not infrequently encountered.[146]

Neoplasms

Both primary and secondary (metastatic) neoplasms of the central nervous system (CNS) are characterized by their distinctive histologic appearance, location(s), and immunohistochemical phenotype. Preoperative neuroimaging studies, including magnetic resonance spectroscopy (to look for levels of *N*-acetylaspartate, choline, and creatine, as well as choline:creatine ratios) may be helpful in predicting how aggressive a neoplasm is likely to be.[57] The predicted biologic behavior of *primary* brain tumors is reflected in how they are categorized according to the World Health Organization (WHO) classification system.[90,91] When astrocytic tumors are considered as a major subset of all infiltrating glial neoplasms (*gliomas*), their degree of malignancy is readily ascertained by examining distinctive histologic features present in the tumorâ€"characteristics that can quite accurately be evaluated in a simple hematoxylin-eosinâ€"stained tissue section.[46] Unfortunately, these grading parameters appear to be less useful in evaluating CNS tumors in the pediatric age group.[66] However, the neuropathologic diagnosis and study of brain neoplasms is now being rapidly refined using tools of immunohistochemistry and molecular genetics.[112] These methodologies will almost certainly supersede evaluation of the subjective or semi-objective histologic criteria upon which tumor diagnosis is now based, in terms of their predictive value. Immunohistochemical techniques can detect evidence of tumor differentiation along astrocytic and/or neuronal lines, or (in the case of a metastasis) suggest a site of origin of the neoplasm, even when this is not apparent on initial workup of a given patient. Assessment of the â€œproliferative potentialâ€ of tumor cells can now be undertaken by using one or more several straightforward immunohistochemical markers (e.g., anti-Ki-67), many of them effectively used in paraffin sections,[133,134] thereby allowing for meaningful studies on archival material. Without question, modifications of the histopathologic approach to classify CNS neoplasms have also resulted from recent molecular-genetic studies. Further advances in the â€œmolecular pathologyâ€ of CNS neoplasia are likely to revolutionize how we categorize and treat gliomas, which remain highly refractory to even the â€œbestâ€ medical therapy. Association between allelic losses and sensitivity to polychemotherapy in oligodendrogliomas[58,63,81,171] or epigenetic regulation of D-6-methylguanine-DNA methyltransferase (MGMT) with better responsiveness to temozolomide are hallmarks of this progress.[74] Even tumors that we have in the past â€œlumped togetherâ€ (e.g., using the term *glioblastoma*) are now known to have distinctive molecular signatures (defined by patterns of expression of epidermal growth factor receptor [EGFR] components and PTEN) that predict how these neoplasms are likely to respond to EGFR kinase inhibitors.[114] Highly individualized therapy for primary brain tumors is likely to result from such advances. Further analysis of the complex molecular genetic interface between familial brain tumor syndromes (e.g., neurofibromatosis) and neurocutaneous disorders/phakomatoses is rapidly evolving.[95,102,103,112]

The study of neoplasms associated with epilepsy, which in general tend to behave in an anomalous (and usually fairly benign) fashion, by means of these new cellular and molecular tools will be of particular interest. However, it is important to remember that *any* intra-axial neoplasm, in particular one with a cortical (especially hippocampal) component (Fig. 1), can cause seizures, as can any extra-axial tumor that significantly compresses, displaces, or invades the cerebral hemispheres. In one large series of almost 500 patients with brain metastases, seizures were noted at the time of presentation or at some point during the course of the illness in over 25% of individuals. Seizure likelihood was highest with melanoma (occurring in two thirds of affected individuals), while tumors that had spread to the CNS from lung, breast, or an unknown primary were also a common cause of seizures.[55] Seizures have been estimated to occur in 80% of low-grade (2 out of 4) glioma patients, in almost one third of those with high-grade glioma, 20% of those who harbor a meningioma, and one tenth of patients with primary CNS lymphoma.[77] The pathophysiology of tumor-related seizures is multifactorial and extremely complex (for an excellent topical review, see reference 148). Important factors that contribute to tumor-related seizures may include a relative loss of inhibitory synapses or inhibitory interneurons in tumor-adjacent tissue, subtle pH alterations (peritumoral pH is slightly alkaline), ion level changes (e.g., decreased extracellular Mg^{2+}), amino acid fluctuations (e.g., affecting alanine, phosphoethanolamine, and glutamine), enzymatic derangements and increased excitatory activity in peritumoral tissue secondary to abnormal glutamatergic transmission associated with altered receptor subunit expression, and abnormal intercellular communication resulting from derangements in gap junction proteins (e.g., connexins CX43 on astrocytes, CX32 on oligodendroglia, and CX26 and CX32 on neurons).

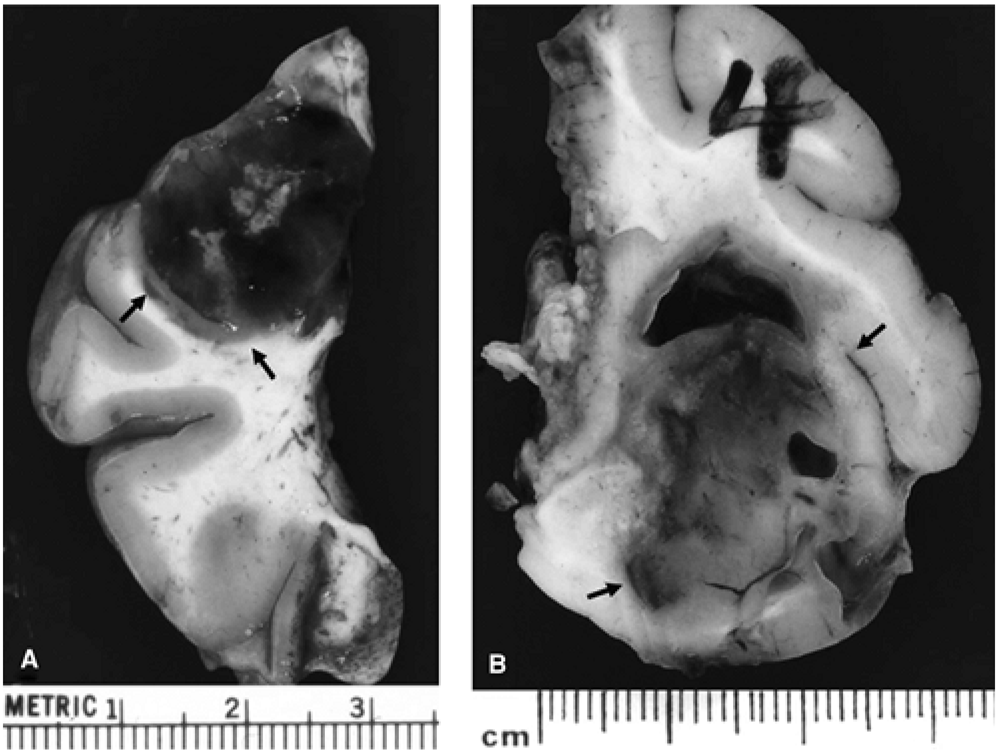

FIGURE 1. Tumors associated with intractable epilepsy, resected from two different patients. Note clear demarcation of the tumors from surrounding brain (indicated by *arrows*). Tumor shown in panel **A** is significantly hemorrhagic, whereas neoplasm in panel **B** is relatively homogeneous with focal cavitation. Both tumors clearly involve the cortex. (See the color insert.)

Table 1 Brain Tumors Associated with Epilepsy

Consecutive series of 722 tumor specimens obtained from the German neuropathologic data bank for epilepsy surgery

Tumor Entity	WHO grade	Number (%)	Age (yr)	Duration (yr)
Ganglioglioma	I	423 (58)	25	13.6
DNET	I	129 (17)	26.9	12.9
Astrocytoma, pilocytic	I	37 (5)	27.2	17.2

Astrocytoma, isomorphic variant*	I	13 (2)	29.4	17.8
Astrocytoma, pleomorphic and xanthochromic	II	22 (3)	30.7	17.0
Astrocytoma, fibrillary	II	40 (6)	33.5	8.6
Oligodendroglioma	II	36 (5)	36.6	11.1
Astrocytoma, anaplastic	III	22 (3)	40.1	3.2

DNET, dysembryoplastic neuroepithelial tumor; WHO, World Health Organization.
Consecutive series of 722 tumor specimens obtained from the German neuropathologic data bank for epilepsy surgery (www.epilepsie-register.de).
* A new epilepsy-associated isomorphic variant of diffuse astrocytomas was recently described.[101]
Number of patients encountered in our series (% of total, n = 722). Age at operation, duration of epilepsy. Note that 82% of all patients were under age 30 and had a seizure history of more than 13 years at the time of operation.

The proportion of tumors seen among resected specimens from epileptic patients varies tremendously among epilepsy surgery centers, depending obviously on the interests and expertise of local clinicians as well as referral patterns to a given institution. In large series describing the neuropathologic features of temporal lobe resections carried out for pharmacoresistent seizures, neoplasms account for 25% to more than 50% of the resultant specimens.[104,105,131,179,180,181] Some tumors (see below) may coexist with foci of cortical disorganization or dysplasia. In patients with pharmacoresistent TLE, dual and even multiple lesions may be encountered (e.g., hippocampal sclerosis together with malformations of cortical development and/or low-grade neoplasms).[56] The range of tumors encountered in patients with TLE is variable and includes the full spectrum of primary brain tumors, although gangliogliomas, pilocytic astrocytomas, and dysembryoplastic neuroepithelial tumors (WHO grade I tumors) are unusually common.[179,180,181] Extratemporal resections for intractable epilepsy also often yield neoplasms, usually of low histologic grade and having histopathologic features comparable to those encountered in

the temporal lobes. All studiesâ€"in both adults and childrenâ€"emphasize the remarkably high likelihood of patients being seizure free (i.e., an Engel class I outcome) after tumor resection, even when only a â€œlesionectomyâ€ is performed.[31,67] The Bonn group, with one of the world's largest experiences of epilepsy-associated neoplasia, has emphasized that biologically aggressive infiltrating glial tumors or tumors with a ganglion cell component (astrocytoma or ganglioglioma WHO grade III) are distinctly unusual among tumor resections performed for intractable seizure disorders.[104] The biologic behavior and appearance of some of the specific tumor types commonly encountered are worth reviewing in greater detail (see Table 1).

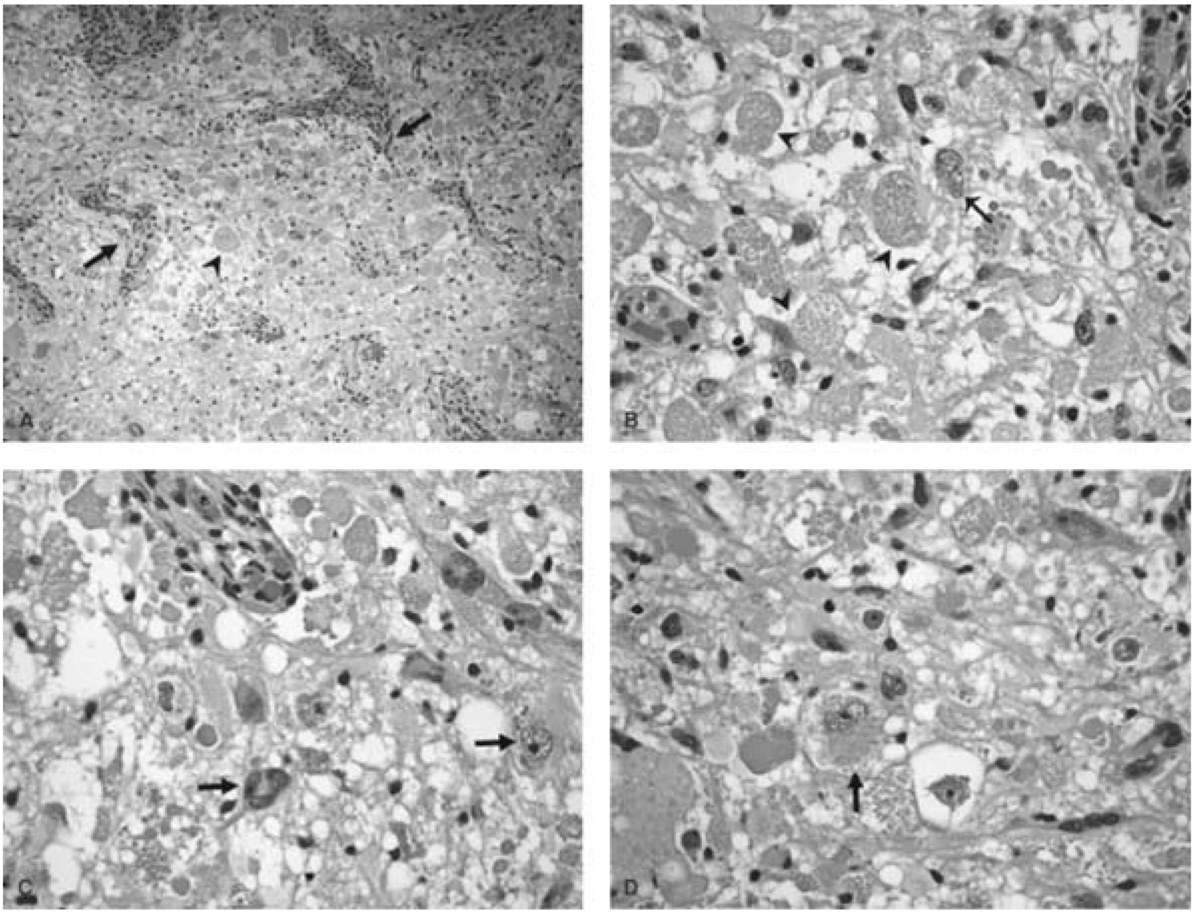

FIGURE 2. Ganglioglioma. **A.** Prominent vascularity in the tumor, with scattered perivascular lymphocytes (*arrows*). *Arrowhead* indicates a granular eosinophilic (cytoid) body; several of these are shown at higher magnification in panel **B.** *Arrow* in panel B shows a lobulated, dysmorphic nucleus. **C.** Several lobulated and bizarre nuclei are seen, though at least one cell (at right) retains neuronal features, including nucleolated nucleus and basophilic cytoplasm. **D.** Several dysmorphic neurons (e.g., highlighted by *arrow*). (All sections stained with hematoxylin & eosin.) (See the color insert.)

Ganglioglioma

This tumor has been recognized as a distinct entity at least since the 1930s.[112] Several excellent clinicopathologic reviews of experience with this entity have been published in recent years, including detailed immunohistochemical and mutational analyses that link them to malformative lesions (cortical

P.108

dysplasia, tubers of tuberous sclerosis).[22,25,106,136,152,155,183] Most commonly, epileptic seizures are the initial clinical manifestation of gangliogliomas (GGs), with focal neurologic deficits the presenting feature in fewer than 10% of cases. Patients may be symptomatic for long time periods (sometimes 10 to 20 years or more) before they come to surgical attention. Most often found in a supratentorial location, GGs are frequently encountered in the temporal lobes, and sometimes even in unusual loci such as the optic chiasm.[100] Their histopathologic features and clinical behavior both suggest that these neoplasms are very slow growing (the vast majority are WHO grade I), and they seem to be most effectively treated by complete or radical surgical excision. When these tumors are resected in patients with intractable epilepsy, there is almost always a marked improvement in the seizure disorder, or at least a diminution in seizure frequency and severity; often, the surgery is curative.[22,136,152,155,183] The UCLA group has estimated that progression-free survivals after gross total resection of both low- and high-grade GGs was almost identical, 78% and 75%, respectively, while these rates were 63% and 25% after *subtotal* resection.[152]

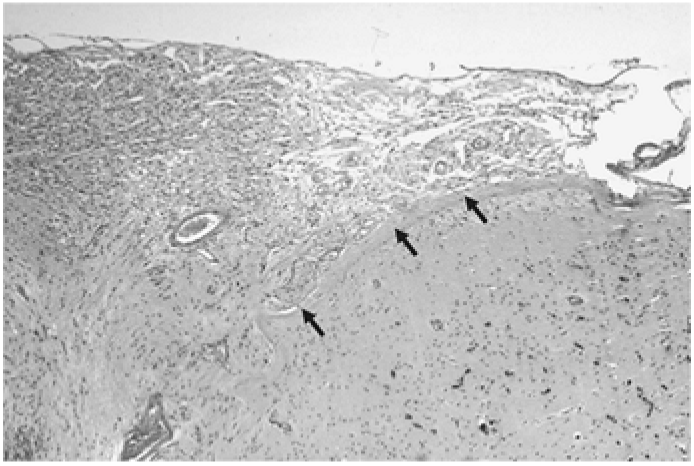

FIGURE 3. Gangliogliomas often extend into the subarachnoid space, even when they otherwise lack malignant (high-grade) features. *Arrows* indicate pial margin; large excrescence of tumor is seen at upper left. (Hematoxylin & eosin stain.) (See the color insert.)

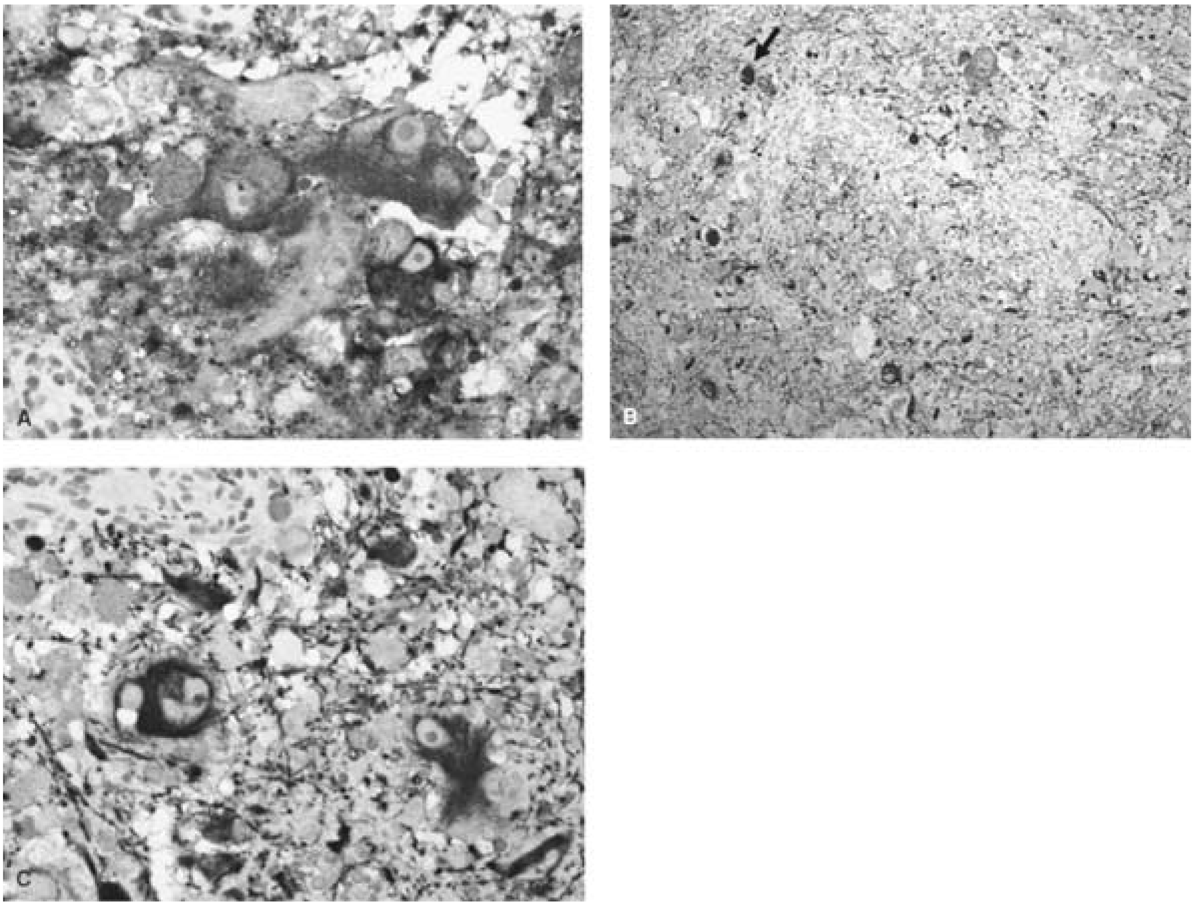

FIGURE 4. Immunohistochemical features of ganglioglioma. Panel **A** shows a section immunostained with antisynaptophysin, whereas panels **B** and **C** show sections immunostained with primary antibodies to neurofilament. All antibodies â€œdecorateâ€ atypical and dysmorphic neurons; antineurofilament also highlights neuronal processes throughout the field. (See the color insert.)

GGs are characterized by an admixture of neoplastic glial elements and atypical and disorganized neuronal (ganglion) cells (Figs. 2 and 3), sometimes including binucleate or multinucleate forms and ganglion cells with dysmorphic nuclei. (A rare variant of this tumor is composed exclusively of atypical neurons, and thus more appropriately described as a gangliocytoma.) Gliosis and calcification are common in and around the neoplasm, as are cytoid bodies.[112] The greatest challenge to the surgical neuropathologist is to distinguish ganglioglioma from an infiltrating glial neoplasm that extends into normal cortex; in the latter situation, neurons retain their distinctly characteristic cytologic and nuclear features. (This differential diagnosis may be extremely problematic, even impossible, at the time of frozen section/intraoperative consultation.) Most GGs are WHO grade I or II, the difference between these two grades being highly subjective, though such tumors are characterized by a relatively uniform glial component and the absence of mitoses. The glial element within the tumor may include elongated bipolar cells, typical gemistocytes, and sometimes even foci resembling oligodendroglioma. With increasing cytologic atypia and mitotic activity (usually in the glial component), the tumor grade increases to III; rarely, an otherwise typical glioblastoma (WHO grade IV) has a significant neuronal component and is thus presumed to have originated from a GG. Regions of cortex adjacent to a GG may show clear evidence

of cortical dysplasia,[40,117] and these tumors frequently extend into the subarachnoid space (Fig. 3).

Immunohistochemistry with antibodies to CD34 and MAP2 may further help to distinguish between dysplastic/neoplastic ganglion cells and entrapped normal neurons.[21,22,24,112,136] As expected, the glial element within a GG is usually glial fibrillary acidic protein (GFAP) immunoreactive (though only rarely is this immunoreactivity uniform throughout the neoplasm), while the ganglionic/neuronal component is immunoreactive with antibodies to neurofilament and synaptic proteins, especially synaptophysin (Fig. 4).[112] Synaptophysin immuno-stains often show a pattern of punctate immunoreactivity along ganglion cell membranes. Given the appearances of GGs, it is tempting to speculate that atypical neuronal cells within the tumors are â€œgeneratingâ€ epileptic seizure activity; however, the authors are aware of no good electrophysiologic evidence for this. There is a relative paucity of molecular genetic data on these tumors, though they frequently show polymorphisms (but not mutations) of the genes associated with tuberous sclerosis complex (*TSC1* and *TSC2*). Ultrastructural examination of GGs, which is seldom necessary to confirm the diagnosis, shows cytoplasmic dense core vesicles (usually 125 to 180 nm in diameter) and occasional synapselike contacts between cells, the latter probably an explanation for the distinctive membranous punctate synaptophysin immunoreactivity that is a â€œsignatureâ€ of GG, though also seen in other CNS lesions, including cortical dysplasia and the cortical tubers of tuberous sclerosis. Recent immunocytochemical and immunoblot investigations have found prominent neuronal expression of multidrug transporter proteins, including multidrug resistanceâ€“associated protein 1 (MRP1) and P-glycoprotein, in both gangliogliomas and cortical dysplasia. Major vault protein (MVP), which may also play a role in multidrug resistance, was found to be prominently expressed in GG.[7,9] One obvious implication of such studies is that overexpression of molecules related to multidrug resistance may contribute to

the intractability of tumor-related seizures. GGs and dysembryoplastic neuroepithelial tumors (see below) also contain a significant complement of microgliaâ€”their density correlating with duration of a given epilepsy as well as with seizure frequency prior to tumor resectionâ€”suggesting a functional relationship to the seizure-causing lesion, though of unclear causal significance.[8] Expression of survivin, an antiapoptotic protein, has been detected in the astrocytic component of GGsâ€”expression in more than 5% of cells being associated with more aggressive tumor behavior.[143] Reelin pathway components *disabled-1* and *p35* have been examined using molecular techniques in GGs and were found to contain no mutations, although the relevant gene transcripts were seen in lower levels in GGs than controls.[83] Immunolaser microdissection together with in situ reverse transcription and real-time polymerase chain reaction (RT-PCR) methodology has been used to study neuronal elements within GGs. The rather straightforward conclusion reached (that GGs contain neuronal elements with compromised or atypical differentiation) is perhaps less important than the compelling evidence that such technology can be used to study epilepsy-associated tumors and malformative lesions in exquisite molecular detail.[62]

GGs are relatively uncommon tumors in children, in whom they are also most frequently encountered in a supratentorial location, usually in the temporal lobes.[67] A variant of GG with associated dense desmoplasia, appropriately termed *desmoplastic ganglioglioma (DIG)*, has been described in infants and children.[35,125] Rarely, as with almost any other neoplasm that usually behaves in an indolent fashion, an otherwise typical example of GG shows malignant â€œdegeneration,â€ with the neoplastic transformation affecting both the glial and neuronal components or the glial component alone.[2,22,112] On rare occasions, GG may evolve into glioblastoma.[89] However, the vast majority of GGs are benign, with only a 3% recurrence rate, 2% malignant progression, and 1% death according to one series of 184 patients with a median follow-up period of 8 years.[105]

Dysembryoplastic Neuroepithelial Tumors

This category of neoplasm, identified and defined <20 years ago,[44,45,112] shows extremely indolent behavior and a very strong association with epilepsy. Dysembryoplastic neuroepithelial tumors (DNETs) almost always occur in association with partial seizures that start before the age of 20 years, often with no associated neurologic deficit or evidence for a neurocutaneous disorder/phakomatosis. Neoplasms that would now probably be classified as DNETs were described by other names in earlier reports.[112] Even though represented disproportionately in epilepsy surgery centers, they constitute just over 1% of CNS neuroepithelial tumors in those under 20 years of age, and only about 0.2% of such lesions in older patients. Large series show a slightly higher incidence of DNETs in men than in women. On gross inspection, DNETs give the appearance of â€œmucoid nodules situated within an expanded cortical ribbon.â€[112] Histologically, the tumors are characterized by (a) cortical location (most often in the temporal lobes, though DNETs have been reported in virtually all regions of the central neuraxis); (b) multinodular architecture, the nodules showing astrocytic, oligoastrocytic, or pure oligodendroglial differentiation with admixed normal-appearing neurons and astrocytes (Fig. 5); (c) foci of (nearby) cortical disorganization/dysplasia; (d) a glioneuronal element showing a columnar or alveolar structure perpendicular to the cortical surface; and (e) a characteristic appearance of neurons that appear to be floating or suspended within the myxoid matrix of the tumor.

â€œSimpleâ€ and â€œcomplexâ€ forms of the tumor have been defined, the latter characterized by zones almost identical to pilocytic or fibrillary astrocytoma or oligoastrocytoma. DNETs may show nuclear atypia (among the glial element) and infrequent mitoses, although of interest is the finding in some laboratories that markers of cell proliferation can label a high proportion of cells in some regions of the tumor, a surprising observation in view of the widely held view that these mass lesions may be more akin to malformations/hamartomas than true neoplasms. They are almost always considered to be WHO grade I tumors. DNETs have slow growth, as reflected in low labeling indices for the proliferating cell marker MIB-1 (Ki-67). Neuronal cells within DNETs have been shown to be immunolabeled with antibodies to a developmentally regulated embryonal form of the neural cell adhesion molecule (E-NCAM).[179] Not surprisingly, DNETs can also be immunolabeled with GFAP and a variety of neuronal markers, including *Î²*-tubulin, microtubule-associated protein-2 (MAP-2), phosphorylated and nonphosphorylated neurofilament, NeuN neuronal nuclear protein, synaptophysin, and myelin oligodendrocyte glycoprotein, among others.[72,112] There is an excellent chance of complete freedom from seizures with total removal of a DNET.[36,44,45,112,122] Just as with GGs (see above), the â€œepileptogenicityâ€ of DNETs may result from foci of cortical dysplasia *adjacent to* the neoplasm, rather than the tumor itselfâ€"which has obvious implications for its definitive surgical treatment, ascertainment of â€œtumor-freeâ€ resection margins, etc.[145,161]

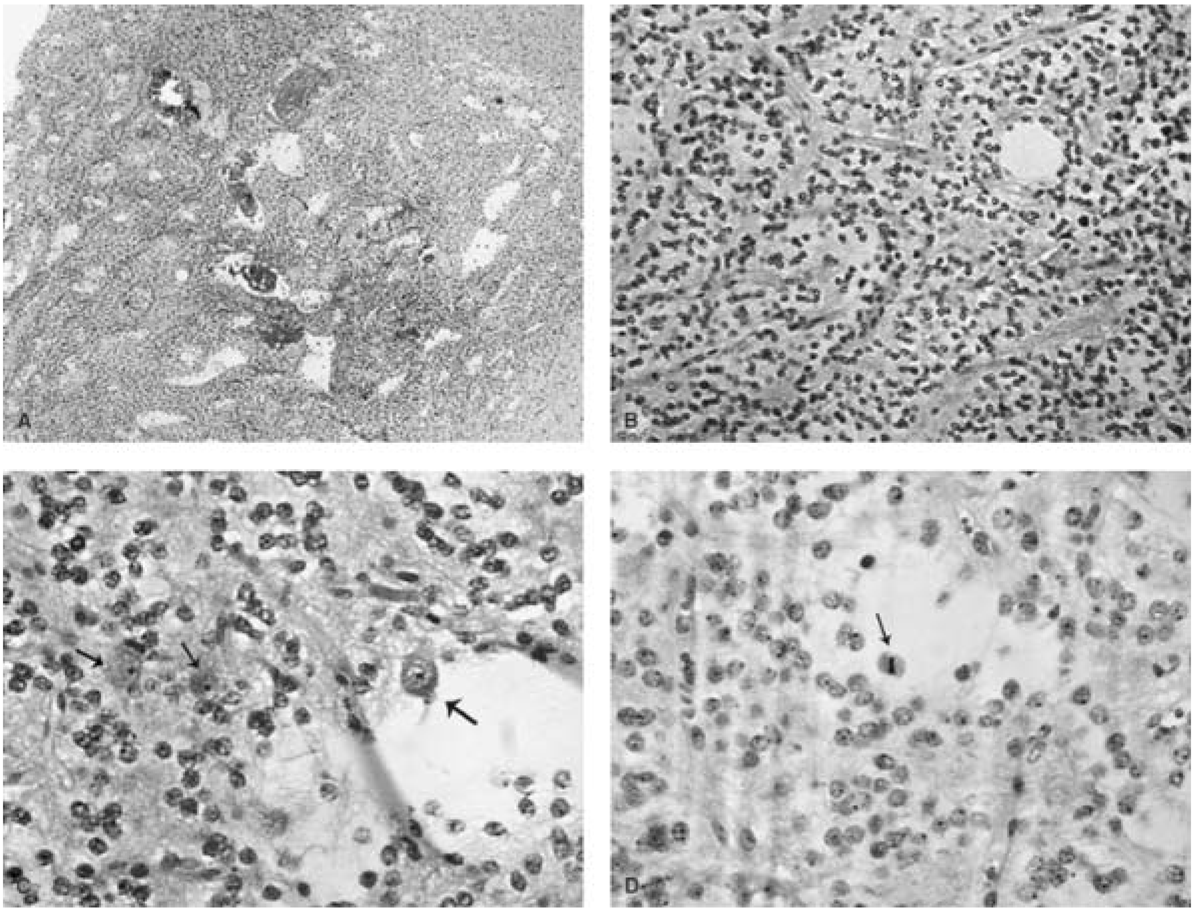

FIGURE 5. Dysembryoplastic neuroepithelial tumor. **A,B.** Representative fields in the tumor show sheets of relatively uniform round, oligodendroglia-like cells with compact nuclei and microcystic spaces. Panel **C** shows cells with distinctly neuronal phenotype (*arrows*). Neuron at right of this panel appears to be â€œsuspendedâ€ in a vaguely mucoid matrix. Panel **D** shows a mitotic figure (*arrow*), an unusual feature in this neoplasm. (All sections stained with hematoxylin & eosin.) (See the color insert.)

Pleomorphic Xanthoastrocytoma

Pleomorphic xanthoastrocytoma (PXA), initially defined and characterized by Kepes in the early 1970s,[86,87] usually appears as a superficially growing lesion with a meningeal component in young people (*meningocortical* PXA); presentation is usually before the age of 30 years, although as with most tumors, â€œoutlierâ€ examples have been encountered in older patients. PXA occurs with equal frequency in male and female patients.[47,112] Ten of 47 patients documented in a review of the literature[119] died at a mean of 7.5 years after diagnosis. A longstanding (mean, 4 years; range, 3 months to 16 years) history of seizures is found in almost 80% of affected patients.[80] Almost one third of tumors recur following initial resection, but a 70% 10-year survival rate compares favorably with that of glioblastoma. The tumor may arise from subpial astrocytes and shows novel histopathologic features (Fig. 6): A prominent xanthomatous or foam cell component, bizarre nuclear atypia and pleomorphism with a relative paucity of mitotic figures and regions of necrosis, and frequent mononuclear inflammatory infiltrates. Some who describe this neoplasm comment on its biphasic appearance, one â€œphaseâ€ including compact spindle-shaped cells in a fascicular pattern, the other composed of large eosinophilic astrocyte-like cells (sometimes multinucleated) containing foamy cytoplasm.[112]

Special stains and immunohistochemistry demonstrate that many of the cells in a PXA are immunoreactive with anti-GFAP (Fig. 7) antibodies and have a rich reticulin network among nests of tumor cells or surrounding individual tumor cells. In addition, almost 75% of tumor specimens can be labeled with antibodies against the CD34 epitope.[140] A difficult differential diagnosis may be between gigantocellular glioblastoma and PXA; immunohistochemical approaches to making this distinction have been suggested (e.g., using antibodies to different neuronal antigens).[109] A rare â€œpigmentedâ€ variant of PXA has been described.[153] Although PXA is graded as WHO II, it is recognized that anaplastic transformation may occur if there are more than five mitoses per ten high-power fields found on microscopic examinationâ€"these tumors are sometimes described as â€œ*pleomorphic* xanthoastrocytoma with *anaplastic* featuresâ€ (which seems oddly redundant) and designated WHO grade III[112]

Novel, Rare and â€œEmergingâ€ Tumor Entities

An isomorphic variant of diffuse astrocytomas has been identified from a series of 207 long-term epilepsy-associated tumors (LEATs).[23,150] These tumors can occur in different lobes, including a temporal location; diffusely infiltrate the neocortex; and express GFAP. In contrast to ordinary astrocytomas, neither MAP2 nor p53 are expressed within them and the proliferative activity is very low (Ki-67 labeling index usually <1%). By use of Kaplan-Meier curves, this isomorphic subtype had 50% fewer recurrences at 7.5 years and an estimated long-term survival of 80%. Temporal location did not influence the outcome, and the presence of epilepsy per se in affected patients was also not a prognostic factor.

A novel epilepsy-related clinicopathologic entity was recently designated as angiocentric neuroepithelial tumor (ANET).[98,174] Neuropathologic hallmarks of ANETs include an angiocentric polarity with GFAP-positive fusiform and bipolar astrocytic cells arranged around blood vessels. There is also a neuronal component, which may be best visualized using immunohistochemical markers for synaptophysin, chromogranin, or neurofilament protein. An ependymal component may also be present (expressing epithelial membrane antigen [EMA] immunoreactivity) and most tumors show stalk-like extensions to the ventricle on MRI.

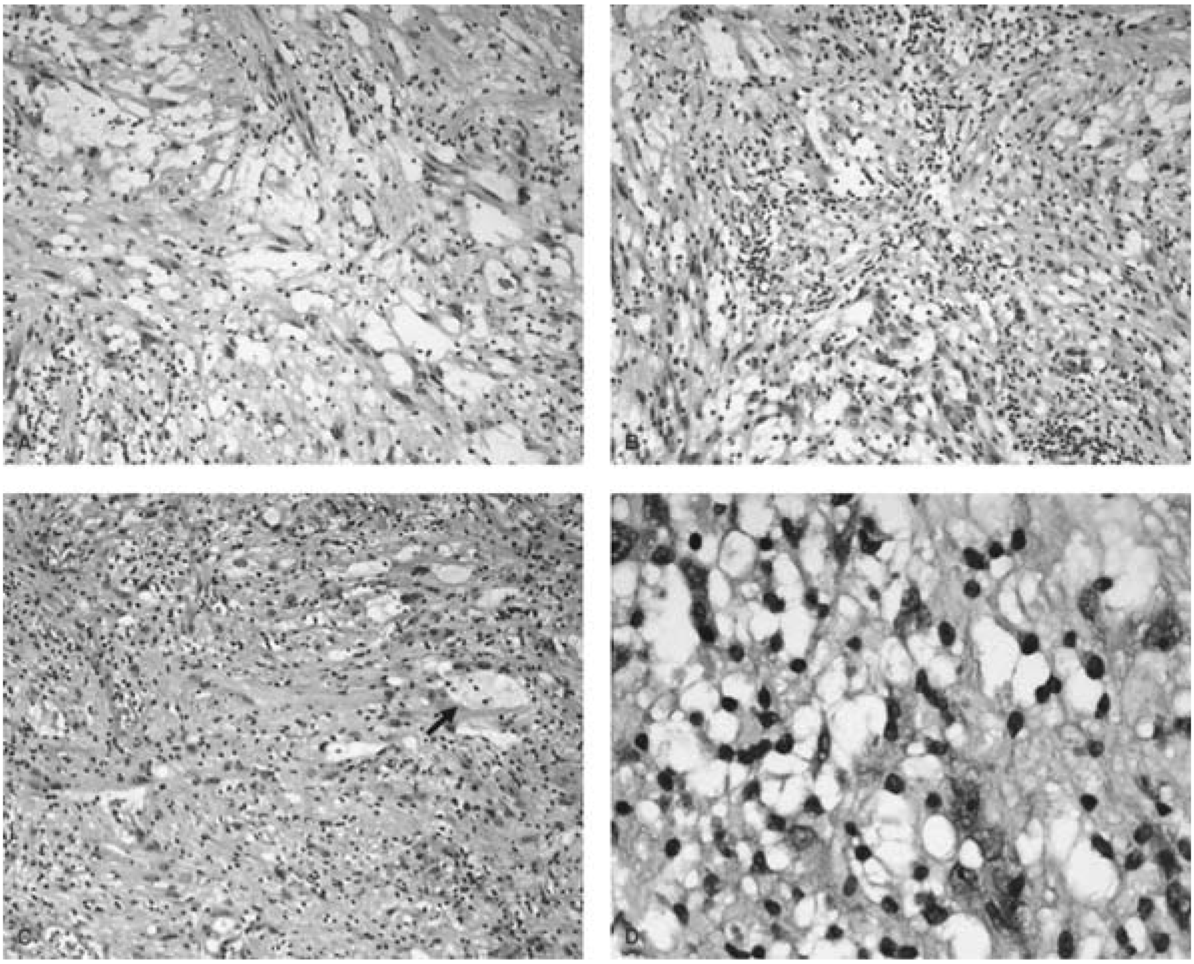

FIGURE 6. Pleomorphic xanthoastrocytoma. All panels (from hematoxylin & eosinâ€“stained sections) show a pleomorphic neoplasm composed of spindled or compact cytoplasmic elements. Panel **B** shows a sparse lymphoid infiltrate, a common finding in this tumor. Xanthomatous or foamy cells sometimes aggregate into small groups (*arrow* in panel **C**). Cells with foamy, clear, and multiloculated cytoplasm and pleomorphic nuclei are highlighted in panel **D**. Despite this, mitoses are relatively rare in this tumor. (See the color insert.)

In considering LEAT, ANET, and other â€œnewâ€ tumors, there has been an unfortunate and disorienting tendency to â€œre-reviewâ€ clinicopathologic material and to redefine tumor entities, including those associated with epilepsy.[32] For example, DNETs would in most instances have simply been described as astrocytomas, oligoastrocytomas (mixed gliomas), or gliomas before the â€œbirthâ€ of this new entityâ€”the nosology of which, however, is now widely accepted. This means that earlier series describing tumor-associated epilepsy or epilepsy-associated tumors need to be re-evaluated in light of the newly evolving tumor nomenclature, which perhaps has created some confusion and an implicit tendency to discount older studies of epilepsy-associated CNS neoplasms, but has led to a more realistic appreciation of the neurobiology of tumors that cause (or are often associated with) seizures.

Meningioangiomatosis (MA), a rare entity, deserves mention because of its strong association with intractable epilepsy and its unique nosologyâ€”understanding MA involves the combined study of neurogenetics and vascular, malformative, and neoplastic diseases of the CNS.[69] This lesion often occurs with

P.112

neurofibromatosis type 2 (NF2) and usually presents before the age of 20 years with headache and intractable seizures. Grossly, the lesions appear as plaque-like structures overlying the cortex, single in sporadic examples but often multiple when present in the context of NF2. Neuropathologic features in a resection specimen include disorganized and gliotic islands of neuroglial tissue surrounding thickened, sclerotic, and focally calcified blood vessels, which may in turn contain meningothelial elements in their wallsâ€"psammoma body-like structures may be present in the adjacent brain, which may also harbor an overlying meningioma (Fig. 8).

Brain Inflammation and Epilepsy

One of the most common â€œinflammatoryâ€ lesions encountered in corticectomies (including temporal lobectomies) for epilepsy is the chronic inflammatory reaction (often with a pronounced granulomatous component) that is left by depth electrodes implanted for preoperative monitoring purposes within the brain parenchyma. Leaving aside the obvious fact that any inflammatory disorder of the brain (especially viral encephalitides, e.g., caused by herpes simplex or West Nile virus infection) may be accompanied by seizure activity, evidence is emerging of an increasingly important role for brain inflammation in epilepsy (see Chapter 25). Steroids and adrenocorticotropic hormone (ACTH) have powerful anticonvulsant effects, especially in children with infantile spasms or West syndrome. Seizure activity is regularly associated with a cerebrospinal fluid (CSF) pleocytosis and elevated CSF proinflammatory cytokines. Though controversial, evidence is emerging that patients who develop temporal lobe epilepsy with hippocampal sclerosis (TLE-HS) following febrile convulsions may have been at risk for developing TLE-HS because of polymorphisms in the interleukin (IL)-1Î²-511T allele.[84] Studies of temporal lobes resected from patients with temporal lobe epilepsy have demonstrated overexpression of NFÎºB, a transcription factor involved in acute inflammation.[39] There is indirect evidence that new-onset refractory status epilepticus (NORSE) may have an inflammatory basis in that many patients have an antecedent

P.113

P.114

inflammatory/infectious illness and CSF usually shows a pleocytosis.[177] A subgroup of patients with encephalitis may go on to develop postencephalitic catastrophic epilepsy with progressive brain atrophy due to persistence of the inflammatory process.[11,169]

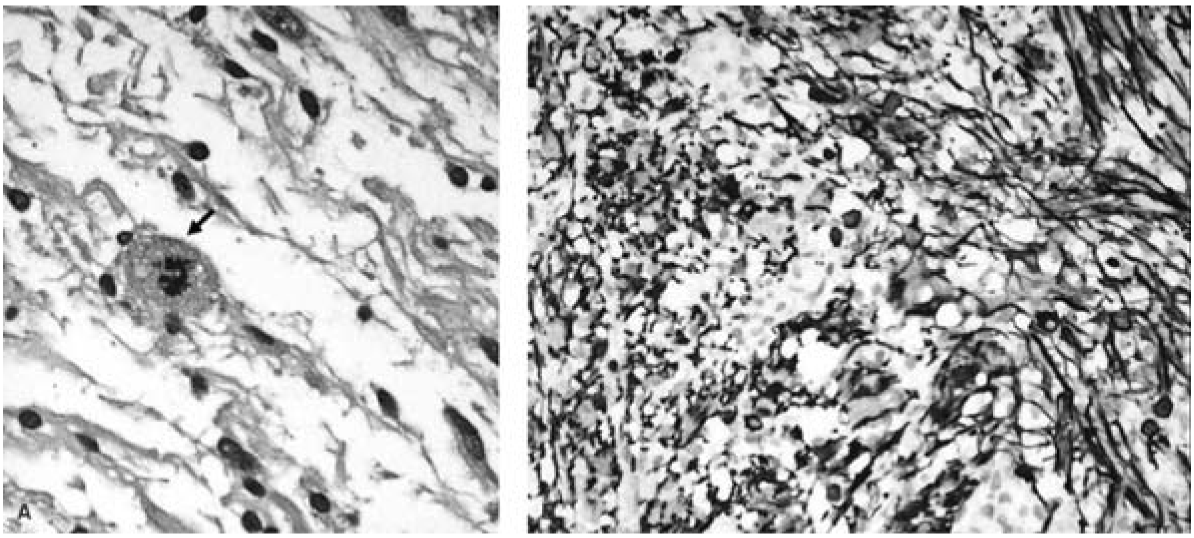

FIGURE 7. Pleomorphic xanthoastrocytoma (PXA). **A.** Atypical mitosis, a relatively rare finding in most PXAs (Hematoxylin & eosinâ€"stained section.) **B.** Glial fibrillary acidic proteinâ€"immunostained section shows prominent cytoplasmic immunoreactivity. (See the color insert.)

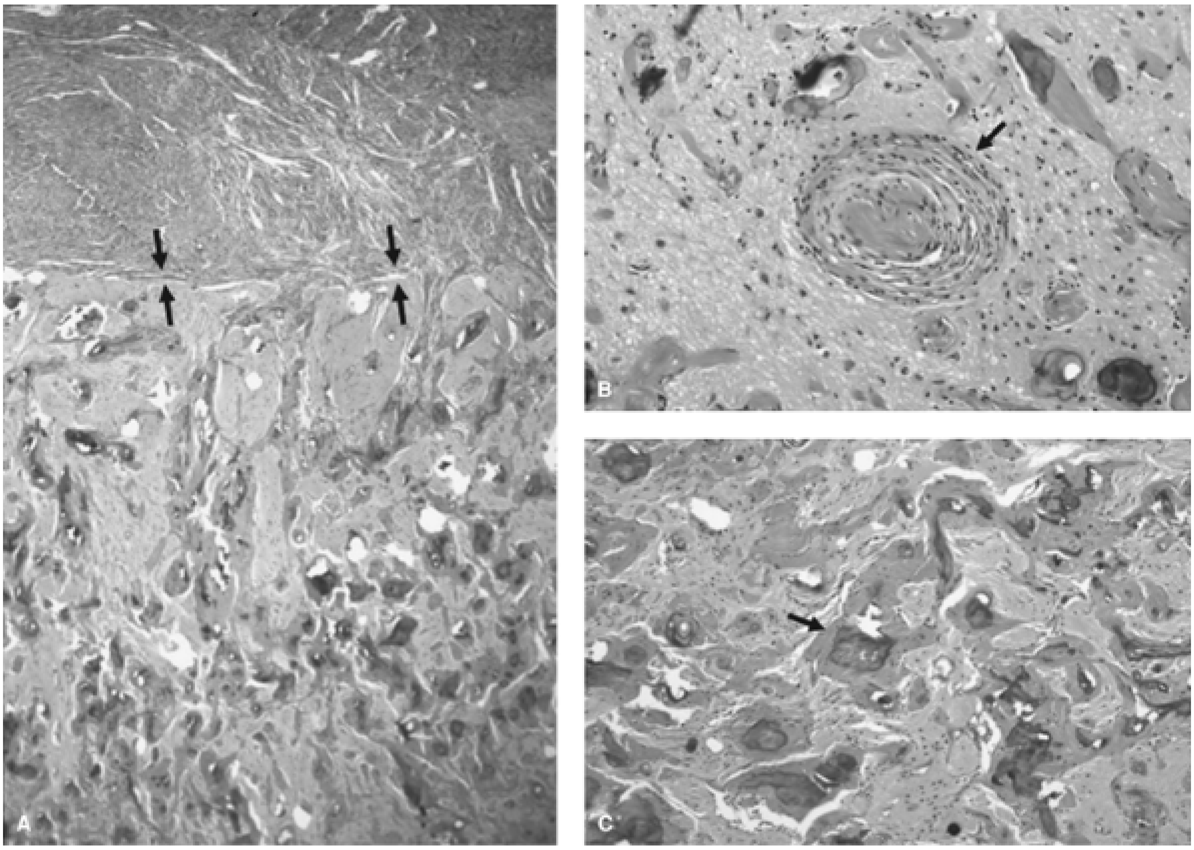

FIGURE 8. Meningioangiomatosis, with overlying meningioma. **A.** *Arrows* indicate the interface between brain parenchyma (lower portion of the image) and meningioma (above). The brain parenchyma shows thickened, focally calcified blood vessels surrounding islands of disorganized neuroglial tissue. Details of the parenchymal abnormality are seen in panel **C**; *arrow* (in C) highlights a region of dystrophic calcification. Panel **B** shows a thrombosed thickened artery (*arrow*) with prominent smooth muscle cell hyperplasia in its wall. (All sections stained with hematoxylin & eosin.) (See the color insert.)

Table 2 Rasmussen Syndrome: Diagnostic Criteria

Rasmussen encephalitis (RE) can be diagnosed if either all three criteria of Part A or two out of three criteria of Part B are present. Check first for the features of Part A, then, if these are not fulfilled, of Part B.

PART A:

1. Clinical focal seizures (with or without epilepsia partialis continua) and unilateral cortical deficit(s)
2. Electroencephalographic (EEG) unihemispheric slowing with or without epileptiform activity and unilateral seizure onset
3. Magnetic resonance imaging (MRI) unihemispheric focal cortical atrophy and at least one of the following:

a. Gray or white matter T2/fluid-attenuated inversion recovery (FLAIR) hyperintense signal
b. Hyperintense signal or atrophy of the ipsilateral caudate head

PART B:

1. Clinical epilepsia partialis continua or progressive* unilateral cortical deficit(s)
2. MRI progressive* unihemispheric focal cortical atrophy
3. Histopathology T-cell-dominated encephalitis with activated microglial cells (typically but not necessarily forming nodules) and reactive astrogliosis

Numerous parenchymal macrophages, B cells, or plasma cells or viral inclusion bodies exclude the diagnosis of RE.

---

* â€œProgressiveâ€ means that at least two sequential clinical examinations or MRI studies are required to meet the respective criteria. To indicate clinical progression, each of these examinations must document a neurologic deficit, and this must increase over time. To indicate progressive hemiatrophy, each MRI must show hemiatrophy, and this must increase over time (Reproduced with permission from Bien CG, Granata T, Antozzi C, et al. Pathogenesis, diagnosis and treatment of Rasmussen encephalitis: a European consensus statement. *Brain.* 2005;128:454-471.)

Rasmussen Syndrome

Rasmussen syndrome (RS; Rasmussen encephalitis [RE]), the classic form of epilepsy-associated chronic inflammatory disorder, is characterized by intractable focal seizures (usually epilepsia partialis continua [EPC]) with progressive hemiparesis, both attributed to chronic pathogen-free inflammation of gray and white matter, with progression to unihemispheric atrophy.[137,138,141] A recent European consensus meeting on RS has formulated diagnostic criteria, which incorporate clinical, electroencephalographic (EEG), MR, and pathologic findings[19] (see Table 2). The cause of RS remains a mystery. Although the pathologic appearances of affected brain tissue suggest a chronic viral infection, no such virus has ever been consistently isolated from RS brain tissue or discovered within it using modern molecular techniques (e.g., PCR).[59,173] Circulating anti-glu-R3 antibodies were reported to be of etiologic importance in some patients with RS,[5,142] but subsequently these antibodies were found to also occur in other seizure disorders.[107,176] Furthermore, it has never been possible to passively transfer RS to animals using glu-R3 antibodies. Very recently, autoantibodies against the NMDA glutamate receptor (NMDA-type GluR) Îµ2 subunit and its epitopes were reported in RS patients.[162] However, although the initial report is highly promising, the diagnostic specificity of GluRÎµ2 for RS remains to be confirmed. Any explanation for RS will ultimately have to account for the unihemispheric nature of the disorder. Rarely have pathologic studies demonstrated bihemispheric involvement.[168]

Neuropathologic Findings

The neuropathology of RS is said to comprise four merging stages,[19,20,129] the earliest of which is characterized by inflammation, especially perivascular lymphocytes, and microglial nodule formation within brain parenchyma, but little morphologic evidence of neuronal injury. In stage 2, lymphocytic infiltration increases in density and both astrocytes and microglial cells become more extensive in distribution, tending to involve all cortical layersâ€”a so-called â€œpanlaminarâ€ pattern of cortical inflammation and gliosis. Patchy neuronal loss may be present. In stage 3 the neuronal population is depleted either patchily or in a panlaminar pattern, with severe cortical degeneration and gliosis. In stage 4 there is profound cortical atrophy with gliosis and vacuolation of the neuropil, rising to the level of cavitation in many cases (Figs. 9 and 10). Frequently, areas of relative cortical normality surround zones of atrophic cortex. This geographically defined severe pathologic change, often seen a few micrometers away from relatively (or entirely!) normal brain parenchyma, means that a negative brain biopsy taken with the intent of establishing the diagnosis of RE never truly *excludes* the diagnosis, because of the risk of sampling an unaffected region in a cerebral hemisphere that actually harbors RS. Occasionally, dual pathology including malformative elements of cortical dysplasia or vascular malformations *and* chronic inflammation are seen in a corticectomy originating from an epilepsy patient, suggesting that the two lesions may be etiologically connected, though the precise *mechanism* of this linkage remains speculative.[73]

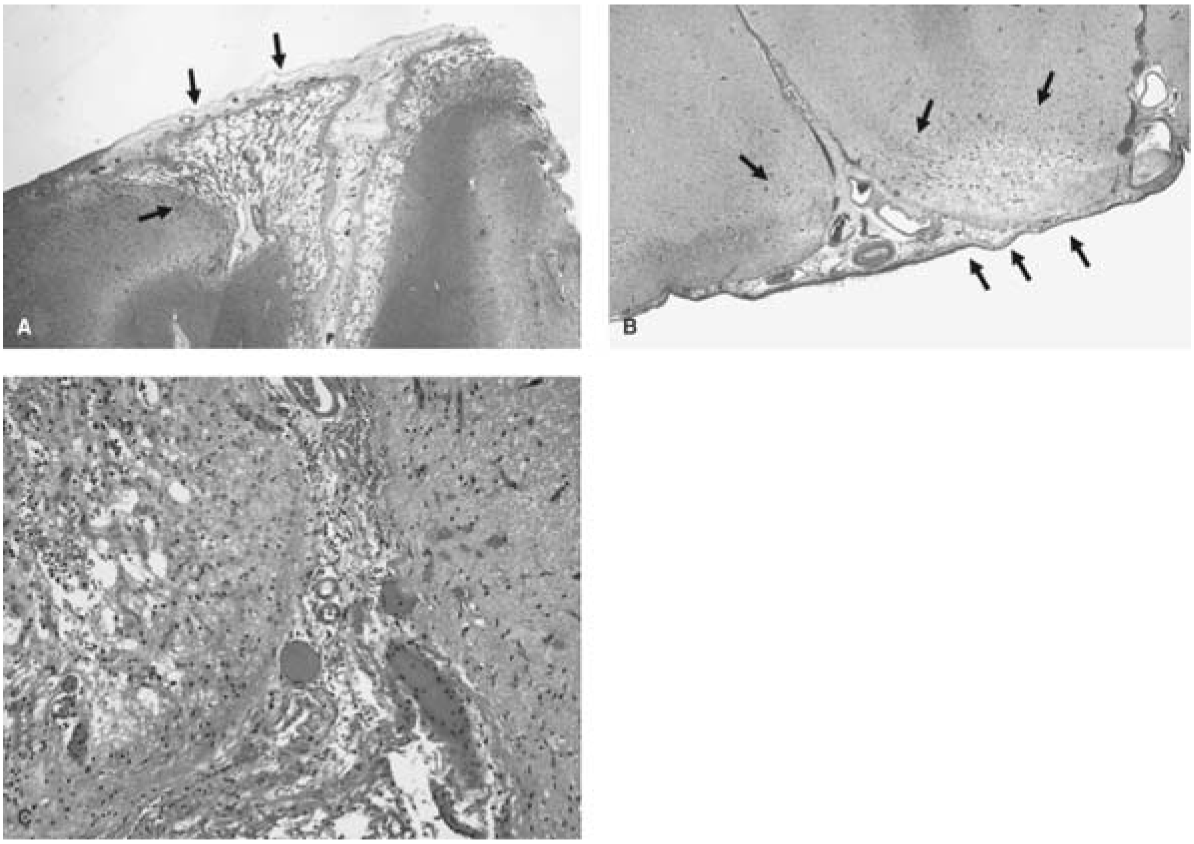

FIGURE 9. Rasmussen encephalitis (RE). Panel **A** shows extensive cortical cavitation, in one region affecting an entire gyrus (*arrows*). Panel **B** shows a more circumscribed region of cortical injury showing faint cystic cavitation, delineated by the *arrows*. Panel **C** shows detail of the region of microvacuolization, with intense astrocytic gliosis. (All panels are from sections stained with hematoxylin & eosin.) (See the color insert.)

There is little interlobar variation in severity of the disease, though usually the occipital cortex is less severely involved than

the others. Subcortical white matter may show evidence of axonal injury in the form of neuroaxonal spheroids, though whether this is secondary to Wallerian degeneration or represents a separate cytotoxic attack on axons is uncertain. Deep central gray matter may also be involved. Areas completely devoid of inflammation or neuronal loss may be located in close proximity to areas showing intense inflammation and cell loss. Furthermore, the inflammation/neuronal destruction varies in its *timing and progression* from area to area. Early changes consisting of inflammation only may be located adjacent to areas showing intense neuronal loss and gliosis. In this respect the regional variability in timing and intensity of inflammation is similar to other immune-mediated neurologic disorders of unknown etiology such as multiple sclerosis. However, the almost unique unilateral nature of RS separates it from all other immune-mediated disorders of the nervous system. Ultrastructural studies of RE/RS have failed to demonstrate viral particles consistently in brain biopsies/resections from affected patients, though rarely measles virus-like particles have been noted; rare cerebral endothelial cells in one case contained tubuloreticular inclusions of the type usually seen in skeletal muscle endothelium of patients with dermatomyositis.[130] Gene expression profiling of a brain specimen from an RE patient has shown a dramatic *increase* in expression of several genes related to inflammation, and a pronounced *down-regulation* of several GluRs, especially GluR4.[16]

Immunopathology/Immunopathogenesis

The lymphocytic infiltrate in RS brain consists predominantly of CD8-positive T cells.[18,61] The lymphocytes lie adjacent to major histocompatibility complex (MHC) class I(+)â€“expressing neurons and contain granzyme B, which has been suggested as the local mediator of T-cellâ€“mediated cytotoxic neuronal death in RS.[18] There is little evidence to support a humoral process in that B cells, immunoglobulin, and complement are rarely found in RS brain tissue. The T-cell infiltrate is of relatively restricted clonality,[99] but as with oligoclonal bands in MS, this does not provide much enlightenment on possible or likely immunogenic stimuli that evoked the response in the first place.

As indicated above, the patchy nature of the inflammatory infiltrate in RS raises the possibility that brain biopsy, even in patients with relatively well-established disease, might yield a spuriously negative result. Therefore, the recently formulated diagnostic criteria for RE,[19] which include clinical and neuroimaging considerations, are a welcome addition; adherence to these criteria may obviate the need for brain biopsy in future. However, the validity of the criteria awaits testing in prospective studies.

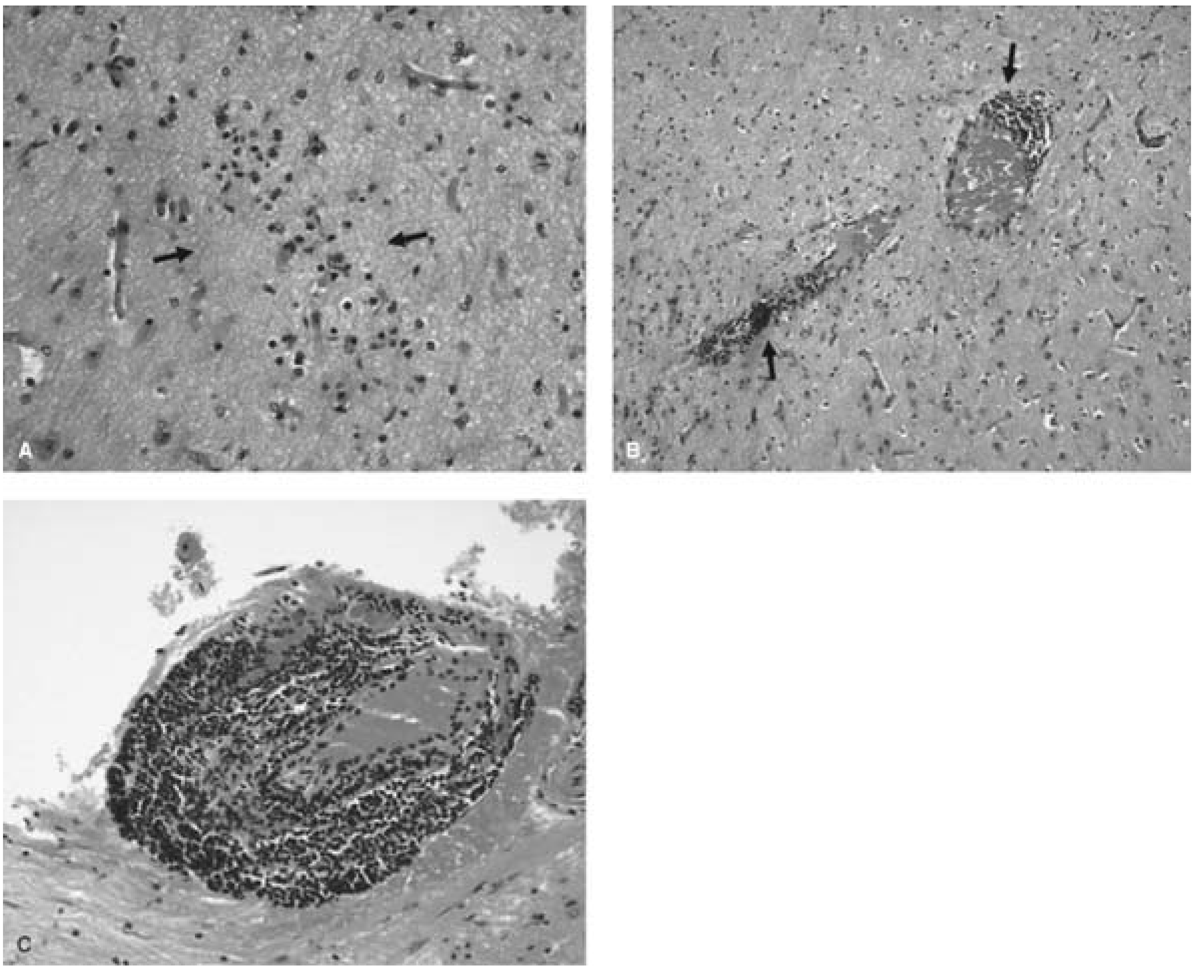

FIGURE 10. Rasmussen encephalitis/Rasmussen syndrome. **A.** *Arrows* indicate a poorly defined

inflammatory/microglial nodule. **B.** Prominent angiocentric chronic inflammation in a region of brain with slight rarefaction and gliosis. Notice patchy nature of the inflammatory infiltrate. **C.** A meningeal vein showing dense transmural lymphocytic infiltrate *without* evidence of injury of the vessel wall or thrombus. (All panels are from sections stained with hematoxylin & eosin.) (See the color insert.)

Treatment

Hemispherectomy remains the mainstay of RS treatment. Decisions to offer hemispherectomy are based on the patient's age; involvement of dominant hemisphere; severity of motor and speech deficits at the time of presentation; and the severity of seizures. The primary goal is to minimize seizure frequency and severity and, where possible, to preserve motor and language functions. In many cases this goal is not obtainable. Paradoxically, seizure activity may subside spontaneously in the later stages of the illness. A therapeutic algorithm is included in the

consensus report on RE/RS.[19] To date, trials of treatment have not taken place and most outcome reports are anecdotal. Individualized treatments carefully chosen on the basis of patient's age, neurologic deficit, seizure frequency, and phase of the illness will remain the basis for management in the immediate future. Carefully designed multicenter trials will almost certainly be essential to establish optimal therapeutic guidelines for this rare disorder.

It has been suggested that the unilaterality of RE may in part be due to a synergy between seizures and the underlying inflammatory process.[19] However, other brain lesions that give rise to intractable partial epilepsy generally do not show inflammatory changes similar to those seen in RE, so it is difficult to argue that the inflammatory changes are a secondary phenomenon, although we have seen rare cases in which cortical dysplasia is accompanied by focally prominent chronic inflammation, prompting consideration of â€œdual pathologyâ€ (malformative and inflammatory) in these individuals. Also, in our experience, some patients with fatal classic RS may be found at autopsy to have little or no evidence of an underlying inflammatory process, showing instead intense gliosis Â± atrophy, restricted to one cerebral hemisphere. These cases are particularly difficult to understand. While the inflammatory process may have burned itself out by the time of death, the possibility remains that these unusual cases represent another disease process.

Recent insights into possible mechanisms of virally triggered immune-mediated encephalitis may go some way toward explaining RE/RS. Neonatal mice eliminate lymphocytic choriomeningitis virus (LCMV) from all tissues except the brain, where the virus persists for several years. These viral-rich neurones remain in perfect harmony with virus-specific cytotoxic T cells. Later, following exposure in adulthood to wild-type LCMV (the precipitating virus), cytotoxic T cells are triggered to attack mouse brain, causing an encephalitis similar in many respects to that seen in adult humans with RE. Infiltrating T cells exhibit biased receptor usage highly suggestive of an antigen-specific process.[115]

Destructive Lesions

Destructive lesions, with the appearance of regions of cystic encephalomalacia, are commonly encountered in corticectomies for epilepsy, especially in infants and children.[60,172] They are presumed to represent sequelae of intrauterine, perinatal, or (rarely) postnatal brain infarcts and/or hemorrhages, the etiology of which is multifactorial, extremely complex, and beyond the scope of this chapter. For an excellent recent monograph on pathophysiologic mechanisms important in the evolution of destructive brain lesions that may cause seizures, see reference 69.

Summary and Conclusions

Neuropathology has made vital contributions to understanding morphologic substrates of seizure disorders. This has rarely, however, been done in isolationâ€"simple morphologic characterization of *epileptogenic* lesions has finite value. Rather, important advances have resulted from synergistic interactions between neuropathologists and their clinical colleagues, electrophysiologists, and (especially in recent years) neuroradiologists. The combined multidisciplinary approach to analysis of complex lesions is illuminating. Indeed, one of the great challenges going forward will be to closely compare neurohistologic findings in *epileptogenic tissue* with its appearances assessed using (preoperative) high-resolution and metabolic neuroimaging studies. Neurophysiologists will continue to provide important information on whether *structurally abnormal* tissue is also functioning in such a way as to produce abnormal discharges that may manifest as seizuresâ€"the *disconnect* between morphologic and functional abnormalities can often be striking and, paradoxically, informative. These correlations will be facilitated by new approaches to examining gene expression patterns in tissue, something that is now done almost routinely. High-throughput methodologies such as tissue microarray[118] will be useful for comparing signaling pathway regulation in vast numbers of (surgically resected) brain specimens. The novel properties of neoplasms that cause seizures (especially GGs and DNETs; see above) will be better understood through the same molecular genetic approaches that have yielded crucial dataâ€"ones that now greatly impact treatment strategiesâ€"on high-grade gliomas. Unlike the situation with high-grade gliomas, however, most tumors that cause seizures are cured by an operation. Rasmussen encephalitis remains, unfortunately, nearly as enigmatic as it was when first described almost 50 years ago. There is much work to be done!

Chapter 13

Hippocampal Sclerosis

Gary W. Mathern

Charles L. Wilson

Heinz Beck

Introduction

Hippocampal sclerosis is the most frequent pathologic finding in patients with temporal lobe epilepsy undergoing resective neurosurgery, and its association with epilepsy has been recognized since the early 1800s. This chapter will focus on the following: The first section reviews the important historical literature to introduce the pathology and highlight some of the clinical controversies that often first arose years ago that are still argued about today.[189] The middle section describes in vivo electrophysiologic findings associated with hippocampal sclerosis, with special emphasis on newly identified fast ripples that may be a surrogate marker of epileptogenesis. The final section highlights recent molecular studies that are beginning to identify possible epileptogenic mechanisms in hippocampal sclerosis related to changes in synaptic circuits, postsynaptic receptors, and intrinsic membrane properties. Because of the extensive literature, this chapter emphasizes findings mainly from human studies. Relevant studies related to animal models of temporal lobe epilepsy can be found in Chapters 36 and 40 and in other texts.[163]

Early History and Histopathologic Description of Hippocampal Sclerosis

The literature describing the clinicopathologic relationship between seizures and hippocampal pathology spans more than 150 years. Early studies were limited to autopsy material and concentrated on determining if individuals with seizures of any type showed cerebral and hippocampal pathology. It was not until autopsy studies in the 1930s and correlative surgical-pathology studies in the 1960s that the mesial temporal lobe epilepsy syndrome was linked to severe neuronal loss in a characteristic pattern, referred to in this chapter as *hippocampal sclerosis*. This clinicopathologic association has been complicated by a literature that uses numerous names for the hippocampal pathology found in individuals with epilepsy. Understanding the historical use of these terms in the context of the different clinicopathologic studies is perhaps the best way to comprehend what constitutes hippocampal sclerosis and the relationship of this pathologic substrate with temporal lobe epilepsy.

Early autopsy studies frequently observed hippocampal damage in patients with different types of epilepsy. At first, the term *sclerosis* referred to the gross macroscopic features of a hard shrunken hippocampus, first described by Bouchet and Cazauvielh in 1825,[31] and in other autopsy studies of that era of individuals with chronic epilepsy.[141,160] Probably the first microscopic description of hippocampal sclerosis was by Sommer in 1880,[178] and his case study illustrates several important clinicopathologic features of temporal lobe epilepsy that are still relevant today. The patient was a 25-year-old man with what were described as two to six â€œpetit malâ€ attacks each day, and several â€œcompleteâ€ seizures each week. As part of his epileptic syndrome, he had vivid hallucinations in which God told him he could fly, and once, as proof of his belief, he jumped from a roof. He survived the fall only to die some years later of a systemic infection. Sommer observed that the only cerebral pathology found at autopsy involved the hippocampus, and using a microscope he noted a unique pattern of neuron loss. Specifically, the pyramidal neurons of the Ammon horn were largely destroyed, especially in the portion of the hippocampus that Lorente de NÃ³[106] would later label as CA1 and prosubiculum. Neuron loss in CA1 is such a consistent finding in hippocampal sclerosis that this region is often referred to as the *Sommer sector* (see *SS* in Fig. 1B). Furthermore, Sommer described other hippocampal damage involving the granule cells and hilar neurons of the fascia dentate.

Sommer's other historical contribution, in addition to the earliest microscopic description, was his interpretation that there must be a pathologic relationship between hippocampal damage and clinical seizure symptoms. He reasoned that the hippocampus was probably the initial site for seizure generation involving a prodrome of abnormal sensory phenomena or illusions. This is probably the first time that hippocampal pathology was associated with clinical features of what would probably be recognized today as mesial temporal lobe epilepsy.

The other important historical figure of the 1800s was Bratz.[36] His contribution was a detailed histologic description of hippocampal sclerosis and the observation that not all seizure types were associated with hippocampal pathology. He reported pathologic findings in the brain from 50 autopsy specimens of patients with antemortem chronic seizures associated with various etiologies common in his day, such as syphilis and cysticercosis. Bratz found hippocampal sclerosis in 25 (50%) specimens. His 1899 microscopic observations were remarkably accurate, and neuropathologists today would use the same histopathologic criteria to define hippocampal sclerosis (Fig. 1). Bratz noted that there was severe pyramidal neuron loss and gliosis throughout the hippocampus, especially in the Sommer sector of the Ammon horn. In addition, he noted that subicular neurons were not as depleted and that a fairly sharp boundary separated the profound prosubiculum neuron loss from the relatively preserved subiculum (Fig. 1B, *dashed line*). Within the remainder of the hippocampus, there was a second area of severe damage involving neurons between the granule cell blades. This area, later termed the *end folium* by Margerison and Corsellis,[111] included the CA4 pyramids and hilar neurons as described by Lorente de NÃ³.[106] By comparison, fascia dentate granule cells were only partially destroyed. In contrast to the severe neuron loss in the Sommer sector and the end folium, pyramidal neurons in CA3 and, especially, CA2 seemed to be more â€œresistantâ€ to injury (therefore termed the *resistant sector*).

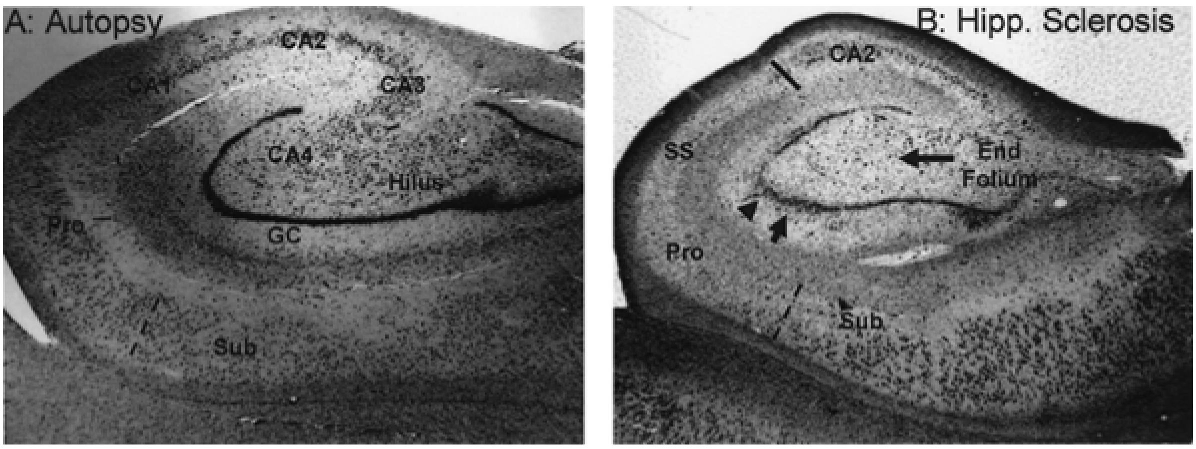

FIGURE 1. Examples of human hippocampus with Nissl staining, demonstrating normal appearance and hippocampal sclerosis. **A:** Normal autopsy. The hippocampal subfields are labeled using the nomenclature of Lorente de NÃ³ (1934) for fascia dentate granule cells (*GC*) and hilar neurons (*Hilus*). The four cornu ammonis subfields are labeled *CA1* to *CA4*, along with the prosubiculum (*Pro*) and subicular (*Sub*) neurons. The border between the prosubiculum and subiculum is identified by the *dashed line*. **B:** Hippocampal sclerosis. There is severe damage in the Sommer sector (*SS*; CA1 and prosubiculum; area between *solid* and *dashed lines*) and end folium (CA4 and hilus; *arrow*). The subiculum is spared and there is a relatively â€œresistantâ€ sector in CA2. Granule cells also show damage and dispersion (*arrowheads*).

Bratz's histopathologic description of hippocampal sclerosis is different from the hippocampal neuronal injury associated with other cerebral diseases. For example, neuron loss related to chronic liver disease or hypoxia-ischemia involves the entire hippocampus, including CA2, along with the subiculum and parahippocampal gyrus. Hence, neuron loss and gliosis by themselves are insufficient histopathologic criteria for the diagnosis of hippocampal sclerosis. This explains the confusion that has arisen from claims by some authors that hippocampal sclerosis can be found in conditions without seizures, such as Alzheimer disease.[1,84] Thus, the histopathologic diagnosis of *hippocampal sclerosis* should be restricted to specimens that display the microscopic pattern of selective neuron loss as originally described by Bratz.

Bratz also noted that the neuronal loss in hippocampal sclerosis appeared old and chronic. Because hippocampal sclerosis was found in only half of the autopsy specimens of patients with epilepsy, he reasoned that this pattern of damage was not the result of repeated seizures. Instead, he suggested that hippocampal sclerosis probably generated certain types of seizures, similar to the conclusion of Sommer.[178] Bratz's final contribution was his observation that many of the patients with hippocampal sclerosis had clinical histories involving early childhood convulsions. This finding would resurface about 60 years later in clinicopathologic studies of surgical patients with mesial temporal lobe epilepsy, and the nearly continuous debate since then about the pathogenesis of hippocampal sclerosis.

Clinicopathologic Studies of Patients with Temporal Lobe Epilepsy

The studies of the 1800s confirmed an association between seizures and hippocampal pathology, but the link between hippocampal sclerosis with psychomotor and complex partial temporal lobe seizures took several more decades to confirm. The clinical autopsy study of Stauder[187] was probably the first. He studied 53 patients with chronic epilepsy to determine whether hippocampal sclerosis was associated with those ictal symptoms and signs that he was convinced could only be attributed to temporal lobe seizures, such as olfactory and gustatory auras. Autopsy cases were separated into three clinical groups with definite, probable, or no ictal temporal lobe symptoms by clinical description. Of the 36 hippocampal sclerosis cases at autopsy, 33 (92%) had a history of definite or probable temporal lobe seizures. By contrast, of the 17 cases without sclerosis, only two (12%) showed only probable (not definite) temporal lobe seizure symptoms and 15 (88%) had none of his defined clinical signs. These results linked antemortem temporal lobe seizure symptoms with hippocampal sclerosis at autopsy.

In another famous autopsy study from the 1960s, Margerison and Corsellis[111] examined pathology results in 55 patients with epilepsy and found a clinicopathologic association between antemortem temporal lobe seizures using clinical and electroencephalogram (EEG) criteria and postmortem hippocampal sclerosis. This study is often cited in the literature, and the reader should be aware of this study's design, findings, and limitations. For example, their patient population is somewhat different than contemporary surgical case series of temporal lobe epilepsy patients. The patients resided in two long-term care hospitals in London because of severe mental and physical handicaps. Fifteen (27%) patients had chronic motor paralysis; in 17 (31%) the first habitual seizure was before the age of 1 year, and in 20 (36%) there were other cerebral cortical abnormalities such as congenital brain malformations, evidence of cerebral trauma, or old infections. Surgical patients with temporal lobe epilepsy typically have a lower incidence of paralysis and cerebral malformations, and the first habitual seizure usually begins around the age of 10 years.[114] Margerison and Corsellis found that most of their patients regularly experienced generalized convulsions and only a proportion of the time had temporal lobe seizures. Margerison used clinical characteristics (n = 26; 47%) or interictal scalp EEG (n = 33; 60%) to identify those cases that in addition to generalized seizures, also probably had temporal lobe convul-sions.

Table 1 Autopsy-based Comparison of Qualitative Hippocampal Pathology in Patients with Intractable Seizures, Including Temporal Lobe Epilepsy

Criteria	Typical hippocampal	End-folium sclerosis	No hippocampal

	sclerosis		pathology
Clinical			
TLE+ (n = 26)	15 (58%)	7 (27%)	4 (15%)
TLE- (n = 29)	7 (24%)	7 (24%)	15 (52%)
Interictal EEG			
TLF+ (n = 33)	19 (58%)	10 (30%)	4 (12%)
TLE- (n = 22)	3 (14%)	4 (18%)	15 (68%)

Clinical TLE+, patients with temporal lobe epilepsy based on clinical criteria; clinical TLE-, patients with typical seizures that, by the authorsâ€™ criteria, were not temporal lobe epilepsy TLE, were questionable, or were not known; TLF+, temporal lobe focus based on interictal electroencephalogram (EEG) criteria; TLE-, without temporal lobe focus based on interictal EEG criteria.
Modified from Margerison JH, Corsellis JA. Epilepsy and the temporal lobes. A clinical, electroencephalographic and neuropathological study of the brain in epilepsy, with particular reference to the temporal lobes. *Brain.*1966;89:499â€“530 (Fig. 12).

At autopsy, Corsellis defined two types of hippocampal damage. The first consisted of classic â€œAmmon horn sclerosisâ€

P.123

and the second was a new entity characterized by neuron loss limited only to the end folium. Corsellis introduced the term *hippocampal sclerosis* and defined it as an inclusive term that included both Ammon horn sclerosis and end folium sclerosis. (As a reminder, this chapter uses the term *hippocampal sclerosis* only to refer to what Corsellis considered classic *Ammon horn sclerosis*.) As shown in Table 1, hippocampal sclerosis (Ammon horn sclerosis) was found in 58% of autopsy specimens of patients with clinical or EEG criteria for temporal lobe seizures. By contrast, 60% of patients without clinical or EEG criteria for temporal lobe epilepsy had no hippocampal pathology (Chi-square; $p < 0.005$). The incidence of end folium sclerosis averaged 25% for all patients with epilepsy, and was not associated with temporal lobe seizures ($p < 0.25$). Hence, as in Stauder's 1936 study,[187] hippocampal sclerosis at autopsy was linked specifically to clinical and EEG characteristics of temporal lobe epilepsy. End folium sclerosis, however, was associated with repeated generalized seizures and was not a marker of temporal lobe epilepsy, as has been suggested by some authors.[177]

In addition to hippocampal neuron injury, Margerison and Corsellis found that there could be damage to other cerebral brain areas. For example, in their 22 cases of hippocampal sclerosis, additional damage was noted in the amygdala (64%), thalamus (50%), and neocortex (27%). Such findings are not limited to autopsy studies of patients with temporal lobe epilepsy. Falconer et al.[67] found pathologic evidence for injury to the amygdala and white matter in an unspecified number of en bloc temporal lobe surgical specimens from patients with temporal lobe epilepsy and hippocampal sclerosis. These authors proposed the term *mesial temporal sclerosis* to indicate damage to the hippocampus and other mesial temporal sites. Recent magnetic resonance imaging (MRI) studies confirm the original autopsy pathology studies by finding evidence for extrahippocampal signal changes in a proportion of patients with temporal lobe epilepsy.[19,48,145,208] Thus, while the traditional focus has been on hippocampal sclerosis as the probable site that generates chronic seizures, many patients will also demonstrate extrahippocampal injury. Such findings are germane to understand the pathogenesis of hippocampal sclerosis and how this pathology contributes to the development of seizures, and in deciding the extent of surgical resection in order to best achieve seizure control.

The Asymmetric Nature of Hippocampal Injury in Temporal Lobe Epilepsy

Autopsy and surgical studies support the idea that patients with intractable temporal lobe epilepsy frequently have bilateral hippocampal damage. However, the amount of damage is usually asymmetric, with one side showing hippocampal sclerosis and the other side milder forms of neuron loss. The best evidence comes from the study of Margerison and Corsellis,[111] where of the 22 patients with EEG criteria for temporal lobe epilepsy and hippocampal sclerosis, the sclerosis was unilateral in 90% and bilateral in 10%. Similar results were reported by Sano and Malamud[168] in another autopsy study of 29 patients with antemortem ictal â€œpsychic phenomena.â€ Bilateral hippocampal damage was noted in 11 cases (39%). Meencke and Veith[138] reported on results from 650 autopsy cases of patients with chronic epilepsy. They found hippocampal sclerosis in 198 (30.5%) and in 56% of these, the findings were bilateral but asymmetric. Similar results have been reported in the limited number of surgically treated temporal lobe epilepsy patients who later died and in whom the other hippocampus became available for study.[6,126] In agreement with the pathology studies, brain MRI findings have shown that many patients with temporal lobe epilepsy have abnormal signal changes contralateral to the atrophic epileptogenic hippocampus.[174,198] Thus, the available data support the concept that while hippocampal damage is often bilateral in patients with temporal lobe epilepsy, most of the time hippocampal sclerosis is unilateral and coincides with the epileptogenic focus.

Pathogenesis of Hippocampal Sclerosis

The pathologic origins of hippocampal sclerosis have been debated, often contentiously, for over 60 years, and center on whether neuron loss is the â€œcauseâ€ or â€œconsequenceâ€ of

P.124

repeated temporal lobe seizures. Despite the remarkable astute clinicopathologic observations of Sommer[178] and Bratz[36] supporting the hypothesis that hippocampal sclerosis represented an area of chronic damage and gliosis that probably generated seizures, Spielmeyer,[183] Scholz,[172] Peiffer,[159] and more recently Sutula and Pitkanen[189] have argued that hippocampal injury is the consequence of repeated seizures. As will be detailed below, the correct answer probably lies somewhere in between.

Earnest debate of the pathogenesis of hippocampal sclerosis began in the 1950s when surgical specimens became available from patients with temporal lobe epilepsy. Probably the first â€œmodernâ€ concept regarding pathogenesis was that of Earle et al.[60] They examined 157 of Penfield's temporal lobe resections and found macroscopic pathologic abnormalities in 100, ranging from focal gyral toughness to atrophy of the entire lobe. It should be noted that for many years Penfield did not routinely remove the hippocampus en bloc for histopathologic examination. Earl et al.[60] suggested that the most likely explanation as to the â€œcauseâ€ of hippocampal sclerosis was transtentorial herniation of the mesial temporal lobe during a difficult delivery or as a result of birth anoxia with secondary brain swelling. They proposed that in herniating across the tentorium, the mesial temporal lobe compressed the adjacent posterior cerebral and anterior choroidal arteries to generate an ischemic lesion they termed *incisural sclerosis*. With time, this brain lesion â€œripenedâ€ into an epileptic focus. Of interest, however, is that only 10% of their patients had a difficult birth history.

For the next 10 years, birth injury was considered to be the pathogenic etiology for hippocampal sclerosis, and this concept was initially supported by Falconer et al. in the United Kingdom.[43,140] However, after reviewing their first 100 surgical cases in the early 1960s, Falconer began to realize that there was more than one possible clinical factor associated with hippocampal sclerosis. Of 47 cases of hippocampal sclerosis, a history of difficult birth, early childhood convulsions, or head injury was noted in 42 (89%). Of these, childhood seizures were the most common predisposing factor. Falconer et al. concluded that there was a strong association between a clinical history of childhood seizures, especially febrile seizures, and the finding of hippocampal sclerosis at surgery,[39,67,68] and hypothesized that early seizures are a cause of hippocampal sclerosis. This idea has subsequently been referred to as Meyer's hypothesis.[139]

This concept, however, has been challenged by epidemiologic studies showing that the risk of temporal lobe epilepsy after febrile convulsions is very low.[3,42,149] Beginning in the mid-1990s, the UCLA group readdressed Falconer's hypothesis in clinicopathologic studies of a large series of surgical patients with temporal lobe epilepsy.[118,121,125] By expanding the concept of potential brain insults to include any significant medical event likely to injure the brain that occurred before the onset of epilepsy, the authors found that initial precipitating injuries were strongly linked to hippocampal sclerosis in surgical cases (Fig. 2A). However, initial precipitating injuries, while most likely to occur under age 5 years, were not restricted to a young age or to febrile convulsions. In fact, studies of hippocampi removed from pediatric patients with frequent nontemporal lobe seizures generally find only limited hippocampal neuron loss, an observation that supports the notion that childhood seizures, by themselves, do not lead to hippocampal sclerosis.[121,123] Thus, the UCLA data supported previous arguments that hippocampal sclerosis predates the onset of epilepsy, is associated with some significant brain injury not necessarily linked with seizures or an early age, and is probably a cause of temporal lobe epilepsy. However, the UCLA group also found that seizure durations of 15 years or more were associated with progressive hippocampal neuron loss in all subfields of the hippocampus, and this occurred in temporal lobe epilepsy patients with or without hippocampal sclerosis (Fig. 2B). In other words, repeated seizures over time are associated with hippocampal neuron loss, but the damage is throughout the hippocampus and not in the selective pattern consistent with sclerosis. Recent neuroimaging and other studies have supported this conclusion.[189] Thus, the pathogenesis of most cases of hippocampal sclerosis appears to be from some antecedent brain injury (thus acquired), but there is also progressive neuron loss with longer seizure durations. The latter finding may impact the decision as to when to refer patients with temporal lobe epilepsy for surgery.

Dual Pathology

Surgical patients with temporal lobe epilepsy sometimes have more than one lesion or area of injury within the temporal lobe. This is termed *dual pathology*, and it appears to be more common in younger patients with temporal lobe epilepsy.[144] It has been difficult to interpret these studies because the definition of what constitutes a â€œsecondâ€ pathology is sometimes vague, and it may also be unclear if both abnormalities are epileptogenic. For example, Babb and Brown[7] found a 13% incidence of dual pathology when the other pathology was defined as a macroscopic mass lesion. Levesque et al.,[96] using the same UCLA database, included microscopic lesions, such as heterotopias, and found dual pathology in 30% of temporal lobe resections. Other authors have reported rates of dual pathology ranging from 3% to 95% depending on the definition of a second pathology.[5,88,190] Thus, a variable percentage of temporal lobe epilepsy patients will have hippocampal sclerosis plus some other histopathologic finding in the surgical specimen, such as an increase in heterotopic neurons in the subcortical white matter, but whether that second pathology contributes to seizure generation remains unclear despite recent attempts using intracranial EEG recordings.[69,86]

In Vivo Electrophysiologic Studies of Hippocampal Sclerosis

Intraoperative electrophysiologic recordings in the form of electrocorticography (ECoG) were the original source of functional data used to localize interictal spikes (see also Chapter 172). Histologic changes such as gliosis and neuronal loss in the resected tissue often correlate with interictal spikes and other abnormalities in the ECoG. A limitation of ECoG is that the activity comes from the cortical surface, not from deep structures like the hippocampus. Early attempts to examine the properties of the â€œepileptic neuronâ€ were based on single unit recordings from the lateral temporal or frontal cortex carried out in the late 1960s and early 1970s.[41,165] In a slightly later study, Wyler et al.[207] sought to evaluate cellular discharges during intracranial recordings by identifying single unit burst discharge patterns that accompanied interictal spikes, and described synchronization of single unit discharges with one another and with local and surface field potentials during occasional intraoperative ictal events.

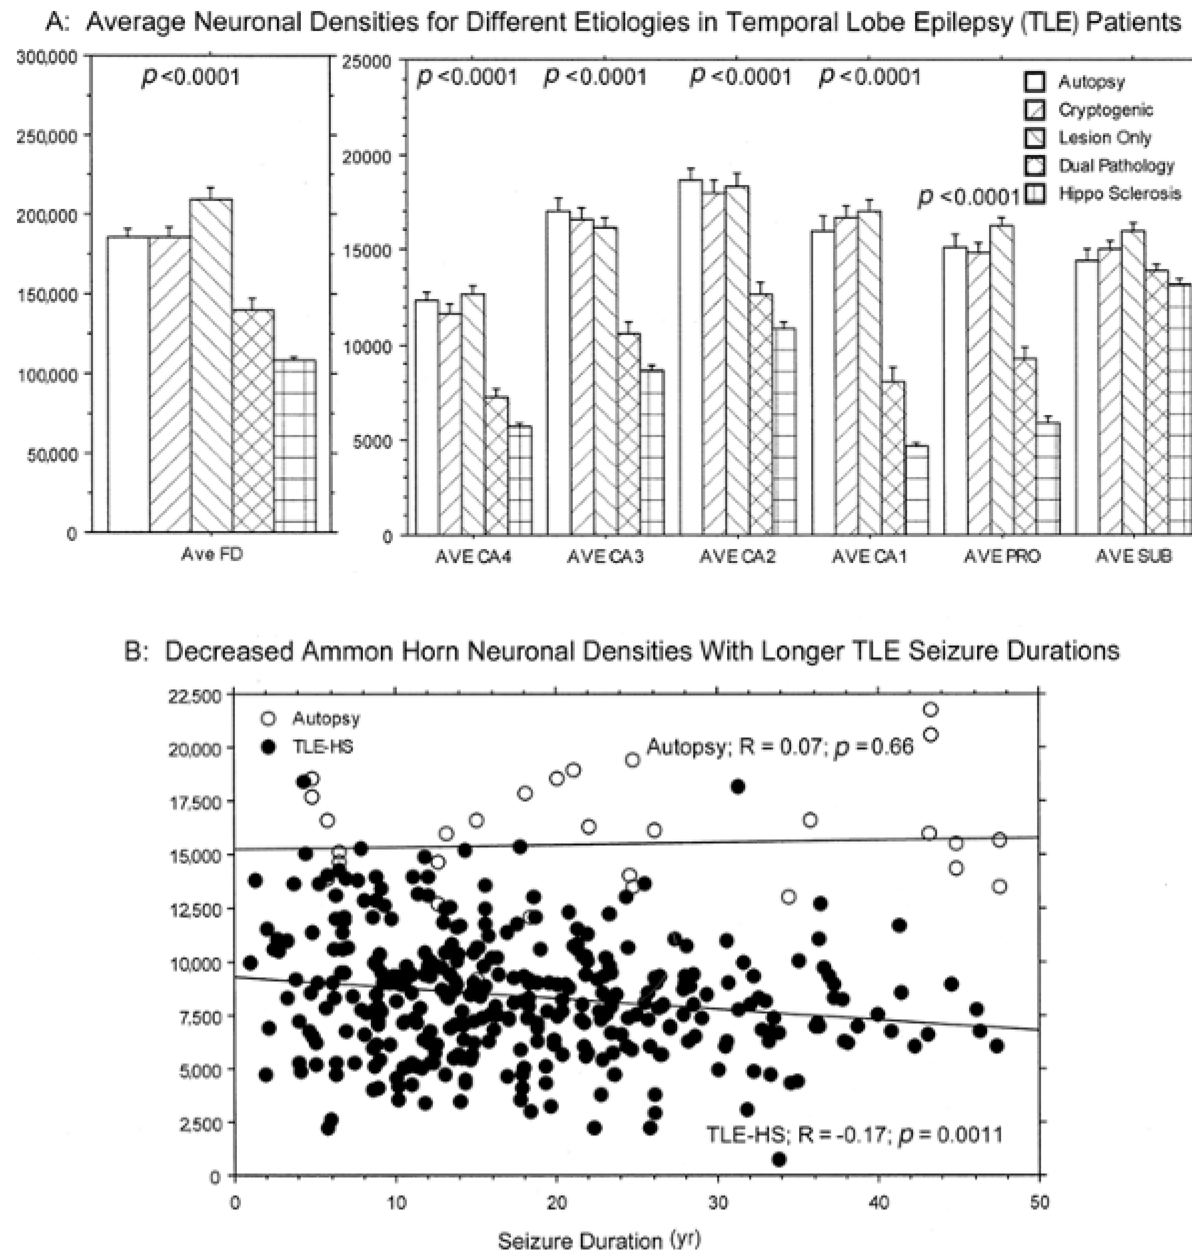

FIGURE 2. A: Bar graphs showing the mean (Â± SEM) neuron densities for the hippocampal subfields as labeled in FIGURE 1A for different etiology subgroups of temporal lobe epilepsy patients. Cryptogenic cases are those without magnetic resonance imaging (MRI) or histopathology-identified epileptogenic lesions. Lesion-only cases had an MRI-identified mass, such as a tumor or area of cortical dysplasia without hippocampal sclerosis. Dual pathology represents cases with hippocampal sclerosis and a mass lesion outside the hippocampus. An initial precipitating injury (IPI) was noted in 87% of patients with hippocampal sclerosis alone compared with 54% for those with dual pathology and 23% for those with cryptogenic temporal lobe epilepsy. ANOVA *p* values are illustrated above each subfield. Notice that neuronal densities for cryptogenic and lesion-only patients were similar to nonseizure autopsy cases, while dual pathology and hippocampal sclerosis patients with the higher incidence of IPIs had neuron loss in the profile expected with more damage in CA4, CA1, and prosubiculum. By comparison, damage in the subiculum for all cases was much less. **B:** Scatter plot illustrating progressive neuronal loss for the entire Ammon horn with longer duration of seizures in hippocampal sclerosis patients compared with autopsy cases. Notice that the progressive neuron loss in sclerosis patients required over 20 years of seizures and a large number of patients in the study group.

Although McKhann et al.[135] described use of ECoG re-corded directly from the hippocampus for determining the extent of hippocampal resection, intraoperative single neuron recordings from hippocampus are technically challenging and difficult to perform, particularly in terms of correlating such activity with hippocampal sclerosis. Perhaps the most direct intraoperative electrophysiologic correlates of hippocampal sclerosis were published by Rutecki et al.[166] Prior to resection of hippocampal tissue, they stimulated the entorhinal cortex or alveus and recorded either from the surface of or from within the hippocampus. They compared evoked potentials recorded

in 16 patients with hippocampal sclerosis and eight without sclerosis. They found that the patients with hippocampal sclerosis showed simple monophasic or biphasic responses with long-onset latencies (mean, 21.9 msec), whereas those without sclerosis responded with complex, multiphasic potentials that had much shorter-onset latencies (11.8 msec). This is consistent with expectations for hippocampi with severe neuronal damage and gliosis characteristic of hippocampal sclerosis. However, such findings do not explain the epileptogenicity of hippocampal sclerosis, nor do they provide histologic identification of the position of the recording electrode in relation to hippocampal laminae. Of more promise are recent investigations using multiple contact microelectrodes with vertical spacing small enough to study the voltage depth profile of tissue in hippocampal sclerosis.[192]

Electrical Stimulation and Hippocampal Sclerosis

Intra- and extraoperative electrical stimulation has been used since the time of Penfield in the evaluation of epilepsy patients. Studies carried out in patients with depth electrodes have focused on the mental phenomena or memories evoked in awake subjects during trains of high-frequency hippocampal stimulation.[17,73,75] However, electrical stimulation of mesial temporal structures, including hippocampus, has also provided localizing data based on evocation of the stereotyped auras or behavioral changes associated with a patient's characteristic spontaneous seizures.[23] Although the relationship between behavioral responses to stimulation and hippocampal sclerosis is unclear, hippocampal stimulation has provided evidence for both increased evoked potential thresholds and increased afterdischarge thresholds in sclerotic hippocampi compared with nonsclerotic tissue.[45] In 74 patients with depth electrodes, single pulse stimulation was used to measure the functional intrinsic connectivity and the efferent and afferent connections of hippocampus with other mesial temporal and limbic structures.[202] Latencies and conduction velocities of field potentials evoked by single pulses of electrical stimulation varied among the seven limbic sites studied, but the two mesial temporal structures that showed greatest connectivity with all other areas were the entorhinal cortex and the presubiculum. This finding is expected based on the known afferent and efferent pathways of the hippocampus. In a subsequent study, functional connections on the side of seizure onset were found to be significantly decreased within the entorhinal cortex, between the anterior and more posterior hippocampus, and between the hippocampus and amygdala.[200] If one assumes that the preponderance of unilateral mesial temporal onsets in these patients were associated with the presence of sclerotic hippocampi, these results provide further support for reductions in neuronal network connectivity in hippocampal sclerosis.

Paired pulse stimulation has also been employed in evaluating excitability in the hippocampus.[203] In 15 patients, paired pulse suppression in the perforant pathway was significantly greater in the epileptogenic hippocampus compared to the contralateral side. These results demonstrate that inhibition is maintained or even increased in the synaptically reorganized hippocampus in spite of the cell loss and gliosis characteristic of hippocampal sclerosis.

Microdialysis Studies in Hippocampal Sclerosis

In some surgical centers, electrophysiologic recording from depth electrodes has been accompanied by in vivo micro-dialysis.[59,204] This has provided an opportunity to evaluate the release of glutamate and other neurotransmitters associated with hippocampal seizure activity. During and Spencer[59] showed that glutamate release occurred not only during seizures, but also preceding seizure onset. Furthermore, the glutamate release was much greater on the side of seizure onset in patients with hippocampal sclerosis. They suggested that the high levels of glutamate occurring during seizures could reach neurotoxic levels and play a role in the progressive neuronal loss associated with hippocampal sclerosis (Fig. 2B). They also speculated that reuptake transporters were not functioning properly. This study also showed prominent Î³-aminobutyric acid (GABA) release during seizures in the nonsclerotic hippocampus and less release on the side of hippocampal sclerosis. In another paper, During et al.[58] showed that GABA release during K^+depolarization was increased in the hippocampus of the epileptogenic temporal lobe, but there was no difference from baseline when the microdialysis perfusate was Ca^{+2} free. During et al. provided additional evidence suggesting that this GABA release was mediated by reverse transport, not synaptic release. Such findings are consistent with anatomic data showing changes in glutamate and GABA transporters.[124] A more recent study by Cavus et al.,[44] using zero flow measures of baseline amino acids, supports the conclusion that hippocampal sclerosis is associated with high lactate levels, a general reduction in the glutamate-glutamine cycle and glutamate uptake, which leads to increased glutamate levels and neurotoxicity (see Chapter 87).

Ictal and Interictal EEG Correlates of Hippocampal Sclerosis

The well-established association between histologic damage and seizure propensity has been clarified over the years by correlating the electrographic changes recorded using depth electrodes with various measures of neuronal loss. These include the presence of hippocampal sclerosis with focal ictal onsets or interictal spikes,[64,102,197] the pattern of hippocampal pyramidal and granule cell loss correlated with the area of hippocampal ictal onset,[8,12,180,181] cell density in sclerotic or atrophic hippocampus correlated with interhemispheric propagation time,[99,101,179,182] or hippocampal thiopental EEG activation.[100] The correlation of interictal spikes with hippocampal sclerosis is clearly state dependent, because interictal spikes are widespread during slow-wave sleep but may be focal during rapid eye movement (REM) sleep.[103,109,110,167] Sensory-evoked or event-related potentials also have been considered a means of assessing hippocampal or mesial temporal damage associated with temporal lobe epilepsy.[46,75,133,134,136,137]

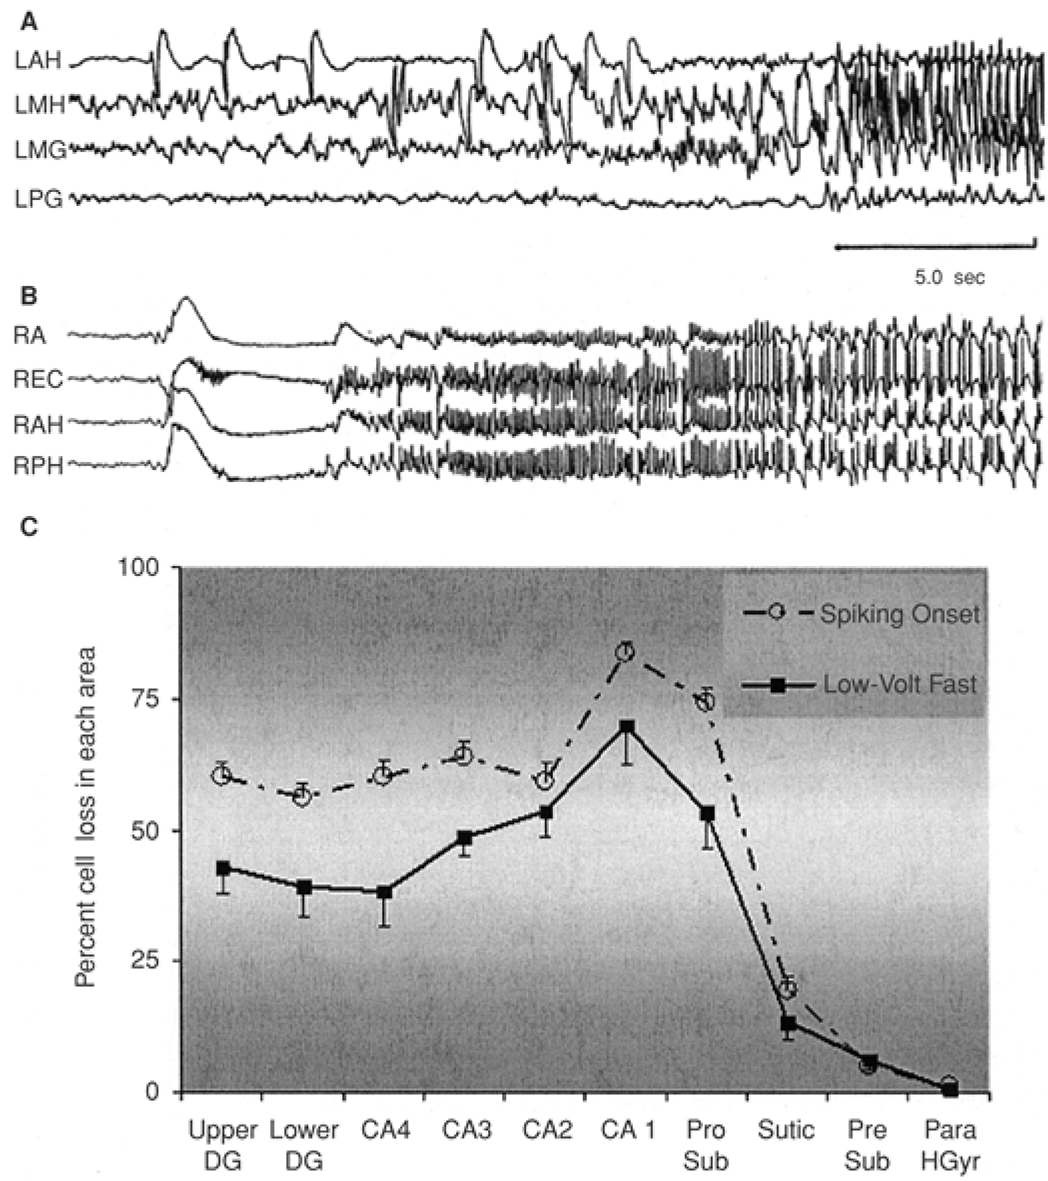

FIGURE 3. Unilateral recordings from hippocampus and adjacent structures in two different patients. **A:** A hypersynchronous spiking on-set. LAH, left anterior hippocampus; LMH, left middle hippocampus; LMG, left middle parahippocampal gyrus; LPG, left posterior parahippocampal gyrus. **B:** A low-voltage fast (LVF) onset. RA, right amygdala; REC, right entorhinal cortex; RAH, right anterior hippocampus; RPH, right posterior hippocampus. **C:** Mean percentage cell loss (Â± SEM), with LVF (14 patients) versus hypersynchronous (29 patients) on-sets. Notice that both groups have a neuronal loss profile consistent with hippocampal sclerosis with slightly less damage in those with the hypersynchronous spiking onset. Upper DG, upper blade of dentate gyrus; Lower DG, lower blade of dentate gyrus; CA1â€"4, hippocampal fields 1â€"4; Pro Sub, prosubiculum; Subic, subiculum; Pre Sub, presubiculum; Para HGyr, parahippocampal gyrus. All sites were significantly different at p <0.05 or better with the ex-ception of CA2, Subic, Pre Sub, and Para HGyr.

One of the most studied depth electrode EEG correlates of hippocampal sclerosis has been the morphology of ictal onsets.[63,108,157,171,180,181,194] In these studies, a clear marker of hippocampal sclerosis has been seizure onsets characterized by repetitive high-amplitude sharp waves just before or at ictal onset. This has been variously called â€œhypersynchronous spiking,â€ â€œperiodic spiking,â€ â€œrepetitive spike pattern,â€ or â€œrhythmic sharp wavesâ€ (Fig. 3A), although some difference of opinion still exists over whether the spiking precedes or is part of the onset.[198] A second pattern that is commonly seen in depth EEG recordings is a low-voltage fast discharge (Fig. 3B), which occurs more commonly in nonsclerotic mesial temporal lobe, in sclerotic hippocampus after periodic or repetitive spiking, or in sclerotic hippocampus at the point of propagation to the contralateral hemisphere. Quantification of hippocampal cell loss is different between these two ictal patterns in all hippocampal fields except CA2, with cell loss greater in patients with the hypersynchronous spiking type of onset (Fig. 3C).

Microelectrode Recordings in Hippocampal Sclerosis

As was the case with some of the first studies using chronic depth electrodes, early microelectrode studies obtained chronically from patients outside the operating room often assumed the presence of hippocampal sclerosis without providing quantitative evidence based on cell counts. Thus, studies by Babb et al.[9] and Babb and Crandall[10] focused on descriptions of the bursting patterns of action potential discharge in the hippocampus of patients with mesial temporal lobe epilepsy or changes in firing rates that occurred at seizure onset.[16] Later studies compared hippocampal unit activity recorded from the epileptogenic temporal lobe with that of the contralateral nonepileptic side and quantified differences in a number of measures of neuronal discharge.[201] For example, the duration of firing suppression following single pulse electrical stimulation was significantly greater on the side of seizure onset, and cells showing this suppression were those that fired synchronously with adjacent neurons.[83] Early quantification of firing rate, burst discharge, and degree of synchronous discharge was difficult to interpret until later studies showed that these variables were highly state dependent.[186] Although there were no significant differences during the waking state, recordings during polysomnographically staged non-REM sleep and REM sleep showed that neurons on the side of seizure onset had significantly greater firing rates, burst propensity, and synchronous firing as might be expected for epileptogenic tissue.

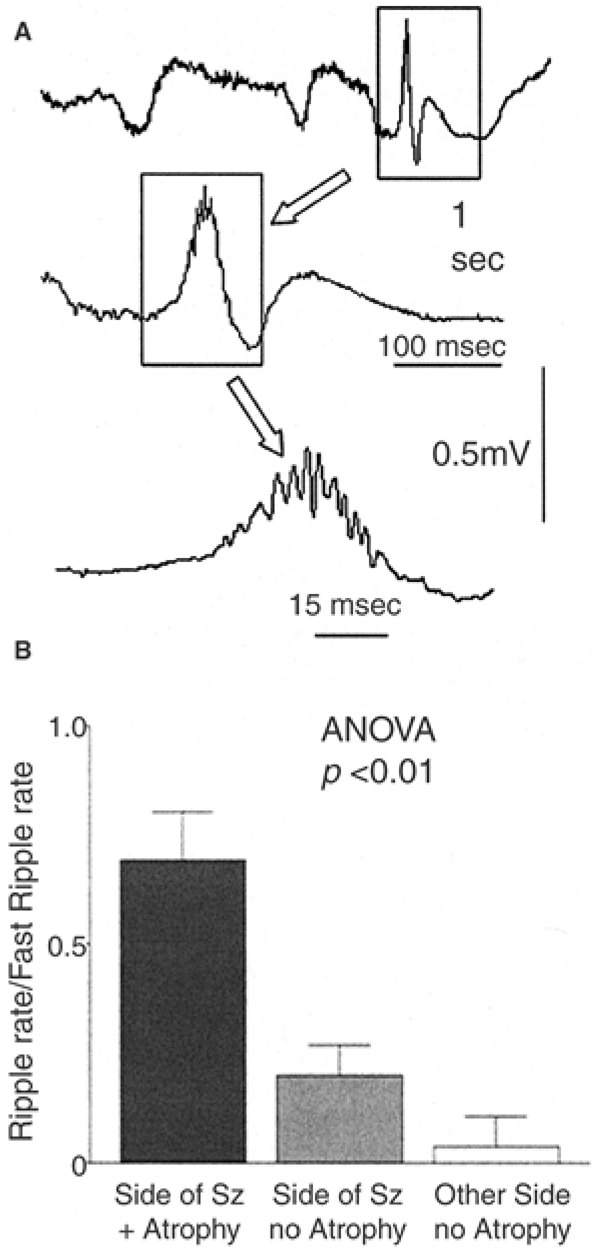

FIGURE 4. A: Interictal spike in wide band electroencephalogram with slow time base appears similar to those commonly seen in conventional recordings. When time base is increased to 100 msec, high-frequency oscillation becomes evident, and with a 15 msec time base, the interictal spike is revealed as a 300 Hz fast ripple oscillation. **B:** When ripple oscillation rate is divided by the fast ripple rate of discharge recorded from the mesial temporal lobes of a group of 25 patients with temporal lobe epilepsy, the resulting ratio is clearly greater on the side of seizure onset in the presence of hippocampal atrophy (and presumed sclerosis) compared with either the side of seizure onset without atrophy or the contralateral side.

High frequency oscillations (HFOs) in the range of 80 to 500 Hz were discovered by Bragin et al.[33,34] during wide band field recordings from depth microelectrodes in the human hippocampus. Oscillations in the range of 100 to 200 Hz had previously been described in the normal rat hippocampus as â€œrippleâ€ oscillations,[209] but in the unilateral intrahippocampal kainic acidâ€"injected rat, oscillatory activity up to 500 or even 600 Hz can be recorded.[35] Therefore, high-frequency oscillations in both epileptic rat and epileptic human hippocampus are called â€œfast rippleâ€ oscillations to distinguish them from endogenous ripples. In patients with temporal lobe epilepsy, these oscillations are often associated with interictal spikes in which the use of wide band microelectrode recordings reveals high-frequency oscillations (Fig. 4). Quantitative studies by Staba et al.[185] showed that the distribution of high-frequency activity recorded in patients was bimodal, with ripples falling in the range of 80 to 150 Hz and fast ripples from 150 to 500 Hz. When oscillations were separated on the basis of the temporal lobe of seizure onset versus the contralateral temporal lobe,

fast ripple activity was found most frequently in the former and ripple activity in the latter (Fig. 4B). Of patients with unilateral seizure onsets, those with hippocampal atrophy have a higher rate of fast ripple oscillations and a lower rate of endogenous ripple oscillations.

Subsequent analysis has shown that the degree of atrophy and percent of cell loss correlates with the ratio of ripple to fast ripple discharges, indicating that hippocampal sclerosis is associated with a decrease in the rate of normal endogenous ripples and an increase in the rate of pathologic fast ripple oscillations.[184] In addition, the presence of high-frequency discharges during seizure onset has been demonstrated in patients with temporal lobe epilepsy during hypersynchronous spiking seizure onsets in the epileptic rat[32] and during spiking and low-voltage fast seizure onsets in human hippocampus.[85] Because of the association between fast ripple oscillations and hippocampal epileptogenesis, the presence of these oscillations has been suggested as a surrogate marker for localization sites for surgical treatment of mesial temporal lobe epilepsy.[65] In FIGURE 5, an example of both ripple and fast ripple oscillations during the onset of a low-voltage fast seizure onset is shown during a wide band recording (C. Wilson, unpublished data). In FIGURE 5A, with a time base of 200 msec in this wide band recording, fast oscillations and details of the unit activity in entorhinal cortex are visible, and with a time base of 25 msec, oscillations of 400 Hz are present on a hippocampal microelectrode (Fig. 5B). In the study by Jirsch et al.,[85] similar high-frequency oscillations were recorded using wide band amplifiers, but without microelectrodes, indicating that this marker of potential pathologic tissue may be visible in wide band recordings from depth electrodes without microelectrodes.

Hippocampal Sclerosis and Epileptogenesis

Multiple cellular and molecular changes have now been described in human hippocampal sclerosis. One of the challenges for epilepsy researchers is to determine which of these are related to the neuron loss associated with hippocampal sclerosis and which are from repeated seizures. To sort this out, most studies compare findings from temporal lobe epilepsy patients with hippocampal sclerosis with findings from patients whose seizures arise from macroscopic mass lesions where the hippocampus is less damaged.[116,117] The advantage of this experimental design is that tissue from both groups can be identically processed after surgical removal, which is especially suitable for experiments that require living tissue (i.e., molecular biology, electrophysiology). While hippocampi from patients with lesions are less severely affected than those with hippocampal sclerosis, they still must be considered abnormal because of frequent seizures. Thus, parallel studies in animal models of temporal lobe epilepsy have proved to be a fruitful approach to delineate mechanisms underlying the development of neuropathologic and functional changes. Conversely, experiments on human tissue have been important to evaluate which aspects of human temporal lobe epilepsy are best replicated by animal models.

From experiments using tissue from humans with hippocampal sclerosis and experimental models of temporal lobe epilepsy, several molecular and cellular changes have emerged that likely play an important role in the propensity of the human hippocampus to generate seizures. Possible mechanisms of epileptogenesis can be broadly categorized into three groups: Changes in synaptic properties, neuronal connectivity, and alterations in the intrinsic properties of neurons. In additional to changes in neurons, glial cells have emerged as important players in mediating hyperexcitability in hippocampal sclerosis.

Synaptic Changes in Hippocampal Sclerosis

In association with neuronal loss, aberrant axon and synaptic reorganization is a characteristic feature of human hippocampal sclerosis.[11,188] The best characterized type of aberrant axon sprouting, both in human and experimental epilepsy, is the synaptic reorganization of the mossy fiber system (the axons of dentate granule neurons) because mossy fibers can be easily identified using the Timm staining procedure (Fig. 6). Mossy fiber sprouting is characterized by the formation of novel, aberrant synaptic contacts of mossy fibers onto the proximal dendrites of hippocampal dentate granule neurons.[40,79,82] The trigger that initiates synaptic reorganization probably involves multiple mechanisms. The traditional concept is that loss of axon afferents onto the proximal dendrites of granule cells from death of hilar neurons initiates this process.[49] This idea is in line with neuropathologic studies demonstrating that the amount of hippocampal pyramidal cell loss in the CA3 region correlates with the extent of mossy fiber sprouting.[62] Another hypothesis has suggested that granule cell neurogenesis, which is increased following status epilepticus in rats, may lead to outgrowth of new mossy fiber axons, which are then misrouted. Evidence from animal models argues against a profound impact of neurogenesis in synaptic reorganization, because disrupting status epilepticusâ€"induced granule cell neurogenesis by irradiation does not inhibit mossy fiber sprouting.[155] Given the prominence of axon reorganization in human hippocampal sclerosis (Fig. 6), studies have focused on determining the distribution of proteins that are known to influence axonal outgrowth and targeting. In hippocampal sclerosis, changes in some of these proteins have been reported, such as the extracellular matrix component tenascin and the reticulin protein Nogo-A.[18,170]

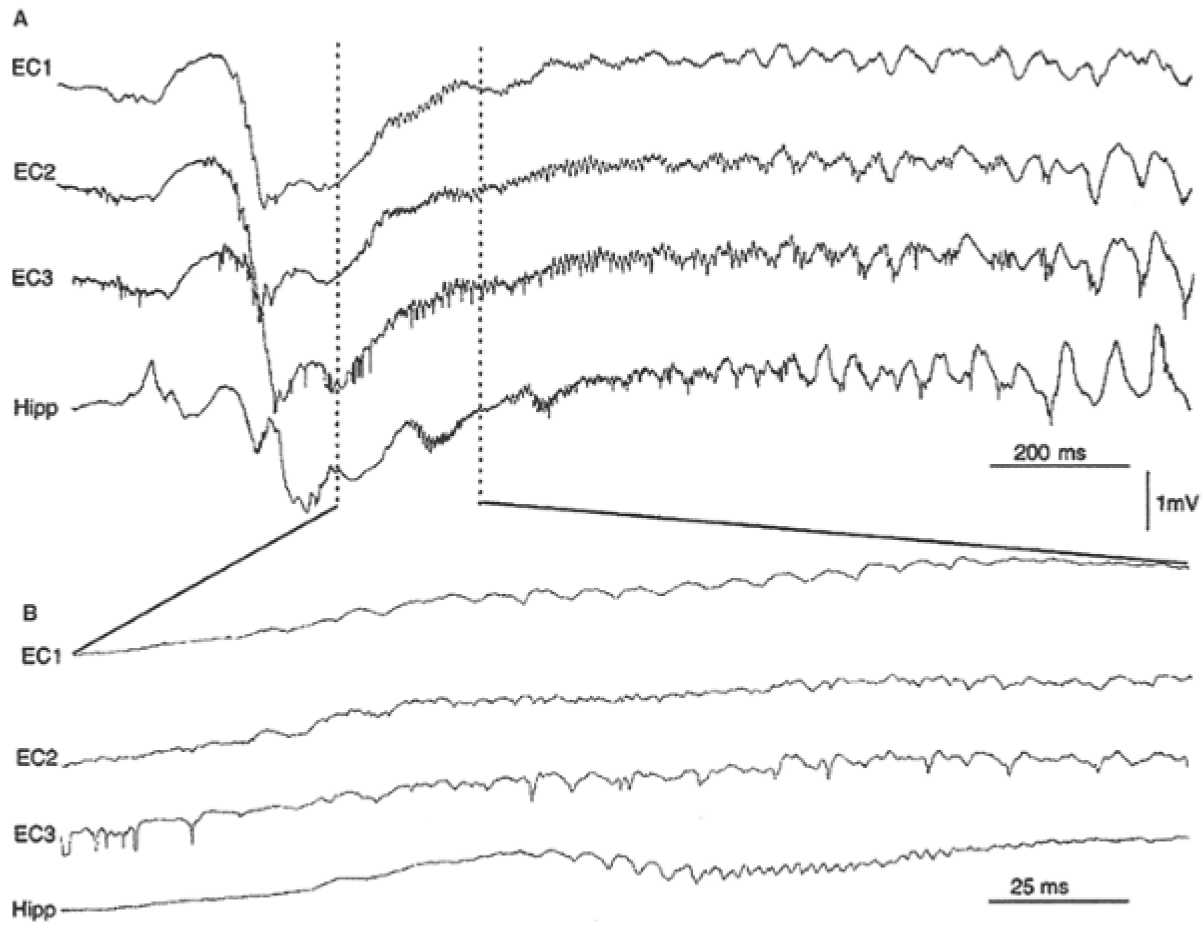

FIGURE 5. Wide band microelectrode recording of the initial 1.5 seconds of the seizure onset shown in FIGURE 2B (low-voltage fast onset) at two time resolutions, illustrating high-frequency oscillations (HFOs) in three microelectrodes from the left entorhinal cortex (EC1,2,3) and the right anterior hippocampus (Hipp). Single-unit activity is visible in EC3. The activity in hippocampus indicated by the arrow has a frequency of approximately 400 Hz.

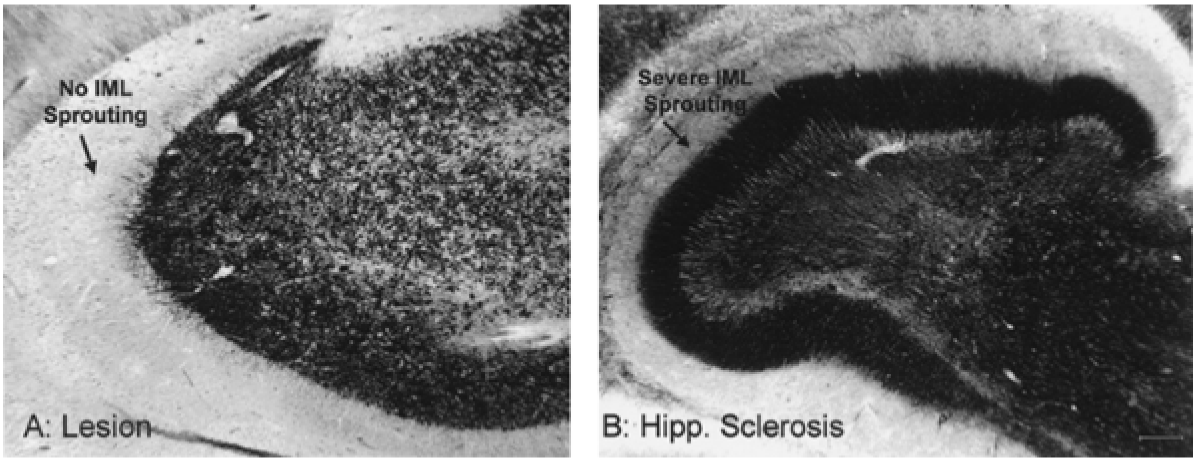

FIGURE 6. Examples of neo-Timm staining illustrating aberrant inner molecular layer (IML) mossy fiber sprouting in human temporal lobe epilepsy patients. **A:** This patient has a tumor generating seizures from the anterior temporal pole. Neo-Timm staining shows only a few black stained strands in the IML. **B:** By comparison, this patient with hippocampal sclerosis demonstrates robust neo-Timm staining in the IML consistent with aberrant mossy fiber sprouting.

The formation of recurrent collaterals of granule cell axons onto other granule cells has been proposed as a major epileptogenic mechanism that may compromise the normally inhibitory function of the dentate gyrus promoting spontaneous seizures.[11,188] The properties and functional importance of this aberrant circuitry has been partially demonstrated in human hippocampal sclerosis patients.[70,79,80] However, in animal models of hippocampal sclerosis, recordings from such aberrant synaptic connections support the existence of monosyn-aptic excitatory recurrent synapses consistent with mossy fibers.[70,80,81,82] It should be noted that under normal circumstances, an excitatory disynaptic feedback circuit via mossy fiber activation of mossy cells, which project back to the dentate gyrus, also exists. Due to the loss of mossy cells and the presence of recurrent mossy fiber sprouting in hippocampal sclerosis, this normal disynaptic circuit is replaced by an abnormal more local monosynaptic one.[40] Apart from creating a monosynaptic recurrent excitatory loop, a mechanism that may further compromise inhibition is the synaptic-mediated release of zinc by mossy fibers onto the proximal dendrites of granule neurons. Because granule cells in chronic human and experimental epilepsy express GABA receptors with increased zinc sensitivity, this has been thought to cause a collapse of GABAergic inhibition, especially at the start of seizure activity.[37,38]

Synaptic reorganization in hippocampal sclerosis is not restricted to the fascia dentata and excitatory mossy fiber system. Aberrant axon collaterals of CA1 pyramidal cells are increased in human and experimental temporal lobe epilepsy, and project to the stratum pyramidale and the stratum radiatum of area CA1.[95] In addition, it is likely that the projections of GABAergic interneurons also undergo significant axon reorganization[15,115] as noted for Chandelier cells.[4] It is likely that newly formed synapses have properties that distinguish them from pre-existing synapses, and it will be important to extend our understanding of the elementary properties of these synapses in determining mechanisms of epileptogenesis in hippocampal sclerosis.[169]

Glutamate and GABA Receptor Alterations in Hippocampal Sclerosis

Considerable effort has been expended on characterizing inhibitory and excitatory neurotransmission in the epileptic human hippocampus.[13,14,25,26,30,51,52,53,54,55,112,113,119,122,127,128,129,130,131,132] Excitatory glutamatergic synaptic transmission is altered in hippocampal sclerosis.[81] *N*-methyl-D-aspartate (NMDA) receptors, one type of inotropic glutamate receptor, are assembled from different subunits termed NR1 and NR2 Aâ€"D.[146] The subunit composition of NMDA receptors and their alternative splicing determine the functional properties of the receptor channel. Hyperexcitability in human epilepsy has been attributed in part to modified NMDA receptor function, presumably due to prolongation of channel opening, increase in agonist sensitivity, and/or decrease in Mg^{2+} sensitivity.[90,104] Changes in the expression of NMDA receptor subunits have been described on the protein and mRNA levels, as well as in ligand binding studies in human hippocampal sclerosis.[51,53,80,81,128,132] In addition to changes in the expression of NMDA receptor subunits, their posttranscriptional regulation appears to play an important role in chronic epilepsy. The increased open times observed in human epileptic tissues are likely due to a persistent decrease in calcineurin activity, an intracellular phosphatase that normally curtails NMDA receptor openings.[191]

Î±-Amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors, another class of inotropic glutamate receptor, are composed of the GluR1-4 subunits, each of which exists in two alternatively spliced forms. The functional properties of AMPA receptors are critically dependent on their subunit composition and the process of alternative RNA splicing.[148,195] Studies in human surgical tissue have demonstrated region-specific changes in AMPA receptor expression on the mRNA and protein level.[13,26] Similar findings have been reported for kainate receptor subunits, another type of inotropic glutamate receptor subtype.[127]

Metabotropic glutamate receptors (mGluRs) are also altered in human epilepsy with hippocampal sclerosis,[28,97,151] and these may profoundly modulate the generation and propagation of epileptiform activity.[205] The mGluR family consists of at least eight different subtypes.[150] Activation of class I mGluRs (i.e., mGluR1 and mGluR5) leads to an excitatory membrane depolarization followed by release of Ca^{2+} from intracellular stores, which appears to be mediated by inositol phosphate hydrolysis. Class II (mGluR2 and mGluR3) and class III (mGluR4 and mGluR6-8) mGluRs operate mainly via a G-proteinâ€“mediated inhibition of adenylate cyclase. mGLuR receptors are predominantly presynaptic, and they reduce transmitter release in rodent and human hippocampus,[56] probably via inhibition of voltage-gated Ca^{2+} channels.[173]

GABA is the predominant inhibitory neurotransmitter in the adult brain and plays a critical role in the regulation of excitability of neuronal networks.[142] GABA binding to inotropic $GABA_A$ receptors opens the receptor ionophore, which is permeable to Cl^- and, to a lesser extent, to HCO_3. In the presence of a normal adult transmembranous Cl^- gradient, this results in expression of an inhibitory postsynaptic current that hyperpolarizes the postsynaptic neuronal membrane. $GABA_A$ receptorâ€“mediated synaptic currents have been studied in human hippocampal neurons from epilepsy patients.[37,176] These studies have revealed a significantly higher sensitivity of human $GABA_A$ receptors to zinc, a finding also observed in chronic epilepsy animal models. Increased zinc sensitivity of $GABA_A$ receptors is thought to render them susceptible to blockade by zinc released from recurrent mossy fibers during seizures, potentially causing a breakdown of dentate inhibition.[142] Studies of mRNA expression for different $GABA_A$ receptor subunits and correlation with physiologic and pharmacologic properties suggest that $GABA_A$ receptors are regulated in a coordinate fashion in human hippocampal neurons.[38] The epilepsy-associated regulation of $GABA_A$ receptor subunits has been addressed using immunohistochemistry and in situ hybridization in hippocampal sclerosis.[107,161]

Apart from changes in GABA receptors, GABAergic neurotransmission is also influenced by changes in the transmembrane chloride gradient. Indeed, $GABA_A$ receptor activation becomes depolarizing because of altered chloride homeostasis in a subset of subicular neurons in human epilepsy.[47,206] GABAergic inhibitory postsynaptic potentials are governed by the time course with which GABA is removed from the synaptic cleft. This task is subserved by GABA transporters, which may be impaired in the human dentate gyrus.[158] The molecular substrate for this phenomenon may be down-regulation of the underlying transporter proteins.[93,124] Impaired uptake of GABA may underlie prolonged $GABA_A$-mediated responses in hippocampal sclerosis.[199] Metabotropic $GABA_B$ receptors inhibit neurotransmitter release from presynaptic terminals and mediate the late inhibitory postsynaptic potential. The expression of $GABA_B$ receptors has been examined in human temporal lobe epilepsy using various approaches, including in situ hybridization, immunohistochemistry, and ligand labeling.[164] Given the significant changes in synaptic properties as well as the profound changes in Ca^{2+} dynamics and handling, it is not surprising that synaptic plasticity is greatly impaired in hippocampal sclerosis.[20]

Intrinsic Neuronal Properties in Hippocampal Sclerosis

In addition to synaptic properties, the inputâ€“output relation of neurons also depends on intrinsic membrane properties of dendrites that influence the propagation of synaptic potentials toward the cell body. At the cell soma and axon initial segment, intrinsic neuronal properties shape the neuronal firing pattern following synaptic activation. Thus, activity-dependent changes in the inputâ€“output relations of neurons that increased excitability may involve alterations either in synaptic strength and/or in intrinsic membrane properties. In human hippocampal sclerosis, our knowledge about changes in intrinsic properties of neurons is limited compared to the extensive literature from animal models. Nevertheless, changes in the expression or regulation of different classes of voltage-gated ion channels have been described. Changes on a transcriptional level have been found for Na^+ channel subunit expression in human epilepsy.[105,196]

Both pore-forming and auxiliary voltage-gated Ca^{2+} channel subunits have also been shown to be differentially expressed in human hippocampal sclerosis using immuno-histochemistry.[57,98] Notably, astrocytes, which usually do not express calcium channel subunits, were strongly immunoreactive for a Ca^{2+} channel subunit mediating L-type Ca^{2+} currents in hippocampal sclerosis, suggesting that Ca^{2+} channel subunits may be ectopically expressed. It should be noted that voltage-gated calcium channels are powerfully regulated by second messenger systems, as well as by the intracellular calcium concentration. It appears that regulation of human hippocampal calcium channels by intracellular calcium may be altered in hippocampal sclerosis, due to loss of the intracellular calcium-binding protein calbindin D-28k. The loss of this protein from hippocampal neurons markedly increased the Ca^{2+}-dependent inactivation of voltage-dependent Ca^{2+} currents, thereby diminishing Ca^{2+} influx during repetitive neuronal firing.[147] In addition, other voltage-gated channels such as the H-current, a mixed cationic current activated by hyperpolarization, are also regulated in hippocampal sclerosis in a cell-typeâ€“specific manner.[21]

In summary, seizure activity and neuron loss associated with hippocampal sclerosis may evoke multiple transcriptional modifications of ion channels. In addition, there are examples of posttranslational modifications of ion channel proteins.[22] There is also evidence for altered regulation of ion channels by accessory subunits, the lipid environment, or intracellular Ca^{2+}.[147] Thus, the picture of changes regarding voltage-gated ion channels in human epilepsy is far from complete, and in parts is at odds with experimental models of epilepsy. A concerted effort will be required to determine which of the many potential intrinsic changes are relevant for human epilepsy with hippocampal sclerosis.

Metabolic Dysfunction and Energy Failure in Hippocampal Sclerosis

Metabolic dysfunction has been implicated in the pathogenesis of temporal lobe epilepsy, and the cellular basis for this effect is beginning to emerge. In hippocampal sclerosis, as well as lesion-associated epilepsy, fluorescent recording of NADP(H) levels has revealed changes indicative of impaired energy supply in the dentate gyrus, CA3, CA1, and subiculum regions.[87] It is likely that altered mitochondrial function contributes to this effect. Mitochondria are cellular organelles crucial for energy supply and calcium homeostasis in neurons, and their dysfunction causes seizure activity in some rare human epilepsies. Indeed, temporal lobe epilepsy patients with hippocampal sclerosis show specific deficiency of complex I of the mitochondrial respiratory chain in hippocampal tissue. In contrast, temporal lobe epilepsy patients with a parahippocampal epileptic focus showed reduced complex I activity only in parahippocampal tissue.[92] Functional experiments revealed that the observed reduction in complex I activity is sufficient to affect the adenosine triphosphate production rate.

Glial Dysfunction in Hippocampal Sclerosis

Glial cells have classically been thought to mediate homeostasis of the extracellular space. This includes controlling activity-dependent rises in extracellular K^+, uptake of neurotransmitters, and metabolic support of neurons. While glial cells have recently been shown to be capable of subserving functions initially thought to be exclusively neuronal, astrocytes do mediate extracellular space homeostasis in the normal central nervous system (CNS). There are several lines of evidence suggesting that these functions are disrupted in human hippocampal sclerosis.[175,193] First, uptake of K^+ into astrocytes seems to be impaired in hippocampal sclerosis.

This is suggested by experiments in which the K^+ channels primarily mediating astrocytic K^+ uptake were blocked with low concentration of Ba^{2+}. Following application of Ba^{2+}, stimulation-induced rises in the extracellular K^+ concentration measured with ion-selective microelectrodes were strongly increased in nonsclerosis human hippocampal specimens. In marked contrast, Ba^{2+} effects were lost in hippocampal sclerosis specimens, which is consistent with a loss of glial Ba^{2+}-sensitive K^+ uptake pathways.[71,72,89] Indeed, a careful examination of K^+ channels expressed in astrocytes has revealed that inwardly rectifying K^+ current densities are significantly smaller in astrocytes from the hippocampal sclerosis group compared with lesion-associated temporal lobe epilepsy patients.[77]

Experimental studies have shown that clearance of extracellular K^+ is compromised by removal of the perivascular pool of the water channel aquaporin 4 (AQP4)[2] or knockout of this protein,[24] suggesting that an efficient clearance of K^+ depends on a concomitant water flux through astrocyte membranes. AQP4, the predominant water channel in the brain, displays pronounced changes in human hippocampal sclerosis. Overall, a significant increase in AQP4 was observed in sclerotic, but not in nonsclerotic, hippocampi.[94] A more detailed analysis,

however, revealed that the density of AQP4 along the perivascular membrane of astrocytes was in fact strongly reduced in sclerotic versus nonsclerotic hippocampus.[61] These findings are also interesting because the increase in the T2-weighted signal in magnetic resonance imaging and the higher diffusion coefficient in diffusion-weighted imaging indicate higher water content in hippocampal sclerosis in vivo.

Taken together, these studies suggest impaired K^+ handling in hippocampal sclerosis. This would be expected to result in a more pronounced and prolonged depolarization of glial cells and neurons in response to activity-dependent K^+ release. Indeed, induction of epileptiform activity in human hippocampal slices by elevation of extracellular K^+ requires smaller increases in K^+ in slices displaying hippocampal sclerosis compared to nonsclerosis slices.[72]

Neurogenesis and Granule Cell Dispersion

It was long held as an axiom of neurobiology that new neurons are not produced in the adult brain. It has now become clear that niches in the adult brain of rodents contain neuronal precursors that continue to produce new neurons throughout life. Whether this occurs in the normal adult human brain with hippocampal sclerosis is still unclear. One such area is the subgranular zone in the hippocampus, in which the generation of new dentate granule cells persists throughout life in rodents.[91] In humans, it has been possible to demonstrate generation of new granule cells in terminally ill cancer patients receiving bromodeoxyuridine (BrDU), which can be used to label dividing cells in vivo.[66] It has also been possible to isolate multipotent precursor cells from human dentate gyrus that can give rise to functional neurons in culture.[143] It is well established that neurogenesis in the dentate gyrus is increased in animal models of mesial temporal lobe epilepsy.[154,155,156] In human epilepsy, demonstrating increased neurogenesis unequivocally has been more difficult, primarily because labeling dividing cells in vivo is not possible. Nevertheless, a few studies have shown increased expression of division markers, as well as increased expression of markers labeling neural progenitors and immature neurons in patients with temporal lobe epilepsy. These include, among others, Musashi-1, a marker of neural progenitors, nestin, doublecortin, and the polysialated neural cell adhesion molecule PSA-NCAM.[29,50] These findings suggest the possibility that neural progenitors proliferate in hippocampal sclerosis. However, hippocampal sclerosis patients do not demonstrate increased granule cell neuronal densities arguing against neurogenesis, and children with severe epilepsy demonstrate evidence for decreased granule cell neurogenesis.[115,121]

The generation of new neurons in the epileptic dentate gyrus raises the question of where and how these neurons integrate into the pre-existing neuronal network. A systematic analysis of where newly generated neurons incorporate has revealed that progenitors migrate aberrantly to the hilus and molecular layer after prolonged seizures and differentiate into ectopic dentate granule cells (DGCs) in rats.[153] In human hippocampal sclerosis, ectopic putative DGCs were also found in the hilus and molecular layer of epileptic human dentate gyrus. Furthermore, hippocampal sclerosis is frequently accompanied by granulecell dispersion, a broadening of the granule cell layer suggestive of aberrant migration.[78]

It has been speculated that granule cell dispersion results from abnormal positioning of newly generated granule cells. The positioning of granule neurons in the dentate gyrus is controlled by the reelin protein, which acts as a stop signal for migrating neurons. In human hippocampal sclerosis, numbers of calretinin-containing putative Cajal-Retzius cells were increased.[27] Interestingly, expression of reelin mRNA by hippocampal Cajal-Retzius cells is decreased, and correlates with the extent of granule cell dispersion, raising the possibility that decreased reelin production may contribute to granule cell dispersion in human temporal lobe epilepsy.[74] It is also possible that other proteins such as, for instance, cystatin C, a protease inhibitor linked to both neurodegeneration and neurogenesis, may play a role in granule cell dispersion.[162] However, it should be noted that granule cell dispersion is observed in only 50% of patients with hippocampal sclerosis (not all cases), has not been observed in children with early-onset epilepsy, and has been found in circumstances of hippocampal damage without seizures.[76,120,123] Thus, the etiology of granule cell dispersion, its relationship with neurogenesis, and the role these cells might play in epileptogenesis remains unclear.

Summary and Conclusions

Since its discovery in the 19th century, much has been learned about hippocampal sclerosis and its relation to temporal lobe epilepsy. The pace of discovery has accelerated, particularly with the increased availability of human tissue following temporal lobe resections and the application of the tools of cellular and molecular neurobiology. There are still many unanswered questions, however, and we still do not know how to treat mesial temporal lobe epilepsy without surgery. There are also a number of clinically important questions that remain to be answered. For example, it is not clear why only a minority of patients exposed to initial precipitating brain injuries, like childhood febrile convulsions, develop hippocampal sclerosis and temporal lobe epilepsy. What are the genetic or clinical factors that predispose an individual to developing sclerosis after being exposed to injuries that otherwise do not harm others? Are there surrogate markers that can be used to identify individuals at risk for developing hippocampal sclerosis after an initial precipitating injury? Can the processes, like synaptic reorganization, that convert a damaged hippocampus into one capable of producing seizures be identified and, more critically, be augmented or prevented? What are the molecular markers and processes that produce seizures in hippocampal sclerosis?[152] Can we begin to take what appear to be diverse findings from molecular and electrophysiologic studies and convert them into a unified global hypothesis of epileptogenesis in hippocampal sclerosis? Can these ideas lead to treatments without surgery, or at least prevent late recurrent seizures after surgical treatment? These and other questions pose future challenges to the study and treatment of temporal lobe epilepsy patients with hippocampal sclerosis.

Gary W. Mathern

Introduction

Structural lesions associated with epilepsy can be categorized into the following groups: (a) malformative, (b) neoplastic, (c) familial/metabolic, (d) vascular/traumatic, (e) infectious/inflammatory, and (f) associated with Ammon's horn (hippocampal, mesial temporal) sclerosis.[44,184] Several authors have suggested that some of these pathologic processes may overlap in epilepsy patients,[12,16] and *dual pathology* (e.g., a corticectomy showing features of both a malformative and destructive lesion) may occasionally be encountered.[116] Some of the causal lesions are amenable to definitive surgical treatment (e.g., low-grade neoplasms), whereas others (e.g., metabolic diseases) frequently undergo diagnostic brain biopsy, sometimes unintentionally. This chapter focuses on developmental malformations of the neocortex that account for the majority of structural lesions seen in infants and children with intractable epilepsy, especially those with infantile spasms (IS). (The other categories of *epileptogenic* structural lesions are discussed elsewhere.) More subtle malformations are also recognized with increasing frequency in adults with epilepsy.

Neocortical malformations have usually been considered to represent developmental disorders of neuronal migration (or vascular formation), and have variously been classified with regard to morphology or putative etiology.[8,135,138] The categorization of these heterogeneous lesions is increasingly being modified by (a) the availability of high-resolution multimodality neuroimaging techniques that can be used to predict pathologic abnormalities in a given patient[24,26,158] and (b) molecular genetic clues to pathogenesis based on techniques such as gene expression profiling following laser capture microdissection of surgical specimens.[32] The genetic basis of some types of lissencephaly (e.g., Miller-Dieker syndrome) is now quite well understood.[32,147] They can be roughly categorized as follows: (a) cortical dysplasia (CD), which accounts for the majority of malformations associated with pediatric epilepsy and encompasses the full spectrum of neuronal migration disorders (NMDs), sometimes also described as malformations of cortical development (MCDs), ranging from the most subtle to the most severe; (b) structural lesions associated with tuberous sclerosis complex (TSC); (c) Sturge-Weber-Dimitri syndrome (SWDS), also known as encephalotrigeminal angiomatosis; (d) neurofibromatosis type 2, which may be associated with meningio-angiomatosis; and (e) vascular malformations.

This chapter discusses clinicopathologic associations between the recognized pediatric epilepsy syndromes and their neuroradiologic and neuropathologic substrates. We review the terminology used to characterize these complex malformative lesions in the light of modern neuroimaging data. We give a brief overview of development of the cerebral cortex and identify the points of susceptibility at which the error or errors (genetic or environmental) resulting in cortical malformations may occur.

Clinicopathologic Features

Epilepsy has traditionally been classified into syndromes based on clinical presentation and electroencephalographic (EEG) findings. However, there is often a marked discrepancy between the clinical phenomenology of a seizure disorder and its neuropathologic substrate(s). Infantile spasms (IS, West syndrome) and Lennox-Gastaut syndrome can be seen with a wide range of cerebral lesions,[69,106,153] indicating the nonspecific nature of these seizure disorders. The clinical form of epilepsy seen in a given patient appears to depend more on *when* during cerebral development the lesion occurred than on the specific *type* or topographic distribution of lesions.[69,108] It has been suggested that the central nervous system (CNS) lesions associated with IS can be functionally categorized into three groups: (a) diffuse, (b) focal or multifocal cerebral lesions, and (c) cases with minimal neuropathologic change.[153] Diffuse hemispheric lesions include hemimegalencephaly (HME), agyria/pachygyria-lissencephaly, and Aicardi syndrome.[1] Focal and multifocal lesions include CD and destructive lesions (vascular and infectious), as well as cortical tubers seen in patients with TSC.

Developmental malformations of the neocortex (malformations of cortical development, MCDs) can be considered a spectrum of CD resulting from derangement of the normal process of cortical development.[117,120,130,131,142] This spectrum consists of a range of morphologic features associated with multiple putative etiologic factors, including genetic and environmental (e.g., destructive) influences. CD encompasses the full spectrum of neocortical malformations, ranging from the most subtle (*microdysgenesis*) to the most severe (HME), and includes such conditions as agyria/pachygyria-lissencephaly, polymicrogyria (PMG), and focal CD. CD, therefore, comprises a spectrum of derangements in neocortical development that are associated with a range of morphologic features and with multiple putative etiologic factors, including genetic and environmental influences. The resultant neuropathologic features may reflect abnormalities that probably occur within discrete time windows during brain development. Clinically there is an inverse correlation between the size and severity of CD and the age at clinical presentation,[26,117] supporting the notion that there is a predominance of pathologically severe CD in neonates and infants with seizures, including those

P.138

with IS.[73] Although CD accounts for the majority of malformations associated with pediatric epilepsy, other malformative lesions are also capable of producing these epilepsy syndromes, and they frequently show neuropathologic changes that overlap significantly with those seen in patients with CD.

Jellinger[69] noted that the clinical severity of a given seizure disorder appears to be more closely related to the *timing* of the insult (whether genetic or environmental) and its effect on the processes of development than to the nature of the lesion itself. This may explain some of the heterogeneity of neuropathologic lesions seen in children with epilepsy because the clinical phenotype results not only from the lesion or putative insult to the developing CNS, but also from the developmental processes it affects.

A puzzling feature noted in pediatric epilepsy is the finding in cases of IS of diffuse and transient suppression of cortical activity in the presence of focal or multifocal lesions.[153] This diffuse cortical suppression has not been linked to particular distributions or types of neuropathologic change. Rather, Robain and Vinters suggested that this feature of IS is associated with neocortical immaturity.[153] The pattern of evolution of IS from transient and diffuse suppression of cortical discharge to ultimately focal or generalized seizures may represent a maturation of the malformed cortex.[153]

Nosology

The nosology and understanding of the full spectrum of CD are evolving and reflect a progressive elucidation of the basis of these extremely complex lesions. Initially, cortical malformations were referred to largely by their gross characteristics (i.e., agyria/pachygyria-lissencephaly, HME, microgyria). As investigators discovered the range of microscopic cortical malformations that produce epilepsy but show no (or relatively mild) gross abnormalities, additional terms such as *microdysgenesis*,[57,107,108] *dysplastic cortical architecture* (not otherwise specified),[157] *focal cortical dysplasia*,[119,174] and *generalized or diffuse cortical dysplasia*[78,83,96] were added to the literature. The nomenclature of CD has evolved through several schema of classification, each intended to provide correlations with morphology of seizures and reflect etiologic mechanisms.[8,9,117] *Focal cortical dysplasia* was initially used to specify lesions in which cytomegalic neurons were present,[174] although its frequent use to refer to a localized *region* of CD renders the term somewhat ambiguous. Some investigators prefer to use a traditional classification of migrational disorders into four main groups: (a) agyria/pachygyria-lissencephaly, (b) microgyria-polymicrogyria, (c) dysplastic cortical architecture, and (d) heterotopias.[157] Others, to denote the belief that these lesions are related and reflect developmental abnormalities along a continuous spectrum, have chosen to refer to this group of lesions as neuronal migration disorders or *NMDs*,[8,130,131] *cerebral dysgenesis*,[159] or *synaptic dysgenesis*.[13] The nosology of developmental neocortical malformations will continue to evolve, especially in the era of high-resolution magnetic resonance imaging (MRI), and reflect a progressive understanding of the underlying biology of these complex lesions (see Chapter 259). A recent consensus conference resulted in a proposal to subclassify CD or grade its severity (in surgical resection specimens) using simple morphologic criteria identifiable by any experienced neuropathologist, for example, presence or absence of cortical disorganization, enlarged or dysmorphic neuronal cell bodies, and â€œballoon cellsâ€ (see later discussion).[132] This classification scheme has been adopted widely enough that surgical pathology reports on corticectomy specimens now frequently contain the terminology â€œ*Cortical dysplasia, Palmini type*â€¦.â€

Development of the Neocortex

Overview of Neocortical Development

The neuropathologic changes seen in children with epilepsy frequently represent the end results of insults to a rapidly developing brain. This section briefly summarizes the normal process of neocortical development and identifies the points of susceptibility at which the error or errors (genetic, environmental, or both) result in cases of pediatric epilepsyâ€"usually due to CD. We also briefly introduce some recent advances in the genetic and molecular mechanisms that regulate cortical development. Many excellent reviews have summarized the historical evolution in our understanding of the complex neurobiologic, cellular, and molecular processes that work in concert to create a normally functioning cerebral cortex.[30,52,67,141,160] Neocortical development after neural tube formation can roughly be considered to be the result of a series of overlapping processes: (a) cell proliferation in the ventricular zone and subventricular zone (VZ/SVZ), (b) early differentiation of neuroblasts and glioblasts, (c) programmed cell death of neuronal precursors and neurons, (d) migration of neuroblasts to form the cortical plate, (e) late neuronal migration, (f) organization and maturation of the cortex, and (g) synaptogenesis.[1,8,157,175] Abnormalities of these processes result in abnormalities of cortical architecture and, by inference, its electrophysiologic properties. Most developmental disorders of the brain commonly associated with epilepsy are believed to originate from the perturbation of developmental events *after* the embryonic period, i.e., after 6 weeks' gestation, when cell proliferation starts along the wall of the neural tube. This generates a collection of matrix cells,[45] or precursor cells for all neuroblasts and glioblasts, forming ventricular and subventricular zones (VZ/SVZ) in the pallium, as well as the ganglionic eminence in the subpallium (Table 1).

Table 1 Major stages of human central nervous system development and associated epileptic disorders

Stages	Time of occurrence (wk)	Morphologic changes and events	Corresponding disorders commonly associated with intractable epilepsy
Embryonic period			

Formation and separation of germ layers	2	Neural plate	Enterogenous cysts and fistulas Split notochord syndrome
Dorsal induction: primary neurulation	3â€“4	Neural tube, neural crest and derivatives	Anencephaly, encephalocele
		Closure of rostral and caudal neuropores	Chiari malformation
Ventral induction: telencephalization	4â€“6	Development of forebrain and face	Holoprosencephaly
		Formation of cerebral vesicles Optic and olfactory placodes	Dandy-Walker malformation
Fetal period			
Neuronal and glial proliferation	6â€“16	Cell proliferation in ventricular and subventricular zones	Microcephaly Hemimegalencephaly
		Early differentiation of neuroblasts and glioblasts	Cortical tuber of tuberous sclerosis Cortical dysplasia with balloon cells
		Programmmed cell death	Dysembryoplastic neuroepithelial tumor ganglioglioma, gangliocytoma
Migration	12â€“24	Migration of cortical neurons	Type I lissencephaly
		Formation of corpus callosum	Type II lissencephaly (cobblestone) Heterotopia

Perinatal period			
Organization	24 to postnatal	Late neuronal migration	Polymicrogyria, schizencephaly
		Organization and maturation of cerebral cortex Synaptogenesis	Cortical dysplasia without balloon cells Mild cortical dysplasia â€œMicrodysgenesisâ€
Myelination	24 to 2 yr postnatally		Destructive lesions Myelination disorders

Modified from Aicardi (1992), Barkovich et al. (2005), and ten Donkelaar et al. (2006).

Programmed cell death (PCD) is an essential mechanism for normal brain development, determining the size and shape of the nervous system. In normal brain development, there is a 25% to 50% overproduction of neuroblasts; these undergo physiologic PCD.[159] Neuroblasts and glia undergo this process as well. PCD appears to be under tight genetic control, as demonstrated in the *Caenorhabditis elegans* model.[39] It is an active process that can be blocked by inhibitors of protein synthesis and RNA transcription.[70] Failure of PCD may lead to mechanical barriers to migration and abnormal numbers of neurons. Supplemental to PCD, there is a conspicuous elimination of synapses occurring during development that is essential to remodeling of the cortex.[140] This may be accomplished by different mechanisms, and competition for trophic substances has been suggested as one. Synapse elimination is highly intertwined with the remodeling of cortical connections and is a highly dynamic process[140] demonstrated both in vivo and in vitro.[180]

Terminal differentiation of a neuroblast appears to be a multistep process.[22,102,128] Cell surface properties and extracellular matrix molecules play a crucial role in influencing migration and terminal differentiation of neuroblasts. Neural adhesion and migration are governed by a series of morphoregulatory molecules, cell-adhesion molecules (CAMs), and substrate-adhesion molecules (SAMs). CAMs

P.139

are transmembrane molecules bearing extracellular domains that are homologous to domains of the immunoglobulin superfamily[38] and are engaged in homotypic binding. The binding functions interact with the cytoskeleton because CAMs are transmembrane molecules. These molecules are involved in cell adhesion, axon binding, growth cone interactions, and other migrational mechanisms. SAMs, extracellular matrix molecules, are involved in the regulation of cell shape, motion, and process extension.[36] These molecules are expressed in a spatial-temporal fashion and are under the control of homeobox-containing genes that are known to govern place-dependent morphology.[74,75] The time-dependent levels of expression of the molecules are characteristic of a given anatomic area but are dynamically regulated and subject to local influences. The activities of these molecules are further modulated by neural activity itself.[37] These morphoregulatory molecules can mediate neuronâ€“neuron interactions (NCAMs), neuronâ€“glia interactions (Ng-CAMs), or neuronâ€“extracellular matrix interactions.[30,60,61] Extracellular matrix molecules also appear to be important in cell motion, attraction, repulsion, and growth cone migration; soluble trophic factors have an important role in these processes.[34]

Radial Migration of Neuroblasts from the Subventricular Zone

Radial migration refers to the process by which neuroblasts from the VZ/SVZ migrate along the processes of radial glia to reach the (neo)cortex. Radial glia initially have cell bodies in the ventricular zone and end-feet on the pial surface; with time, they detach themselves from the ventricular lining and migrate toward the cortex.[32a,41] They function as a permissive scaffold on which neuroblasts may migrate from the ventricular zone to the cortical plate.[60] At approximately 4 weeks' gestation, the neural tube forms with a simple pseudostratified neuroepithelium, component cells of which then proliferate around the developing ventricular system, eventually becoming the ventricular zone. The ventricular zone can be described as a mosaic of precursors that will give rise to neurons, astrocytes, and oligodendroglia, as demonstrated using retroviral markers.[139] The first postmitotic cells form the preplate or primordial plexiform layer[98,110,112,168,194] above the ventricular zone and beneath the pia. Toward the end of the embryonic period, cells from the ventricular zone migrate to form the cortical plate within the preplate; that is, the cortical plate is formed dividing

the preplate (preplate splitting) into (a) a thin superficial component, the marginal zone, and (b) a thick, deeper component, the subplate. The intermediate zone or future subcortical white matter also appears by this stage,[157] and this cortical plate formation continues until 16 weeks' gestation.[9] The neocortex is formed in an â€œinside-outâ€ fashion: Neuroblasts born first, destined for the deepest cortical layers, migrate first, whereas neuroblasts born later, destined for the more superficial cortical layers, migrate past the already present cortical neuroblasts,[6] eventually forming a six-layered structure.[163] Even after this point, however, neuroblasts continue to migrate through the intermediate zone (future white matter) to the cortex, a process that can continue up to a few months after birth.[163] Abnormalities of radial glia may occur through various molecular mechanisms either focally or diffusely in malformations of cortical development (MCDs), including Fukuyama congenital muscular dystrophy (FCMD)[169] and tuberous sclerosis complex (TSC).[133] Alterations of signaling pathways that regulate microtubule dynamics either directly or indirectly may also result in a derangement of radial glial fibers, as has been demonstrated in *reeler* mice[64] and *Lis1* mutant mice.[19] Radial glia have long been known to serve as guides for migrating neuroblasts and finally give rise to cortical astrocytes. However, recent evidence in mice indicates that radial glial cells also generate neurons in the developing cerebral cortex. Three distinct subsets are thus identified, including subpopulations important in gliogenesis, neurogenesis, and both.[7,58]

Tangential Migration of GABAergic Interneurons From Ganglionic Eminence

Tangential migration refers to the process by which neuroblasts from the ganglionic eminence migrate in a nonradial, â€œneurophilicâ€ fashion, possibly along neuronal processes rather than radial glial fibers, moving tangential to the pial surface to form complex three-dimensional neural structures.[143] Ganglionic eminence, primarily considered to be a source of basal ganglia neurons, consists of three parts. The medial ganglionic eminence, derived from the diencephalon, gives rise to globus pallidus. The lateral ganglionic eminence, derived from the telencephalon, gives rise to the caudate nucleus and putamen. The caudal ganglionic eminence primarily gives rise to amygdala. Both lateral and median ganglionic eminences, however, are also involved in the formation of cerebral cortex. In fact, mechanically separating the ganglionic eminence from the cortex results in a loss of calbindin and Î³-aminobutyric acid (GABA)â€“positive neurons in the cortex,[2] and 35% of cortical GABAergic interneurons arise form both ganglionic eminences by way of tangential migration.[3,87] This contrasts with the origin of pyramidal neurons of the cerebral cortex, which arise from the ventricular zone of the pallium by way of radial migration. Although 65% of cortical GABAergic interneurons arise from the ventricular zone of the pallium, they are considered to migrate in nonradial, neurophilic fashion at least within the VZ/SVZ.[87] Migration of GABAergic interneurons seems to be much more complex, because â€œventricle-directed migrationâ€ has also been demonstrated in mice.[122] GABAergic interneurons are immunoreactive for calcium-binding proteins such as calbindin. Studies of macaque monkey brain have suggested that calcium-binding-proteinâ€“containing interneurons make up 90% of all GABAergic neurons in the cerebral cortex.[91] The number and distribution of calcium-binding-proteinâ€“containing neurons in the neocortex can be reorganized in early postnatal life[149]; by 28 weeks after birth, the laminar distribution of calbindin-immunoreactive cells shifts from layer IV to layer II. It has been suggested that doublecortin (DCX) is important for nonradial migration because it is rather selectively expressed in tangentially oriented postmitotic neurons in the subventricular and intermediate zones.[113]

Origin of Cajal-Retzius Cells and Their Biologic Significance

The marginal zone, future molecular layer or cortical layer I, is composed largely of Cajal-Retzius cells. They secrete the extracellular glycoprotein reelin that is required for the normal inside-out positioning of neurons as they migrate from the ventricular zone along radial glia. Human Cajal-Retzius cells, characterized by the combined expression of reelin and p73, are transient cells, are present from the preplate stage at 8 weeks' gestation, and gradually increase in number (by tangential migration) until they disappear by the end of gestation.[110,113] One possible origin of Cajal-Retzius cells is considered to be the boundary between prospective hippocampus and choroid plexus epithelium or â€œcortical hemâ€ in the dorsal telencephalon.[113] In mice carrying mutations in *RELN* (*reeler* mice) and in *disabled-1* (*Dab1*) as well as in mice carrying double mutations of both very low density lipoprotein receptor (*VLDLR*) and apolipoprotein E receptor 2 (*ApoER2*), normal neuroblast migration with an inside-out fashion is inverted.[178] This suggests a role for these genes in the control of cell positioning in the developing central nervous system and even predicts a pattern of cytoarchitectural alteration in patients carrying alterations in the reelin/lipoprotein receptor/Dab1 pathway, as well as *RELN* mutations causing lissencephaly.[63] LIS1 also appears to have important effects on neuronal migration, and significant interactions with Cajal-Retzius cells: LIS1 deficiency negatively affects the migration and differentiation of both doublecortin- and reelin-positive neurons in the developing human brain.[114]

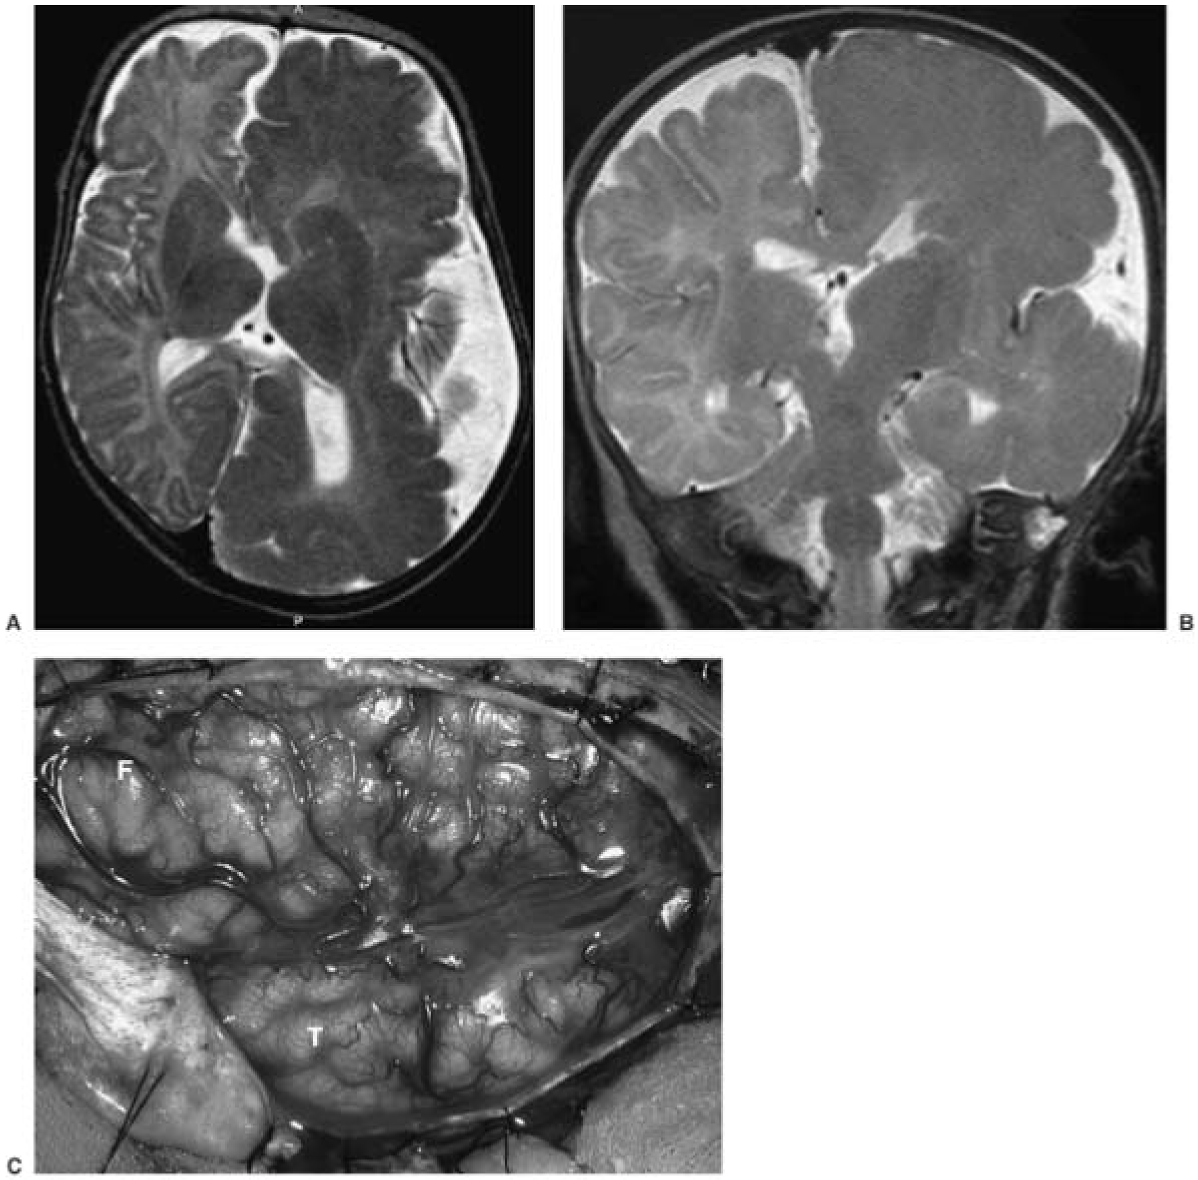

FIGURE 1. Hemimegalencephaly (HME) in a 6-month-old child. Axial **(A)** and coronal **(B)** T2-weighted magnetic resonance imaging (MRI) images show markedly enlarged left cerebral hemisphere with thickened gyri and smooth surface, consistent with HME. The left lateral ventricle and caudate head are deformed. White matter is diffusely hypointense compared with the unaffected right cerebral hemisphere, suggesting accentuated myelination. **C:** Intraoperative photograph of the region of HME oriented with the frontal lobe (F) in the top left and the temporal lobe (T) in the lower middle portions of the image. Notice the diffuse cortical disorganization of all gyri. This child had a monozygotic twin who was normal. (Panel B is from Salamon N, Andres M, Chute DJ, et al. Contralateral hemimicrencephaly and clinical-pathological correlations in children with hemimegalencephaly. *Brain*. 2006;129:352â€“365; with permission of the editor of *Brain* and Oxford University Press.)

Origin of Superficial Granular Layer and Its Biologic Significance

The superficial or subpial granular layer (SGL) is a transient cell layer and appears beneath the pial surface between 13 and 24 weeks' gestation.[18,44] Cells in the SGL originate from the basal periolfactory subventricular zone[18,46,111] and migrate tangentially beneath the pia to cover the neocortical marginal zone. Cells in this layer express interneuron markers such as calretinin, calbindin, and GABA,[145] suggesting that they are equivalent to GABAergic interneurons. The biologic significance of the SGL, however, remains to be elucidated. Programmed cell death may, at least in part, contribute to elimination of the SGL.[166] There is controversy in this research area because the SGL is also suggested to be an additional source of cortical interneurons; it disappears probably as the result of inward or ventricle-directed migration of its component cells.[122,144,145]

Subplate Neurons as Pioneer Cells to Form Early Thalamocortical Projections

The human subplate contains large multipolar neurons. Subplate neurons in the developing cerebrum, although they are transient and most disappear in early postnatal life, are believed to be important in organizing cortical connections in the developing cerebrum. They are believed to act as pioneer corticofugal axons.[29,49,50,101]

A B C

FIGURE 4. Axial FLAIR (fluid attenuated inversion recovery) **(A)** and T2-weighted axial **(B)** images demonstrate hyperintense signal area in the subcortical white matter of the right frontal operculum in a 4-year-old girl. The gray matter in this region is thickened, but there is no mass effect. The findings are suggestive of cortical dysplasia. **C:** View of the lesion intraoperatively (*arrow*). Histopathology of this lesion showed classic features of Palmini grade IIB cortical dysplasia. F, frontal lobe.

Neuropathology and Pathophysiologic Significance of Cortical Dysplasia

The Pediatric Epilepsy Surgery program at UCLA Center For the Health Sciences, active since 1986, has enabled us to examine over 500 surgically resected specimens from infants and children with intractable seizures, ranging from partial lobectomies to complete and partial (functional) hemispherectomies. The most common morphologic substrate for this was CD, this being of etiologic importance as a cause of intractable pediatric seizures in >80% of children <3 years of age. The extent of CD neuropathology can be predicted by high-resolution neuroimaging studies. Such neuroimaging allows for stratification of CD cases into those that show hemimegalencephaly (HME), with diffuse enlargement of the gray and white matter, including thickening of the cortical ribbon, within an entire cerebral hemisphere (Figs. 1 and 2); hemispheric CD, with multifocal CD affecting one cerebral hemisphere (although *not* causing enlargement of that hemisphere); and multilobar, lobar, or focal CD (Figs. 3 and 4), the latter affecting as few as one or two adjacent gyri. HME is easily recognized by neuroimaging. The MRI findings include an enlarged cerebral hemisphere and markedly thickened gyri, with loss of sulcation. There is deformity and enlargement of the ipsilateral ventricle. Palmini type IIB CD is also easily identified by MRI, with focal thickness of the gyrus (gyri) and associated hyperintense T2-weighted signal changes in the adjacent white matter. It is difficult to visualize Palmini type I CD by MRI; however, on combining this with other modalities, such as positron emission tomography (PET) and magnetic source imaging (MSI), the detectability of this

P.142

lesion increases and foci of subtle grayâ€"white matter blurring may be visualized intraoperatively.

Macroscopic heterotopia and polymicrogyria (PMG) are occasionally seen in resection specimens from such patients. Loss of the normal cortexâ€"white matter junction, best appreciated with a KlÃ¼ver-Barrera or other myelin stain, is a frequent accompaniment and excellent predictor of severe microscopic CD. Many specimens, however, exhibit no striking gross cortical abnormalities. CD can be further characterized with regard to specific and easily identifiable microscopic abnormalities,

P.143

which include cortical laminar disorganization (Fig. 5), single heterotopic white matter neurons, excess neurons in the neocortical molecular layer, marginal glioneuronal heterotopia, white matter neuronal heterotopia, neuronal cytomegaly with or without associated dysmorphic features of the cytoplasm (the latter almost invariably accompanied by cytoskeletal abnormalities) (Fig. 6), and balloon cell change (Fig. 7).[117] These microscopic features can be used as the basis for a grading system for CD; one widely used schema is that presented recently by Palmini et al.[132]

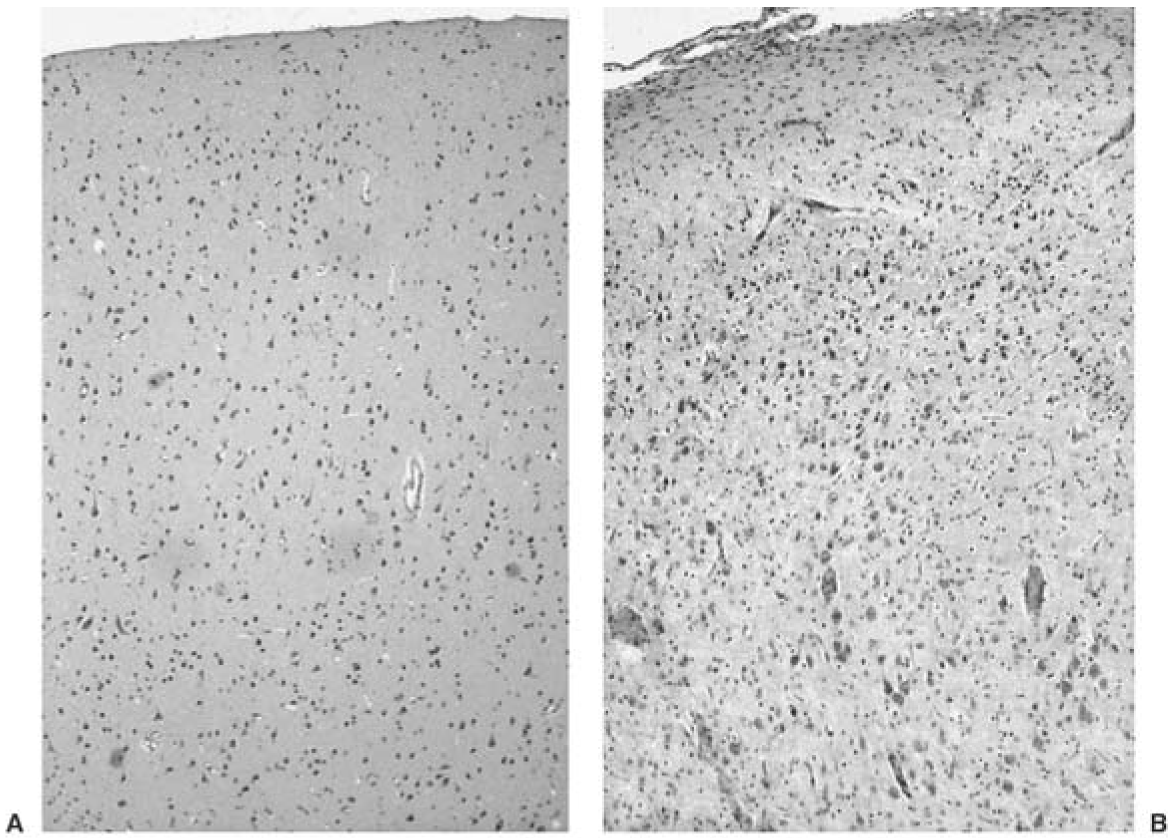

FIGURE 5. A: Relatively normally organized cerebral cortex from a surgical resection specimen. **B:** Region with severe cortical dysplasia shows pronounced cortical disorganization, with abnormal crowding of

neurons and abnormal orientation of many cells. Both panels are from micrographs photographed at the same magnification from sections stained with routine hematoxylin and eosin stains. (See the color insert.)

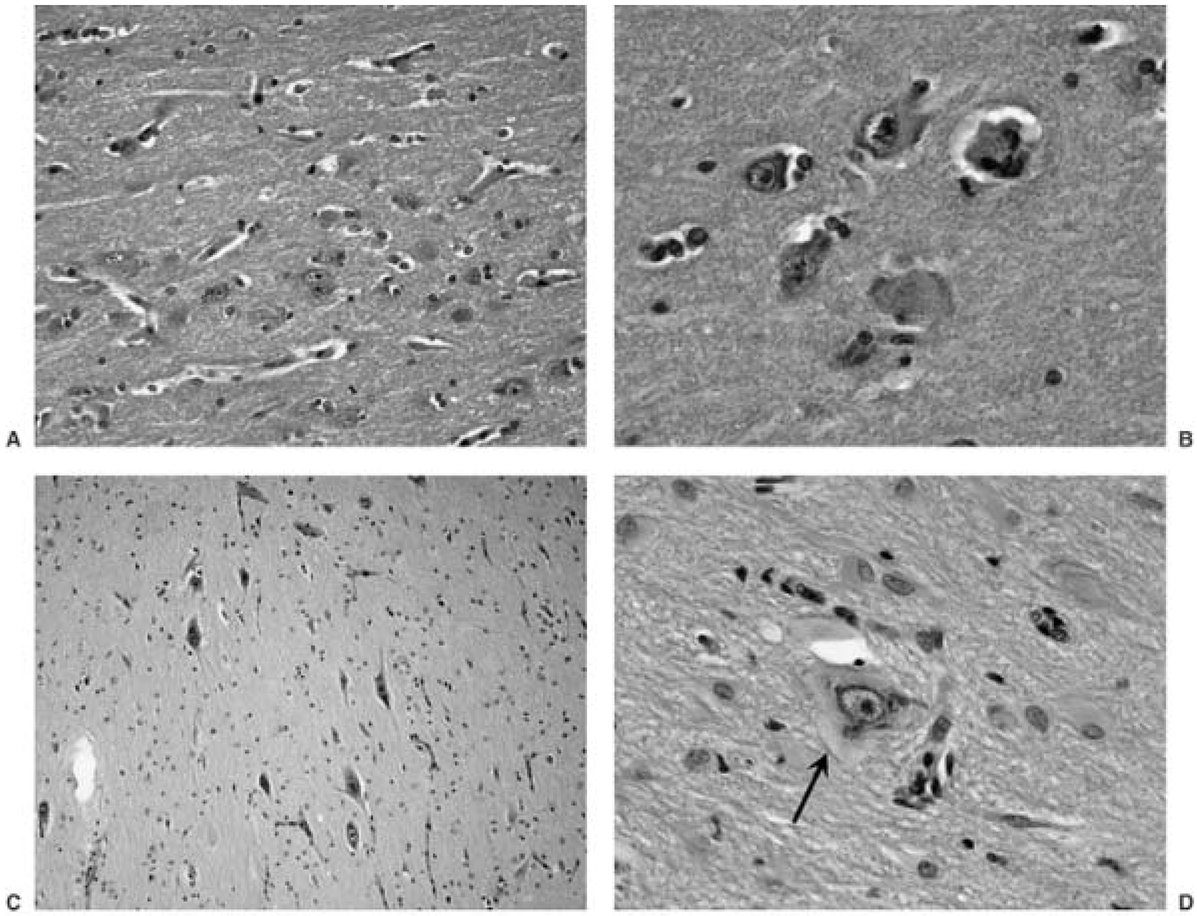

FIGURE 6. Neuronal disorganization and dysmorphism in cortical dysplasia/malformations of cortical development. **A:** Intermediate-magnification micrograph shows crowded and abnormally oriented neuronal cell bodies. **B:** Same features shown at a higher magnification. **C:** Variably enlarged and abnormally distributed neurons near the cortexâ€“white matter junction. **D:** Magnified view of a dysmorphic neuron (*arrow*) with clumping of Nissl substance around the nucleus and clearing of the peripheral cytoplasm. Gemistocytic astrocytes are seen distributed around this neuron. (All panels are from hematoxylin and eosinâ€“stained sections.) (See the color insert.)

Cortical laminar disorganization is the most ubiquitous microscopic finding, obviously because it represents a defining histopathologic feature of CD. Because neocortical architecture is the end result of the developmental processes of proliferation of neuronal precursors, migration, terminal differentiation, PCD, and cortical remodeling (see earlier discussion), abnormalities in any of these processes may result in abnormal cortical architecture. Cortical disorganization (as well as cytologic abnormalities in individual neurons, especially when fairly subtle) can be highlighted using immunohistochemistry that incorporates primary antibodies to neurofilament epitopes (Fig. 8). Although many neurons still reside in the intermediate zone/white matter in the last trimester of pregnancy and even into postnatal life,[80,163] the phenomenon of single heterotopic neurons in the white matter is accentuated in CD.[108] It is present in the majority of our patients with CD, and has been demonstrated in other series using morphometric techniques.[105] It has been suggested that injury to the radial glial fibers leads to a stranding of the migrating neuroblasts within the white matter, where they further differentiate into

mature neurons.[159] Alternatively, overproduction of neurons late in neurogenesis may lead to crowding of migrating neurons toward the cortical surface.[5] Morphometric analysis has also demonstrated a statistically significant increase in the number of neurons within the molecular layer of the cortex in epileptic patients versus controls,[107] and this is considered to be evidence of a slight maldevelopment of the neocortex, sometimes described as *microdysgenesis*, although this term is now felt to be imprecise and best avoided.[132] Persistence of the superficial granular layer (SGL) has been seen in association with many cortical malformations.[117] Marginal glioneuronal heterotopia consists of excrescences of disorganized neuroglial tissue extending from the pial surface into the subarachnoid space. They are often found in association with persistent SGL and tend to occur in the same brain region as the other malformations. These lesions may be associated with a failure of the glia limitans.[117] White matter neuronal heterotopia consists of disorganized masses of neurons in the white matter that usually occur in a periventricular position with a nodular morphology, although rare instances of laminar subcortical bands of heterotopic gray matter have been known to produce the appearance of a double cortex. It has been suggested that these are associated with injury to a group of radial glia, leading to failure of a group of neuroblasts to migrate.[159] Alternatively, a defect in genes controlling neuroglial interactions, neuroblast proliferation, and PCD has been suggested as being causal.[157]

PMG denotes small meandering gyri, often with bridging of the sulci by fusion of the molecular layers. It consists of two histologic types: Four-layered PMG is most frequently considered to result from a destructive lesion occurring approximately at 20 to 24 weeks' gestation, whereas an unlayered form is believed to result from an insult earlier in development (at approximately 13â€“16 weeks).[5] Whether PMG represents a destructive lesion with secondary malformation or a primary malformative lesion continues to be debated.[124,126,158]

Neuronal cytomegaly denotes enlarged neurons, some of which may also be dysmorphic (Fig. 9); these were first described by Taylor et al.[174] in association with seizure-producing focal cortical malformations or regions of dysplasia. Nerve cell hypertrophy was convincingly shown by Bignami et al.[15] using quantitative histochemistry in a case of HME. The differentiation of *cytomegalic* versus *dysmorphic* neurons is of importance in assigning a Palmini grade to a given lesion. Neurons that show enlargement of their cell bodies only are, in association with cortical architectural disorganization, typical of Palmini type IB lesions, whereas corticectomies that also contain dysmorphic neurons (defined as showing abnormalities of shape with abnormal orientation, cytoskeletal structure, and atypical dendritic arborizations) are characteristic of Palmini type II CD; when balloon cells are absent, the lesion is described as Palmini type IIA, and when they are present, it becomes Palmini type IIB. (Palmini IIB CD corresponds to what has been described as *Taylor-type focal cortical dysplasia* [T-FCD].) Dysmorphic neurons bear an extremely complex dendritic arborization as well as an abundance of perisomatic synapses and a paucity of axosomatic synapses.[28,154] Increased neuronal size has been associated with an increased DNA and RNA content, as well as increased nuclear and nucleolar volume suggestive of heteroploidy.[13,95] Many cytomegalic and dysmorphic neurons contain cytoskeletal abnormalities. Argyrophilic, neurofibrillary-like tangles, and cytoplasmic vacuoles have been demonstrated within many such neurons,[186] as has the existence of paracrystalline intracytoplasmic structures

visible on ultrastructural examination.[33] These neurofibrillary-like cytoplasmic inclusions are, like the neurofibrillary tangles seen in Alzheimer disease, strongly immunoreactive with antibodies to high- and medium-molecular-weight neurofilament (including phosphorylated and nonphosphorylated proteins), ubiquitin, and tau. However, they differ from the neurofibrillary tangles of Alzheimer disease in that they do not harbor paired helical filaments.[35] It is of interest that many cells within a focus of CD can coexpress neuronal and astrocytic epitopes, a phenomenon that can be easily demonstrated using confocal laser microscopy or immunohistochemistry on serial sections (Fig. 10).[32]

Balloon cells, showing considerable similarity to gemistocytic astrocytes, have eccentric nuclei and ballooned, opalescent eosinophilic cytoplasm (Fig. 7). They often demonstrate binucleation or dysmorphic nuclei, sometimes showing bridges of nucleoplasm between two separate islands of nuclear material within a cell.

They are noted to cluster at the cortexâ€“white matter junction or may be abundant within subcortical white matter.[32,184] Frequently, they are admixed with dysmorphic and enlarged neuronal cell bodies. Ultrastructurally, they are packed with filaments ranging in size from 400 to 600 nm in length and 30 nm in thickness, interspersed with nonâ€“membrane-bound, electron-dense, helical structures.[42] Vinters et al.[186] and others have demonstrated dual staining of many cells in dysplastic cortex (including some balloon cells) with antibodies to both neuronal and glial markers (synaptophysin and glial fibrillary acidic protein), implying either a failure of the cells to commit to a specific phenotype or a dedifferentiation. The resemblance of balloon cells to cells found within the cortical tubers of TSC has suggested the possibility that cases of CD harboring balloon cell change may represent a *forme fruste* of TSC,[32,42,130,131,155] as is discussed later. At least one group[179] has suggested that T-FCD (Palmini type IIB cortical dysplasia), when resected, has good postsurgical outcome.

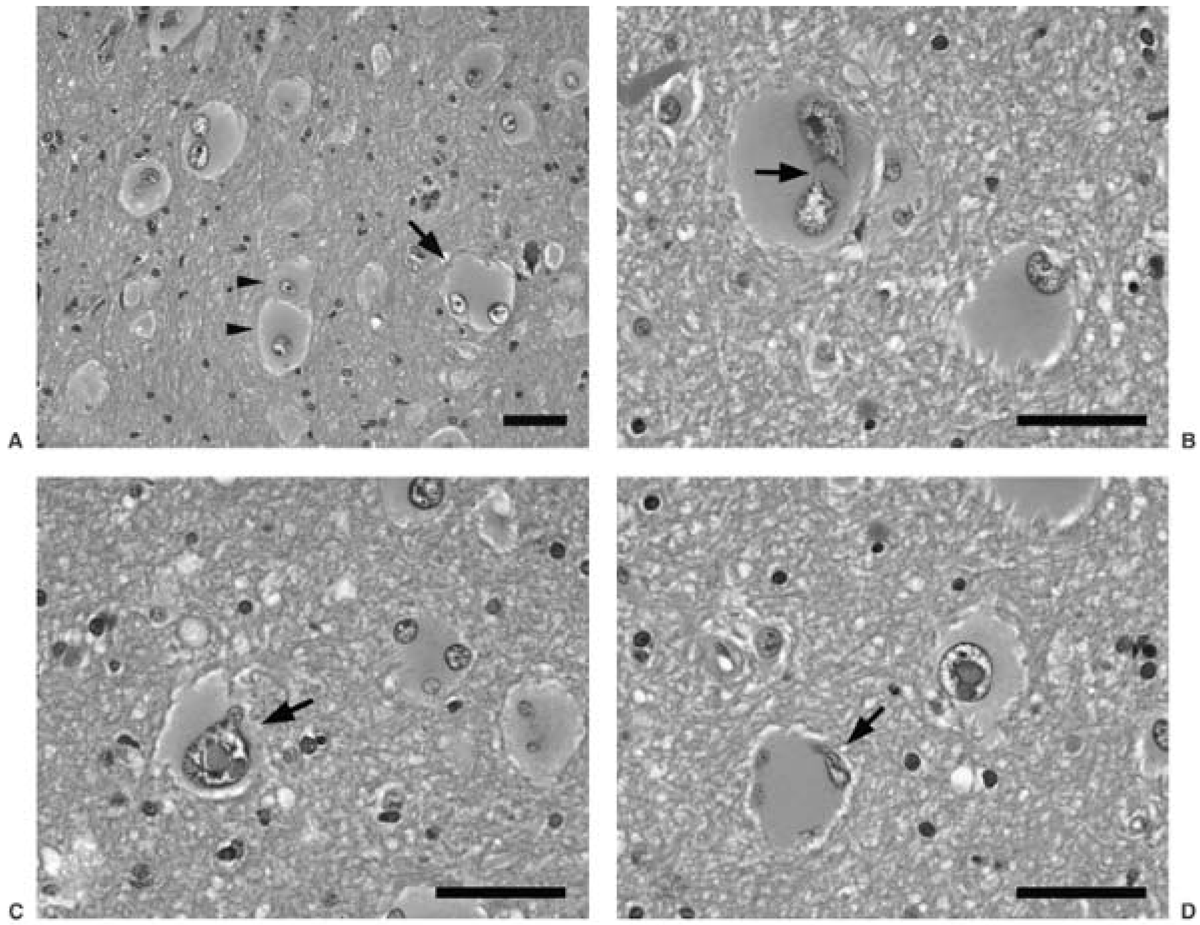

FIGURE 7. Typical balloon cells, with variably pronounced nuclear atypia. Hematoxylin and eosin stains. **A:** Balloon cells often show binucleation (*arrow*). Paired balloon cells are also seen (*arrowheads*). **B:** A balloon cell with a nuclear bridge connecting two nuclei (*arrow*). **C:** Balloon cell with marked nuclear atypia and/or nuclear invagination with nuclear budding (*arrow*). Also note the Marinesco body-like intranuclear inclusion. **D:** Balloon cell with multinucleation and/or micronucleation (*arrow*). Bars = 50 Âµm. (From Crino PB, Miyata H, Vinters HV. Neurodevelopmental disorders as a cause of seizures: neuropathologic, genetic, and mechanistic considerations. *Brain Pathol*. 2002;12:212â€“233; with permission.) (See the color insert.)

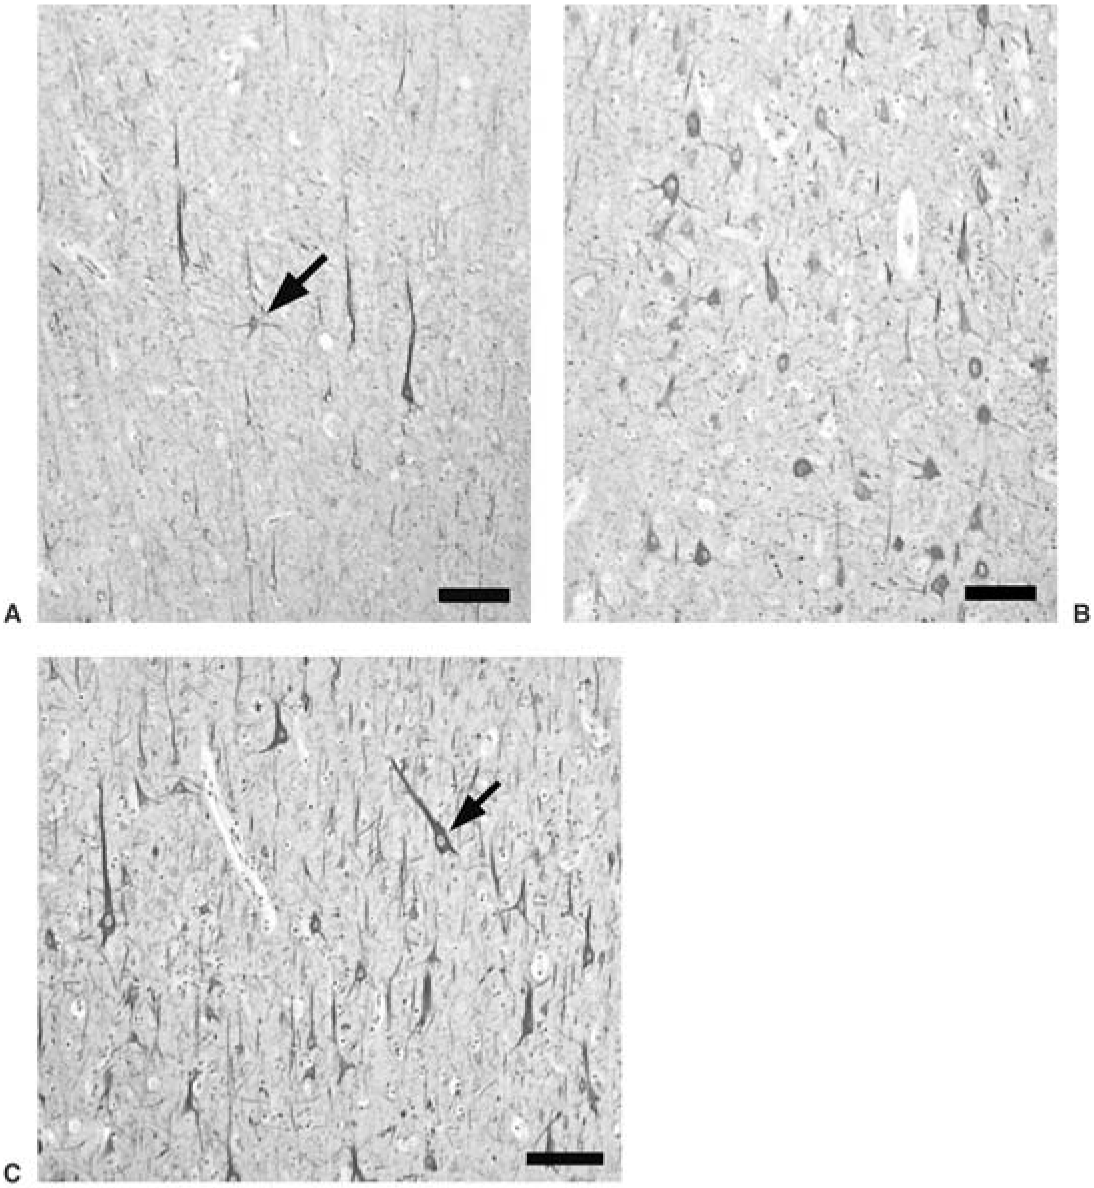

FIGURE 8. Neurofilament (N52, high-molecular-weight neurofilament antibody) immunohistochemistry of surgically resected corticectomies. **A:** Relatively normal cortex from a patient with temporal lobe epilepsy. Some, although not all, of the pyramidal neurons in layers III and V as well as multipolar interneurons (*arrow*) are positive for N52. **B:** Focal cortical dysplasia. Neuronal dyslamination and dysmorphic, multipolar, cytomegalic neurons are evident. **C:** Relatively normal cortex adjacent to a region of cortical dysplasia. More pyramidal neurons (in layers III and V) are more strongly immunoreactive for N52 than in control cortex (A), and an abnormally oriented pyramidal neuron (*arrow*) is also easily identified. The pial surface is at the top in each panel. Bars = 100 Âµm. (From Crino PB, Miyata H, Vinters HV. Neurodevelopmental disorders as a cause of seizures: neuropathologic, genetic, and mechanistic considerations. *Brain Pathol*. 2002;12:212â€"233; with permission.) (See the color insert.)

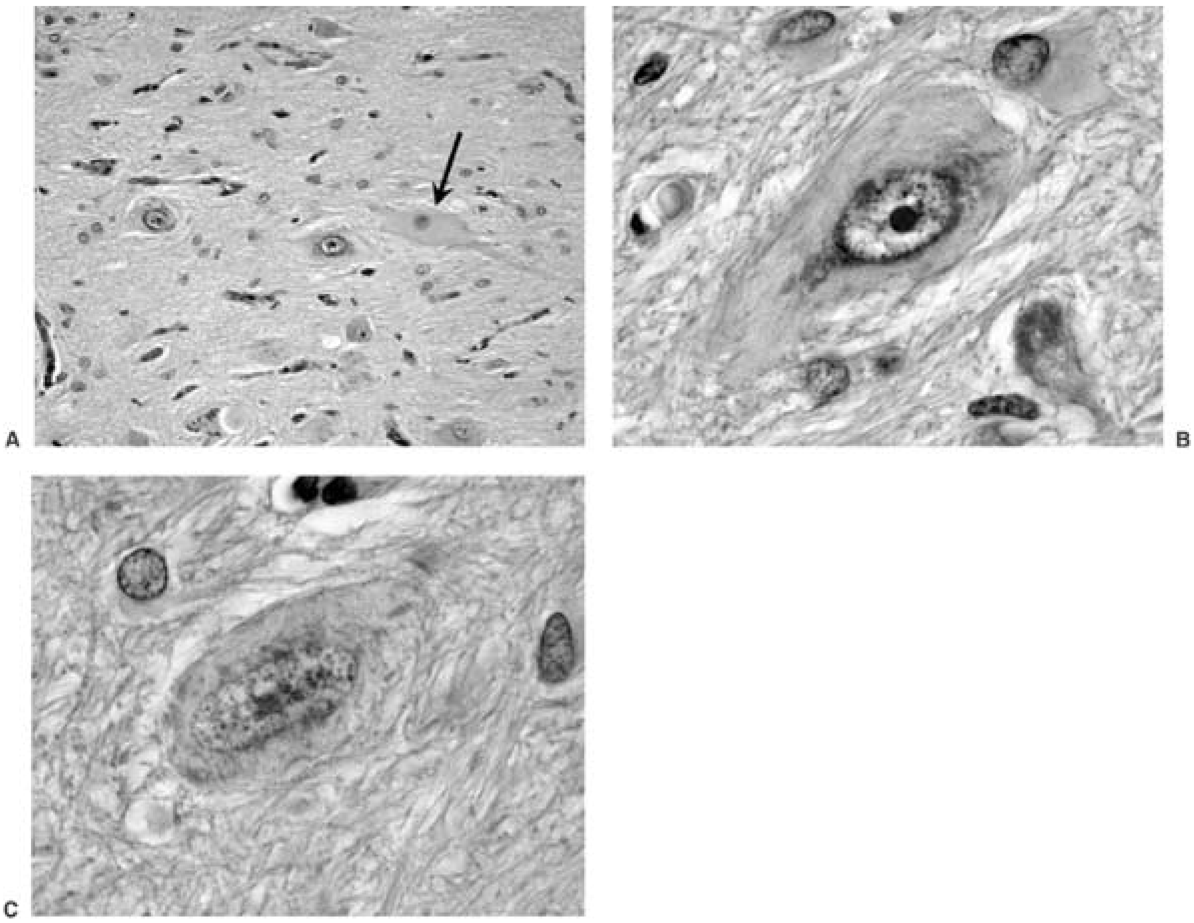

FIGURE 9. Histologic features of severe cortical dysplasia. **A:** Dysmorphic and enlarged neuronal cell bodies. Arrow indicates a cell that shows a â€œneuronalâ€ nucleus but pale, glassy amphophilic cytoplasm (lacking Nissl substance) of the type more commonly seen in gemistocytic astrocytes. **B, C:** Dysmorphic, enlarged neurons with coarseness of the cytoplasm, suggestive of neurofibrillary change. (All panels are micrographs from hematoxylin and eosinâ€“stained sections.). (See the color insert.)

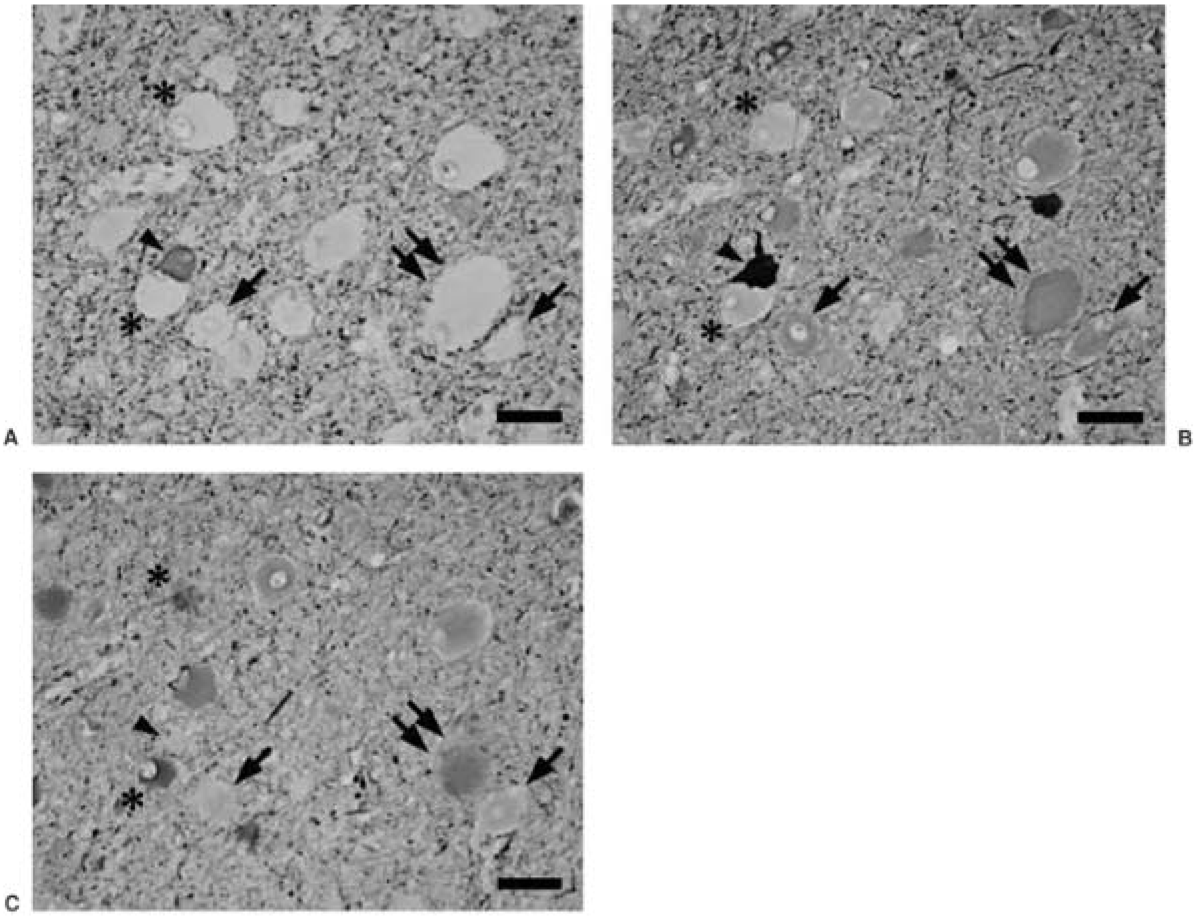

FIGURE 10. Balloon cells show various patterns of neuroectodermal differentiation. Some show only glial (glial fibrillary acidic protein [GFAP]) or neuronal (neurofilament) differentiation, whereas others show both GFAP and neurofilament immunoreactivity. Only rare balloon cells are immunoreactive for phosphorylated neurofilament (*arrowhead*, panel A). However, most are immunoreactive with nonphosphorylated neurofilament (panel B) with varying intensities. Some are immunoreactive for both GFAP and nonphosphorylated neurofilament (*double arrows*, panels B and C). Symbols and arrows in all panels indicate the same cell identified in serial sections. Arrowhead indicates a balloon cell that is phosphorylated neurofilament (p-NF)-positive, NF-positive, and GFAP-negative. Arrows indicate balloon cells that are p-NF-negative, NF-positive, and GFAP-negative. Asterisks indicate balloon cells that are p-NF and NF-negative but GFAP-positive. Double arrow indicates a balloon cell that is p-NF-negative, NF-positive, and GFAP-positive. Bars = 50 Âµm. (Panel A, section stained with primary antibody to phospho-NF, panel B with primary antibody to NF, panel C with primary antibody to GFAP). (From Crino PB, Miyata H, Vinters HV. Neurodevelopmental disorders as a cause of seizures: neuropathologic, genetic, and mechanistic considerations. *Brain Pathol*. 2002;12:212â€"233; with permission.) (See the color insert.)

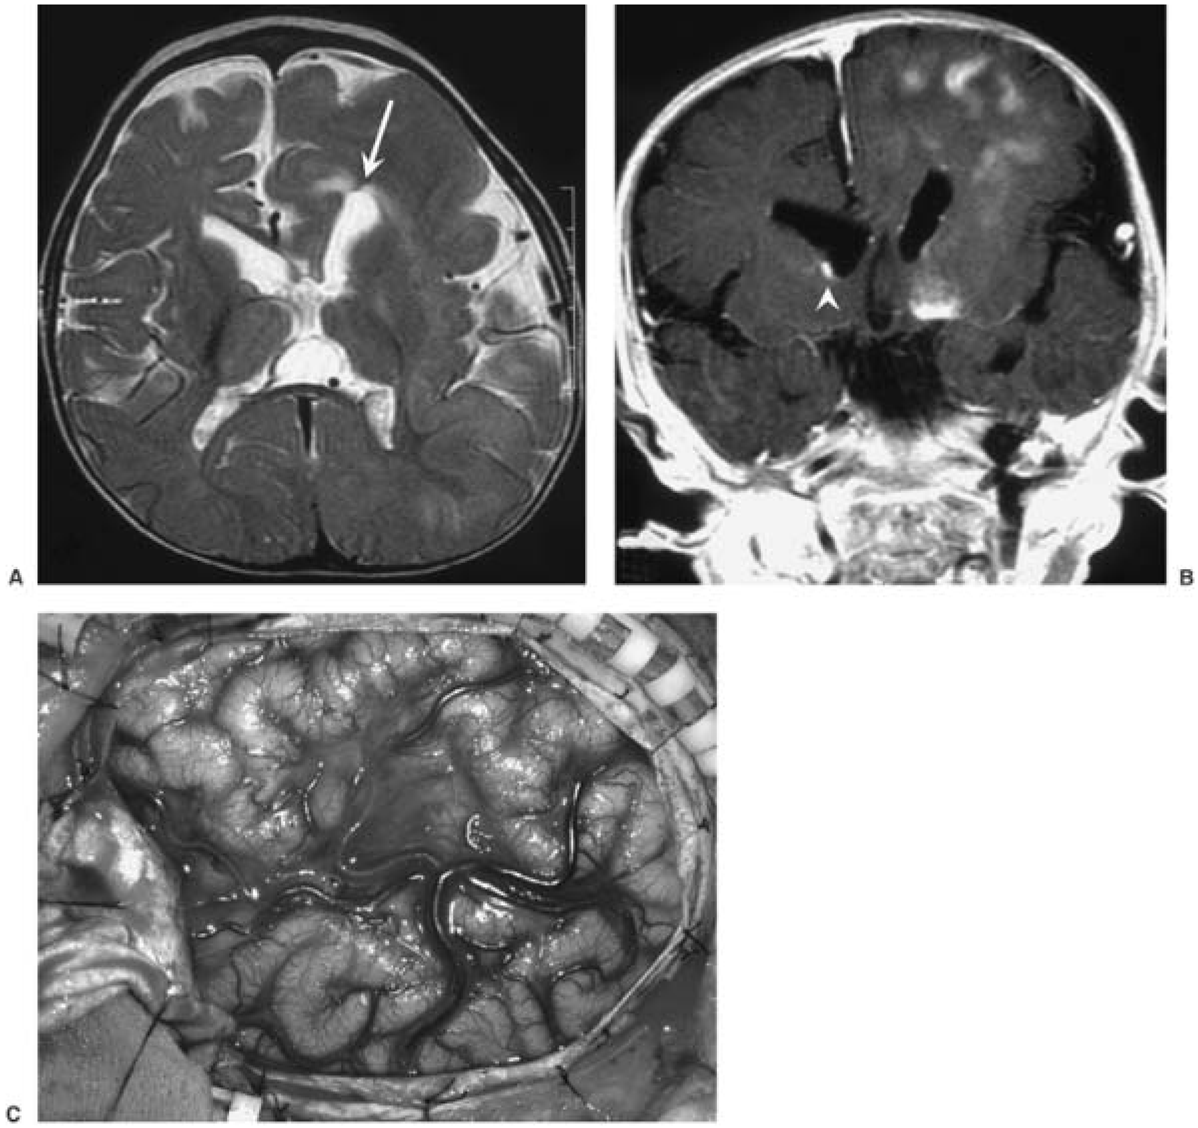

FIGURE 11. Hemimegalencephaly (HME) in a 13-month-old child with tuberous sclerosis complex (TSC). **A:** Axial T2-weighted image shows thickened gyri of the left frontal lobe, with an enlarged left cerebral hemisphere, suggesting HME. Most of the white matter in the left cerebral hemisphere is poorly myelinated. A well-defined subcortical hyperintense T2-weighted signal is noted in the left anterior cingulate gyrus, consistent with a tuber (*white arrow*). **B:** Postcontrast T1-weighted coronal image shows patchy foci of enhancement in the left cerebral hemispheric white matter, suggesting locations of tubers. A small, round focus of enhancement in the inferior aspect of the right frontal horn of the lateral ventricle (*white arrowhead*) represents a subependymal nodule, also characteristic of TSC. **C:** Intraoperative view of the left cerebral hemisphere showing multiple areas of abnormal cortical organization. The frontal lobe is in the upper left and the parietal lobe is in the upper right of the image.

Pathogenesis of Cortical Dysplasia

Although it is accepted that cortical dysplasia involves abnormal cerebral cortical development, it is unclear when it occurs

P.146

and how it produces seizures. Most classification systems of MCDs are based on speculating when the first development steps involving cell proliferation, neuronal migration, and cortical organization abnormality occurs to produce the malformed cortex. Previously, the presumed mechanisms of surgically treated CD pathogenesis have been believed to be defects in neuronal migration to explain subcortical heterotopic neurons, and altered periventricular neuroglial differentiation to account for the abnormal cytomegalic and dysmorphic neurons and balloon cells.[146,161,179] Although such mechanisms appear to be operant in genetic forms of malformations of cortical development, clinicopathologic investigations have challenged this singular interpretation in surgically treated cortical dysplasia.[8,23,24,25,26]

In recent studies, the UCLA group has found evidence that surgically treated cortical dysplasia seems to involve retention of cells of the human pre- and subplate along with overproliferation of cortical neurons. Prenatal human subplate cells have morphologic features similar to those of dysmorphic neurons found in postnatal CD tissue.[23] The normal human subplate contains large multipolar neurons similar to cytomegalic neurons, and polymorphous and fusiform neurons with thick primary dendrites along with inverted pyramidal-shaped neurons, a feature seen in dysmorphic CD neurons.[80] Most human subplate cells degenerate in the 4 to 6 weeks prior to birth,[29,43] which coincides with increasing definition of the grayâ€"white matter junction and secondary gyral folding.[27] Furthermore, toward the end of normal neurogenesis, periventricular radial glial cells attach themselves to the tailing processes of the last-produced cortical pyramidal neurons and migrate toward the cortex, where they detach and eventually transform into protoplasmic astrocytes.[82,121,123] This may explain why balloon cells in CD tissue have morphologic and other characteristics similar to those of radial glia.[40,176,193]

The UCLA group has proposed that CD pathogenesis probably involves partial failure of later phases of corticogenesis. As a consequence, subplate and radial glial degeneration and transformation would be reduced or prevented, giving the appearance of abnormal dysmorphic cells in postnatal CD tissue. In addition, failure of late cortical maturation could explain the

presence of abnormally thickened gyri with indistinct cortical grayâ€"white matter junctions in MRI scans of CD patients.[24] The timing of these events during cortical development would explain the different forms of CD identified by MRI and severity of CD by histopathology. Developmental alterations during the late second or early third trimester would account for severe CD, like hemimegalencephaly, whereas events occurring closer to birth (after the subplate has nearly degenerated) would explain milder forms of CD. In addition, it appears that there is an overproduction of neurons in later phases of cortical development. MRI cerebral hemisphere volumes were normal or increased in the case of hemimegalencephaly, and cortical thickness was the same or slightly increased.[5,158] Furthermore, neuronal densities were increased in the upper gray matter, molecular layer, and subcortical white matter. The location of excess neurons would be consistent with the idea that this process occurred in later periventricular cell cycles (i.e., the ones toward the end of neurogenesis). Thus, heterotopic subcortical white matter neurons are likely the result of excessive late generated pyramidal neurons trying to migrate toward the already overly crowded cortical ribbon, in combination with residual prenatal subplate neurons that failed to degenerate prior to birth.

Cortical Tubers of Tuberous Sclerosis Complex (TSC)

Tuberous sclerosis complex (TSC, or Bourneville disease) is an autosomal-dominant, multisystem disorder in which the CNS, eyes, kidneys, skin, and heart are most commonly

affected by malformative, hamartomatous, or neoplastic lesions.[31,51,84,162,187] It has an incidence of 1 in 9,400 to 10,000 births[31,51]; however, accurate estimates are difficult to ascertain because of the markedly variable penetrance of the disorder; it may go unrecognized for many years, and a high rate of spontaneous TSC gene mutations has been described.[31,188] The clinical presentation of an individual with TSC may be with infantile spasms, autism, or mental retardation. Approximately 85% of TSC patients who come to medical attention have experienced an epileptic seizure at some time. Because genetic analysis to confirm the diagnosis of TSC remains unavailable to most physicians, *diagnostic criteria* for TSC have been enunciated.[151,152] In the 1992 iteration, these included *primary* features of the disease (facial angiofibromas, multiple subungual fibromas, a [histologically confirmed] cortical tuber, [histologically confirmed] subependymal nodule (SEN) or subependymal giant cell astrocytoma (SEGA), [radiographically confirmed] multiple calcified SENs protruding into the ventricular cavity, and multiple retinal astrocytomas); *secondary* features (an affected first-degree relative, cardiac rhabdomyoma [confirmed by histopathology or radiographically], retinal hamartoma or achromic patch, cerebral tubers [radiographically confirmed], a Shagreen patch, forehead plaque, [histopathologically confirmed] pulmonary lymphangiomyomatosis or renal cysts); and *tertiary* features (hypomelanotic macules, [radiographically confirmed] renal cysts, etc.). In the 1998 revised criteria, some clinical features previously thought to be pathognomonic for TSC were considered less specific, whereas clinical/radiographic features of the disease were subdivided into major and minor categories based on their apparent degree of specificity for TSC. Based on these newer revised criteria, a definitive diagnosis of TSC is made by the confirmation of two or more distinct types of lesion in a patient, rather than multiple lesions of the same type (e.g., tubers) in the same organ system. In other words, no single lesion is one that *defines* the disease.

Neuropathology of Cortical Tubers as a Cause of Seizures

Individuals with TSC may rarely present with HME (Fig. 11). However, the characteristic brain abnormalities of TSC include neocortical tubers (Figs. 12 and 13), SENs, and SEGAs. Cortical tubers are very often associated with infantile spasms and intractable epilepsy in children. The lesions manifest as enlarged gyri in which the cortex/white matter junction has become blurred, resembling sporadic, severe cortical dysplasia.[32,117] Histologically, these lesions show disorganized neocortex, with a variety of dysmorphic, markedly enlarged neurons and bizarre gemistocytic astrocyte-like â€œballoon cellsâ€ having eccentric nuclei containing relatively coarse chromatin and glassy eosinophilic cytoplasm (Fig. 13). Balloon cells seen in TSC strongly resemble those seen in severe cortical dysplasia or focal cortical dysplasia of Taylor type. This observation has frequently raised the possibility that cases of CD with

balloon cell change represent a *forme fruste* of TSC.[42,130,131,155] Balloon cells, like those seen in FCD, show morphologic and immunohistochemical features of both neurons and astrocytes, suggesting a failure of commitment in neuroglial differentiation (Fig. 14), that is, they are variably immunoreactive, even among cells within a tuber, for glial fibrillary acidic protein (GFAP) and neuronal markers. Balloon cells may cluster together, particularly in the subpial region or subcortical white matter, or be scattered among dysmorphic neurons. Tubers may show prominent punctate calcification. Whereas cortical tubers demonstrate reduced immunoreactivity for the synaptic protein synapsin 1,[88] giant cells within TSC tubers show dramatic halos of synaptophysin immunoreactivity resembling those noted in gangliogliomas, as well as strong immunostaining with antibodies to the microtubule-associated protein 2 (MAP-2).[192] Alpha B-crystallin, a member of the heat-shock-protein family of peptides, is found in abundance within dysgenetic cells of tubers and within both SEGAs and SENs.[66] Dysmorphic cytomegalic neurons express high levels of tuberin, as do individual cells within SEGAs and SENs. In a developmental time frame, tuberin appears to be present in most neuronal populations of the CNS from at least 20 weeks of gestation, with an apparent upregulation of its expression after 40 weeks of gestation.[187] Hamartin was found, albeit with a weaker signal, in the same cell types during CNS development.

Whereas architectural disarray is a defining feature of a tuber, cellularity of a lesion may be extremely variable, although when high cell density is noted, a tuber may resemble a ganglioglioma.[150,187] Although the proliferative potential of these lesions appears to be low, as judged by immunohistochemistry for Ki-67, other markers of cellular proliferation (e.g., collapsin response mediator protein 4 [CRMP4], doublecortin) are expressed within giant cells of cortical tubers and SEGAs (human-derived material) and SENs of Eker rats, suggesting that they may represent newly generated cells that have migrated into tubers from the subventricular zone.[86]

Genetic and Molecular Biologic Aspects of Tuberous Sclerosis Complex Pathogenesis

Our understanding of the molecular pathogenesis of TSC represents a triumph of multidisciplinary, multicenter (often multicontinent) collaborations through the early 1990s focused on characterizing the complex gene defects that cause this disorder.[41,68,137,181] TSC is caused by mutations in one of two nonhomologous tumor suppressor genes: *TSC1*[181] on chromosome 9 (9q34) encoding a 130-kDa protein, hamartin, and *TSC2*[41] on chromosome 16 (16p13.3) encoding a 200-kDa protein, tuberin. About half of TSC families show linkage to each of the two identified genes. *TSC1* mutations, accounting for a minority of mutations identified, are slightly less common in sporadic TSC patients and are more common in familial cases (13%â€“50%).[94] The putative functions of both *TSC1* and *TSC2* gene products have been intensively studied using

mostly *Drosophila* and rodent models of TSC, but also using human tissues and loss-of-heterozygosity analyses of TSC hamartomas. These initially suggested that both *TSC1* and *TSC2* gene products, even before the details of their encoded proteins were known, had growth suppressor properties.[20,53,54] Significant interactions of TSC genes with intracellular signaling pathways have been implicated, as shown in FIGURE 15. Hamartin possesses a coiled-coil domain in its carboxy region, suggesting the possibility of a functional proteinâ€“protein interaction with tuberin[181] to regulate cell proliferation and cell cycle progression.[21,62]

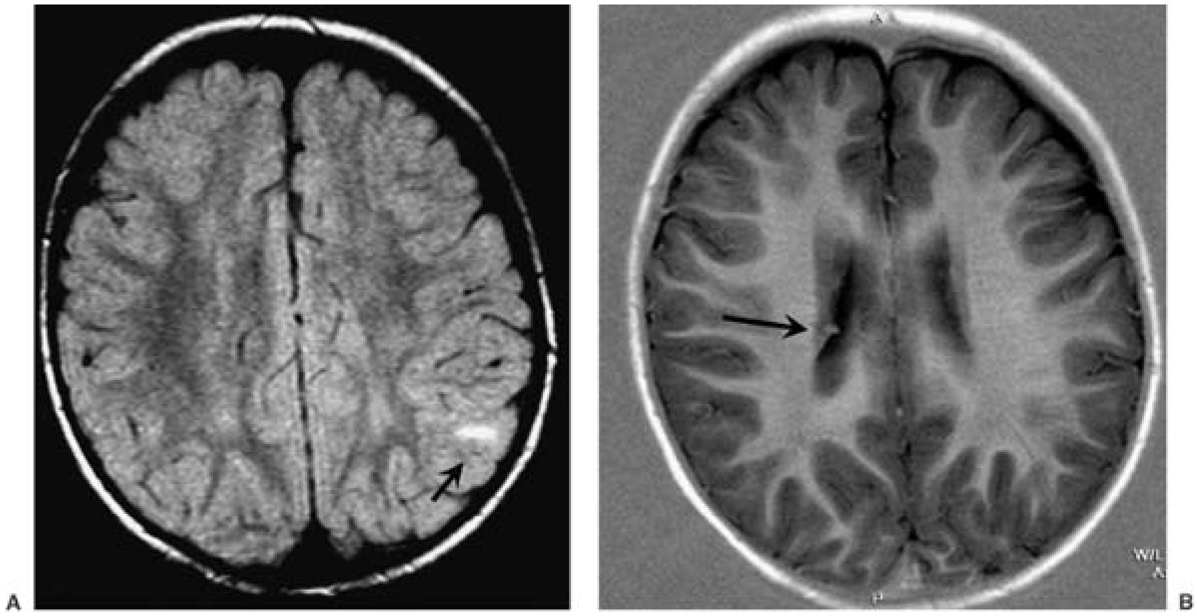

FIGURE 12. Tuber of tuberous sclerosis complex. **A:** Axial FLAIR (fluid attenuated inversion recovery) image shows a focus of hyperintensity in the left parietal lobe subcortical white matter (*arrow*). This patient also has multiple similar foci in the cerebrum. **B:** Axial T1-weighted inversion recovery image shows foci of subependymal nodules (*arrow*) along the ventricular wall.

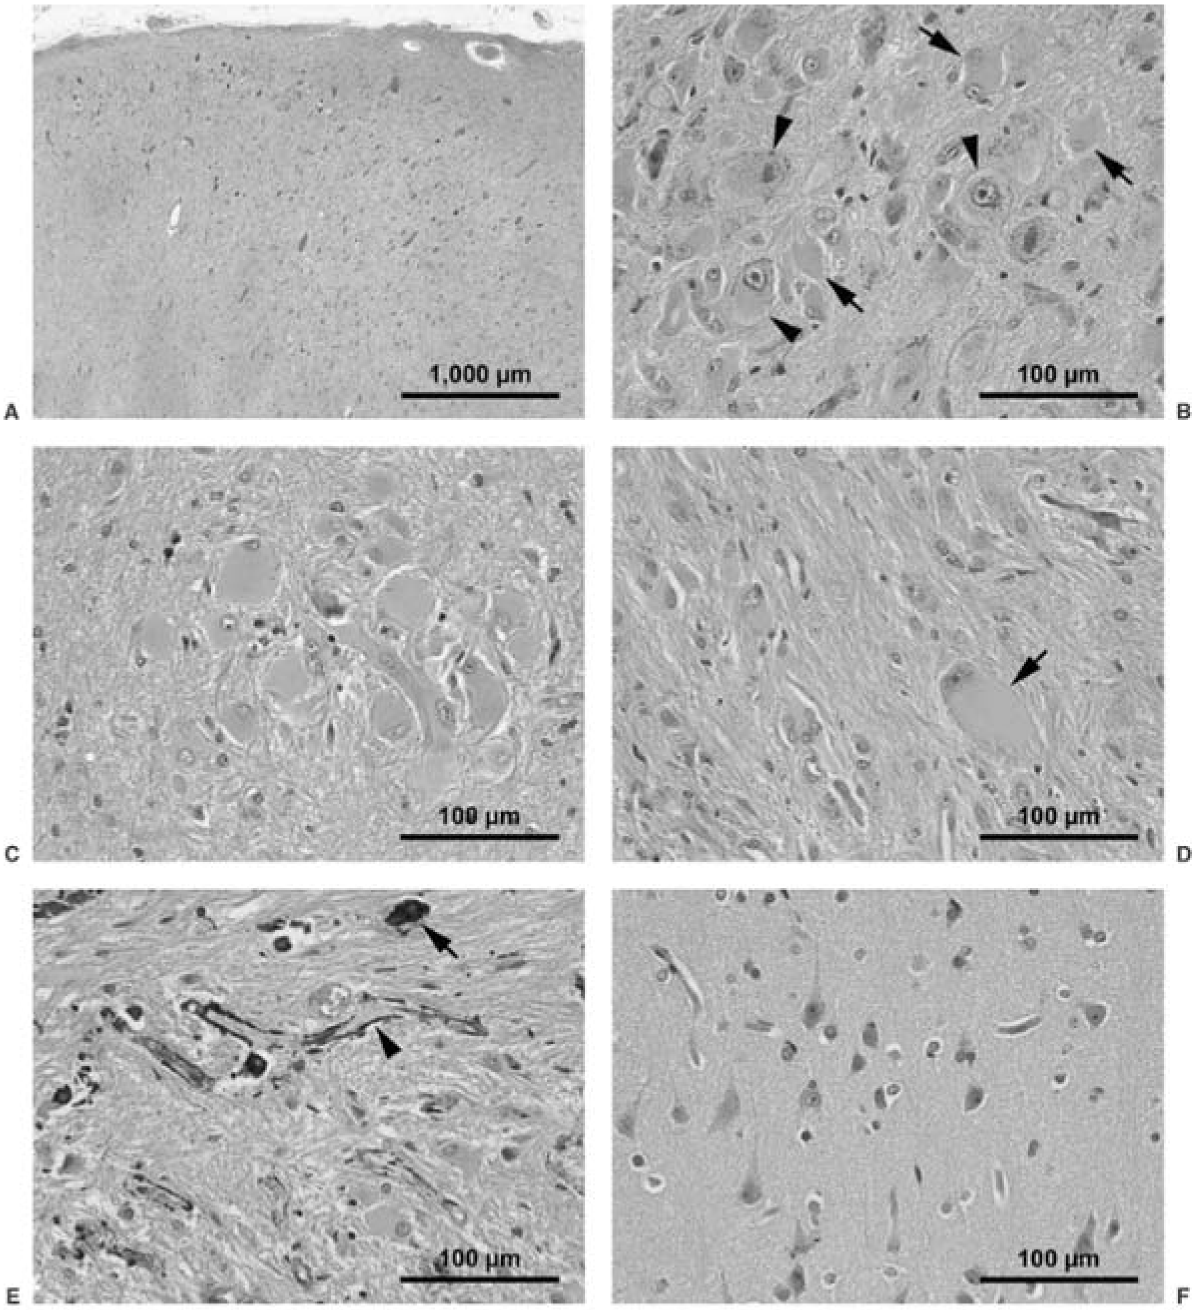

FIGURE 13. Cortical tuber in a child with tuberous sclerosis complex (TSC). **A:** Low-magnification view shows a disorganized collection of neuroglial cells, some enlarged. **B:** Magnified view of the lesion showing â€œballoon cellsâ€ with eccentric nuclei and glassy eosinophilic cytoplasm (*arrows*), admixed with dysmorphic, markedly enlarged neurons containing Nissl substance in their cytoplasm (*arrowheads*). **C:** A cluster of balloon cells within the tuber. **D:** An abnormal neuroglial cell showing morphologic features of both dysplastic neuron and balloon cell (*arrow*). Note the eccentric nucleolated nucleus and the enlarged pale but slightly basophilic cytoplasm, raising the possibility that the cell represents a transitional form of neuroglial cell. **E:** Various degrees of punctate calcification (*arrows*) and calcifications along vessel walls (*arrowheads*) are often seen in TSC tubers. **F:** Morphologically normal cerebral cortex (for comparison with features of the tuber). (All panels are micrographs from sections stained with hematoxylin and eosin.) (See the color insert.)

Hamartin may also interact with other proteins, including the ERM (ezrin, radixin, and moesin) family of actin-binding proteins, to activate small GTPases of the Rho subfamily (Rho GTPases).[85] Rho GTPases are important regulators of the actin cytoskeleton and are thought to be involved in neuronal developmental processes including neuronal migration, establishment of polarity, axon growth and guidance, dendrite elaboration and plasticity, and synapse formation.[92] ERM proteins belong to the band-4.1 superfamily of membrane-cytoskeleton linking proteins.[173] These proteins are believed to function in multiple different fashions according to their interaction with various membrane proteins, Ras superfamily GTPases, and the actin cytoskeleton, and appear to be involved in the formation of microvilli, cellâ€"cell adhesion, maintenance of cell shape, cell motility, and membrane trafficking.[90] The fact that hamartin binds to ezrin in vivo and can modulate the activity of RhoA (Ras homologous member A)[85] suggests that tuberin and hamartin may be attached to the membrane-cytoskeletal cortex through activated ERM proteins.[72] Evidence from several reports suggests that ERM proteins function at a position upstream and downstream of Rho GTPases to regulate cellular adhesion and motility.[103,170,171] ERM proteins (ezrin and moesin) are expressed in germinal matrix cells, migrating cells, and radial glial fibers in the developing human brain,[72] correlating with RhoA expression in proliferating and migrating cells in the developing rat brain.[129] Dysfunction of tuberin and hamartin may perturb communication between ERM proteins and Rho GTPase to cause abnormal neuronal migration, polarity, and morphology, resulting in the formation of dysplastic

cortex. Hamartin and tuberin are coexpressed within a population of abnormal neuroglial cells,[71] and both TSC gene products and ERM proteins are also coexpressed within a subpopulation of abnormal neuroglial cells in TSC tubers,[72] suggesting the upregulation of ERM proteins within these cells in response to a TSC gene mutation. Abnormalities of radial glia have also been implicated in the pathogenesis of brain lesions of TSC.[133]

Tuberin contains a conserved 163-amino acid carboxy-terminal region that exhibits sequence homology to the catalytic domain of a GTPase-activating protein (GAP) for the low-molecular-weight GTPase Rap1[189] and for Rab5.[191] Based on in situ hybridization with a digoxigenin-labeled cDNA probe, TSC2 mRNA was found to be widely expressed in various cell types throughout the body, including epithelia, lymphocytes, and endocrine organs; within the CNS, it was prominently and selectively expressed within neurons, especially motor neurons, including cortical, brainstem, and spinal cord neurons.[109] Widespread expression of the *TSC2* gene within developing and adult nervous system was noted in another study using reverse transcription-polymerase chain reaction (RT-PCR), Northern blot, and in situ hybridization analysis.[48] The results of a study in mice showed that tuberin localized to the perinuclear region of cerebellar Purkinje cells, whereas hamartin was noted to distribute along neuronal or astrocytic processes.[56] Bases on human autopsy and biopsy material, *TSC2* mRNA and tuberin were found in abundance in many CNS cell types, including neurons and ependymal cells.[79] *TSC2*-negative fibroblasts show inactivation of the cyclin-dependent kinase inhibitor p27.[165] Mutations in *TSC2* may result in constitutive activation of Rap1, leading to enhanced proliferation or incomplete cellular differentiation.[164]

TSC1 and *TSC2* gene products colocalize within tubers (and sometimes within individual dysmorphic cells) of patients with TSC.[71] Tissue culture experiments in various cell types, using both confocal laser microscopy and coimmunoprecipitation, show that both hamartin and tuberin interact with the G2/M cyclin-dependent kinase CDK1.[21] It has further been suggested that hamartin and tuberin have separable functions in mammalian cell cycle regulation,[115] that is, that hamartin itself has the ability to modulate cell proliferation independent of the presence of functional tuberin, and binding to hamartin is not always essential for tuberin to affect cell proliferation. *Tsc1* and *Tsc2*, *Drosophila* homologs of *TSC1* and *TSC2*, function together in vivo to negatively regulate cell size, cell proliferation, and organ size in the insulin signaling pathway (PI3Kinase-Akt/PKB-mTOR-S6K-S6) at a position downstream of *dAkt* (*Drosophila Akt*) and upstream of *dS6k* (*Drosophila S6 kinase*).[136] This has been clearly confirmed in surgically resected TSC tubers by means of quantitative immunohistochemical evaluation using tissue microarray methodology,[118] and constitutive activation of S6K has been observed in TSC tubers but not in focal cortical dysplasia of Taylor type (T-FCD or CD Palmini type IIB), suggesting one difference between these MCDs (Fig. 16).[11,118] Recent studies have also revealed Rheb (Ras homolog enriched in brain) GAP activity of tuberin playing a role in regulation of S6K and 4E-BP1,[65,167,195] indicating indirect regulation of the insulin signaling pathway by TSC genes through the inhibition of Rheb activity.

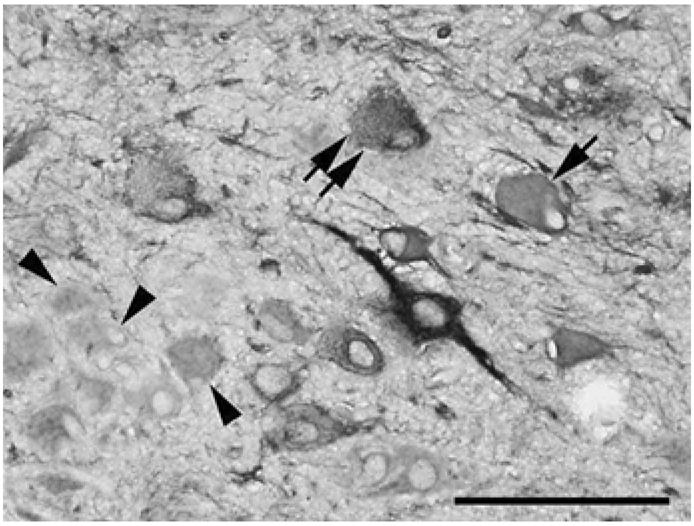

FIGURE 14. Immunohistochemical findings in a tuberous sclerosis complex (TSC) tuber. Double-label immunohistochemistry confirms colocalization of glial fibrillary acidic protein (GFAP) (*brown color*) and nonphosphorylated neurofilament (*purplish-blue*) in a subpopulation of balloon cells (*arrowheads*) in a TSC tuber, suggesting a failure of commitment in neuroglial differentiation. Note that some abnormal neuroglial cells are immunoreactive for GFAP (*arrow*) or nonphosphorylated neurofilament (*double arrows*). Scale bar = 100 Âµm. (See the color insert.)

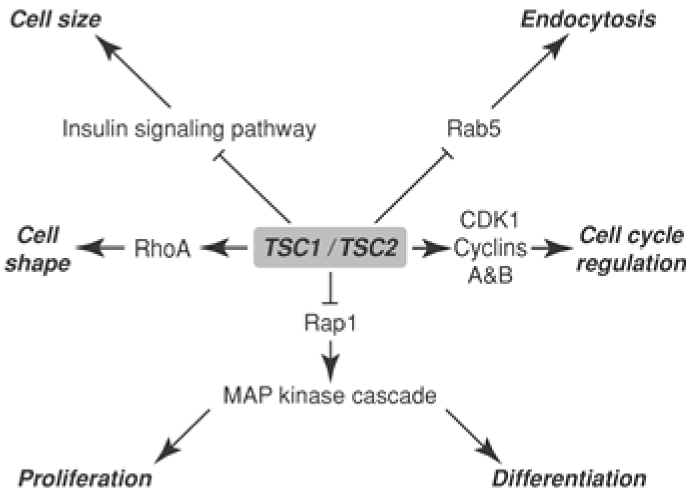

FIGURE 15. Schematic summary of the functions of tuberous sclerosis complex (TSC) genes. The functions of both *TSC1* and *TSC2* gene products have been intensively studied using mostly *Drosophila*, tissue culture, and rodent models. This diagram briefly summarizes significant interactions of TSC genes with intracellular signaling pathways. CDK, cyclin-dependent kinase; MAP, microtubule-associated protein.

Sturge-Weber-Dimitri Syndrome/Encephalo-Trigeminal Angiomatosis

This is a rare, nonfamilial, neurocutaneous syndrome of unknown etiology[124,126,182] encountered in surgical specimens from infants and children with intractable epilepsy, although much less commonly than destructive and malformative/hamartomatous lesions. The frequency of Sturge-Weber-Dimitri (SWD) syndrome is estimated to be 1 per 50,000 live births,[59] and 75% to 90% of children with SWD syndrome

develop partial seizures by 3 years of age.[97] Clinicopathologic reports describe the association of the cerebral lesion, usually localized to the occipital cortex, with facial capillary hemangioma (â€œport-wine stainâ€) in the distribution of the ophthalmic division of the trigeminal nerve, and provide excellent accounts of the natural history of the disorder.[127,182,190] Visceral angiomas may be encountered in some patients.[14] Neuroimaging features are highly characteristic (Fig. 17).

Neuropathologic abnormalities in cortical resection specimens (Fig. 18) are easily appreciated at low magnification, and soft tissue radiographs of the sliced specimen may show the characteristic â€œtram-trackâ€ pattern of neocortical calcification. The leptomeningeal angiomatosis is a key diagnostic feature of SWD syndrome,[177] characterized by some authors as a venous angioma,[190] consisting of dilated and tortuous thin-walled blood vessels within the subarachnoid space and pia, which may extend into the underlying cerebral cortex and even subcortical white matter. The cortex itself shows calcifications centered on microvessels, with associated neuronal loss, astrocytic gliosis, and extensive cortical atrophy[124,126] that is assumed to result from ischemic phenomena secondary, at least in part, to the meningeal angiomatosis. Associated malformations such as polymicrogyria, agyria/pachygyria, heterotopias, and cortical disorganization can also be seen.[182] Ultrastructural studies of the parenchymal calcifications in Sturge-Weber brain have suggested that the earliest calcium deposits occur within perithelial cells of small blood vessels, and that the underlying cause of the calcification may be anoxic injury to endothelial, perithelial, and glial mitochondria due to stasis and abnormally increased vascular permeability of vessels in the hemangioma.[55,125]

Neurofibromatosis, Meningio-angiomatosis, and Other Neurocutaneous Syndromes

Central neurofibromatosis (NF-2) is a genetic disorder characterized by neoplastic and dysplastic lesions of Schwann cells, meningeal cells, and glia.[89,104] It is associated with (a) Schwannomas, both central and peripheral, including bilateral acoustic Schwannomas; (b) meningiomas; (c) gliomas; and (d) glial hamartomas. It is inherited in an autosomal-dominant fashion, with a high rate of sporadic mutations (up to 50%).[89,104] The *NF-2* gene, postulated to be a tumor-suppressor gene, has been localized to chromosome 22q12 and encodes a widely expressed protein, merlin (moesin, ezrin, radixinâ€“like protein) or schwannomin, which is a new member of the protein 4.1 family of cytoskeleton-associated proteins.[89,93] Although seizures can develop in patients with NF-2, these are usually caused by a primary neoplasm rather than a primary malformative lesion. The most frequent malformations seen in association with NF-2 are meningio-angiomatosis and glial hamartomas. Meningio-angiomatosis[77,134] is a rare malformation of the cerebral cortex of unknown etiology, described in more detail in Chapter 12, where it is placed in the context of other neoplasms that are associated with seizures. Rare neurocutaneous syndromes, such as epidermal nevus syndrome and hypomelanosis of Ito,[81] have also been associated with pediatric epilepsy, serving to emphasize the interrelated development of the CNS and overlying mesenchyme. The pathologic changes seen within the cerebral cortex of these patients are virtually identical to those seen in patients with CD.

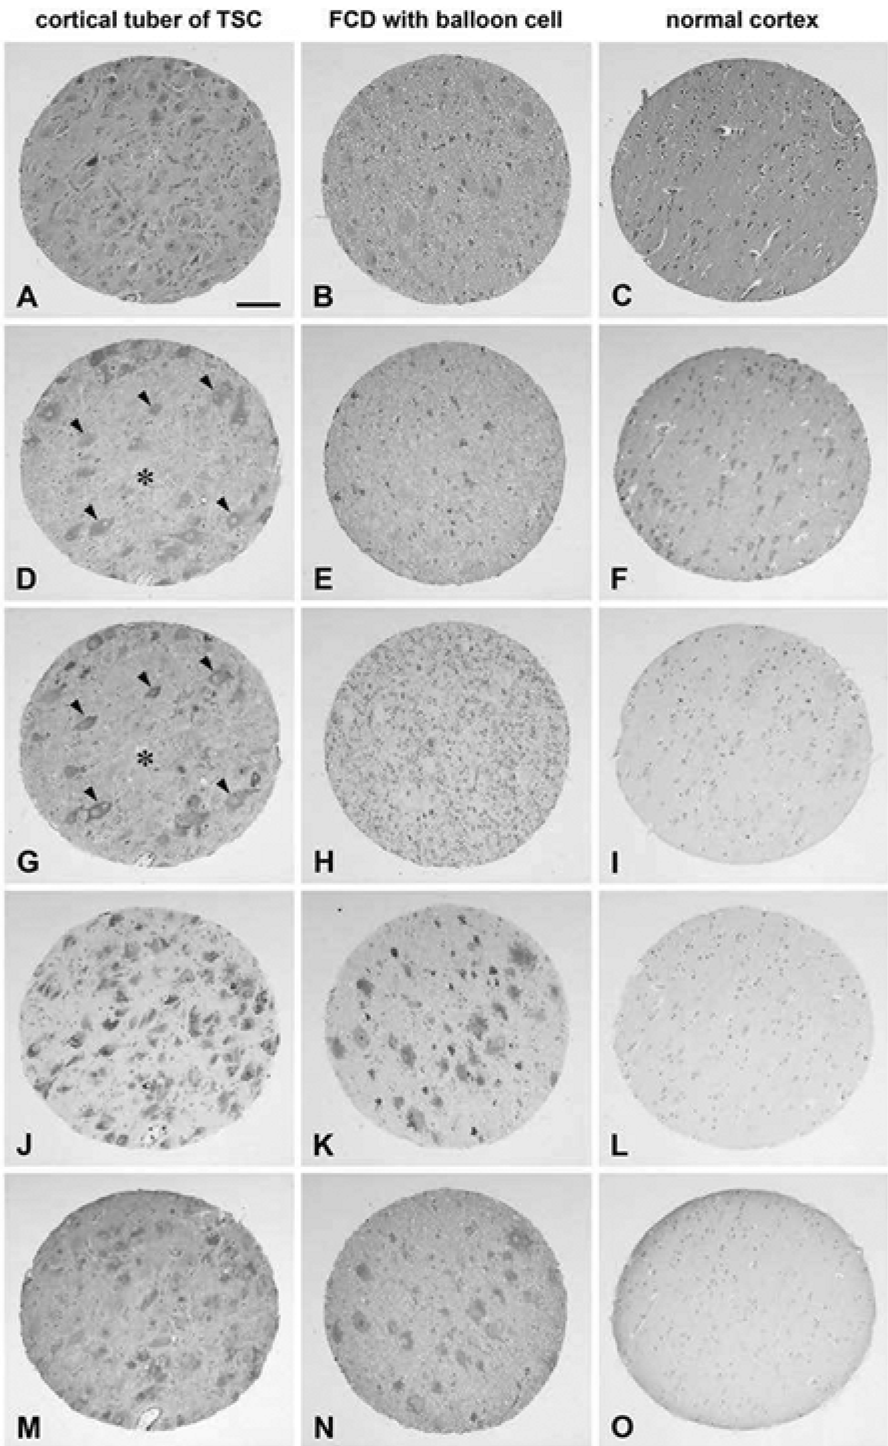

FIGURE 16. Tissue microarray (TMA) analysis of insulin signaling pathways in tuberous sclerosis complex (TSC) tubers, focal cortical dysplasia, and control tissues. The left column represents sample cores from a TSC tuber **(A, D, G, J, M)**; the middle column represents focal cortical dysplasia (FCD) with balloon cells (Palmini type IIB) **(B, E, H, K, N)**; and the right column represents histologically normal cerebral cortex **(C, F, I, L, O)**. Stained with hematoxylin and eosin (H&E) (Aâ€"C), p-mTOR (Dâ€"F), p-p70S6K (Gâ€"I), p-S6 (Jâ€"L), and p-eIF4G (Mâ€"O). Immunostains were performed on consecutive serial sections, and the same cells can be easily identified in different stains (e.g., *arrowheads* in D and G). Expression of p-p70S6K appears to be specific to the TSC tuber (panel G). Note the population of abnormal neuroglial cells in the TSC tuber expressing p-S6 and/or p-eIF4G (e.g., central area of each

core shown in panels J and M), despite negative expression of p-mTOR and p-p70S6K (the same areas indicated by asterisks in panels D and G). Each core has a 0.6-mm diameter. Bar = 100 Âµm. eIF4G, eukaryotic translation initiation factor 4G; mTOR, mammalian target of rapamycin; p-, phospho-; p70S6K, 70-kDa ribosomal protein S6 kinase; S6, 40S ribosomal protein S6. For details of methodology, see Miyata et al. (2004). (From Miyata H, Chiang ACY, Vinters HV. Insulin signaling pathways in cortical dysplasia and TSC-tubers: tissue microarray analysis. *Ann Neurol*. 2004;56:510â€“519; with permission.) (See the color insert.)

Vascular Malformations

Cerebral vascular malformations are a group of â€œcongenitalâ€ developmental abnormalities of the cerebral blood vessels, which can be divided, based on pathologic features, into five main groups: (a) arteriovenous malformations, (b) cavernous hemangiomas, (c) venous angiomas, (d) capillary telangiectases, and (e) varix or aneurysm of the great vein of Galen (which is actually an arteriovenous malformation or fistula).[76,100,183] The term â€œcongenitalâ€ is placed in quotation marks because neuropathologists almost never encounter these lesions (with the exception of vein of Galen aneurysms) in infants or young children. Despite this, there is a widespread belief that the nidus of a future vascular malformation is present early in brain development. Arteriovenous malformations

P.154

(AVMs) consist of a tangle of tightly interwoven blood vessels in the leptomeninges and underlying cerebral cortex and white matter. Brain tissue fragments among and adjacent to the abnormal vascular channels of a hemangioma (AVM) often show disorganization and reactive gliotic change, some of which may suggest the propensity of the tissue to generate seizures. These vascular lesions contain arteries, veins, and â€œarterialized veins,â€ muscularized vessels intermediate between an arterial and venous channel (Fig. 19). Cavernous hemangiomas are composed of a cluster of dilated, ectatic, and hyalinized vessels with no normal intervening brain parenchyma, and there is almost always abundant surrounding evidence of old hemorrhage. Venous angiomas contain dilated ectatic and venous channels with normal intervening brain parenchyma. Capillary telangiectases consist of dilated capillaries separated by normal brain parenchyma. The varix of vein of Galen (vein of Galen aneurysm) is a large, dilated, ectatic vein of Galen, which is usually in direct connection to a branch of one of the major arterial blood vessels at the base of the brain; varix of vein of Galen can therefore be considered a variant of AVM.[47,76,100]

Clinically, AVMs are the vascular malformations most likely to cause symptoms, although cavernous hemangiomas and occasionally venous angiomas can be symptomatic.[99] Mechanisms of seizure genesis by these lesions include subclinical hemorrhage, compression and scarring of brain tissue around the vascular malformation, and a â€œstealâ€ of blood from normal brain, rendering it at risk for seizure activity. Capillary telangiectases usually represent an incidental finding at autopsy and are almost never found within cortex or subcortical white matter.[47,76] Although hemorrhage is the most common and severe manifestation of AVMs, seizures occur at some time in up to 70% of affected patients.[99,100] Seizures are also frequently

P.155

P.156

seen (in addition to congestive heart failure) in infants and neonates with varix of the vein of Galen.[76,99,100,172]

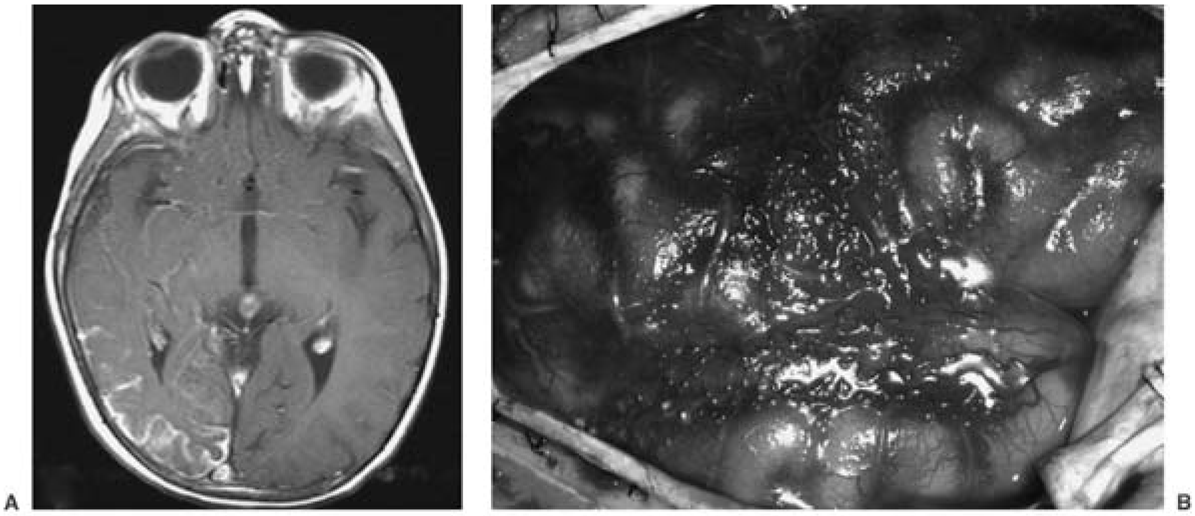

FIGURE 17. Sturge-Weber-Dimitri syndrome (SWDS). **A:** Postcontrast T1-weighted axial image shows global right cerebral hemispheric atrophy with smooth leptomeningeal enhancement along the right parieto-occipital region. There is faint meningeal enhancement in the right frontal operculum. Enlarged deep white matter veins are also seen in the right frontal region. The right frontal calvarium is thicker than the left. These features are consistent with SWDS. **B:** Intraoperative photograph illustrating marked angiomatosis of the arachnoidal surface in the frontal region over the sensorimotor cortex.

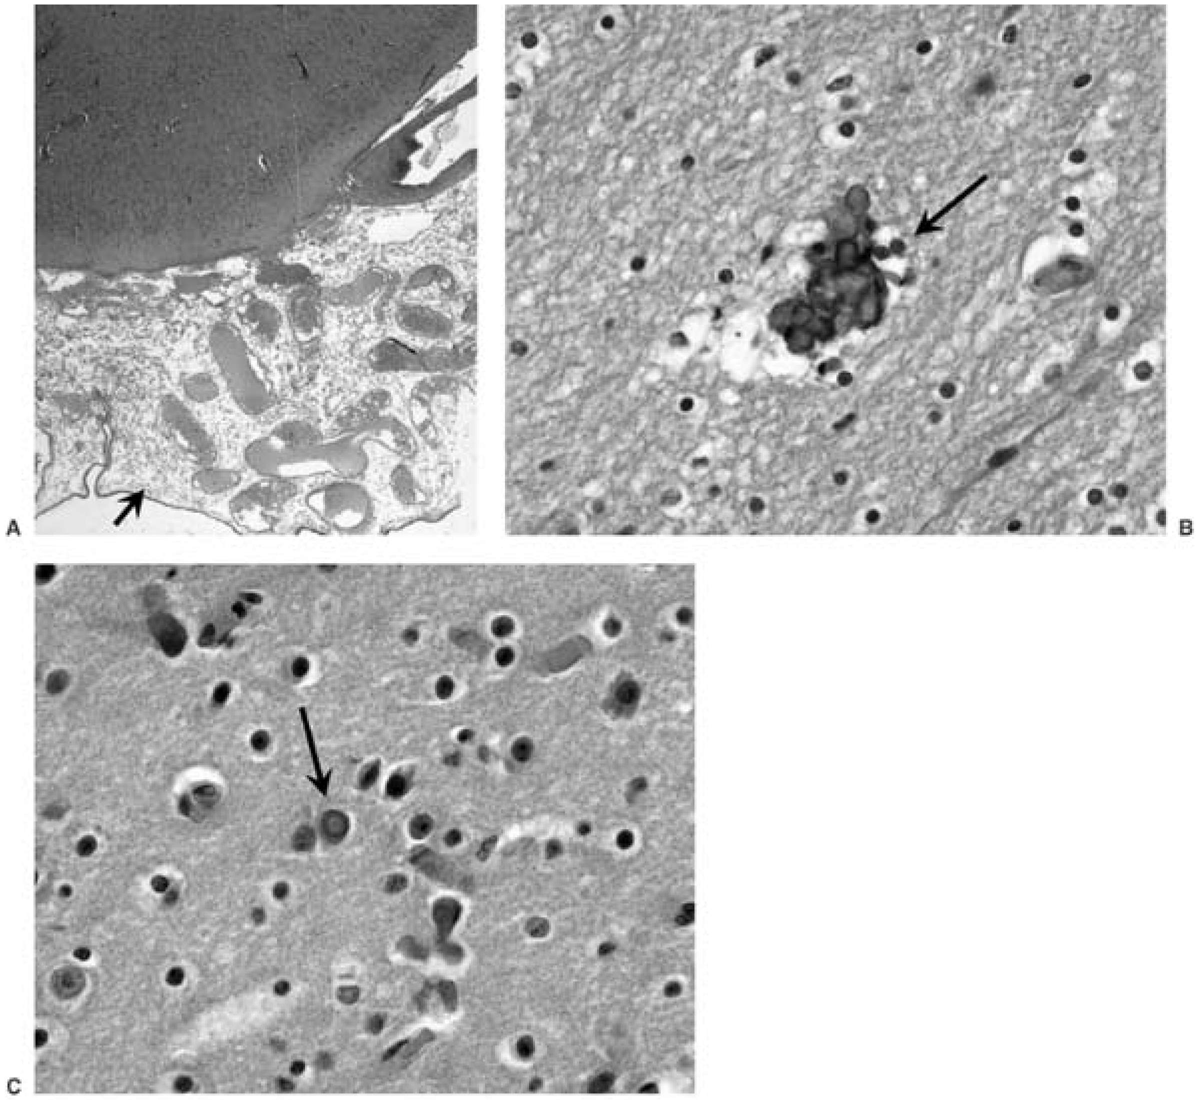

FIGURE 18. Sturge-Weber-Dimitri syndrome, microsco-pic features. **A:** Dense angiomatosis of meningeal vessels in the occipital region (*arrow*). **B, C:** Punctate calcifications (*arrows*) in the underlying brain parenchyma. (See the color insert.)

Summary and Conclusions

The neuropathologist plays a crucial role in the evaluation of the complex lesions described in this chapter, which produce seizures as a major clinical manifestation. She or he has a major role in giving a definitive diagnosis for the structural abnormality/abnormalities present within a corticectomy specimen and at least suggesting how it may have contributed to intractable seizures (the latter assignment often more challenging than the former). Gross and microscopic examinations remain the gold standard for the diagnosis of CD as well as for other nonmalformative structural lesions of the neocortex.

Correlation between pathologic features and clinical presentation is essential for understanding biologic behavior.[185] Furthermore, neuropathologic examination of resected tissue can yield important clues regarding the timing of a putative developmental aberration that led to the development of a lesion, which can aid in understanding the causes and course of CD and related developmental abnormalities. Because the resected specimens represent a valuable resource for furthering our understanding of cortical development and maldevelopment, the neuropathologist plays a role as a conduit for the resected tissue, ensuring maximal effective use for diagnosis and research that utilizes the specimen. Research questions can only be addressed (in human brain tissue specimens) using optimally preserved resection specimens that are preserved for electrophysiologic, neurochemical, and molecular investigations.[4,17] However, when such tissue is available, it is as valuable asâ€"and arguably more valuable thanâ€"tissues obtained from experimental animals. For example, laser capture microscopy coupled with molecular analytic techniques has facilitated the study of neurotransmitter receptor subunit analysis in HME.[10]

Malformative lesions of the neocortex are responsible for the majority of structural pathologic features seen in infants and children with seizure disorders, especially in those with IS. CD, which represents a spectrum of neuropathologic changes associated with disruption of development of the normal neocortex, accounts for most of these malformations, although structural lesions associated with TSC, SWDS, NF-2, and meningio-angiomatosis and vascular malformations are also seen. Multiple etiologic factors have been associated with these developmental disorders, including genetic mutations, prenatal vascular insults,[148] and toxic and environmental exposures.

Although advances have been made in understanding these complex developmental lesions, especially from neuroimaging and molecular perspectives, much remains to be learned. Promising animal models have been developed[156] in which cortical malformations have been induced in rats. These experimental lesions, which conferred an increased propensity for seizures, demonstrated some changes identical to those seen in patients with CD, including cortical laminar disorganization, neurons in the cortical molecular layer, and periventricular and laminar heterotopia.[156] Experimental models such as this one provide an excellent opportunity for examining the basic biologic derangements that occur in the evolution of epileptogenic cortical malformations. Continued morphologic, immunohistochemical, clinicopathologic, and molecular research is necessary to characterize better the time course and associations of these lesions. Investigations seeking to understand the molecular events involved in the basic processes of cell proliferation, migration, terminal differentiation, PCD, and cortical remodeling will help to elucidate the fundamental mechanisms of brain development and significantly aid in the understanding of cortical malformations responsible for seizure disorders.

Acknowledgments

We thank Alex Brooks, Nelly Vehabedian, and Matthew Lynch for ongoing expert technical assistance and help with manuscript preparation and Carol Appleton for preparation of many of the figures. We also thank Drs. Michael Menchine, Jessica Emelin, Michael DeRosa, Michael W. Johnson, and Michael A. Farrell for past contributions to this work. Chapter 15

Genetic Epidemiology

Ruth Ottman

Melodie R. Winawer

Introduction

A genetic contribution to the epilepsies has been suspected for centuries, but until recently, progress in elucidating the specific genetic influences was relatively slow. This slow progress was attributed in part to methodologic problems in research design and analysis, and in part to inherent complexity in the role that genetic factors play in increasing the risk for epilepsy. With the rapid development of research tools in molecular genetics, however, significant advances have been made over the last 10 years, and a number of genes that influence risk for either idiopathic or symptomatic epilepsy syndromes have been identified. Despite these very important advances, most epilepsy is not explained by mutations in these genes, and efforts to identify other genetic influences are continuing.

Identification of genes that influence risk for epilepsy has great implications for public health. It is a first step in investigating the physiologic effects of the susceptibility genes, which can lead to a better understanding of pathogenesis of epilepsy and to new strategies for treatment and prevention. It also facilitates early identification and treatment of susceptible individuals, and perhaps someday, even prevention of epilepsy in some people. See Chapters 17 and 18 for further discussion of these and other related issues.

Gene discoveries also raise important ethical and social issues. For example, when is it appropriate to offer genetic testing, who should offer it, and how should the results be presented to patients (e.g., by the treating physician or a genetic counselor)? These issues have only begun to be considered as the pace of discoveries in genetic research on the epilepsies increases. Some of these issues are discussed in Chapter 19.

Genetic Influences on the Epilepsies: Current Knowledge

So far, almost all of the progress in epilepsy gene identification has come from analysis of rare families with mendelian modes of inheritance (autosomal dominant, autosomal recessive, or X-linked). As of December 2005, 12 genes had been identified in autosomal dominant forms of eight idiopathic epilepsy syndromes (Table 1). All but two of these genes encode voltage-gated or ligand-gated ion channels. In families with benign familial neonatal seizures, mutations have been found in the potassium channel genes KCNQ2 and KCNQ3.[18,106] Mutations in the genes encoding three sodium channel subunits, SCN1A, SCN1B, and SCN2A, have been found in different families with generalized epilepsy with febrile seizures plus (GEFS+),[30,107,111,112,126] and mutations in SCN2A have also been found in families with a different phenotype, benign familial neonatal-infantile seizures.[12,43] Mutations in GABRG2, the gene encoding the Î³-2 subunit of the Î³-aminobutyric acid subtype A (GABA$_A$) receptor, have been found in families with GEFS+[10,38] and in families with childhood absence epilepsy with febrile seizures.[50,125] In a large French Canadian family with an autosomal dominant form of juvenile myoclonic epilepsy (JME), a mutation was identified in GABRA1, encoding the Î±-1 subunit of the GABA$_A$ receptor.[21] Mutations in EFHC1, encoding a protein with an EF-hand motif that appears to influence calcium currents, were identified in another set of families with JME.[114] In three families with an autosomal dominant form of idiopathic generalized epilepsy (IGE) with a range of different syndromes, mutations were identified in the chloride channel gene CLCN2.[40] Mutations have been found in the genes encoding two subunits of the neuronal nicotinic acetylcholine receptor (CHRNA4 and CHRNB2) in families with autosomal dominant nocturnal frontal lobe epilepsy.[22,108] In families with autosomal dominant partial epilepsy with auditory features (ADPEAF), mutations have been found in the leucine-rich glioma inactivated 1 gene (LGI1), which encodes a leucine-rich repeat protein.[49,62,88] The mechanism by which LGI1 influences epilepsy risk is still not well understood, but based on protein homology, it appears likely to be involved in development of the central nervous system.[49]

Genes have also been identified in a number of mendelian symptomatic epilepsy syndromes. These include progressive myoclonic epilepsies (e.g., Unverricht Lundborg disease, Lafora disease, and the neuronal ceroid lipofuscinoses[104]), X-linked myoclonic epilepsy with mental retardation,[109] and cortical malformation syndromes such as polymicrogyria, pac-hygyria, and periventricular nodular heterotopia.[35,61] In addition, mutations in SCN1A have been identified in many patients with severe myoclonic epilepsy of infancy (SMEI).[19,69,110,124]

Despite the clear importance of these gene discoveries, they apply to only a small proportion of people with epilepsy. Most people with epilepsy have no affected relatives, and only a tiny fraction come from families with mendelian modes of inheritance. In the Epilepsy Family Study of Columbia University (EFSCU),[79,83,86,87] we collected family history information on 1,957 people with epilepsy, ascertained from voluntary organizations for epilepsy without regard to their family histories. The proportion of subjects with a positive family history (with one or more first-degree relatives with epilepsy) was 15% in those with IGE and 12% in those with cryptogenic localization-related epilepsy (LRE). Moreover, most of those with a family history had just one affected relative (probands with IGE 77%, cryptogenic LRE 79%), and very few families appeared consistent with a mendelian mode of inheritance.[81]

Table 1 Mendelian Idiopathic Epilepsy Syndromes with Genes Identified by Positional Cloning (as of December, 2005)

Epilepsy syndrome	Gene	Chromosomal location	References
Benign familial neonatal seizures	KCNQ2	20q13	106
	KCNQ3	8q24	18
Generalized epilepsy with febrile seizures plus	SCN1B	19q13	126
	SCN1A[b]	2q24	30,111
	SCN2A[a]	2q24	112
	GABRG2[a]	5q31	10,38
Benign familial neonatal-infantile seizures	SCN2A[a]	2q24	12,43

Childhood absence epilepsy with febrile seizures	GABRG2[a]	5q31	50,125
Autosomal dominant juvenile myoclonic epilepsy	GABRA1	5q34	21
	EFHC1	6p12	114
Autosomal dominant idiopathic generalized epilepsy	CLCN2	3q26	40
Autosomal dominant nocturnal frontal lobe epilepsy	CHRNA4	20q13	108
	CHRNB2	1q21	22
Autosomal dominant partial epilepsy with auditory features	LGI1	10q24	49,62

[a] Mutations identified in more than one epilepsy syndrome.

[b] Mutations (many of which are *de novo*) also identified in severe myoclonic epilepsy of infancy.

In the large group of people with nonmendelian forms of epilepsy, the genetic influences on risk probably consist mainly of â€œcomplexâ€ disease genesâ€"that is, genes with only a small effect, which act additively to raise risk, possibly in combination with environmental factors.[70] Research is under way to identify these complex epilepsy genes, but progress has been slow and few findings have been confirmed.[116] Given that most of the genes identified in families with mendelian inheritance so far have encoded voltage-gated or ligand-gated ion channels, variants in ion channel genes may well contribute to risk for genetically complex epilepsies also.

P.162

Other types of genetic effects may also play a role in some cases. First, some â€œsporadicâ€ epilepsies (i.e., those occurring in the absence of a family history) may be caused by *de novo* mutations. This mechanism is important in SMEI, where many of the mutations identified in SCN1A have been *de novo*.[19,69,110,124] Second, some epilepsies may be caused by somatic mutations occurring in critical brain regions. Third, mitochondrial genetic defects have been demonstrated to underlie disorders in which epilepsy is a significant part of the phenotype (myoclonus epilepsy with ragged red fibers [MERRF] and mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes [MELAS]),[24] and could be involved in other forms of epilepsy as well.[82] Finally, some of the genetic influences on epilepsy may involve either genomic imprinting, in which expression of a genotype is influenced by the sex of the parent from whom it is inherited,[36] or trinucleotide repeat expansion, involving an amplification of the number of tandem repeats in a DNA sequence rather than a change in the nucleic acid sequence *per se*.[115]

Complexities in the Genetics of the Epilepsies

The search for genetic contributions to epilepsy is complicated by a number of factors. The relations between genotype (i.e., the genes that influence risk) and phenotype (i.e., the detectable clinical signs and symptoms) in the epilepsies are not at all straightforward. Even in the genes identified in families with mendelian forms of epilepsy, most of the identified mutations have *reduced penetrance*: Some of those who inherit the mutation are unaffected. This implies that some other factorâ€"an environmental exposure or genotype at a different locusâ€"is required for phenotypic expression of the mutation. Consequently, in families with multiple affected individuals, one cannot assume that unaffected individuals do not carry a susceptibility gene. A special case of this is age-related penetrance: Because risk for epilepsy increases with age, gene carriers may be unaffected if studied at young ages.

Another complication is *etiologic* and *genetic heterogeneity*. The epilepsies are extremely clinically heterogeneous, varying by seizure types, ages at onset, brain localization, electrophysiologic and neuroanatomic abnormalities, response to treatment, and many other factors. These differences are so striking that most epileptologists view the epilepsies as a collection of different disorders, or syndromes, with different etiologies. But to what extent do the different clinical entities also differ with respect to their genetic contributions? Which features can best be used to separate the epilepsies into subgroups likely to share susceptibility genes? The answers to these questions are still unknown. Discovery of clinical features that distinguish between epilepsies with larger and smaller genetic contributions and investigation of shared and distinct genetic contributions to different types of epilepsy are important research goals. Such distinctions could aid in the design of studies aimed at gene identification and greatly refine classification of syndromes.

With *locus heterogeneity*, different genes influence the risk for the same epilepsy syndrome; hence, different families with the same syndrome carry mutations in different susceptibility genes. This phenomenon is well documented in the epilepsies. Multiple autosomal dominant susceptibility genes have been identified in four syndromes: Benign familial neonatal seizures (KCNQ2 and KCNQ3), autosomal dominant nocturnal frontal lobe epilepsy (CHRNA4 and CHRNB2), GEFS+ (SCN1A, SCN1B, SCN2A, and GABRG2), and autosomal dominant JME (GABRA1 and EFHC1). Moreover, different genetic mechanismsâ€"single gene versus complexâ€"can produce the same syndrome in different families, making it impossible to classify syndromes according to genetic mechanisms. For example, the IGEs are genetically complex in most cases, but some families have autosomal dominant inheritance.[21,40,114] Although mutations in LGI1 have been found in 50% of families containing two or more subjects with temporal lobe epilepsy with ictal auditory symptoms,[88] most patients with these symptoms are sporadic and do not have LGI1 mutations.[15,32]

Another complication is *variable expressivity*, in which a mutation in a single gene produces different epilepsy phenotypes in different individuals. For example, in GEFS+, the seizure disorders in family members who have inherited the same SCN1A mutation can vary from simple febrile

seizures, febrile seizures plus (in which febrile seizures persist beyond age 6 or are accompanied by afebrile generalized tonicâ€"clonic seizures), idiopathic generalized epilepsy, temporal lobe epilepsy, or myoclonic-astatic epilepsy.[107] This variable expressivity within families suggests that other genes or environmental factors are involved in the causal pathway leading to a particular epilepsy phenotype. Further, in three of the four genes found to be mutated in GEFS+ families, mutations have been identified in other syndromes also: SCN1A mutations (many of which are de novo) in patients with SMEI,[19,69,110,124] SCN2A mutations in families with benign familial neonatal infantile seizures,[43] and GABRG2 mutations in families with childhood absence epilepsy with febrile seizures.[50,125] Again, this variable expression across families probably reflects the involvement of other genes or environmental factors in the phenotypes under study, although variation in the types of mutations in the gene involved may also play a role.

Finally, the effects of some genotypes on epilepsy may involve *geneâ€"environment interaction*, that is, the joint influence of genetic and environmental factors in a causal pathway leading to disease.[71,72,95] Geneâ€"environment interaction might explain some of the reduced penetrance observed in the epilepsy genes discovered so far. For example, some genotypes might not affect risk directly, but instead might increase susceptibility to the effects of environmental factors. In this case, individuals who inherit the risk-raising genotype would not develop epilepsy unless they were also exposed to the environmental factor; hence, some susceptibility genes might contribute to remote symptomatic epilepsy and even to acute symptomatic seizures as well. In a study by Schaumann et al.,[98] seizure risk was increased in the relatives of people who had seizures associated with heavy alcohol consumption (either unprovoked seizures associated with chronic alcohol abuse or acute symptomatic seizures associated with alcohol intoxication), suggesting that some genotypes may interact with alcohol exposure to raise risk. In the same study, however, risk was not increased in the relatives of people with posttraumatic epilepsy.

Research Approaches in Genetic Epidemiology

In the study of a complex disorder such as epilepsy, genetic epidemiologists use a series of study designs to elucidate the genetic contributions on the population, family, and molecular levels. These studies begin with the assessment of *familial aggregation*: To what extent is the risk of epilepsy (or other disorders) increased in the relatives of people with epilepsy? Evidence of familial aggregation has only limited utility in evaluating genetic hypotheses; significant familial clustering can arise from shared environmental exposures (e.g., air pollutants) or high-risk behavior practices (such as diet) in members of the same family, in addition to genetic factors. Thus, the next step is to use special designs such as *twin studies* or *adoption studies* to ask: To what extent is the familial aggregation due to shared genes as opposed to shared environment? If a significant genetic effect is observed, additional studies must be carried out to determine what types of genetic effects underlie susceptibility. At one extreme, the genetic effects could involve single genes with a major effect on susceptibility, whether autosomal or X-linked, dominant or recessive. At the opposite extreme, some genetic influences could be polygenic; that is, they could be a consequence of the effects of a large number of genes at different loci, each of which individually contributes only slightly to the risk. Between these two extremes, some influences might involve pairs or small groups of genes, possibly with interactive (epistatic) effects. One method that can be used to distinguish among these possibilities, *segregation analysis*, involves examining the distribution of disease occurrence in families and testing its consistency with various mendelian models (autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, X-linked dominant). This method has been used in only a few studies of human epilepsies.[34,47,68,81,92] Finally, studies must be designed to investigate the molecular mechanisms by which the genes influence risk. At this stage, the specific genes involved need to be identified, and their basic pathophysiologic effects studied. So far, most studies aimed at gene identification have employed *linkage analysis* and subsequent positional cloning; many newer studies are using *allelic association* designs. Below we review these approaches and what has been learned from each in genetic studies of the epilepsies.

Collection of Family History Data

Accurate information about seizure occurrence in family members is essential for almost all designs used to test genetic hypotheses about epilepsy and other seizure disorders. In most genetic studies of epilepsy, data are obtained indirectly, in â€œfamily historyâ€ interviews in which the proband with epilepsy (or a parent or other caregiver, if the proband is a child) is interviewed about seizures in other family members. For many disorders, family history data obtained in this way have low sensitivityâ€"many truly affected relatives are misclassified as unaffected. This problem can usually be remedied by using a â€œfamily studyâ€ design, in which each relative is examined or given a diagnostic interview directly. Study of the genetic epidemiology of epilepsy presents a unique problem, however, because the diagnosis in both probands and relatives cannot usually be made on the basis of physical examination or laboratory testing. It is essentially historical, based on a description of seizure events that occurred prior to visiting the physician.

Ottman et al. evaluated the validity of family history data on parents and siblings, collected in semistructured family history interviews with adults with epilepsy.[83] In this study, many of the parents and siblings of these subjects were also interviewed about their own seizure histories and those of their other family members. The relatives' self-reports or their mother's reports were used as the â€œgold standardâ€ in deciding whether or not they had seizure disorders. The results suggested that adults with epilepsy can report reasonably accurately about epilepsy in their parents and siblings, but isolated unprovoked seizures and acute symptomatic seizures are underreported. Sensitivity for epilepsy (i.e., the proportion of relatives with epilepsy who were correctly reported to have had seizures in the family history interview) was 87% assuming the mother's report was correct, and 93% assuming the self-report was correct. For other seizure disorders in relatives, sensitivity was only 32% assuming the mother's report was correct, and 18% assuming the self-report was correct.

Evidence also suggests that family history information on epilepsy is less accurate for older relatives than for younger relatives. One study based on family history reports found an apparent â€œcohort effectâ€ in the familial risks for epilepsy, with a 50% increase in the proportion of relatives reported to be affected, for each 20-year increase in birth year of the relatives.[85] This effect could not be attributed to a real change in risk over time, because the age-specific incidence rates of epilepsy among persons younger than 40 years did not increase during the time periods investigated.[42] Instead, the apparent cohort effect was probably an artifact of better recall of recent events than of past events. In the older relatives, a diagnosis of childhood onset epilepsy would have occurred many years before the family history interviews were done, whereas in the younger relatives such a diagnosis would have occurred more recently. Thus, the subjects who were interviewed about their family histories were probably less likely to remember (or even to know

about) epilepsy in their older relatives than in their younger relatives.

Familial Aggregation Studies

Most early studies of the genetics of epilepsy were devoted to assessing familial aggregation, that is, an increased risk for epilepsy in the relatives of affected persons compared with risks in the general population (or relatives of unaffected persons). In familial aggregation studies a sample of people with epilepsy (probands) is ascertained, and then the risk of epilepsy is examined in the relatives of the probands and compared with the risk in the population or in the relatives of controls without epilepsy. The probands may also be divided into subsets based on syndromes or other clinical features (etiology, age at onset, seizure type, etc.), and the risks in the relatives of the different subsets compared. Also, the risks of specific clinically defined subsets of epilepsy (or other disorders) may be examined in the relatives and compared with the risks of the same outcomes in the relatives of controls (or the general population).

Several problems of epidemiologic design and analysis have impeded progress in these studies. Many studies used highly selected populations, possibly introducing bias in the estimates of the magnitude of increased risk. Few studies used comparison groups, rigorous methods for obtaining information about family history, or standardized interview methods. Many studies failed to specify which classes of relatives were included. In the analysis of risks in relatives, age adjustments were seldom made. Definitions of epilepsy were often ambiguous. The outcome of interest in the relatives was seldom clearly defined. Some studies defined only those with epilepsy as affected, whereas others included those with any type of seizure disorder or those with only electroencephalogram (EEG) abnormalities.

The best estimates of familial aggregation are derived from the work of Annegers et al., using population-based data from the Rochester Epidemiology Project.[3,5,6,7,76,77,78] The Rochester Epidemiology Project is a unique exception to the usual methods used in familial aggregation studies of the epilepsies and other disorders. It takes advantage of the records linkage system of the Mayo Clinic, which includes essentially all medical, surgical, and pathologic diagnoses of residents of Olmsted County from 1922 to the present, and therefore provides an excellent resource for epidemiologic studies of epilepsy and other disorders.[8,59] This system was adapted for collection of genetic information using a three-step procedure that avoids the use of interviews completely. First, probands with epilepsy were identified by searching the records of the Mayo Clinic to identify all children aged younger than 16 years with diagnoses of idiopathic or cryptogenic epilepsy or isolated unprovoked seizures while residing in Rochester after 1935. Second, the records were used to identify the parents of these probands, and all of the other descendants of the parents (i.e., the probands' siblings, children, nieces and nephews, and grandnieces and grandnephews). Third, the medical records of these relatives at the Mayo Clinic and all other medical facilities serving southeastern Minnesota were reviewed for evidence of seizure dis-orders.

This study design offers several unique advantages for genetic studies. The problem of selection bias is avoided because all incident cases of epilepsy during a specified time period were included; the data on seizure disorders in relatives have high validity, because they are obtained by careful, page-by-page review of the relatives' medical records rather than by proband interviews; and the clinical detail on both probands and relatives is extensive. This approach would be impossible in most studies, because family members often live in different areas and access to their medical records is very difficult to obtain.[80] The only major disadvantages are the limitation in sample size imposed by the relatively small population of Rochester and the restriction to probands with childhood onset, idiopathic or cryptogenic epilepsies, which limited some of the comparisons that could be done in the analysis.

In the Annegers et al. study, the cumulative incidence of epilepsy to age 20 years was 3.6% in siblings and 10.6% in offspring of probands with idiopathic or cryptogenic epilepsy beginning before age 16, compared with 1.7% in the Rochester population.[4] The standardized incidence ratios (SIRs) for epilepsy in the relatives of individuals with idiopathic or cryptogenic, childhood-onset epilepsy were 2.5 (95% confidence interval [CI], 1.3 to 4.4) in siblings and 6.7 (95% CI, 1.8 to 17.1) in offspring.[5] Risk for unprovoked seizures was not increased in more distant relatives (e.g., nieces and nephews or grandchildren). In a later study of the same population with additional live births and follow-up, Ottman et al.[76] found that the SIR for offspring was lower than in the Annegers et al. study: 3.4 (95% CI, 2.1 to 5.1). The lower risks in the more recent study were partly due to a larger number of offspring, leading to greater precision in the risk estimates than in the earlier study. Another possible explanation relates to a difference in study design: The probands in the Annegers et al. study were restricted to incident idiopathic or cryptogenic epilepsy cases with onset prior to age 16, whereas those in the Ottman et al. study were all prevalent epilepsy cases during a specified time period (regardless of etiology or age at onset).

Table 2 Risk of Epilepsy in Siblings, by Etiology of Epilepsy in the Proband[a]

	Classification of epilepsy in probands	
	Idiopathic or cryptogenic	**Symptomatic**
Harvald[39]	4.2	1.2
Eisner et al.[28,b]	5.5	
Annegers et al.[4,b]	2.7	
Ottman et al.[79]	2.4	0.8

[a]Cumulative incidence to age 20 reported in all studies except Harvald.
[b]Restricted to siblings of probands with onset prior to age 16.

Familial aggregation studies can provide important information about etiologic and genetic heterogeneity. Comparisons of probands with different epilepsy syndromes or other clinical characteristics, in terms of the risks for seizure disorders in close relatives, have indicated which subgroups are most strongly influenced by a genetic susceptibility. One of the most consistent findings has been that relatives of patients with idiopathic or cryptogenic epilepsy have a higher risk than relatives of those with remote symptomatic epilepsy.[2,39,56,79,86,120] Table 2 shows the results of four studies that reported sibling risks of epilepsy, stratified by the etiology of epilepsy in the probands. Risks to age 20 years ranged from 2% to 5% in the siblings of probands with idiopathic or cryptogenic epilepsy. However, two studies that examined risks in siblings of probands with symptomatic epilepsy found risks of approximately 1%, which is not higher than in the general population. This lack of increased risk in the relatives of probands with symptomatic epilepsies suggests that genetic influences are relatively minor in most symptomatic epilepsies (caused by traumatic brain injury, stroke, brain infection, etc.). On the other hand, genes that raise susceptibility to the effects of specific types of brain insults may play a role in some symptomatic cases. If this is true, then in the families of these symptomatic probands, an increased risk would be

expected only in the relatives who were exposed to the same types of brain insults as the probands. Since these exposures are likely to be uncommon, the risk in their relatives overall (without taking into account which are exposed) is unlikely to be increased.

Risk of epilepsy has also been found to be higher in the relatives of probands with earlier age at onset of epilepsy than in the relatives of those with later onset.[2,28,56,79,86] Lennox[56] reported a gradient of risk in first-degree relatives with proband age at onset. Risks were highest in relatives of probands with onset before 5 years of age, intermediate in relatives of probands with onset between 5 and 19 years of age, and lowest in relatives of probands with older ages at onset. In the Minnesota Clinical Epilepsy Research Program,[2] sibling risks were higher for probands with age of onset at 25 years or less than for those with later ages of onset. Eisner et al.[28] found the highest risks in first-degree relatives of probands with onset before 4 years of age. Ottman et al. also found a higher risk in the relatives of probands with earlier age at onset.[79,86] Moreover, they found that the degree of increased risk diminished with increasing age of the relatives; among relatives who reached age 35 without developing epilepsy, risk was not increased.[79]

Another important finding is that risks are higher in the remaining relatives of probands with a family history than in the relatives of those without a family history.[51,60,81] In one study, the siblings of probands with IGE had a 4% risk of idiopathic or cryptogenic epilepsy overall, but a much higher risk if they also had an affected parent (15%) or another affected sibling (22%) in addition to the proband.[81] In the same study, the siblings of probands with cryptogenic localization-related epilepsy had a 2% risk of idiopathic or cryptogenic epilepsy overall, but a 3% risk if a parent was affected and a 10% risk if another sibling was affected.[81]

It is widely assumed that risk is higher in the relatives of patients with generalized epilepsy than in relatives of those with localization-related epilepsy, but in most studies the difference between these two groups is small.[73,74] In analyses of offspring of epilepsy patients in Rochester, Minnesota,[77] the higher risk in offspring of parents with generalized seizures was entirely attributable to very high risks in offspring of the subset with absence seizures. Thus, for the majority of patients with generalized seizures, risk in offspring was no higher than in the offspring of patients with partial seizures.

In understanding the relations between genotype and phenotype in the epilepsies, two alternative models can be envisioned.[128,130] The first model postulates that different sets of genes influence risk for different epilepsy syndromes (â€œdistinct genetic influencesâ€), and the second, that the same genes influence risk for different epilepsy syndromes (â€œshared genetic influencesâ€). Familial aggregation studies can be used to distinguish between these possibilities by investigating whether, in the families of probands with specific types of epilepsy, risk is increased only for the same types as in the probands or for all types of epilepsy. If the genetic influences on different types of epilepsy are distinct, then among the relatives of probands with a given type, risk will be increased only for the same type as in the proband. On the other hand, if the genetic influences on different types of epilepsy are shared, risk in the relatives will be increased for all types, including those different from that in the proband. In two studies that used this approach, evidence was obtained for shared genetic influences on generalized and localization-related epilepsy. In the relatives of probands with generalized epilepsy, risk for localization-related epilepsy was significantly increased (fourfold), both in population-based data from Rochester, Minnesota,[77] and data from the Epilepsy Family Study of Columbia University.[84]

However, other studies suggest that clinical characteristics of epilepsy tend to cluster in families. Both Tsuboi[119] and Beck-Mannagetta et al.[11] found that the distribution of seizure types in affected relatives was skewed toward the same types of seizures as in the probands, although different seizure types were also seen. In a study of 72 families of probands with idiopathic generalized epilepsies, each of which contained more than three affected individuals, multiple idiopathic generalized epilepsies were seen in 75% of families, but there were very few cases of localization-related epilepsy.[1] These findings are difficult to interpret because they do not take into account what distribution of syndromes would be expected in the families by chance alone.

Winawer et al. developed a method based on permutation testing to test hypotheses about shared and distinct genetic influences on different clinically defined subsets of epilepsy.[128,129,130,131] The method, *family concordance analysis*, assesses the concordance of epilepsy types (syndromes, seizure types, or subsets defined by other clinical features) in families containing multiple affected individuals. The rationale for the analysis is that if some of the genetic influences on different epilepsy types are distinct, families will tend to be concordantâ€”that is, the proportion of families in which all affected individuals have the same type of epilepsy will exceed that expected by chance. The results of studies using this approach have provided evidence for distinct genetic influences on generalized and localization-related epilepsy.[130] Within the IGEs, these studies found evidence for distinct genetic influences on different *seizure types*: Myoclonic, absence, and generalized tonicâ€“clonic.[129,131] With respect to different *syndromes* within the IGEs, they found evidence for distinct genetic influences on JME versus the two absence epilepsy syndromes (childhood absence epilepsy [CAE] and juvenile absence epilepsy [JAE] combined), but not for distinct influences on CAE versus JAE.[129,131]

There is a strong basis for assuming a common genetic basis for epilepsy and febrile seizures. Hauser et al.[41] found that risk for epilepsy is increased to the same extent in relatives of probands with febrile seizures as in relatives of probands with epilepsy. However, when the proband had both epilepsy and febrile seizures, risk for epilepsy was increased to a greater extent, suggesting that a higher genetic liability is required to manifest both disorders. These results parallel those from recent studies of GEFS+, in which the identified genes raise risk for both epilepsy and febrile seizures.[9]

The findings of three previous studies suggest the possibility of a shared genetic susceptibility to epilepsy and cerebral palsy. In the National Collaborative Perinatal Project, incidence of cerebral palsy in offspring was associated with the mother's history of epilepsy[67]; and incidence of nonfebrile seizure disorders in offspring without cerebral palsy was associated with a history of motor deficits in siblings.[66] Similarly, Rimoin and Metrakos[93] reported an increased prevalence of convulsions and epileptiform EEG abnormalities in relatives of children with hemiplegia, a specific form of cerebral palsy. Finally, Ottman et al. found an increased risk of idiopathic or cryptogenic epilepsy in the first-degree relatives of probands with epilepsy associated with neurologic deficits presumed present at birth (many of whom had cerebral palsy), although the numbers were too small to reach statistical significance.[79]

Table 3 Percent of Offspring with Epilepsy, by Sex of Affected Parent

[a]Cumulative incidence of epilepsy to age 25 in offspring.

An intriguing aspect of the familial distribution of epilepsy pertains to the risks in offspring: Risks of epilepsy and febrile seizures are higher in the offspring of affected women than in the offspring of affected men (Table 3).[7,46,76,82,120] This *maternal effect* has been observed consistently in previous studies, and is not compatible with any conventional genetic model.[75,82] In population-based data from Rochester, the risk of epilepsy by age 25 years was 8.7% in offspring of affected women and 2.4% in offspring of affected men, compared with 1.6% in the Rochester population.[76] Additional analyses indicated that this difference could not be explained by intrauterine exposure to seizures or anticonvulsants in offspring of women with epilepsy, or patterns of selective fertility that might lead to a

higher proportion of affected mothers than affected fathers with familial forms of epilepsy.[76,101,102,103] An increased frequency of some complications of pregnancy and delivery has been reported in women with epilepsy, but these complications are not associated with increased risk for seizures in their offspring[113] and thus could not explain the higher seizure risk in offspring of women than of men with epilepsy. The possible roles of mitochondrial genes, imprinted nuclear genes, or expanded repeat mutations remain to be investigated.

Twin Studies

Studies of twins are ideal for disentangling genetic from nongenetic causes of familial aggregation. For this purpose, the within-pair similarities (or concordance rates) of monozygotic (MZ) and dizygotic (DZ) twins are compared, on the assumption that genetic effects would produce greater similarity in the two co-twins of a monozygotic pair (who share 100% of their genes) than in the two co-twins of a dizygotic pair (who share 50% of their genes on average).

Concordance rates for epilepsy are consistently higher in monozygotic twins than in dizygotic twins[13,20,45,52,53,55,57,105,121] (Table 4), although the concordance rates vary across studies because of differences in methodology such as twin ascertainment methods, numbers of pairs included, approaches for diagnosis and classification, and methods used to calculate concordance. In the classic twin study by Lennox,[55] concordance rates were higher in MZ than DZ pairs only for twins with â€œintact brains,â€ illustrating the greater importance of genetic factors in idiopathic or cryptogenic epilepsies than in symptomatic epilepsies.

[a]Reanalysis of data from Lennox.[56]

More recently, twin studies have been used to investigate the shared and distinct genetic influences on different types of epilepsy and to provide evidence for distinct genetic effects on generalized and localization-related epilepsies. In a study of 253 Australian twin pairs, Berkovic et al.[13] found evidence not only for the genetic influences on epilepsy as a whole, but also for specific epilepsy subtypes. For example, MZ concordance rates were higher than DZ concordance rates in analyses restricted to either generalized epilepsy or localization-related epilepsy (Table 4). Among MZ twin pairs concordant for epilepsy, 94% had the same International League against Epilepsy (ILAE) major epilepsy syndrome compared with 71% of DZ twin pairs with epilepsy. Re-examination of Lennox's twin data with classification of seizure types and syndromes by modern ILAE criteria confirmed these findings: 86% of MZ pairs and 60% of DZ pairs were concordant for ILAE syndrome.[121] The results were very similar in another recent population-based twin study.[52] Concordance rates were higher in MZ than in DZ pairs not only for epilepsy overall, but also for generalized epilepsy and localization-related epilepsy specifically (Table 4); and among pairs concordant for epilepsy, 83% of MZ pairs and 65% of DZ pairs were concordant for syndrome. These findings are consistent with those from the family concordance study of Winawer et al.[130] but differ from those in the familial aggregation studies, in which the risks for localization-related epilepsy were elevated in the families of probands with generalized epilepsy.[77,84] One possible explanation is that some genetic influences on generalized and localization-related epilepsies are distinct and others shared, and the different study designs vary in their ability to detect these different influences.

Linkage Analysis

Linkage analysis is a powerful tool used to localize, or map, a gene to a small chromosomal region. This is a first step in *positional cloning*, in which a disease-related gene is identified from among the 20,000 to 30,000 genes in the human genome by first narrowing the search to a small number of genes in a specific chromosomal region, and then examining the nucleotide sequence of the genes in that region to identify a mutation that is likely to affect disease risk. The basic approach to linkage analysis is an investigation of the co-inheritance of genes or disease with genetic marker alleles within families. The closer two genes are on a chromosome, the less likely they are to be separated by recombination; hence, the alleles of genes located close together are inherited together more often than expected by chance. The direct linear relationship between number of recombination events and the distance between genes is at the root of genetic linkage analysis. The statistic used to assess the evidence for linkage is the lod score, defined as the $\log_{10}$ of the ratio of two probabilities: The probability that the family

data would be observed under the hypothesis of linkage at a specific recombination fraction (numerator) and the probability that the data would be observed under the hypothesis of no linkage (denominator). In a genome-wide analysis, a lod score of 3.0 is generally accepted as significant evidence for linkage at $p < 0.05$.

Many linkage findings have been reported in various epilepsy syndromes or subsets. Some, but not all, of these have led to the identification of mutations in risk-raising genes, and some of the published findings will probably turn out to be false positives. The linkage findings are too numerous to list all of them here, but some of the most important and consistent results are summarized below.

An intense effort has been made to identify linkage in the IGE syndromes, which show strong familial aggregation and usually nonmendelian inheritance (although mendelian forms of IGE have also been described, and three genes listed in Table 1, CLCN2,[40] GABRA1,[21] and EFHC1,[114] were identified in these forms). In the genetically complex IGEs, evidence has been reported for linkage to a wide array of chromosomal regions, including 2q36,[97] 3q26,[97] 5p,[25] 6p21,[21,26,34,89,96,117,127] 6p12,[21,114] 8p12,[25,27] 13q31,[117] 14q23,[97] 15q14,[29] and 18q12.[25] The most consistent result is linkage to the HLA region (chromosome 6p21); many of the other linkage findings have been inconsistent across groups.

One particularly promising linkage finding at present is in familial partial epilepsy with variable foci, a syndrome first described in a family with complex partial and secondarily generalized, primarily nocturnal seizures.[99] Interictal EEGs in affected family members revealed frontal, temporal, and occasionally occipital epileptic foci.[99,132] Linkage to chromosome 22q11 has been reported in three large families with this syndrome.[14,16,132] The gene has not yet been identified, but the minimal genetic region has been narrowed to a 5.2 megabase region on chromosome 22. Identification of a gene that raises risk for this syndrome could provide interesting information about the heritable mechanisms underlying multifocal pathology.

A number of studies have used linkage analysis to localize genes for febrile seizures, but these findings have not led to gene discoveries so far. In studies of large families with apparently autosomal dominant inheritance, evidence was found for linkage to four chromosomal regions: FEB1 on chromosome 8q13-21,[123] FEB2 on chromosome 19p13,[48,54] FEB3 on chromosome 2q23-24,[90] and FEB5 on chromosome 6q22-24.[64] In a series of 47 small families, another study found evidence for linkage to another region, FEB4 on chromosome 5q14-15.[65] One of the challenges in these studies is distinguishing the different phenotypes of febrile seizures. In many of the reported families, it is unclear whether the phenotype should be called isolated febrile seizures or GEFS+ (involving febrile seizures persisting to late ages or accompanied by afebrile generalized tonicâ€"clonic seizures), and no standardized criteria for GEFS+ are available to help resolve this problem. For example, some investigators suggested that the family in which the FEB3 locus was reported on chromosome 2q23-24 actually had GEFS+, so the locus should not have been named FEB3.[63,100]

Allelic Association Studies

In epilepsy as in other disorders, allelic association studies are now being used as an alternative to positional cloning for the detection of disease genes.[116] These studies are aimed at detecting genetic variants that are more common in people with epilepsy than in unaffected persons from the same population. A significantly increased frequency of a variant in people with epilepsy would suggest either that it directly affects risk for epilepsy, or that it is located very close to a functional variant on the same chromosome, and very often inherited with the functional variant (linkage disequilibrium). The genetic variants examined are usually single nucleotide polymorphisms (SNPs), common DNA sequence variations where one of the four nucleotides is substituted for another, found every 1,000 to 2,000 nucleotides in the human genome and accounting for about 90% of all DNA polymorphisms. Most allelic association studies have focused on variants in candidate genes with a hypothesized effect on disease risk (such as genes encoding ion channels). Recently, however, investigators have begun to undertake genome-wide association studies, and this approach will be used in the epilepsies soon.[17,44]

Allelic association studies have important advantages for the study of complex diseases. Unlike linkage studies, they do not require families with multiple affected individuals, which are so rare in the epilepsies. Also, they have greater statistical power than linkage studies for the detection of genes with a small effect on disease risk.[94]

Allelic association studies also have potential limitations. The validity of their basic underlying assumptionâ€"that nonmendelian epilepsies result from DNA variations common to a relatively large proportion of cases (the so-called â€œcommon disease-common variant hypothesisâ€)[37]â€"is still unknown. If many different combinations of risk-raising variants in multiple genes produce similar epilepsy phenotypes, none of the variants may be common enough to be detected through allelic association. Also, the contributions of somatic mutations and *de novo* mutations to complex epilepsies are unknown.

The potential for population stratification, a special type of confounding, must be considered in the design and interpretation of allelic association studies. It arises when the cases and controls in a study have different genetic ancestries and the ancestral groups differ in their allelic distributions. As a result, the cases and controls could differ in the frequency of an SNP of interest for reasons unrelated to the disease. The magnitude of the effect of stratification on current allelic association studies is controversial.[118,122] but fortunately, a number of methods have been developed to control for its effects, including family-based association tests,[133] genomic control,[23] and structured association tests.[91]

In the epilepsies, a large number of candidate gene-based allelic association studies have been published, and the pace of publication has increased dramatically in recent years (reviewed in reference 116). Many of the published studies have been plagued by methodologic limitations such as small sample size, lack of control for population stratification, and failure to adjust for multiple statistical tests. Few genetic variants have been examined in more than a single study, and among those that have, few of the reported associations have been replicated.[88,116] Thus, although clearly this approach holds great potential, we are still in the earliest stages of its application in the epilepsies.

Another approach, combining linkage and association analysis, has been used in the IGEs with promising results. A genome scan of 91 families with genetically complex adolescent-onset IGEs provided evidence for a locus common to most IGEs on chromosome 18q21, a locus on chromosome 6p21 for JME, and other loci (on chromosomes 8 and 5) influencing risk for other forms of IGEs.[25] The authors suggested that interactions of different combinations of these genes produce the varied phenotypes found in IGE families. In subsequent association studies in the same set of families, they found an association of JME with two SNPs in the promoter region of the BRD2 (RING3) gene on chromosome 6, suggesting that this might be the chromosome 6p21-linked JME gene, although no causative mutations were identified.[89] They also found evidence for association of IGEs with a haplotype of SNPs within the malic enzyme 2 gene on chromosome 18, suggesting that this might be the chromosome 18-linked gene predisposing to

IGE[33]; however, a subsequent study by other authors failed to confirm this finding.[58]

Studies in *pharmacogenomics* use allelic association designs to attempt to identify genetic variations related to antiepileptic drug response or toxicity. This is a rapidly expanding research area that may transform the use of anticonvulsants as well as other medications.[31] The polymorphisms examined are usually in genes coding for drug-metabolizing enzymes, receptors, and transporters. Understanding the genetic influences on individual variability in drug response may someday help health care practitioners identify patients at risk of toxicity from certain medications, adjust doses based on genetically determined rates of drug metabolism, and select appropriate medications for patients based on their metabolic profile.

Summary and Conclusions

Research in the genetic epidemiology of the epilepsies is advancing very rapidly; a number of genes that influence risk for mendelian forms of epilepsy have already been identified, and efforts to identify others are continuing. Despite the importance of these gene discoveries, however, they apply to only a small minority of patients. Research to elucidate the genetic influences in the remaining patientsâ€"most of whom have no affected relativesâ€"is one of the most challenging and exciting prospects for the near future. Current evidence indicates that the genetic mechanisms that contribute to risk vary across some clinically defined subgroups of epilepsy. Genetic mechanisms also vary across families, even within narrowly defined clinical subsets or syndromes. Environmental factors may also contribute to susceptibility, even in the presence of genetic influences. Further research on the mechanisms by which genes influence risk is extremely important. It could transform clinical management of the epilepsies, leading the way to the development of new therapies and perhaps even ways to prevent epileptogenesis in the future.

Chapter 16

EEG Traits

Timothy A. Pedley

Introduction

At the most fundamental level, cortical excitability and electrical organization are genetically specified, and it is probable that each identifiable electroencephalographic (EEG) pattern is a heritable trait or made up of a combination of heritable traits. As yet, no specific genetic locus has been identified in humans as controlling any spontaneous brain rhythm, whether normal or abnormal, although this will likely one day be possible. A spontaneous, synchronized EEG pattern has been discovered in the *mocha* mice mutant that is regulated by a single recessive locus.[89] In addition, a defect in a single genetic locus can result in generalized spike-and-wave activity in mutant mice, and a number of independent loci have been identified that give rise to phenotypically similar spike-and-wave patterns, but each of these is associated with different abnormalities of cellular excitability[13,88] (see also Chapter 37). In terms of epilepsy, it is now clear that rare epileptic syndromes that aggregate in families result from definable monogenic abnormalities (see Chapters 15 and 18). It is also evident, however, that seizure *susceptibility* reflects complex alterations in multiple factors governing neuronal excitability. At the present time, recording the EEG is the only readily available method for detecting an abnormal seizure tendency in asymptomatic individuals, or for classifying the physiologic basis of persons with seizures or epilepsy. Electroencephalography has accordingly assumed major importance in the genetic analysis of epilepsy.

Genetic Studies of Electroencephalographic Patterns

Normal Electroencephalographic Activity

The role of genetic factors has interested investigators from the beginning of scientific study of EEG phenomena. A variety of evidence supports substantial genetic influence on patterns of cerebral electrical activity, although results of many studies cannot be accepted uncritically. Davis and Davis[20] first pointed out similarities in the EEGs of eight pairs of identical twins, and their observations were corroborated by Loomis et al.[75] and by Raney.[93] Lennox et al.[70,71] studied nonepileptic identical and fraternal twins. Electroencephalograms from monozygotic twins were judged to be identical in 85% of twin pairs, whereas EEGs from nonidentical twins were viewed as different 95% of the time. Later quantitative studies of alpha frequency, voltage and phase relations, and sleep patterns have consistently identified EEGs as concordant from identical but not from nonidentical twins.[59,113] Differences between EEG recordings from a pair of monozygotic twins are no greater than the variations that occur spontaneously in sequential recordings from the same individual. Rates of EEG maturation, the appearance and disappearance of age-specific patterns, and, in older subjects, age-related slow activity are all virtually identical in monozygotic twins.[101,114,115] Lykken et al.[76] studied frequency spectra in twins and found them to be the same in 96% of monozygotic pairs. Butler et al.[12] related asymmetries in alpha rhythm to hereditary factors. Vogel et al. have also reported that other patterns aggregate in families, suggesting a genetic basis. These include low-voltage EEG background activity in children,[115] variants of the alpha rhythm,[116] and some types of beta activity.[112,117] The evidence in support of these last examples is not entirely convincing because of the lack of adequate controls for state of alertness, details about drug effects, and the possible influence of anxiety or stress related to the recording methods and circumstances. However, Kubicki[67] has also reported that the presence of rhythmic posterior beta activity is under genetic control, and Koshino and Isaki[66] demonstrated familial occurrence of the *mu* rhythm. Although different modes of inheritance have been proposed for some of these patterns, none can yet be accepted as proved. A low-voltage alpha EEG pattern is a genetic trait that has been associated with psychiatric disorders, most notably anxiety disorders and alcohol use.[40,41] There is some evidence that this trait is linked to the same region of chromosome 20q as panic disorder. Alpha rhythm traits have not been associated with epilepsy. Ellingson et al.[39] studied the occurrence of 14/s and 6/s positive spike bursts in the EEGs of twins and triplets and concluded that this was genetically determined. However, similar rates for 14/s and 6/s positive spike bursts have been reported in the EEGs of unselected and unrelated children.[74]

Nonspecific Abnormal Electroencephalographic Patterns

Kuhlo et al.[68] more fully characterized a rare pattern of 4- to 5-Hz rhythmic activity over the posterior head regions of young adults; this had been described earlier by Vogel et al.[116] Once present, this finding persisted in serial EEGs. Kuhlo et al.[68] concluded that the pattern was genetically determined, because it occurred identically in two monozygotic twin pairs and in 10% of siblings of affected probands.

Doose et al.[27,29] have described â€œabnormal theta rhythmsâ€ in young children, which they correlated with increased susceptibility to febrile seizures and generalized idiopathic epilepsy. The pattern is mainly one of 4- to 6-Hz rhythmic activity, maximal over the parietal areas, and is more common in boys than girls. The finding was strongly age dependent and occurred in about 30% of siblings at ages 3 to 4 years. More recently, Baier and Doose[4] have demonstrated an increased risk for generalized epileptiform activity in the EEGs of siblings if probands show abnormal theta rhythms. In the authors' laboratory, it has sometimes been difficult to distinguish this pattern unequivocally from rhythmic slow activity occurring normally during drowsiness or as part of nonspecifically abnormal generalized slowing of background activity. Another age-dependent finding is 2- to 4-Hz rhythmic activity over the occipital and posterior head regions.[46] The genetic features of this, however, are even

less clear. First, rhythmic occipital delta waves occurred as often in siblings of controls as in siblings of delta-positive probands. Second, in younger children (ages 3 to 4 years), occipital delta rhythms were more common in the siblings of controls than in siblings of probands, but the reverse was true in older children (ages 5 to 10 years). Third, delta rhythms did not correlate with epileptiform activity, but their occurrence with generalized epileptiform activity reduced the frequency with which generalized spike-and-wave activity or photoparoxysmal responses were identified in siblings.

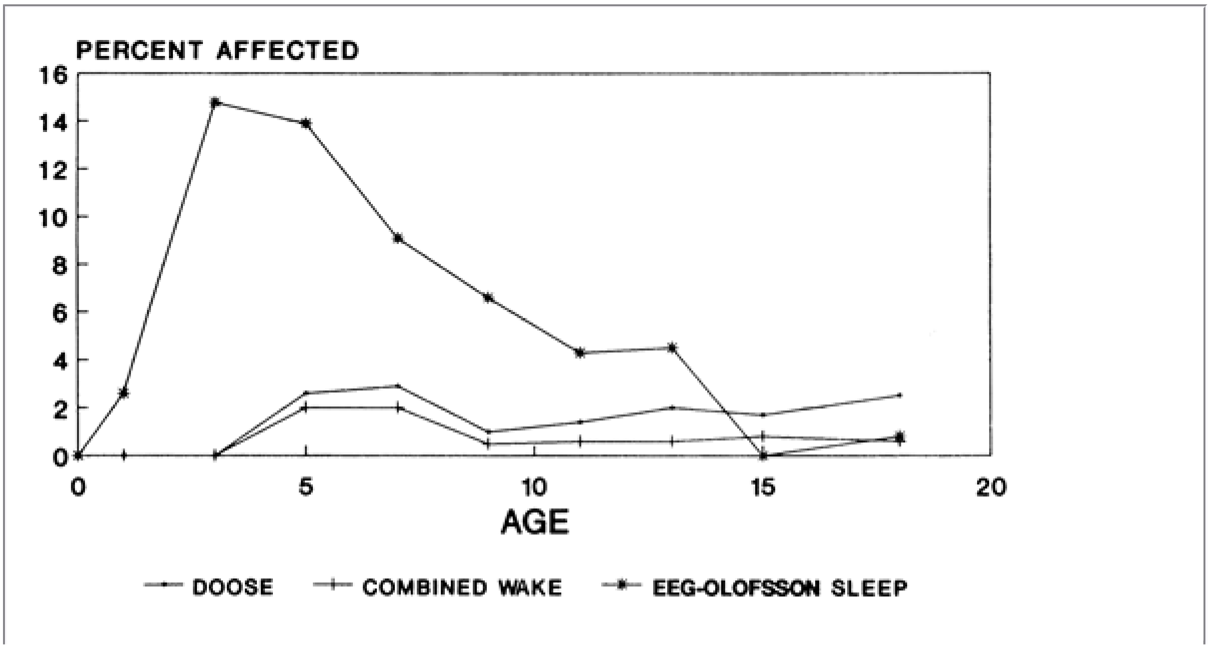

FIGURE 1. Prevalence of generalized spike-and-wave activity in normal children. (Data from Gerken H, Doose H. On the genetics of EEG anomalies in childhood. III. Spikes and waves. *NeuropÃ¤diatrie.* 1973;4:88â€“97 [Table III]; and Eeg-Olofsson O. Hauser.)

Epileptiform Activity

Generalized Spike-and-Wave Activity

Generalized spike-and-wave (GSW) activity is a genetically determined epileptiform pattern that aggregates in families. Lennox[70] first proposed that GSW discharges were the manifestation of a genetic trait, and the now classic studies of the Metrakoses et al.[81,82,83,84] unambiguously established the familial occurrence of GSW activity. About 35% of siblings and about 10% of parents of probands with GSW discharges show a similar (but not necessarily identical) epileptiform abnormality in their EEGs.[83] Metrakos and Metrakos[83] concluded that GSW activity was caused by an autosomal dominant gene with age-dependent penetrance. In the general population, GSW discharges have been reported in the waking EEGs of 0.3% to 1.8% of all children,[14,37,38,47] but the finding is age dependent and peak prevalence is 2.8% in children 7 to 8 years old (Fig. 1). If EEGs include sleep, GSW activity can be demonstrated in 15% of normal 3- to 4-year-old Swedish children (7.9% of Swedish children of all ages)[38] and in 16.8% of normal 3-year-old Japanese children.[106,107] Studies of GSW activity in siblings and offspring are complicated by the presence of epilepsy in most probands. That the two may not be invariably linked is clear from the studies of Metrakos and Metrakos,[82,84] who showed that the EEG spike-and-wave trait can be dissociated from clinical seizures. Thus, it is possible that the rates of GSW activity reported in relatives are confounded by the presence of epilepsy, and presumably the type of epilepsy, in the proband. Nonetheless, it is unarguable that a substantial percentage of siblings of children with epilepsy and GSW activity will also exhibit the spike-and-wave trait. Figures range from 7% to 17%,[24,47] but as in population studies, rates are age dependent and, perhaps additionally, related to the subtype of idiopathic epilepsy. Thus, 13% of siblings of all probands have GSW activity between the ages of 3 and 6 years.[47] In probands with â€œgeneralized minor seizures,â€ the figure increases to 34% in siblings between the ages of 2 and 3 years.[25] In children of parents with idiopathic generalized epilepsy, 19% manifest GSW activity in their EEGs,[6] and multiple spike-and-wave (â€œpolyspikeâ€) activity occurs in 15% of family members with myoclonic seizures.[109] Degen and Degen[21] have reported that 72% of siblings of patients with absence epilepsy and nearly 50% of siblings of probands with febrile seizures have EEGs showing generalized 2.5- to 4-Hz spike-and-wave activity, but these data cannot be accepted without further confirmation. The exact mode of inheritance of the GSW EEG trait remains uncertain, and both autosomal dominant and polygenic modes of inheritance have been proposed.

A susceptibility gene at the EJM1 locus on chromosome 6 is involved in the juvenile myoclonic epilepsy phenotype in some families.[51] The same gene also seems to influence expression of the EEG abnormality in juvenile myoclonic epilepsy.[36,50]

GSW discharges most likely involve epileptogenic alterations in thalamocortical circuitry that have been implicated in absence seizures based on studies of spontaneously occurring homozygous mouse mutants[11] (Chapter 37), the WAG/Rij rat model of absence epilepsy,[80] and supporting clinical data. The three key elements in the circuit are believed to be thalamic relay neurons, thalamic reticular neurons, and cortical pyramidal neurons.[15] Abnormalities in this thalamocortical system predispose to absence seizures and characteristic EEG discharges,[100] although details remain incomplete. A contributing abnormality appears to be mutations in one of the genes (CACNA1H) that encode the T-type calcium channels that control phasic activation of cortical pyramidal neurons.[16,65] Physiologic studies of several of the mutations have demonstrated functional changes in channel behavior that would favor epileptogenic firing patterns.[65] Point mutations in the CACNA1A gene, which encodes a $Ca_v2.1$ P/Q-type calcium channel, have been implicated in a family in which absence epilepsy is inherited through several generations in an autosomal dominant pattern.[57] Several affected family members also have cerebellar ataxia. In all individuals with both ataxia and absence seizures, there was a point mutation in the CACNA1A gene, which encodes the main subunit of $Ca_V2.1$ channels. In one asymptomatic family member with typical 3-Hz spike-and-wave discharges, however, the mutation was absent. Î³-Aminobutyric acid $(GABA)_B$ mechanisms have also been implicated in absence seizures and generalized spike-and-wave discharges.[12] Thus, while

P.173

thalamocortical circuits, calcium channel mutations, and GABAergic inhibition all seem to be involved in the absence epilepsy phenotypeâ€”and probably other idiopathic generalized epilepsy phenotypes as wellâ€”details of how individual components of these phenotypes, including differences in the pattern of generalized spike-and-wave activity, remain unclear. Recent studies of genetic absence rats from Strasbourg (GAERS) using genomewide scans indicate polygenic control of specific spike-and-wave discharge variables.[96]

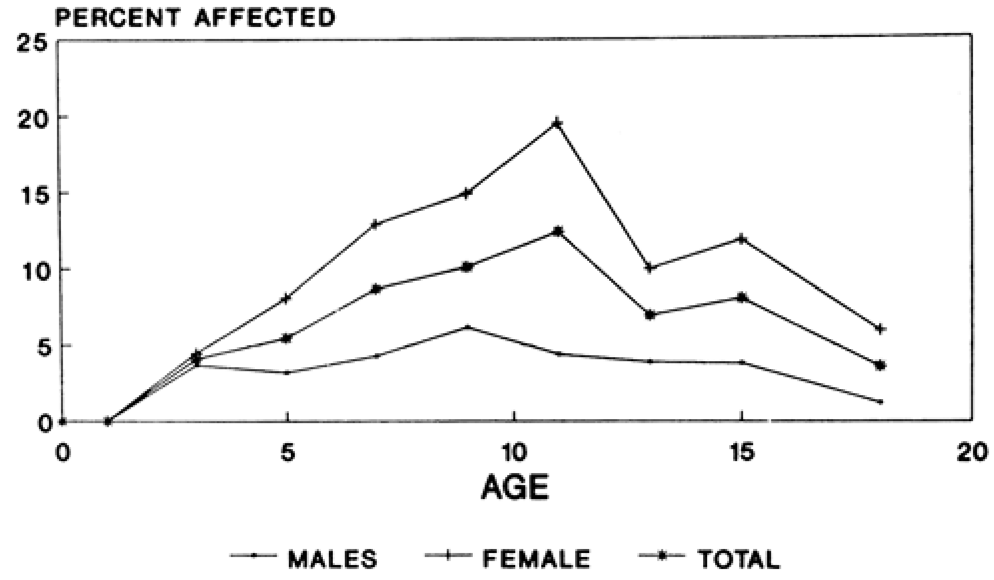

FIGURE 2. Prevalence of photoparoxysmal responses in normal children. (Graphs kindly prepared by Dr. W. A. Hauser and derived from combined data of Doose H, Gerken H. On the genetics of EEG anomalies in childhood IV. Photoconvulsive reaction. *NeuropÃ¤diatrie.* 1973;4:162â€“171; and Eeg-Olofsson O. The development of the electroencephalogram in normal children and adolescents from the age of 16 through 21 years. *NeuropÃ¤diatrie.* 1971;3:11â€“45. [Figs. 7 and 8].)

Photoparoxysmal Responses

Photosensitivityâ€”that is, the development of generalized bursts of irregular spike, multiple spike, and spike-and-wave activity in response to intermittent unpatterned light stimulationâ€”is a familial trait, as first pointed out by Nekhorocheff[86] and then studied more completely by Daly and Bickford,[17] Davidson and Watson,[19] Watson and Davidson,[120] Daly et al.,[18] Schaper,[99] and Watson and Marcus.[121] Despite differences in definitions of photosensitivity, criteria for terming a response photoparoxysmal, and recording methods, these early studies found that photoparoxysmal responses occurred in about 20% to 60% of near relatives of probands. Later studies have found somewhat lower rates. Doose and Gerken[26] and Doose et al.[31,33] compared EEG findings in siblings of children who had photoparoxysmal responses with those of nonepileptic controls. Overall, a photoparoxysmal response could be recorded in about 16% of siblings, but rates were strongly age dependent (Fig. 2). Thus, photoparoxysmal responses to rhythmic light flashes were rare below age 4 but were seen in 32% of siblings ages 11 to 12 years, and abnormal photic responses were more common in girls than in boys. Photoparoxysmal responses occurred in about 5% of control children. Electroencephalographic photosensitivity could be demonstrated in 10% to 20% of siblings of children with epilepsy but without photoparoxysmal responses. The presence of GSW activity in the EEGs of probands did not increase the chance of photoparoxysmal responses occurring in siblings, and photoparoxysmal responses without other EEG abnormalities did not increase seizure risk in siblings. Thus, GSW activity and photoparoxysmal responses appear to be genetically independent phenomena. More recently, Waltz and Stephani[118] also studied photoparoxysmal responses in the siblings of patients with epilepsy. The occurrence of photoparoxysmal responses was age dependent with maximum rates seen between 5 and 15 years of age. If one parent was photosensitive, about 39% of all siblings were also photosensitive. However, in siblings between 5 and 15 years of age, the rate was 50%. When a proband was photosensitive but neither parent was, 14% of siblings demonstrated photosensitivity. Sisters were somewhat more likely to be photosensitive than their brothers.

Photoparoxysmal responses are a feature of the idiopathic generalized epilepsies. They are found in 13% to 18% of patients with absence epilepsy and in 30% to 35% of patients with juvenile myoclonic epilepsy.[52] Tauer et al.[102] performed genomewide linkage scans to identify susceptibility loci for photosensitivity and to determine the genetic relationship with idiopathic generalized epilepsy. Families were studied in which at least two siblings had photoparoxysmal responses. For the analysis, the families were divided into two groups. In one, affected family members had predominantly photoparoxysmal responses or photic-induced seizures (PPR families). The other group included families with photoparoxysmal responses and either unprovoked spontaneous GSW discharges or unprovoked idiopathic generalized seizures (PPR/IGE families). In the PPR families, there was a significant association with chromosomal region 6p21.2. In the PPR/IGE families, there was linkage to chromosomal region on 13q31.3. Based on additional analyses, the authors concluded that the locus on 13q31.3 contributes to an epileptogenic mechanism that is shared by both the photoparoxysmal responses and idiopathic generalized epilepsy. The locus on 6p21.2 appears to predispose to photosensitivity itself. That photoparoxysmal responses are genetically heterogeneous is supported by an earlier report of 16 families with juvenile myoclonic epilepsy.[91] In this study, genomewide scans showed significant linkage to chromosomes 7q32 and 16p13. These findings suggest that different genetic loci for photosensitivity contribute to the different idiopathic generalized epilepsy phenotypes.

Focal Epileptiform Activity

The central-midtemporal sharp wave discharge is associated with idiopathic localization-related epilepsy in children (benign focal epilepsy of childhood with central-midtemporal sharp waves; â€œbenign rolandic epilepsyâ€) but often occurs as an asymptomatic expression of a genetic trait. Central-midtemporal sharp waves occur in about 35% of siblings and in about 3% to 20% of parents of probands with this EEG finding.[9,22,55] The discharges have generally been considered to be highly concordant in twins, but recent data suggest that the genetic influence on benign rolandic epilepsy is much less than previously thought.[108a] In some reports, up to 66% of probands[28] and nearly 15% of siblings and parent[10,95] have

P.174

had bilateral EEG abnormalities that included GSW activity and bursts of intermittent rhythmic delta waves. In other studies, however, transmission of central-midtemporal spikes has not correlated with other genetic EEG patterns.[35,47] Focal spikes, mainly of the central-midtemporal variety, can be detected in about 1% to 3% of normal children in population studies.[14,35,38] Both autosomal dominan[9,55] and polygenic[21] modes of inheritance have been postulated to account for the familial occurrence of the central-midtemporal spike trait, but there has been considerable variability in study design and often failure to separate asymptomatic individuals with EEG abnormalities only from those with the characteristic EEG discharge and benign rolandic epilepsy.

Doose et al.[28] found that only 22% of 147 children with central-midtemporal sharp waves had benign rolandic epilepsy. Other children with central-midtemporal sharp waves had neonatal seizures, febrile seizures, generalized tonicâ€"clonic seizures, or other focal seizures that were not typical of rolandic epilepsy. In an analysis of 18 twin pairs, with at least one twin having typical benign rolandic epilepsy, Vadlamudi et al.[110] were unable to demonstrate concordance for classic rolandic epilepsy, although all twins had seizures. They concluded that the mode of inheritance of benign rolandic epilepsy (*not* just central-midtemporal sharp waves) is much more complex than has been thought, and that noninherited factors are likely to be of importance.

Degen et al.[23] recorded waking and sleep EEGs in patients with complex partial seizures. The study included 19 patients and 29 siblings. Seven asymptomatic siblings (24%) showed epileptiform activity, and seven of the patients (37%) had at least one sibling with an epileptiform EEG.

Gibbs et al.[48,49] were the first to observe occipital sharp waves that disappeared with age in children without seizures. Gastaut[44] drew attention to â€œbenign partial epilepsy with occipital spike waves,â€ although Camfield et al.[13] had earlier described four similar cases as a form of migraine. Today, two forms of benign childhood occipital epilepsy are recognized: An early-onset form (Panayiotopoulos type; see Chapter 237) and a late-onset form (Gastaut type; see Chapter 238). The interictal features of the two syndromes are identical. Occipital sharp waves are found in about 0.6% of normal children between 1 and 16 years of age.[14,38] The highest peak is in younger children: 0.9% of children ages 2 to 4 years will have occipital sharp waves.[14] As with central-midtemporal sharp waves, the prevalence of occipital sharp waves in normal children decreases with age: Only about 0.1% after the age of 6 years.[14,90] In one large EEG laboratory, occipital sharp waves occurred in 10.7% of children referred for a variety of reasons.[60] Genetic aspects of occipital sharp waves and benign occipital epilepsy have been less well studied than central-midtemporal sharp waves and benign rolandic epilepsy. While Gastaut and Zifkin reported that 36% of affected children had a family history of epilepsy,[45] children with benign occipital seizures do not usually have a family history of similar seizures. Ferrie et al.[42] analyzed 113 patients with early-onset benign occipital epilepsy. Febrile seizures occurred in 15%, and there was a history of epilepsy in 7% of first-degree relatives. Other EEG abnormalities occurred in 25% of the patients and included central-midtemporal sharp waves, frontal sharp waves, and generalized discharges. A few families with several affected children have been reported in somewhat more detail. Kuzniecky and Rosenblatt[69] described a family in which three of four children had symptoms consistent with late-onset benign occipital epilepsy. The fourth asymptomatic child had occipital sharp waves on EEG. Occipital sharp waves were also found in 26% of other asymptomatic younger family members. In the family described by Nagendran et al.,[85] two children had occipital sharp waves. One of these had visual hallucinations followed by drowsiness; the other had visual hallucinations and two generalized convulsions. Two children were asymptomatic, but the EEG in one showed central-midtemporal sharp waves and occipital slowing in the other. Doose et al.[32] studied 19 patients with occipital sharp waves. Seizures consistent with early-onset benign occipital epilepsy occurred in 7 (37%); only five of these had occipital sharp wave foci. Occipital foci were found in 43% of 21 relatives. Only 1 of 11 relatives of probands with benign occipital epilepsy also had occipital seizures. Children with occipital seizures also had febrile seizures (one relative), benign rolandic seizures (one relative), and generalized tonicâ€“clonic seizures (six relatives).

Limitations in Using the EEG for Genetic Studies

Although EEG has been, and continues to be, a major tool in genetic studies of epilepsy, several factors limit its utility or at least require careful consideration in study design and data analysis. These include maturational, biologic, and interpretive issues.

Maturational Issues

Virtually all studies of genetic EEG patterns show age dependence. Thus, prevalence figures derived without taking age into account will be inaccurate or even misleading.

All EEG activity in the first decade of life and during much of the second reflects maturational processes taking place within the central nervous system, and some of these are gender related.[7] Although these maturational processes cannot yet be specified in detail for any EEG phenomenon, they presumably are determined by genetically controlled changes in neuronal cell types, numbers, and connectivity; neurotransmitters and receptors; synaptic interactions; myelination; and circuitry. In general, the younger the child, the more pronounced are EEG differences between any two points in time. In premature infants, for example, substantial changes in EEG activity may normally occur at intervals of 1 to 2 weeks. On the other hand, the EEG in a normal 6-year-old child is not very different from that of an 8-year-old, but both can be distinguished from the EEG of a healthy young adult. Acquired brain insults and abnormal genetic influences are superimposed on this normal developmental substrate. Thus, clinical and EEG findings are always the result of complex interactions between normal maturational events and the modifying effects of acquired or adverse genetic factors. It may well be that the expression and character of certain EEG patterns depends on critical interactions occurring within a fairly narrow time window. It is therefore not surprising that age histograms differ for various epileptiform patterns[60,61] (Fig. 3). Furthermore, it is not known how or in what ways genetic control of cerebral excitability and electrical organization is altered in the presence of an abnormal substrate, for example, one injured by hypoxia or intracerebral hemorrhage.

Biologic Issues

Variability of Electroencephalographic Findings

Electroencephalographic activity in the healthy adult is normally very stable over considerably long periods of time.[8,79,105,109,111] Almost nothing, however, is known of the stability of epileptiform patterns, especially in terms of the morphologic and other distinguishing features that form the basis for most interpretations and classifications.

It is well accepted that sleep affects the morphology of generalized epileptiform discharges. This is most readily seen

P.175

P.176

with classic 3-Hz spike-and-wave activity, in which the well-formed spike-and-wave paroxysms seen with the patient awake give way during sleep to discharges of shorter duration, composed of spikes and multiple spikes that recur in a fragmentary way, either with or without a consistent slow-wave component.[87,98,99] It is possible to demonstrate similar although often less dramatic effects of sleep on other types of generalized epileptiform activity as well. To the extent that morphology is used to classify patients with similar seizures or syndromes, awareness of the effect of state is important.

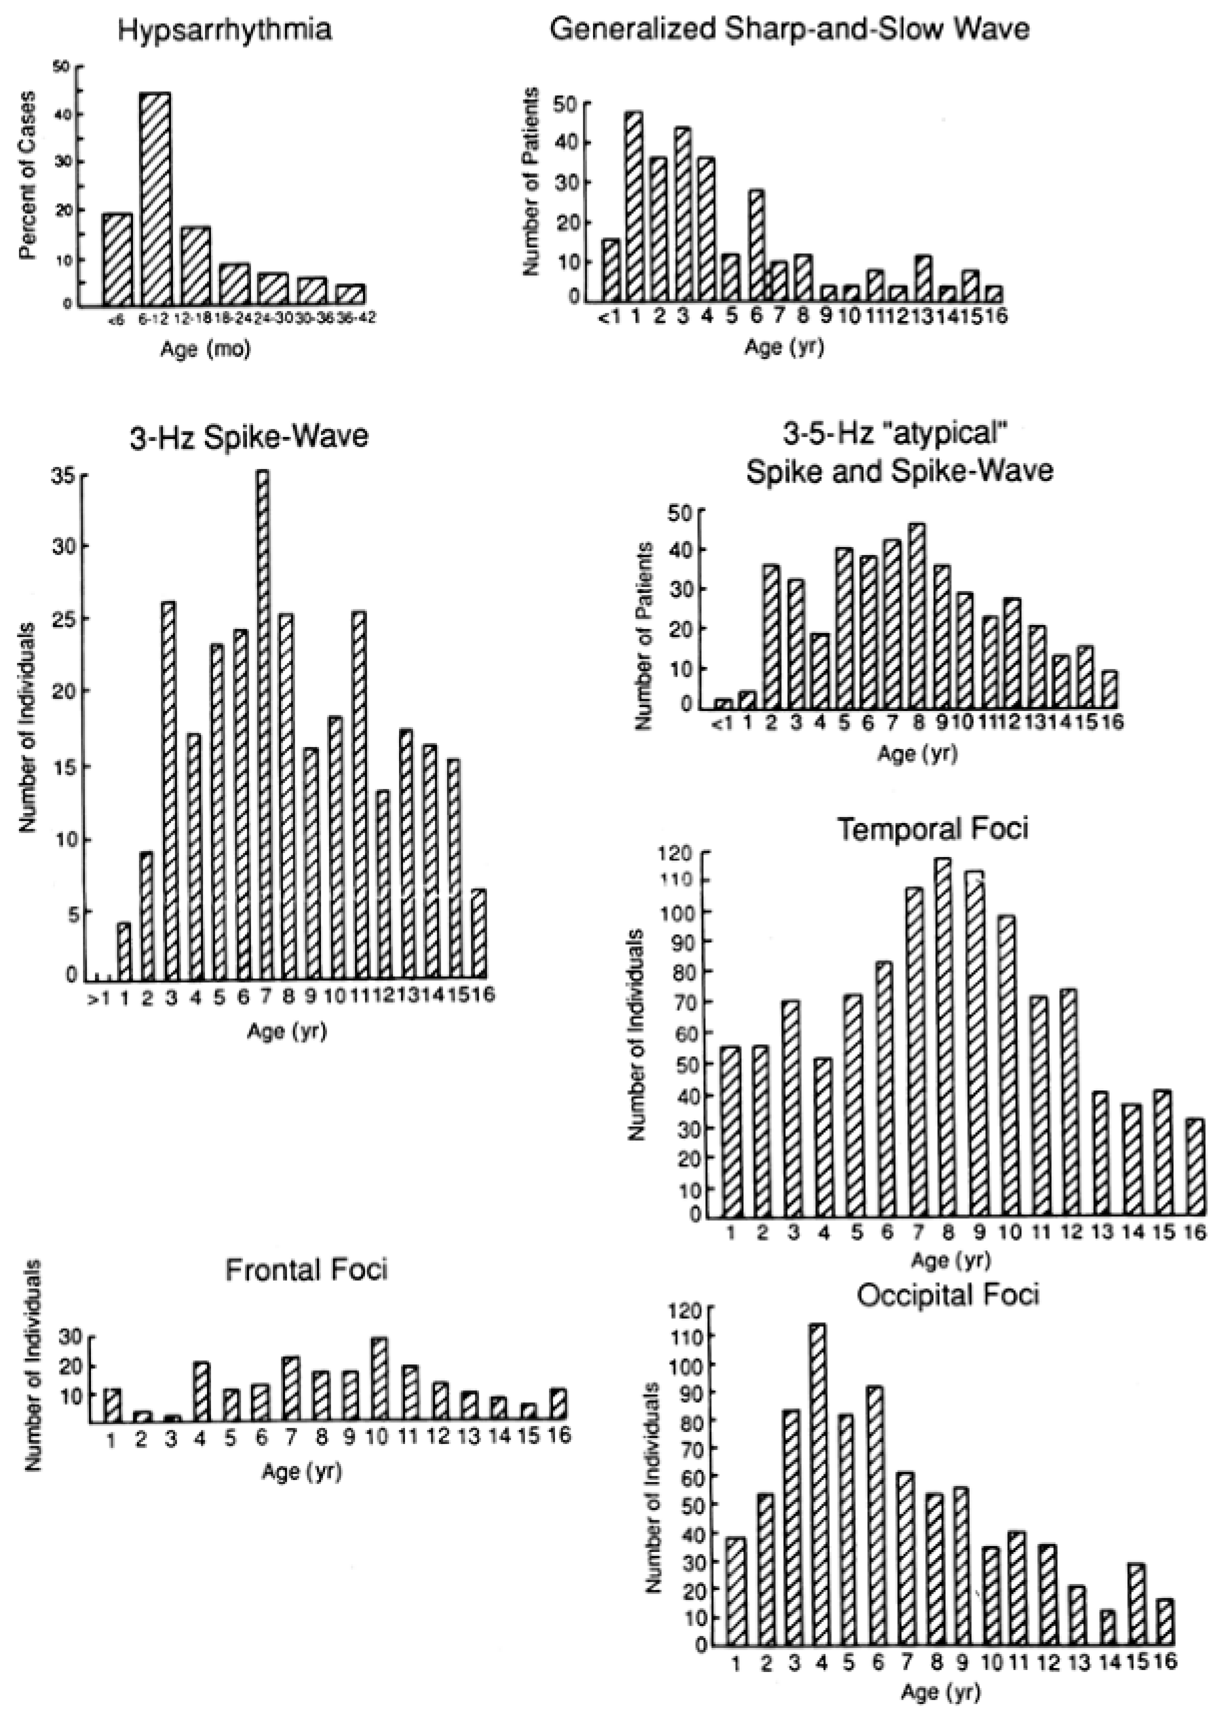

FIGURE 3. Age histograms of various epileptiform patterns in children. (Reproduced from Kellaway P. Maturational and biorhythmic changes in the electroencephalogram. In: Anderson VE, Hauser WA, Penry JK,

et al., eds. *Genetic Basis of the Epilepsies*. New York: Raven Press; 1982:21â€“33.)

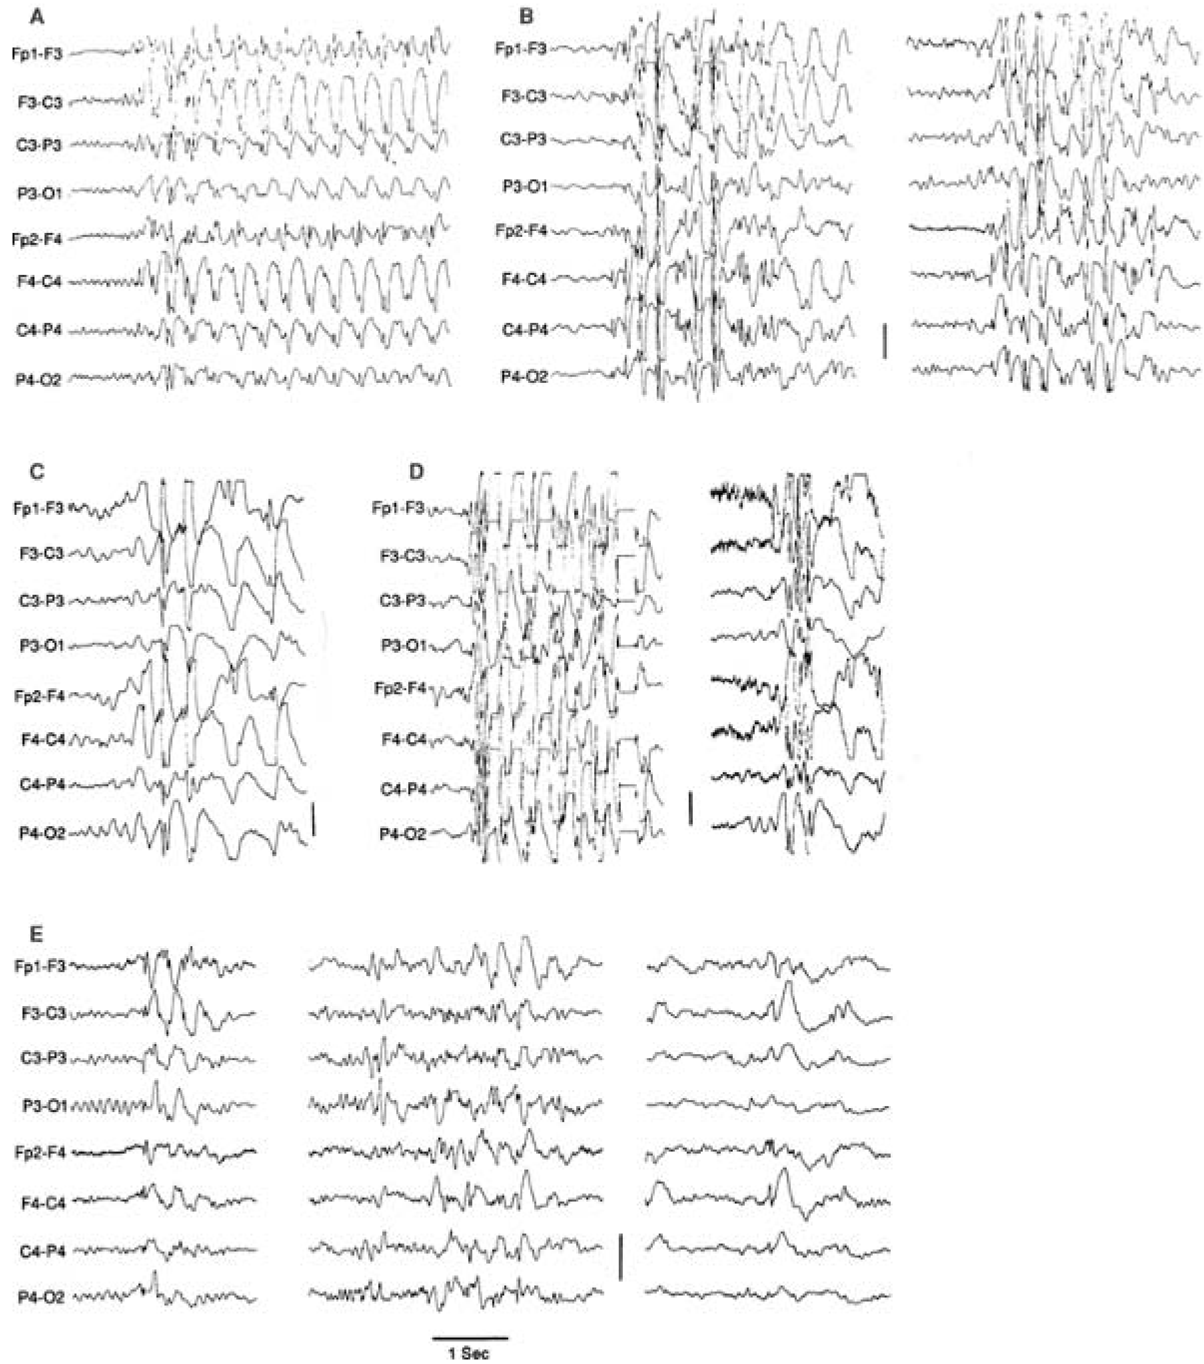

FIGURE 4. Different patterns of generalized spike-and-wave activity.

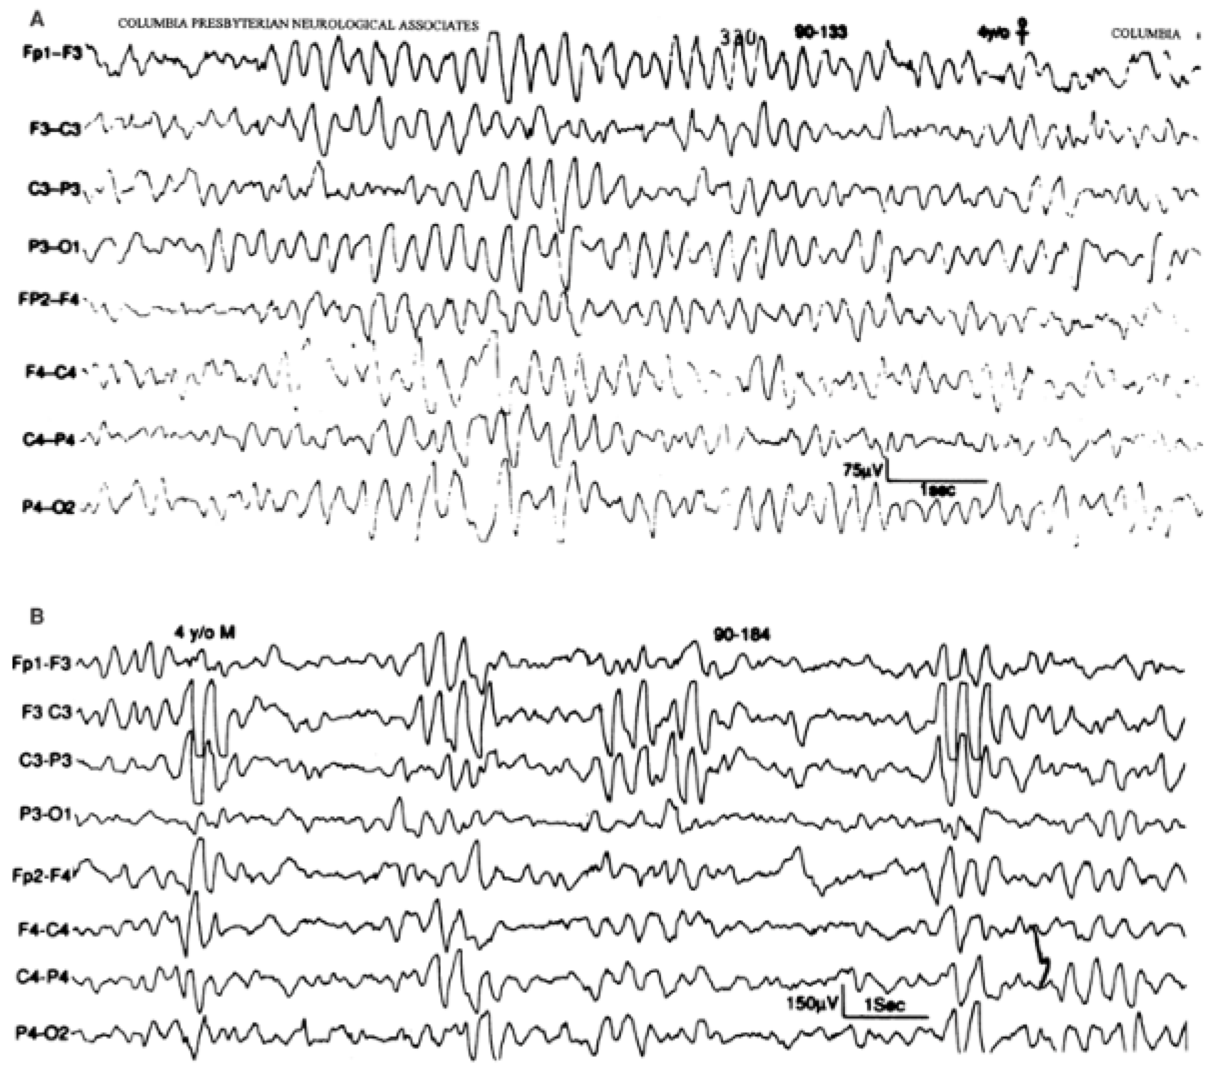

FIGURE 5. Examples of normal drowsy patterns in children. **A:** Continuous generalized rhythmic theta activity. **B:** Paroxysmal bursts of bisynchronous rhythmic delta activity.

In generalized-onset seizures, interictal EEGs show bilateral, symmetric, synchronous spikes with spike-and-wave and multiple spike-and-wave discharges. Beyond this generic description, however, considerable variability exists in details of how the epileptiform activity is expressed (Fig. 4). Patients with mainly generalized tonicâ€"clonic seizures, for example,

P.177

most commonly demonstrate â€œatypicalâ€ spike-and-wave activity, consisting of bursts of spikes and irregularly repeating 4- to 6-Hz spike-and-wave complexes. Sometimes, however, such patients also show 3-Hz spike-and-wave paroxysms or bursts of multiple spike-and-wave activity. In childhood absence seizures, the EEG most commonly reveals classic 3-Hz spike-and-wave activity, but close inspection reveals that the initial frequency is often 4 Hz and that the terminal frequency, especially in paroxysms lasting 10 seconds or longer, is usually 2 to 2.5 Hz. Some children with clinically typical childhood absence seizures show quite irregular spike-and-wave discharges,[72] and this does not appear to affect the character or prognosis of the disorder.[73] In relatives of children with absence seizures, even greater variability is seen in the expression of the spike-and-wave trait. In juvenile myoclonic epilepsy, multiple spike-and-wave activity is considered to be the characteristicâ€"even pathognomonicâ€"interictal EEG finding. Although this pattern may be the most specific, it occurs in fewer than half the patients clinically classified as having the disorder.[58,108] Other common epileptiform abnormalities in single EEGs of patients with juvenile myoclonic epilepsy include 3-Hz spike-and-wave activity and â€œatypicalâ€ 4- to 6-Hz spikes and spike-and-wave activity. No systematic study of the variability in patterns of epileptiform activity over time in individual patients has been performed. In all syndromes of idiopathic generalized epilepsy, almost all variations of GSW activity can be seen, although one or another pattern may statistically predominate in some seizure types.[119] Thus, it is probably not biologically meaningful or even accurate to use frequency or morphologic details of GSW activity as major criteria for narrowly defined epileptic phenotypes. It may, however, be reasonable to attempt to study the genetics of different EEG patterns alone. This issue is of considerable importance as molecular biologists are transforming our understanding of epilepsy by identifying chromosomal loci and specific genes associated with different types of epilepsy. The clinician plays a pivotal role in linkage

studies by providing precise and useful definitions of the condition under study. What role EEG and other features should play in defining epileptic syndromes and how elastic or inflexible these definitions should be are important issues for the genetic study of epilepsy (as well as for classification schemes). Some critical discriminating factors are already evident, as in the need to separate photoparoxysmal responses from spontaneous or hyperventilation-induced GSW activity. Another important issue is the dissociation that can occur between EEG findings and clinical manifestations. Genetic EEG traits can be expressed in asymptomatic individuals in the population at large as well as in families with both clinically affected and unaffected members. More than one heritable EEG pattern may be seen in individuals with a â€œclassicalâ€ clinical phenotype (e.g., central-midtemporal spikes or generalized spike-and-wave discharges in patients with benign occipital epilepsy). Genetic studies that use EEG need to recognize this variability in their design. At present, no single electrical event is unique to a particular form of epilepsy or epileptic syndrome.

Timing of Electroencephalographic Recordings

Kellaway et al.[64] have demonstrated that the occurrence in the EEG of GSW activity shows consistent time distributions that reflect modulation by interactive but independent circadian and ultradian processes. Similar biorhythmic modulation may affect the ability to record focal spikes as well.[63] From a practical standpoint, sleep and sleep deprivation will increase the yield of â€œpositiveâ€ EEGs. Timing of EEG samples, therefore, may be a critical factor in genetic studies. A related problem is that of sampling. Longer EEGs and EEGs recorded on more than one occasion increase the chance of demonstrating a specific epileptiform abnormality. In patients with probable epilepsy, about 29% to 50% will have epileptiform abnormalities on the first EEG, but if multiple EEGs are obtained, the yield increases to 59% to 92%.[77,97]

The Issue of Epileptogenicity

Epileptiform patterns are a reliable signature of an individual's susceptibility to seizures, but they do not quantify the magnitude of this risk. In other words, there is a strong but by no means absolute correlation between seizures and interictal epileptiform discharges. This consideration has implications for using EEG data to estimate seizure risk (see further on). Behavioral and EEG expressions of epilepsy appear to be under at least partially separate genetic control, and development of recurrent seizures best fits a multifactorial model involving both genetic and environmental factors.[1] Thus, prevalence studies in relatives of probands with epilepsy always show higher rates for EEG abnormalities than for seizures.[1] It is clear that the various epileptiform patterns differ in their degree of epileptogenicity. For example, among children referred to an EEG laboratory for various reasons, including known or possible epilepsy, only about 40% of those with central-midtemporal spikes had seizures.[60,61] In the same cohort, on the other hand, seizures occurred in about 90% of children with other temporal spike foci and in about 75% of those with frontal or multifocal spikes. Of children with generalized epileptiform discharges, about 70% with â€œatypicalâ€ 4- to 6-Hz spike-and-wave activity and nearly 100% with 3-Hz spike-and-wave activity had seizures. With rare exceptions, however, there is at present no reliable way to relate quantitatively any interictal measure of epileptiform activity to clinical seizures.[103] Frost et al.[43] provided preliminary evidence of computer-derived parameters of interictal spike waveforms that showed promise in assessing seizure risk.

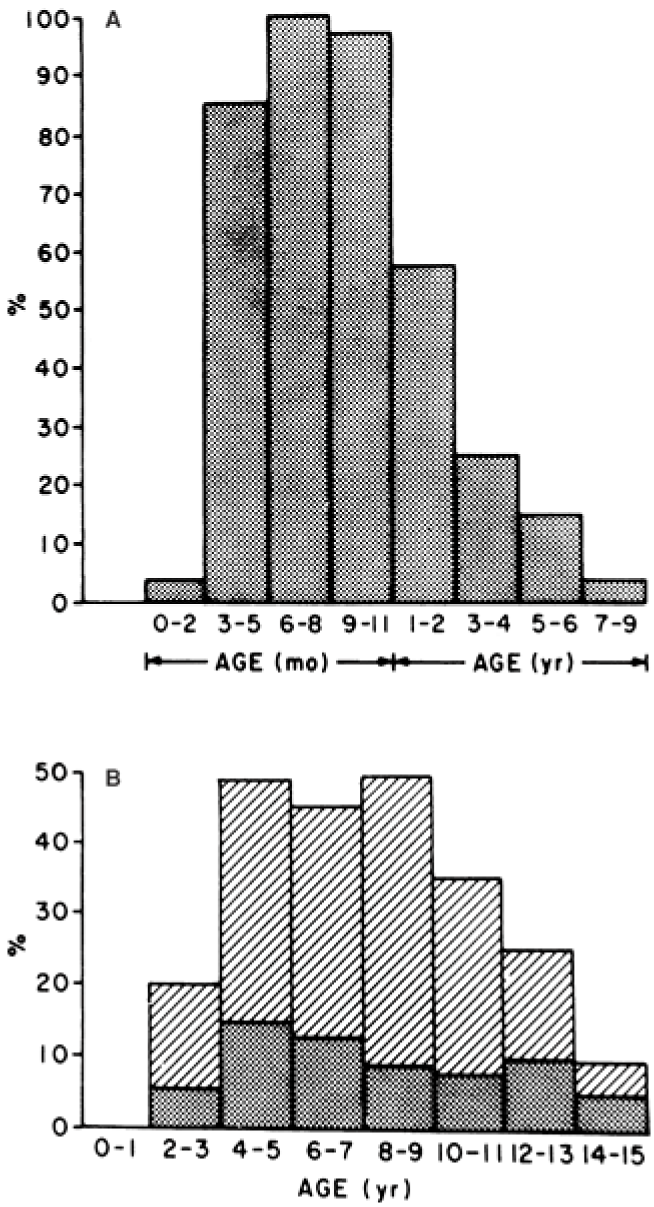

FIGURE 6. Age histograms of continuous **(A)** and paroxysmal **(B)** drowsy patterns in children. Paroxysmal bursts of rhythmic delta activity often normally contain sharply contoured or spikelike components (*lower dotted sections* in B). (Reproduced from Kellaway P. An orderly approach to visual analysis: characteristics of the normal EEG of adults and children. In: Daly DD, Pedley TA, eds. *Current Practice of Clinical Electroencephalography*. 2nd ed. New York: Raven Press; 1990:139â€"199, with permission.)

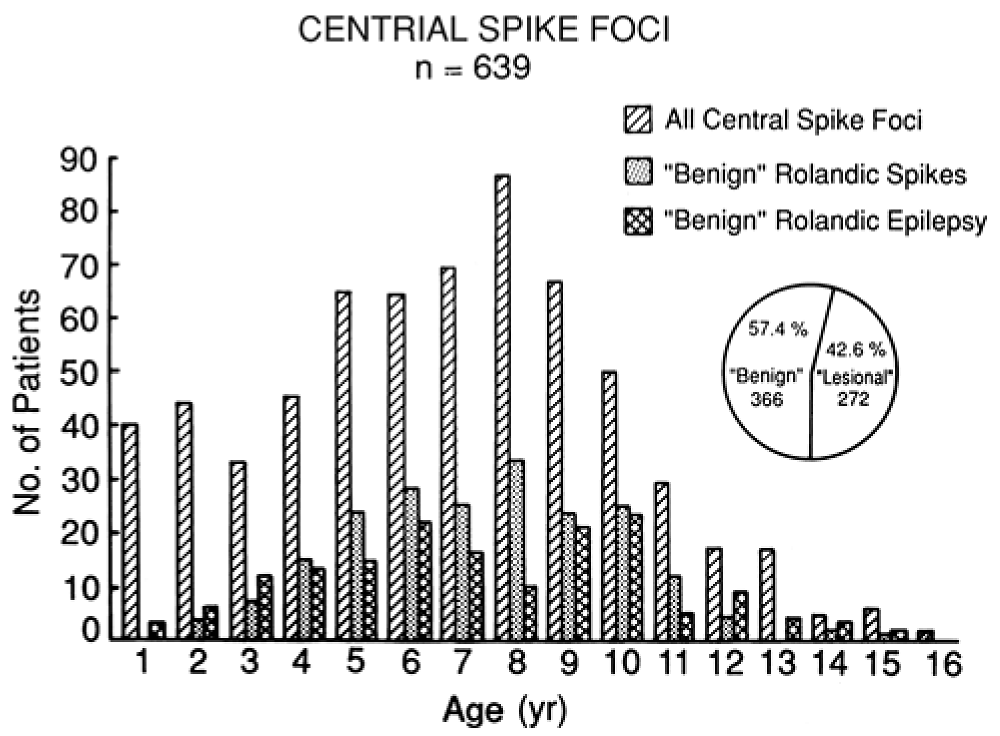

FIGURE 7. Age histograms of â€œlesionalâ€ and â€œbenignâ€ central spike foci in children. (Reproduced from Kellaway P. Maturational and biorhythmic changes in the electroencephalogram. In: Anderson VE, Hauser WA, Penry JK, et al., eds. *Genetic Basis of the Epilepsies*. New York: Raven Press; 1982:21â€“33, with permission.)

Interpretive Issues

Interpretation of the biologic significance of EEG findings by the electroencephalographer can play an important role in genetic studies. At the simplest level is the electroencephalographer's concept of â€œnormalâ€ or â€œabnormalâ€ and view of deviations from normative data (to the extent these exist). What are the limits of normal biologic variability, and when do deviations reflect abnormal brain function? A related issue is the identification of patterns considered epileptogenic. The electroencephalographic literature is an embarrassing repository of confused, ill-considered, and unsupported opinions regarding the epileptic significance of various EEG patterns. Although most electroencephalographers no longer consider 14/s and 6/s positive spike bursts, wicket spikes, rhythmic temporal theta

P.179

bursts of drowsiness (psychomotor variant), or small sharp spikes as anything other than benign variants having no association with seizures, other problems remain. Not all sharply contoured transients or paroxysmal discharges are epileptiform, and not all epileptiform patterns are epileptogenic. Some discrepancies in prevalence figures undoubtedly relate to more or less liberal criteria for considering a discharge epileptiform. Thus, Metrakos and Metrakos[81] reported that GSW activity occurred in 10% of their control subjects, whereas Doose et al.[30,34] and Andermann and Straszak[2] found GSW discharges in fewer than 2% of controls. Paroxysmal delta activity occurring normally during drowsiness in children is an especially vexing problem, because these hypnagogic bursts often contain sharp or spikelike components[62] (Fig. 5). To the eye of this author, for instance, FIGURE 1 of Doose and Gundel[27] does not show â€œabortive bilateral synchronous spikes and wavesâ€ but rather illustrates a nonspecific burst of rhythmic delta waves during drowsiness, probably a normal phenomenon. Furthermore, drowsy patterns in children may be either continuous or paroxysmal, and this characteristic is age elated[62] (Fig. 6). Another seemingly unsolvable problem is that of the 6-Hz spike-and-wave discharge. When this takes the â€œphantomâ€ form described by Marshall,[78] most electroencephalographers consider it of no consequence. When the discharge is of higher voltage and maximal frontally, however, considerable controversy exists regarding its clinical significance. Some investigators deny that it has any relation to epilepsy,[104] whereas others consider it a variation of GSW activity.[56] It is even sometimes difficult to tell from a single EEG if the epileptiform activity is focal or generalized. In many patients with GSW activity, for example, the paroxysmal discharge occasionally appears in a limited or incomplete form. Such fragments of an otherwise typical generalized abnormality then appear as â€œfocalâ€ spikes, especially over the frontal or frontal-central regions. Conversely, some epileptogenic foci, most often those involving mesial parasagittal areas, give rise in scalp EEG recordings to bilateral discharges (â€œsecondary bilateral synchronyâ€), which can be misinterpreted as generalized spike-and-wave activity. Especially if epileptiform activity is not abundant, a single EEG sample may not be sufficient to characterize the discharge unequivocally as focal or generalized. Accurate discrimination among different types of unambiguous spike discharge is also necessary. Thus, not all spikes occurring in the central and midtemporal areas are â€œbenignâ€ (Fig. 7). Finally, there is considerable variability in EEG interpretation, including recognition of artifact, among different observers,[92] and this variability is influenced in part by specific reader characteristics.[122]

Role of Electroencephalogram in Estimating Risk for Seizures in Siblings and Offspring

Despite the limitations already described, knowledge of the proband's EEG is of some help in estimating the risk for epilepsy in siblings. Although data from siblings are frequently used to estimate risk for offspring, the two groups are not, of course, genetically comparable. Epidemiologic studies suggest that risk for epilepsy in offspring is similar to that reported for siblings.[53] However, it is not possible to determine in what way EEG findings modify this risk. This is because data are either unavailable or derived from sample sizes too small to provide reliable risk estimates.

In siblings of probands with epilepsy and GSW activity, risk for seizures or epilepsy does not appear to be increased above that conveyed by the proband's epilepsy alone.[3,53] Similarly, if the proband has epilepsy and a photoparoxysmal response that is not accompanied by spontaneous or hyperventilation-activated GSW activity, sibling risk for seizures is not increased above that related to the proband's epilepsy alone.[3,31,54] However, if the proband's EEG contains both GSW discharges and a photoparoxysmal response, risk for epilepsy in siblings more than doubles.[54] Thus, the genetic effects of GSW activity and photoparoxysmal responses seem to be additive.

Summary and Conclusions

The EEG is an important tool for identifying individuals with increased susceptibility to seizures, including carriers of genetic traits. Evidence is growing that specific EEG patterns are under

P.180

complex and heterogeneous genetic control, and animal studies indicate that similar EEG patterns may arise from different and independent genetic mechanisms. Although the EEG has been and will continue to be an important phenotypic determinant in genetic studies of epilepsy, its use is limited by maturational, biologic, and interpretive considerations. Used with caution, the EEG can be helpful in estimating the risk for seizures in siblings and offspring of probands with epilepsy.

Chapter 17

Genetic Diseases Associated with Epilepsy

Joshua L. Bonkowsky

W. Allen Hauser

V. Elving Anderson

Introduction

Genetics has become increasingly important for understanding epilepsy. Since the advent of molecular genetic technology in the 1980s, it has been possible to categorize and diagnose many neurologic diseases that were previously poorly defined. A number of specific â€œepilepsy genesâ€ have been identified and are discussed in Chapter 18. However, there are also many genetic disorders that feature epilepsy as a common or prominent symptom. In this chapter we review genetic disorders associated with an increased risk for epilepsy.

Patients having genetic or chromosomal syndromes associated with epilepsy account for 2% to 3% of all cases of epilepsy; in fact, these patients are more likely to be seen first by a pediatrician, family practitioner, or geneticist for diagnosis and treatment of the genetic syndrome. What, then, is the benefit of approaching the epilepsies using a framework of genetic classification of disease?

First, for the clinician, knowing which genetic disorders have a high risk for epilepsy can aid in differential diagnosis. The background population rate of epilepsy is 2% to 4%, whereas in some disorders, epilepsy can be present in almost 100% of patients, and the type of epilepsy can be characteristic of the disorder.

Second, investigation of the disorders that are associated with epilepsy is providing insight into the causes of epilepsy. Understanding that epilepsy is not a general consequence of all chromosomal aberrations but is present in specific chromosomal disorders, for example, has led to a search for epilepsy-related genes at specific chromosomal sites.

Third, by studying the effects of specific gene mutations on intracellular and cell membrane function, by creating animal models of human epilepsy disorders, and by studying in detail the cellular effects of human mutations, the mechanisms of epileptogenesis will be better understood. For most of the conditions described below, the actual mechanism of epileptogenesis is at present poorly understood.

Finally, for the patients and their families, diagnosis of their disorder provides the opportunity for treatment, for genetic counseling, and for tailored treatment of their seizures as well as for health maintenance issues that may arise later in the course of their disease.

Basic Genetic Concepts

Most of the conditions in this chapter involve mendelian (single gene locus) inheritance.[71] Because of the rapidly changing knowledge about these disorders, we commonly use two searchable Web-based sites to help with our diagnosis and testing: *GeneTests* (www.genetests.org) and *OMIM* (Online Mendelian Inheritance in Man: www.ncbi.nlm.nih.gov/entrez/query.fcgi?db = OMIM). These sites are funded by the National Institutes of Health (NIH), and include clinical and molecular information about genetic disorders, references, and clinical laboratories that test for the different disorders.

Testing (and thus the diagnosis) of genetic disorders associated with epilepsy continues to provide challenges to the clinician. Further, the technology and means of testing is in constant flux. Again, *GeneTests* is an invaluable resource for finding laboratories that provide clinical testing. Unfortunately, in many instances our knowledge of the diseases has outstripped the ability of laboratories to provide clinical testing. In many diseases any one test is not 100% sensitive, so if the clinical suspicion is high enough, further testing may be warranted.

All testing should be preceded by adequate counseling about the purpose and possible outcomes of the testing and potential choices that might arise (see Chapter 19). The clinical complexity and overlap in phenotypes of these disorders, the implications for genetic testing of other family members, and ramifications on insurance coverage mandate responsible clinical judgment.

A basic grasp of genetic concepts is important for understanding the disorders in this chapter. We have grouped these topics into four areas: Genetic transmission, gene expression, genomic integrity, and genetic heterogeneity.

Genetic Transmission

Four major modes of inheritance have been characterized in detail: Autosomal dominant, autosomal recessive, X-linked recessive, and mitochondrial.

Autosomal dominant traits can be expressed when only one of the paired alleles (genes) at a given locus is of a mutant form. However, apparent â€œskipsâ€ in a pedigree may occur as the result of incomplete *penetrance*. Incomplete penetrance is the presence in an individual of a dominant disease gene without full expression of the mutant phenotype. Sometimes, however, careful examination of individuals carrying a dominant disease gene reveals minimal signs of the condition, indicating variable expression of disease symptoms.

For an *autosomal recessive* trait to be expressed, both alleles must be of a mutant form (although not necessarily with the same mutation). Both parents of an affected individual are heterozygous disease gene carriers, and careful examination or laboratory evaluation may sometimes reveal heterozygous effects. Ordinarily, however, carriers of a single recessive disease gene are clinically asymptomatic. Because autosomal recessive alleles are generally rare, a detailed family history should be taken to search for any consanguinity.

The hallmark of *X-linked diseases* is the absence of male-to-male transmission of the genetic trait, since males pass on a Y chromosome, not an X chromosome, to their sons. Thus, the condition usually is found only in male subjects who are in turn related through female carriers. Some X-linked disorders (such as incontinentia pigmenti) are lethal in affected males,

P.184

so that only female carriers of the abnormal gene survive fetal life.

Mitochondrial mutations follow a maternal inheritance pattern. In this situation, the frequency of a trait is the same in male and female subjects, but the condition is always transmitted from an affected mother to most of her children, never from an affected father. A human egg contains several hundred thousand copies of mitochondrial DNA (mtDNA), compared with only a few in sperm. Theoretically, all children of an affected mother should be affected. The expression of a mitochondrial mutation, however, depends on the relative proportion of mutant and wild-type mtDNAs in a given cell (termed *heteroplasmy*), and this proportion can shift during cell division. Because of a â€œthreshold effect,â€ tissues with a low proportion of mutant mtDNAs may not show an effect, whereas tissues that have reached the threshold begin to show effects of mitochondrial dysfunction. Organs that have a high rate of energy consumption, such as brain, heart, and muscle, are most often affected by mitochondrial disorders. It must also be noted that some mitochondrial disorders result from mutations in nuclear genes; these defects are inherited in a regular mendelian pattern.

Anticipation is the tendency for affected individuals in successive generations to present with earlier and/or more severe symptoms. This occurs in some genetic disorders, especially those associated with trinucleotide repeat expansions. Certain disorders have a predilection for repeat instability when passed on via either the paternal or maternal germ-line.

Mosaicism, or the presence of more than one genotype in the body, must also be considered in situations when multiple siblings have a disorder despite the absence of any family history of the disorder. In this situation, the parent is phenotypically normal because most of the somatic cells of the body carry the wild-type allele, but the germ cells carry the mutant allele, which is thus passed on to all the offspring.

Polygenic disorders remain a major frontier in our understanding of genetic mechanisms of disease. These disorders are common (e.g., idiopathic epilepsy) and show complex inheritance, involving multiple (possibly interacting) genes, with or without additional environmental influences. Identifying the causative genes is challenging.[51]

Gene Expression

The pathways from genes (the genotype) to physical or clinical traits (the phenotype) are extraordinarily complex. The molecular and developmental events that control phenotypic expression are numerous. They include DNA regulatory elements that control location, levels, rate, and timing of gene expression[73]; alternative splicing of the primary mRNA transcript to produce different mRNAs; *imprinting*, or the differential expression of a gene depending on which parent contributed the gene; regulation of mRNA expression by small RNA molecules[107]; and combinatorial protein and enzymatic complexes.

Genomic Integrity

Deletion or duplication of DNA segments on a chromosome can produce significant clinical effects. Larger deletions, duplications, or translocations can disrupt many genes and produce severe symptoms, including mental retardation and growth failure. Microdeletions, which may not be detectable by standard cytogenetic analysis, can produce *contiguous gene syndromes* that involve the loss of several neighboring genes and can lead to unique phenotypes depending upon the specific genes deleted.

Recently, a series of inherited disorders has been shown to involve the expansion of DNA trinucleotide repeat sequences. These include myotonic dystrophy, fragile X syndrome, Huntington disease, and some of the spinocerebellar ataxias. Normal individuals show variation in the number of repeats, but above a certain threshold the repeat length becomes unstable, with a tendency for further increase in number of repeats in later generations. Higher repeat numbers are associated with an earlier onset of the condition, greater severity of symptoms, or bothâ€"a phenomenon known as *anticipation.* The mechanisms by which trinucleotide repeat expansions cause disease remain unknown.

Genetic Heterogeneity

Genetic heterogeneity (or locus heterogeneity) is the phenomenon whereby a single clinical phenotype can result from mutations in different genes. This possibility must be considered in the genetic study of any disorder, as it may affect both diagnosis and treatment and also causes problems in gene mapping studies. Thus, the epilepsies are a limited group of phenotypes that may be caused by a number of different genes. For example, seizures can occur from changes in neuronal excitability, neuronal inhibition, or control of the spread of a seizure state, each of which is regulated by many different genes.

From a diagnostic perspective, it is not sufficient to classify epilepsy simply on the basis of the clinical or electrographic appearance of the seizures; some consideration of the underlying cause must be included. To say that a patient has mental retardation and epilepsy could miss the point that both conditions are manifestations of an underlying cause, for example, Angelman syndrome. On the other hand, a purely genetic classification is not satisfactory either, and lacks the clinical and treatment paradigms. Godfrey[28] emphasized the continuing interdependence between clinicians and molecular scientists in resolving this problem:

> â€œDo we begin to classify disorders on the basis of molecular lesions or on the basis of clinical criteria? Neither alone seems satisfactory any more. Therefore, we will use both, singly and in combination, but heterogeneity will continue to pose dilemmas in our practices and laboratories.â€

Table 1 Risk for Epilepsy, and Other Seizure Associations, in Genetic Disorders

Risk for epilepsy		Seizure associations
>75% Angelman syndrome Fukuyama congenital muscular dystrophy Hemimegalencephaly Lissencephaly MELAS syndrome Periventricular nodular heterotopia Sturge-Weber syndrome Tuberous sclerosis Zellweger spectrum disorders *50%â€“75%* Biotinidase deficiency Christian syndrome Landau-Kleffner syndrome Linear nevus sebaceous syndrome Rett syndrome Wolf-Hirschhorn syndrome *30%â€“50%* Congenital disorders of glycosylation Glycogen storage disease I and III Hypomelanosis of Ito McLeod neuroacanthocytosis syndrome Metachromatic leukodystrophy Niemann-Pick disease, type C Saethre-Chotzen syndrome Schizencephaly	*<30%* Acute intermittent porphyria Adrenoleukodystrophy Alzheimer disease Autism BÃ¶rjeson-Forssman-Lehmann syndrome Brachmann-de Lange syndrome Cardiofaciocutaneous syndrome Cohen syndrome Crouzon syndrome Fragile X syndrome Huntington disease Homocystinuria Leigh syndrome Neurofibromatosis types 1 and 2 Parry-Romberg syndrome Prader-Willi syndrome Trisomy 13 Trisomy 21 Velocardiofacial syndrome Wilson disease *No increased risk* Cri-du-chat syndrome Sex chromosome aneuploidies Subtelomeric deletions Williams syndrome Smith-Magenis syndrome Lesch-Nyhan syndrome Mucopolysaccharidoses	*Burst-suppression* Nonketotic hyperglycinemia *Hypsarrhythmia* Menkes disease Nonketotic hyperglycinemia *Infantile spasms* Hypomelanosis of Ito Lissencephaly Tuberous sclerosis Wolf-Hirschhorn syndrome *Other nonepileptic events* Alzheimer disease (myoclonus) Angelman syndrome (myoclonus) Coffin-Lowry syndrome (stimulus-induced drop attacks) Niemann-Pick disease, type C (gelastic cataplexy) Trisomy 13 (apneic spells)

MELAS, mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes; WAGR, Wilms tumor, aniridia, genitourinary anomalies, and mental retardation.

Genetic Disorders Associated with Epilepsy

Table 1 summarizes the genetic disorders discussed in this chapter. It lists the disease name, its associated gene (if known), and seizure frequency. We have organized the genetic disorders in the following broad categories:

- Chromosome disorders
- Contiguous gene disorders
- Metabolic disorders
- Genetic syndromes; which are further subdivided as follows:
    - Short stature
    - Early overgrowth
    - Skeletal dysplasias
    - Facial defects
    - Connective tissue
    - Neurocutaneous
    - Ectodermal and mesodermal dysplasias
- Disorders of brain development
- Neurodegenerative disorders

P.185

Chromosome Disorders

The chromosome disorders represent a wide array of possible disorders caused by additions, deletions, or rearrangements of chromosomal material (see Chapter 261). Classical cytogenetic methods are now complemented by more sensitive methods such as high-resolution chromosome banding, fluorescent in situ hybridization (FISH), and the polymerase chain reaction (PCR). Small deletions or duplications are now detectable, and the contribution of an individual gene to the overall phenotype of a chromosome disorder can often be determined.

Six percent of patients with epilepsy and intellectual impairment have chromosomal abnormalities, while 50% of patients with epilepsy and multiple congenital abnormalities have chromosomal abnormalities, as noted by Singh et al.[105] in their review of the frequency and types of epilepsies resulting from disorders of each of the chromosomes (see also the review by Battaglia and Guerrini[4]).

Epilepsy occurs in 1% to 10% of patients with *trisomy 21 syndrome* (*Down syndrome*), and electroencephalographic (EEG) abnormalities are present in more than 20%.[21,104,118] EEG abnormalities ranged from slowing, asymmetry, and asynchrony to diffuse or focal epileptiform activity.[21] Seizures most often begin early in childhood, and can be of different types; infantile spasms occur occasionally (0.5% to 2% of patients), while myoclonic seizures are distinctly uncommon.[89,104,123]

Trisomy 13 syndrome is commonly accompanied by severe developmental retardation, microcephaly, and severe craniofacial dysgenesis, including holoprosencephaly. Seizures occur in 25% of patients and apneic spells in 58%.[33]

Trisomy 18 syndrome, the third common autosomal trisomy, is characterized by poor somatic growth and hypoplasia and dysplasia of many internal organs, including the brain. Gross malformations of the brain range from heterotopias to holoprosencephaly, which may be associated with apneic episodes and seizures.[33] Others report a much lower incidence of seizures in trisomy 18 patients than in trisomy 13.[125]

More than 50% of patients with *Wolf-Hirschhorn syndrome* (del4p16) have seizures, which can be difficult to control. Characteristic EEG and seizure patterns (including infantile spasms) are associated with this syndrome.[3] The incidence of seizures may depend on the exact site of the deletion, as the â€œcritical regionâ€ is still being delineated. In contrast, patients with cri-du-chat syndrome (del[5p]) are microcephalic but generally do not have severe seizures.

The *fragile X syndrome* is included here as a chromosome disorder for historical reasons. The first diagnostic test for this disorder was cytogenetic, based on the presence of a visible disruption in the X chromosome (the â€œfragile Xâ€) when cells of affected individuals were grown in a culture medium low in folate. Fragile X syndrome is now known to be a trinucleotide repeat disease caused by the expansion within the *FMR-1* gene of a trinucleotide that is repeated in tandem only a few times in normal individuals. Fragile X syndrome is responsible for about 2% to 5% of all cases of mental retardation in male individuals, and also has been associated with mental retardation in females, although usually less severe than in their

male relatives. In large series, about 20% of males and 5% of females with fragile X syndrome have clinically apparent seizures, and about 50% have abnormal EEGs.[6,121] No patient had infantile spasms. EEG abnormalities included nonspecific slowing as well as epileptiform or paroxysmal discharges; other authors have reported a high incidence of centrotemporal (rolandic) spike discharges in *FMR-1* mutation carriers in the second half of the first decade of life, both with and without clinical seizures. Seizures and EEG abnormalities in individuals with fragile X syndrome tend to improve with age.

Other less common chromosome deletion and translocation syndromes are associated with the presence of epilepsy. Seizures were present in a series of over 400 different chromosome imbalances[105]; eight disorders were highly associated with epilepsy: *Wolf-Hirschhorn (4p-) syndrome*, *Miller-Dieker syndrome* (del 17p13.3), *Angelman syndrome* (del 15q11-q13), the inversion duplication 15 syndrome, terminal deletions of chromosome 1q and 1p, and ring chromosomes 14 and 20. Notably, epilepsy is not a prominent feature of the sex chromosome aneuploidies, such as Turner syndrome or Klinefelter syndrome. Subtelomeric deletions at the ends of chromosomes have been reported to be a significant cause of mental retardation,[61] but seizures appear to only be an occasional association.

Contiguous Gene Disorders

Three contiguous gene disorders associated with seizures are discussed below: *Angelman syndrome*, *Prader-Willi syndrome*, and *Velocardiofacial syndrome* (*Miller-Dieker syndrome* is discussed later in this chapter). Other contiguous gene disorders not associated with an increased risk of seizures include Williams syndrome, WAGR (Wilms tumor, aniridia, genitourinary anomalies, and mental retardation) syndrome, Potocki-Shaffer syndrome, and Smith-Magenis syndrome.

Angelman syndrome was first identified cytogenetically as involving loss of the maternal chromosome region 15q11-13. Affected patients have severe mental retardation, epilepsy, ataxic jerky movements, inappropriate laughter, and absence of speech. *UBE3A*, a ubiquitin-protein ligase, is the minimal gene mutation responsible for the core phenotype, but the phenotypic presentation depends on the type of mutation and which associated genes are involved.[60,70]

Seizures with onset at <3 years of age and EEG abnormalities are findings in more than 80% of patients, and are part of the diagnostic criteria for Angelman syndrome.[120] Abnormal EEGs are commonly present in infancy and may be the first diagnostic sign.[8,24] EEG abnormalities in infants often include irregular, generalized, high-voltage sharp-wave and spike-wave activity. Although only 30% of patients have seizures in the first 2 years of life, by 3 years of age 85% will have developed seizures, most often of the absence, myoclonic, or generalized tonicâ€“clonic types. However, some of the abnormal movements in Angelman syndrome are cortically based myoclonus, responsive to GABAergic (Î³-aminobutyric acid) drugs.

Prader-Willi syndrome also involves chromosome region 15q11-13, but in contrast to Angelman syndrome, results from loss of the paternally derived chromosome. Patients with Prader-Willi syndrome have infantile hypotonia, short stature, small hands and feet, hypogonadism, and mental retardation, and as children develop hyperphagia and obesity.[37] Seizures are present in 15% to 20% of patients, but in contrast to Angelman syndrome, the seizures are not severe, chronic, or therapeutically challenging.[9] Molecular diagnosis is based on abnormal methylation studies, which detect 99% of cases.[13]

Velocardiofacial syndrome, a contiguous gene deletion involving chromosome region 22q11.2, is characterized by congenital heart disease, palatal abnormalities, characteristic facial features, learning difficulties, and immune deficiency. Former names for velocardiofacial syndrome are DiGeorge syndrome and Shprintzen syndrome. Seven percent of patients with velocardiofacial syndrome develop seizures.[57] In addition, infants with velocardiofacial syndrome sometimes present with seizures secondary to hypocalcemia because of parathyroid deficiency.

Metabolic Disorders

There are several general mechanisms by which metabolic disorders can result in seizures (see also Chapters 261 and 262). First, any disorder that alters the cellular metabolic environment (such as hyperammonemia) can provoke seizures. Second, some metabolic disorders can lead to secondary structural abnormalities in the brain. For instance, cortical infarctions can develop in patients with MELAS (mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes) that can act as epileptogenic foci even in the absence of acute systemic metabolic disturbance. Finally, a tendency to epilepsy may be intrinsic to the metabolic disturbance or disease itself, if the metabolic pathway is necessary for the function of neurons and/or glia. The treatment of seizures in patients with metabolic disorders must include treatment of the metabolic derangement; seizures are likely to persist despite anticonvulsant therapy if an untreated metabolic abnormality is present, and anticonvulsant therapy may not be necessary if the metabolic derangement is brought under control.

Wolf et al.[124] reviewed the main characteristics of the epilepsies that are found in the inborn errors of metabolism and outlined a general approach to diagnosis and treatment. For more detailed information see also *The Molecular and Metabolic Basis of Inherited Disease*,[103] *Diagnostic Recognition of Genetic Disease*,[81] and *Atlas of Metabolic Diseases*.[80]

In patients with disorders of carbohydrate metabolism and glycogen storage diseases, seizures occur in association with hypoglycemia or during times of metabolic stress. Accordingly, seizures occur in 25% to 40% of patients with *glycogen storage disease types I* and *III* and rarely in other types, in which systemic hypoglycemia is uncommon. Patients with *d-glyceric acidemia* and *galactosemia* have myoclonic seizures, and abnormal waking EEGs are seen in more than 50% of children with galactosemia.

Niemann-Pick disease, type C (NPC) is a lipid storage disease with a variable age of onset, typically presenting with ataxia, vertical supranuclear gaze palsy, dementia, and, in infants, hypotonia and organomegaly.[85] Inheritance is autosomal recessive; most cases are caused by mutations in *NPC1*, and diagnosis is based on impaired cholesterol esterification in cultured fibroblasts that show positive filipin staining. About one third of patients with NPC have seizures, which are often resistant to treatment. Ironically, seizures tend to decrease with prolonged survival, possibly due to continued neuron loss. Gelastic cataplexy, the sudden loss of muscle tone from humorous stimuli, is present in about 20% of children with NPC.[56,88]

A number of the disorders of amino acid metabolism (including the urea cycle disorders) feature seizures or epilepsy. The urea cycle defects are especially marked by significantly elevated levels of ammonia; about 50% of neonates with elevated ammonia will have seizures, along with cerebral edema.[110] The use of valproic acid is contraindicated in these disorders because it can raise ammonia levels. Seizures are also prominent in *HHH* (*hyperammonemia, hyperornithinemia, hypercitrullinemia*) *syndrome*, *nonketotic hyperglycinemia*, and *homocystinuria*.

HHH syndrome, like other disorders of the urea cycle, may present at any time from infancy to adulthood with lethargy, episodes of vomiting or neurologic dysfunction, seizures, and

coma. It is somewhat more likely to appear later in life than other disorders of the urea cycle, which usually develop in infancy or childhood.

Nonketotic hyperglycinemia (NKH) presents in infancy with intractable generalized or myoclonic seizures, hypotonia, apnea, and high levels of glycine in the blood and cerebrospinal fluid (CSF). NKH has autosomal recessive inheritance, and is caused by mutations in the glycine cleavage system. The EEG most commonly shows a burst-suppression pattern, but hypsarrhythmia can also be seen. NKH should be considered in the differential diagnosis of a patient with infantile spasms. Most patients die before 1 year of age, although affected males have a longer survival rate and better neurologic function.[48] Diagnosis can be made by detecting elevated levels of glycine in the serum, but in some cases CSF amino acid analysis is necessary, as glycine levels may only be elevated in the CSF and not in the serum. Brain magnetic resonance imaging (MRI) can be useful for diagnosis as well, as reported abnormalities include ventriculomegaly, absent corpus callosum, posterior fossa cysts, delayed myelination, areas of diffusion-restriction, and an elevated glycine peak on magnetic resonance spectroscopy (MRS).[59] Treatment with standard anticonvulsants may not be successful, and treatments directed toward lowering glycine levels have met with only mild success.

Homocystinuria is a relatively common metabolic disorder. The frequency of epilepsy in homocystinuria has been estimated at 21%, with the most common seizure type being generalized tonicâ€"clonic seizures.[74] These seizures are not associated with any identifiable metabolic â€œcrisis,â€ and epileptiform EEG findings are common both in patients with seizures and in patients who are clinically asymptomatic.[17]

Pyridoxine-dependent seizures (PDS) occur within the first hours or days of life and respond dramatically to treatment with vitamin B_6. PDS has autosomal recessive inheritance, and several different gene loci have been implicated.[5] Any infant presenting with idiopathic seizures in the first week of life warrants a trial of pyridoxine, as appropriate treatment can lead to a seizure-free, neurologically normal outcome.[115]

Seizures commonly accompany the metabolic crises of not only the urea cycle disorders, but also of the organic acidurias, such as *propionic acidemia*, *isovaleric acidemia*, *biotinidase deficiency*, and *glutaric aciduria, type I*. The most common seizure types are generalized myoclonic or infantile spasms. In general, seizures are more likely to be a presenting feature in infants or young children with these disorders than in children with variants of later onset. Biotinidase deficiency can present with ataxia, developmental delay, seizures, and an eczematous rash. Seizures were the presenting feature in 38% of patients, and 55% of patients had seizures.[100] Glutaric aciduria, type I, is an autosomal recessive disorder presenting with macrocephaly, a progressive movement disorder that can be misdiagnosed as cerebral palsy, and progressive neurologic symptoms that may acutely worsen during periods of illness.[47] MRI may show frontotemporal atrophy and enlarged CSF spaces in the sylvian fissures (â€œbat-wingâ€ appearance)[80] (see also Chapter 262). Seizures more commonly accompany the acute decompensatory episodes.

Mitochondrial disorders typically can be diagnosed by elevated blood and/or CSF lactate levels (see also Chapter 263). *Leigh syndrome* (subacute necrotizing encephalomyelopathy) is a group of disorders that manifests in infancy with lethargy, failed neurologic development, seizures, and progressive respiratory dysfunction. Leigh syndrome can be caused by mutations in mitochondrial or nuclear DNA. Seizures are present in roughly 30% of patients.[90] Older children or adolescents may have symptoms of the mitochondrial deletion disorders *MERRF* (*mitochondrial encephalomyopathy with ragged red fibers*) and *MELAS* (*mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes*). (MERRF is discussed in Chapter 262 as one of the primary genetic epilepsy syndromes.) Seizures in MELAS occur initially at times of metabolic disarray and lactic acidosis, but they may become self-perpetuating as structural lesions accumulate in the brain. During the strokelike episodes, the EEG can show characteristic focal high-voltage delta waves with polyspikes.[25] Seizures are a presenting sign in 28% of patients with MELAS and are present at some point in 96% of patients.[45]

The peroxisome biogenesis disorders (the Zellweger spectrum disorders, including *Zellweger syndrome*, *neonatal adrenoleukodystrophy*, and *infantile Refsum disease*) have autosomal recessive inheritance. Seizures are very common, and are a significant management problem in neonatal adrenoleukodystrophy.[111] The EEG shows diffuse or multifocally abnormal patterns or hypsarrhythmia. In severely affected patients, aberrant cortical structure can sometimes be seen with central nervous system (CNS) imaging. Most severely affected patients die within the first 1 to 2 years of life.

Among the lysosomal storage disorders, epilepsy is a prominent or early feature of *Krabbe disease* and some forms of *Gaucher disease*. Generalized or myoclonic seizures become prominent during the course of *Tay-Sachs disease* and *Sandhoff disease*, and they can also be seen in patients with *sialidosis* and *Farber disease*. Seizures occur as a later phenomenon in about 20% of patients with *adrenoleukodystrophy* and in up to 46% in patients with *metachromatic leukodystrophy*.[1] The EEG features of these diseases have been reviewed.[76]

Acute intermittent porphyria, caused by deficiency of the enzyme porphobilinogen deaminase, leads to recurrent seizures in about 10% to 20% of affected patients. The treatment of seizures is difficult because many of the standard anticonvulsants (phenytoin, valproic acid, and in particular the barbiturates) can trigger metabolic crises in individuals with porphyria and are therefore considered unsafe to use. Reynolds and Miska[94] have recommended diazepam, paraldehyde, or bromides for treatment of seizures during acute metabolic crises. A recent report documents the successful treatment of seizures with gabapentin.[112] Gabapentin and other nonhepatically metabolized drugs such as levetiracetam are appealing drugs to consider in patients with porphyria.

Menkes disease is an X-linked disorder of copper metabolism caused by mutations in the adenosine triphosphatase (ATPase) copper-transporting gene *ATP7A*. Symptoms, which appear within the first 3 months of life, include failure to thrive, developmental regression, hypotonia, coarse short hair, and seizures. EEGs obtained early in the course show multifocal spikes, but hypsarrhythmia develops as the neurologic disorder progresses. Seizures may be generalized or partial, and they are variable in severity. Copper therapy does not affect the EEG, but seizures may respond to standard anticonvulsant therapy.[23]

In general, seizures are not a primary feature of disorders of purine metabolism (e.g., Lesch-Nyhan syndrome), endocrine and exocrine disorders, and the immune deficiency disorders. In addition, the mucopolysaccharidoses, some of which produce profound declines in mental function, are not associated with seizures or epilepsy.

An exciting advance in the past decade has been the recognition of two novel types of metabolic disorders: congenital disorders of glycosylation and CSF neurotransmitter disorders.

Congenital disorders of glycosylation, also known as carbohydrate-deficient glycoprotein syndromes, are a heterogeneous group of disorders with multiorgan effects caused by defects in glycoprotein biosynthesis.[53] Patients may have developmental delay, ataxia, neuropathy, and characteristic physical findings including inverted nipples and facial dysmorphism. Diagnosis is made by serum transferrin isoelectric focusing. Seizures have been reported in up to 50% of patients.[86]

CSF neurotransmitter disorders are a group of metabolic diseases that affect the production of neurotransmitters; diagnosis relies upon CSF fluid collection and measurements of neurotransmitters, their metabolites, and their intermediates. Symptoms include seizures, dystonia and other extrapyramidal disorders, ocular movement abnormalities, autonomic instability, and ataxia.[46,49] Timely diagnosis is difficult but important because of the effective treatments available for many of these disorders. Because of limited data regarding the prevalence and symptoms, seizure frequencies are not known for the different CSF neurotransmitter disorders.

Genetic Syndromes

Many disorders seen by the neurologist or geneticist are not easily classifiable; often, they have been grouped according to a prominent physical finding or abnormality. It is important to realize, however, that disorders lumped into a certain category may share nothing except the presence of a single cardinal feature and yet differ widely in regard to their tendency to cause epilepsy.

In genetics, use of the term *syndrome* implies that a common etiology underlies all symptoms and signs included as part of the syndrome, whereas in the epilepsy literature, *syndrome* is used to describe a collection of signs or symptoms that commonly occur together; a specific or constant etiology is not implied. (For instance, the Lennox-Gastaut epilepsy syndrome may be present in patients with a number of different genetic disorders or syndromes!) In the discussion below, the terms *disease*, *disorder*, and *syndrome* are used interchangeably to refer to genetically defined entities.

The outline of this section follows the format of Smith's Recognizable Patterns of Human Malformation.[54]

Disorders with Short Stature

Seizures are noted particularly in some of the syndromes associated with short stature, including *Brachmann-de Lange syndrome* (14% to 20%),[2,43] Marinesco-SjÃ¶gren syndrome, *Smith-Magenis syndrome*, and the *DeSanctis-Cacchione* variant of *xeroderma pigmentosa* (but not in other variants of xeroderma pigmentosa or in other â€œpremature agingâ€ disorders, such as progeria, Seckel syndrome, or Cockayne syndrome).

Disorders of Early Overgrowth

Seizures have been described in up to 25% of patients with *BÃ¶rjeson-Forssman-Lehmann syndrome*, caused by mutations in the X-linked *PHF6* gene.[68] Further, EEG abnormalities, consisting mostly of low-voltage fast activity or nonspecific slowing, were present in at least 50% of patients, as well as in otherwise asymptomatic female carriers.[96] Neonates with *Beckwith-Wiedemann syndrome* may present with seizures secondary to hypoglycemia, and occasional patients have an ongoing seizure disorder. Finally, seizures with or without severe brain malformation may be seen in patients with hemihypertrophy (which is in itself not a diagnosis, but rather a physical sign of diverse etiologies); patients with significant somatic asymmetry should always be evaluated for CNS structural abnormalities.

The incidence of epilepsy has not been reported to be significantly elevated in the syndromes of Bannayan-Riley-Ruvalcaba, Cohen (6% incidence of seizures), Marshall-Smith, Simpson-Golabi-Behmel, Sotos, and Weaver.

Skeletal Dysplasias

Many of the skeletal dysplasias cause abnormal skull or facial shape. However, deformation of the cranial contents alone does not necessarily result in seizures. Thus, patients with achondroplasia, metaphyseal dysplasias, or the osteopetrosis syndromes do not have a high risk for epilepsy or seizures. However, seizures do occur in patients with bony diseases related to systemic hypocalcemia, such as *Albright osteodystrophy* and *hypophosphatasia* (2% to 24%, greater frequency with earlier age of onset); the seizures are presumably related to the metabolic disruption and are not a primary feature of the bony disease. Patients with *osteogenesis imperfecta* do not have increased seizure risk, although a single study demonstrated EEG abnormalities in half of 56 patients.[93] Finally, cortical dysplasias (and thus an increased risk for seizures) have been reported in thanatophoric dysplasia.

Craniosynostosis can arise from diverse syndromic, chromosomal, metabolic, hematologic, and environmental causes. Thus, the presence of seizures in a patient with craniosynostosis should prompt an evaluation of the etiology of the craniosynostosis, as well as CNS imaging. Seizures occur frequently (percentage in parentheses) in patients with *Christian syndrome* (60%),[33] *Crouzon syndrome* (12%),[64] and *Saethre-Chotzen syndrome* (36%),[20] but not in Apert syndrome.

Disorders with Facial Defects

A large number of genetic syndromes affect facial morphogenesis, or cranial nerve formation, but the majority do not have associated seizures (see Gorlin et al.).[33] Teratogens such as anticonvulsants can also result in facial defects, but these are not discussed here. A significant risk for seizures in patients with oral-facial syndromes is the presence of CNS structural abnormalities. For example, *FG syndrome* is characterized by hypotonia, characteristic facial appearance, and agenesis of the corpus callosum.[34] EEG abnormalities have been described in FG syndrome patients,[82] and seizures have been reported in 0% to 60% of patients.[98]

Cardiofaciocutaneous syndrome (CFC syndrome), characterized by distinctive facial appearance; unusually sparse, brittle, curly hair; skin abnormalities; heart malformations; growth delays; and/or varying degrees of mental retardation, has been reported to have fairly common seizures (5 of 22 cases).[26] Recent molecular evidence shows that CFC syndrome and Noonan syndrome (which also has unusual facies and congenital heart defects) are distinct entities.[52]

Patients with Coffin-Lowry syndrome may have paroxysmal drop attacks (stimulus-induced drop episodes [SIDES]) that in the past were believed to be seizures. However, detailed characterization of these events has revealed that they are nonepileptic events with features of both cataplexy and hyperekplexia.[77]

Eleven percent of patients with *Parry-Romberg syndrome* develop seizures.[108] Affected patients have progressive hemifacial atrophy, often with trigeminal neuralgia and ophthalmologic abnormalities; the etiology is unclear, and there is some discussion as to whether the disease is a form of autoimmune scleroderma.

Facial disorders not associated with an increased risk of seizures include branchial arch syndromes, facial clefting syndromes, Langer-Giedion syndrome, Moebius syndrome, Treacher Collins syndrome, and Smith-Lemli-Opitz syndrome.[58]

Connective Tissue Disorders

Seizures do not occur with increased frequency in any of the connective tissue disorders (Marfan syndrome, Ehlers-Danlos syndromes, osteogenesis imperfecta), with the exception of homocystinuria (discussed above).

Neurocutaneous Disorders

The diagnosis of a neurocutaneous disorder should prompt surveillance for seizures, as epilepsy is a common feature in these disorders.[63]

Neurofibromatosis type 1 (NF1) is the most common of the neurocutaneous disorders. The incidence of epilepsy in NF1 is reported to be 5% to 11%.[119] NF1, also known as von Recklinghausen disease, is characterized by multiple cafÃ© au lait spots, axillary and inguinal freckling, multiple discrete dermal neurofibromas, and iris Lisch nodules. NF1 has autosomal dominant inheritance and its associated gene (neurofibromin) has been identified, but because of the large size of the gene, diagnosis is based on clinical criteria.[38] New-onset seizures in a patient with a personal or family history of NF1 should prompt a search for intracranial neoplasm, as patients have a lifelong increased risk for a variety of CNS tumors, especially optic nerve and brainstem gliomas.

Neurofibromatosis type 2 (NF2), an autosomal dominant mutation in neurofibromin-2 (merlin), is genetically and clinically distinct from NF1. NF2 is associated with bilateral vestibular schwannomas, multiple meningiomas, and other CNS tumors. NF2 has an approximately 8% seizure risk.[22]

Tuberous sclerosis complex (TSC) is characterized by hypomelanotic macules, facial angiofibromas, shagreen patches, ungula fibromas, brain tubers and/or subependymal nodules, seizures, mental retardation, kidney angiomyolipomas, and cardiac rhabdomyomas. Inheritance is autosomal dominant, caused by mutations in either *TSC1* (hamartin) or *TSC2* (tuberin).

Seizures affect up to 80% of TSC patients,[31,64] and infantile spasms occur in up to one third of patients.[113] The most common cause of infantile spasms is TSC; 25% of patients with infantile spasms have TSC. Because of this association, an infant presenting with infantile spasms should have a careful skin examination, and if indicated, an examination with a Wood lamp to look for hypomelanotic macules. Further, significant evidence suggests that first-line treatment for infantile spasms in TSC patients is vigabatrin (not adrenocorticotropic hormone [ACTH], which is used for non-TSC infants with infantile spasms).[40]

Overall, 60% of TSC patients are mentally retarded, and of these 98% have seizures; only 59% of those TSC patients without retardation had seizures.[101] Sixty-four percent of patients with TSC who have infantile spasms will develop mental retardation.[30]

Subependymal glial nodules occur in 90% of individuals with TSC, and cortical or subcortical tubers in 70%.[19] Patients with more than four cortical lesions visible on MRI were more likely to have intractable seizures.[95] Progressive intracranial calcification (of uncertain relevance to the seizure disorder) develops in children with this disease, and they are at risk for brain tumors, in particular giant-cell astrocytomas.

Infantile-onset seizures, often severe, are a presenting feature of *encephalocraniocutaneous lipomatosis*. This disorder involves skin, eye, adipose tissue, and brain. Neurologic manifestations include seizures, ventricular enlargement, calcifications, mental retardation, and cerebellopontine angle tumors.[67]

Proteus syndrome is a complex disorder with uncertain etiology; clinical features include disproportionate, asymmetric overgrowth of body parts; connective tissue nevi; epidermal nevi; vascular malformations of the capillary, venous, and lymphatic types; and dysregulated adipose tissue.[15] Seizures have been reported in association with Proteus syndrome, although the incidence is not known. *Hemimegalencephaly* refers to hamartomatous malformation of the brain with diffuse migrational abnormalities of an entire cerebral hemisphere; there are both â€œisolatedâ€ and syndromic (including some of the neurocutaneous syndromes such as Proteus syndrome) causes. Seizures tend to have onset in infancy and may be difficult to control medically. A recent study listed seizures in 100% of patients, with 26% requiring hemispherectomy to achieve seizure control.[102]

Epidermal nevus syndrome is characterized by nevi following the lines of Blaschko, along with noncutaneous involvement of the brain, eye, and skeletal systems; but it is most likely a collection of several separate entities with similar clinical features (including linear nevus sebaceous syndrome). *Linear nevus sebaceous syndrome* is characterized by midline nevus sebaceous, seizures (in 67% of patients), mental retardation, and associated CNS abnormalities including hemiatrophy and ventricular dilatation.[116]

Sturge-Weber syndrome is a sporadically occurring disorder of the vasculature of the face and head. Intracranially, unilateral leptomeningeal angiomas and calcifications develop, which commonly follow the course of the angiomatous vessels.[87] Seizures occur in 80% of patients with Sturge-Weber syndrome.[109] Unilateral or bilateral epileptiform discharges can be present, with or without unilateral or bilateral background slowing.[10,97]

Incontinentia pigmenti is an X-linked disorder of the skin, hair, nails, teeth, eyes, and CNS, caused by mutations in the NEMO gene (NF-kappaB essential modulator).[106] CNS malformations and seizures have been reported in this disorder, although the prevalence is uncertain. Patients with *hypomelanosis of Ito* have skin depigmentation along the lines of Blaschko and neurologic symptoms including language disabilities, seizures, hypotonia, mental retardation, and autistic behavior, with underlying abnormalities in the CNS white matter.[99] The disorder is probably an etiologically diverse group of conditions with genetic mosaicism as a common feature.[65] Seizures are reported in up to 49% of patients, and infantile spasms in 8% of patients.[84]

Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease), characterized by the presence of multiple arteriovenous malformations (AVMs), does not have an increased risk of seizures. However, brain MRI with vascular imaging is indicated early in life to look for cerebral AVMs, and antibiotic prophylaxis is indicated for patients with a pulmonary AVM, as they can develop a cerebral abscess and seizures. Lipoid proteinosis (Urbach-Wiethe syndrome), nevus basal cell carcinoma syndrome (Gorlin-Goltz syndrome), pseudoxanthoma elasticum, and SjÃ¶gren-Larsson syndrome are not associated with seizures.

Ectodermal and Mesodermal Dysplasias

Seizures are not a feature of the ectodermal dysplasias. Diseases that disrupt the development of primarily mesodermal structures, such as the multiple intestinal polyposis syndromes and the multiple endocrine neoplasias, also are not associated with epilepsy.

Genetic Disorders of Brain Development

The past 10 years have seen an explosion in information about the genetics of CNS developmental abnormalities. In part, this has been facilitated by the advances in CNS imaging made possible by high-resolution MRIs, which have revealed underlying brain abnormalities in many patients with seizures (see Chapters 14, 79, and 260). Guerrini and Filippi[36] reviewed the frequency of seizures and EEG findings in each disorder and also outlined procedures for genetic testing and genetic counseling (see also the review by Mochida[72]).

Holoprosencephaly is characterized by failure of the forebrain to divide into separate hemispheres and ventricles; there is a continuum of clinical features and severity, often with other

P.190

malformations of the CNS and neuronal migrational abnormalities. Causes include teratogens, gross chromosome abnormalities in structure or number (25% to 50% of cases), syndromes, and single gene mutations in 18% to 25% of cases.[75] If genetic testing is indicated, high-resolution chromosome karyotypes should be obtained, and if necessary, FISH analysis of the known genes. About 80% of patients with holoprosencephaly also will have a craniofacial abnormality.[14] Seizures are common, but incidence depends on the etiology of the holoprosencephaly and the extent of malformations. In addition, hypersynchronous activity on EEG was seen in patients with holoprosencephaly without seizures.[39]

Schizencephaly is a structural brain abnormality, in which a CSF-filled cleft, lined by gray matter, extends from the pial surface of the brain to the ventricle. A variety of etiologies are hypothesized, and there are syndromic and familial cases, although no causative genes have yet been identified. Seizures are present in about 50% of patients.[35]

Septo-optic dysplasia (de Morsier syndrome) is a midline CNS disorder characterized by hypoplastic or absent optic discs and nerves, absent septum pellucidum, and pituitary deficiencies; seizures occasionally accompany this disorder. Mutations in the homeobox gene *HESX1* have been found in some patients with septo-optic dysplasia.[16]

Seizures are not a typical feature of the developmental disorders of the posterior fossa, such as Arnold-Chiari malformation, Dandy-Walker malformation, or Joubert syndrome. Seizures have been reported in patients with Arnold-Chiari I malformation (in which the cerebellar tonsils are displaced downward through the foramen magnum), although it is not clear if the incidence is increased.[11] The unusual respiratory pattern and eye movements in infants with Joubert syndrome, however, can mimic seizures.

Lissencephaly, or smooth brain, is a pathologic or MRI finding of abnormal neuronal migration, resulting in absent (agyria) or reduced number (pachygyria) of gyri. Ninety percent of patients with lissencephaly have seizures, with onset before age 6 months in 75%. Almost 80% have infantile spasms. Different types of lissencephaly have been described including *LIS-1*â€“associated lissencephaly (Miller-Dieker syndrome), X-linked lissencephaly with corpus callosum agenesis and ambiguous genitalia (caused by mutations in *ARX*), and *DCX*-associated lissencephaly. Miller-Dieker syndrome is a microdeletion (contiguous gene deletion) of chromosome region 17p13.3, characterized by lissencephaly (with four rather than six nerve cell layers in the cortex) and a specific facial phenotype. The lissencephaly is caused by mutations in *LIS-1*,[92] while the facial features are due to the contiguous genes deleted in the syndrome.

Polymicrogyria is characterized by multiple small gyri with abnormal cortical lamination, frequently accompanied by seizures. Types include bilateral frontoparietal polymicrogyria, bilateral frontal polymicrogyria, and bilateral perisylvian polymicrogyria. *Heterotopias* are abnormal collections of gray matter, typically either in the deep white matter of the cerebral hemispheres or in the periventricular regions. X-linked periventricular nodular heterotopia has been associated with mutations in the *FLN1* and *ARGEF2* genes. Approximately 90% of patients with periventricular nodular heterotopia have epilepsy.

Three disorders have been described with the combination of brain abnormalities and congenital muscular dystrophy: *Muscle-eye-brain disease* (MEB), *Walker-Warburg syndrome* (WWS), and *Fukuyama congenital muscular dystrophy* (FCMD).[32] All three are characterized by infantile hypotonia and a â€œcobblestoneâ€ appearance of lissencephaly in their brain MRIs. There is significant clinical overlap in their symptoms; MEB and WWS also may have eye abnormalities, hydrocephalus, and leukoencephalopathy.[117] MEB and WWS are caused by mutations in genes (*POMGnT1* and *POMT1*, respectively, although there are several other gene loci also identified) involved in the glycosylation of *a*-dystroglycan, a structural protein.[117] FCMD is caused by mutations in the fukutin protein; seizures are present in 80% of patients with an average onset age of 3 years.[126] In MEB and WWS, seizures have been reported, although the incidence has not been established.

Neurodegenerative Disorders

Rett syndrome is an X-linked progressive neurologic disease characterized by initial normal development, followed by a plateau and then regression of cognitive and motor skills, deceleration of head growth, and the development of autistic-like features.[127] The classic phenotype is only present in girls; however, some few cases of affected males (with much worse clinical characteristics) have also been reported. Rett syndrome is caused by mutations in the *MECP2* gene.

EEG abnormalities are an invariable feature of Rett syndrome, and seizures are present in 50% of patients.[78,83] The waking EEG usually shows a poorly organized, slow background, which is interrupted by multifocal or bilaterally synchronous spikes or sharp waves that may become constant during sleep. Later in the course, the EEG may show only nonspecific low-voltage activity. The percentage of rapid eye movement (REM) sleep is diminished throughout the course of the disease. It has also been noted that not all â€œspellsâ€ in patients with Rett syndrome are epileptic.[27] Nearly 25% of 62 patients had episodes of breath holding, staring, laughing, or jerking that were without EEG correlation.

Autism, autistic-spectrum disorders, Asperger disorder, *Landau-Kleffner syndrome* (LKS), and pervasive developmental delay represent a spectrum of disorders with diverse etiologies. Thirteen percent of children with autism have epilepsy; another 22% have EEG abnormalities but no seizures.[12] Exact diagnostic criteria for LKS (or acquired epileptic aphasia) remain contentious, but patients present with a progressive childhood-onset aphasia associated with EEG abnormalities, most commonly continuous spike-and-wave discharges during sleep (electrical status epilepticus of sleep). Up to 70% of patients have clinical seizures.[114]

Seizures occur at an increased frequency in *Alzheimer disease* (10% of autopsy-proven cases,[42] 16.8% of institutionalized patients[7]), but they may not recur or require treatment. Myoclonus occurs in up to 10% of patients, and nonspecific EEG slowing is common, particularly as the disease progresses.

Seizures are a prominent feature of the *neuronal ceroid lipofuscinoses (NCLs)*. Patients present with a combination of visual loss, seizures, and progressive cognitive impairment or dementia. The NCLs are autosomal recessive lysosomal storage disorders, characterized pathologically by electron microscopy revealing fingerprint or curvilinear profiles, or granular osmiophilic deposits.[29] At least six different genes have been identified; diagnosis relies upon a combination of enzymatic testing for the protein defect and/or electron microscopy studies. The seizure disorder may appear as a progressive myoclonic epilepsy.[62] Raininko et al.[91] reported abnormal EEGs in 25 of 33 patients with juvenile NCL; 23 of these 25 EEGs showed paroxysmal activity, either focal or generalized. The EEG typically shows posteriorly prominent, light-induced spikes, and as the disease progresses, low-voltage activity with marked slowing predominates. Treatment of the seizures can be difficult; valproic acid tends to be poorly tolerated because of side effects, while lamotrigine appears to be more effective.[122]

Seizures are reported to occur frequently (30%) in patients with *Huntington disease* whose symptoms first appear in

childhood or adolescence, but much less often (2%) in the more typical adult-onset disease.[41] Huntington disease is caused by an autosomal dominant trinucleotide repeat expansion in the *HD* gene. Generalized, akinetic, or myoclonic seizures, rather than partial seizures, are seen. EEG abnormalities are seen in 74% of juvenile-onset Huntington disease patients.[66]

Epilepsy is not a feature of Parkinson disease and its variants, except that Nygaard et al.[79] reported complex partial seizures in 7 of 55 patients with progressive supranuclear palsy.

The *spinocerebellar ataxias* (SCAs) are a large and heterogeneous group of genetic disorders, characterized chiefly by progressive cerebellar ataxia. Epilepsy is reported in *SCA10*, *SCA17*, and *dentatorubropallidoluysian atrophy* (Haw river syndrome) (DRPLA),[69] which are caused by dominantly inherited triplet repeat expansions. Epilepsy is reported in 20% to 100% of SCA10 patients. Myoclonus and epilepsy are a defining feature of the â€œmyoclonus epilepsyâ€ form of DRPLA, but are infrequent or absent in the ataxic or choreic forms of the disease. Epilepsy occurs in all DRPLA patients with onset before age 20.[50] This disease appears to be less common in the United States than in Japan, where it may be responsible for 10% to 20% of adolescent- or adult-onset progressive myoclonus epilepsy.

In *Wilson disease*, an autosomal recessive disorder of copper metabolism that can present with hepatic, neurologic, or psychiatric disturbances, 6% of patients develop epilepsy with a greater incidence in patients with juvenile onset of symptoms.[18] *McLeod neuroacanthocytosis syndrome* is an X-linked disorder with red blood cell acanthocytosis and basal ganglia degeneration; up to 40% of patients develop seizures.[55] Pantothenate kinaseâ€“associated neurodegeneration (PKAN) (Hallervorden-Spatz syndrome) is characterized by progressive dystonia, dysarthria, rigidity, and pigmentary retinopathy. No seizures were reported in any patient with classic PKAN.[44]

Summary and Conclusions

More than half of the references cited here are new since the first edition of *Epilepsy*. This reflects the impressive strides in diagnosis made possible by advances in molecular and radiologic diagnostics, and the corresponding attention given to the topic both by epileptologists and by geneticists. The material includes comprehensive reviews of the epilepsies in broad genetic categories (such as chromosome abnormalities, inborn errors of metabolism, and neuronal migration disorders) as well as in specific disorders (such as the tuberous sclerosis complex).

In some of the disorders discussed in this chapter, the underlying genetic involvement is obvious, for example, the patient with trisomy 13 and dysmorphic characteristics on examination. In other situations the clinician must associate the findings of history and examination with characteristics of the epilepsy to make a diagnosis, as in patients with Angelman syndrome. A key point is that in many instances, the genetic syndromes with epilepsy now have specific genetic diagnoses.

This discussion of genetic syndromes and epilepsy is not exhaustive, but it provides a summary of the more common disorders a neurologist or geneticist might encounter. Appropriate treatment is dependent upon diagnosis, and diagnosis can be aided by recognizing those genetic syndromes accompanied by epilepsy. Thus, identification of the genetic and molecular bases for these disorders may provide an opportunity for directed pharmacotherapy. It may be noted that this approach complements the study of comorbidities that are observed in patients with primary epilepsies in which seizures are the primary manifestation. With these points in mind, this chapter should be of interest to epileptologists and other neurologists as well as to geneticists.

Title: *Epilepsy: A Comprehensive Textbook, 2nd Edition*

Chapter 18

Genetics of Epilepsy Syndromes

Ortrud K. Steinlein

Introduction

The term *epilepsy* describes a heterogeneous group of disorders, with a lifetime cumulative incidence of 3%. There are disorders in which seizures are the main or only symptom, and those in which seizures are just one symptom among others. The reasons why individuals develop epilepsy are numerous. Examples for mostly nongenetic causes of epilepsy are trauma, tumor, and infections. On the other end of the spectrum are epilepsies that have no obvious etiology but are suspected to be mainly genetic in origin. The latter group of epilepsies has been termed idiopathic, in the meaning that they are â€œnot preceded or occasioned by another disorderâ€[32] and that â€œthere is no underlying cause other than a possible inherited predispositionâ€ and â€œa symptomatic origin is neither detected nor suspected.â€[33] By now the distinction between symptomatic and idiopathic epilepsies has become blurred because of our growing knowledge about the complex and diverse etiology of epilepsies. Genes for several idiopathic epilepsies have already been discovered, and most of these genes are able to (at least temporarily) change the functional state of the brain. Some of them are expressed during embryogenesis, rendering it possible that some of them might even interfere with normal brain development and cause subtle changes of the brain's microanatomy. On the other hand, there is a large group of epilepsies and disorders with epilepsy that have been termed â€œsymptomaticâ€ because they are due to known metabolic, neurodegenerative, or structural brain damage. Many of these disorders have by now shown to be caused by clearly defined genetic factors. It is likely that in the future the terms *nongenetic epilepsies*, *genetic epilepsies*, and *genetic disorders with epilepsy* will more and more replace terms like *idiopathic* and *symptomatic*. For this chapter exemplary members of both groups have been chosen to illustrate principal etiologic categories of the disorder â€œepilepsyâ€ and trace the various genetic pathways to epileptogenesis.

Inheritance and Genes in Common Idiopathic Epilepsies

About 30% to 40% of all epilepsies, especially during childhood and adolescence, are summarized under the term *idiopathic epilepsies*. They can be roughly divided into the group of common, mostly generalized idiopathic epilepsies (IGEs) and the various rare monogenic forms of partial or generalized idiopathic epilepsy. The first group, IGE, includes age-related subtypes like juvenile myoclonic epilepsy, childhood absence epilepsy, juvenile absence epilepsy, and grand mal epilepsy on awakening. The high concordance rates found in twin studies support the hypothesis of an almost complete genetic etiology of IGE.[10] Nevertheless, recurrence risks in first-degree relatives of patients with IGE are considerably lower than in monogenic disorders, arguing for an oligogenic or polygenic model of inheritance. It can be assumed that several susceptibility genes are involved in each patient, and that the interaction between these gene loci is multiplicative rather than additive. Some IGE genes might determine the seizure threshold by influencing neuronal excitability, while other susceptibility genes might be responsible for the age of onset and therefore the seizure subtype.[146]

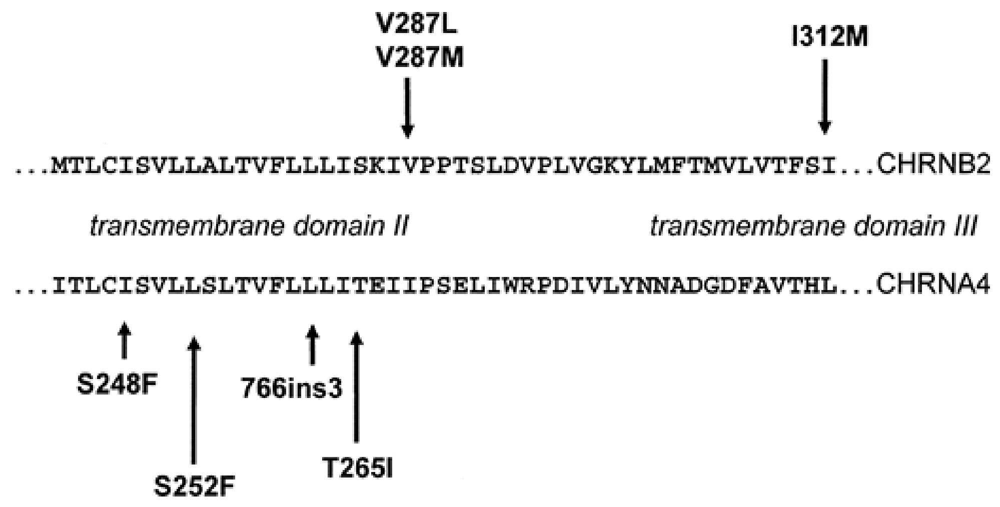

FIGURE 1. Mutational spectrum in autosomal dominant nocturnal frontal lobe epilepsy. The parts of nicotinic acetylcholine receptor subunit genes *CHRNA4* and *CHRNB2* containing transmembrane domains II and III are shown.

Two different models have been proposed to explain the complexity of genetic factors and geneâ€“gene interactions in common IGE. In the *ancestral common variant complex epilepsy* model (ACVCE), the existence of common IGE-associated alleles is assumed. In homogeneous patient samples, such alleles should be detectable by association studies. The second model, named *multiple rare variant complex epilepsy* model (MRVCE), describes the existence of many different rare, slightly deleterious mutations that cannot be detected by association studies. Both models would be able to explain the complex inheritance patterns seen in IGE, and both common and rare gene variants have already been identified.[86] For example, both the ACVCE and the MRVCE models of complex inheritance apply to sequence variants in the T-type calcium channel gene *CACNA1H* on chromosome 16p13.3. Several rare *CACNA1H* variants that markedly alter channel properties have been found in patients with childhood absence epilepsy (F161L, E282K, V831M) or other IGE subtypes (P618L, G755D). Interestingly, a common *CACNA1H* sequence variant exists that, in combination with one of the above-mentioned rare variants, is able to alter the calcium channels' biopharmacologic properties in a way that neither the rare nor the common variant separately do.[67] Additional examples consistent with both the ACVCE and the MRVCE models are found in the *GABRD* gene that codes for the Î´-subunit of the Î³-aminobutyric acid (GABA)$_A$ receptor. The *GABRD* sequence variant E177A was described in one family and, compared to wild-type receptors, was shown to significantly reduce the GABA$_A$ receptor's maximal current. A more common *GABRD* variant, R220H, was detected in both epilepsy patients and controls. Receptors heterozygous for R220H had a significantly decreased peak current in comparison with the wild type; thus, R220H may act additively as a susceptibility factor in combination with other, yet to be identified sequence variants.[38] Nevertheless, *CACNA1H, GABRD*, and other genes that are presently discussed as susceptibility factors probably still account only for a very small fraction of the genetic contribution to common IGE syndromes. Many more genes remain to be discovered, a process that has so far been most successful in the monogenic forms of idiopathic epilepsy described in the next paragraphs.

Idiopathic Epilepsies Are Often Channelopathies

The progress in identification of genes in monogenic forms of epilepsy illustrates the important role of ion channels in epileptogenesis. A great variety of different ion channels regulate brain excitability and prevent hypersynchronization of neuronal networks. Mutations in any of those ion channels might change the delicate balance between excitatory and inhibitory input, resulting in recurrent firing, hyperexcitability, and, finally, seizures.

Familial Nocturnal Frontal Lobe Epilepsy

In 1994, autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) was first described as an inherited form of partial epilepsy. ADNFLE is characterized by clusters of brief motor seizures, which occur mostly during nonâ€“rapid eye movement (REM) sleep.[106] Nonspecific aura phenomena including epigastric, sensory, or psychic symptoms sometimes precede the seizures. The seizures start with gasps, grunts, or some vocalizations followed by thrashing hyperkinetic activity or tonic stiffening of the limbs, often with superimposed clonic jerking. The consciousness is only infrequently impaired. Seizure frequency can be highly variable even within the same family. In some of the patients seizures are frequent and tend to cluster, while in others seizure occurrence is more sporadic and long periods of spontaneous remission are reported. In general, seizure frequency tends to decrease in later adulthood. Physical examinations and brain imaging results are usually normal. Interictal electroencephalographic (EEG) abnormalities are rarely seen, and only some patients show ictal epileptiform activity. The onset of ADNFLE is usually during childhood or early adolescence, with a penetrance of 70% to 80%. Seizures are often, but not in all patients readily controlled by antiepileptic drugs, especially carbamazepine.

Mutations in two genes have so far been identified in different ADNFLE families.[46,121] *CHRNA4* and *CHRNB2* encode the Î±4- and Î²2-subunits of the neuronal nicotinic acetylcholine receptor (nAChR), respectively. The first *CHRNA4* mutation, a S248F amino acid exchange within the second transmembrane domain, was identified in 1995.[121] Descriptions of other nAChR mutations, either in *CHRNA4* or in *CHRNB2*, followed.[62,73,98,122] With the exception of one mutation (*CHRNB2*-I312M in transmembrane domain III), all known ADNFLE mutations are located within the second transmembrane domain. Both the second and the third transmembrane domain contribute to the walls of the ion channel; thus, it seems that only mutations that have a direct effect on the ion pore are able to cause ADNFLE. In total, four *CHRNA4* and three *CHRNB2* mutations have been described. These include six amino acid exchanges and one small *in frame* insertion. Some of those mutations have been found again in unrelated families. They offer the opportunity to study the effects differences in genetic and ethical backgrounds might have on the penetrance of the disorder and the clinical features associated with these mutations (Fig. 1).

The nAChRs, like the glycine, $GABA_A$, and serotonin receptors, are members of the large family of ligand-gated ion channels. They are constituted by the assembly of five subunits arranged pseudosymmetrically around the central axis, forming a cation-selective ion pore. Pharmacologic and ligand-binding studies have shown that, depending on their subunit composition, the different subtypes of homo- or heteropentameric nAChRs not only vary with respect to their expression patterns in the brain, but also display different biopharmacologic channel properties.[11] Both Î±4- and Î²2-subunits are found in almost all brain regions, and the heteropentameric *Î±*4/*Î²*2 receptor is thought to be the major high-affinity nicotine nAChR subtype in mammalian brain. The surprising and so far not very well understood part is that an nAChR subtype ubiquitously present in brain is able to cause a partial type of epilepsy rather than a generalized one. In support of the recognized importance of the cholinergic system in brain functions, recent work has shown that nAChR mutations not only cause epilepsy, but can also be associated with additional neurologic and psychiatric features or cognitive deficits.[29,62,80] Examples are the *CHRNA4*-776ins3 mutation and the *CHRNA4*-S252L mutation. The 776ins3 mutation was found in 11 members of a large Norwegian ADNFLE family. Six of the 11 mutation carriers not only had epilepsy, but also had serious psychiatric problems, mostly schizophrenia, negative symptoms of schizophrenia, or recurrent unclassified psychosis. These observations suggest that the 776ins3 mutation may be a risk factor for psychiatric disorders.[80] The S252L mutation has been described in two unrelated families of Korean and Japanese origin. In both families the seizures not only tended to be resistant to carbamazepine treatment, but were also associated with a high rate of mental retardation and/or behavioral problems.[29,62] The similarities of the clinical phenotype in two families with different genetic background but the same S252L-ADNFLE mutation strongly suggest that the associated neurologic features are mutation specific rather than caused by modifying genes or environmental factors (Fig. 2).

P.197

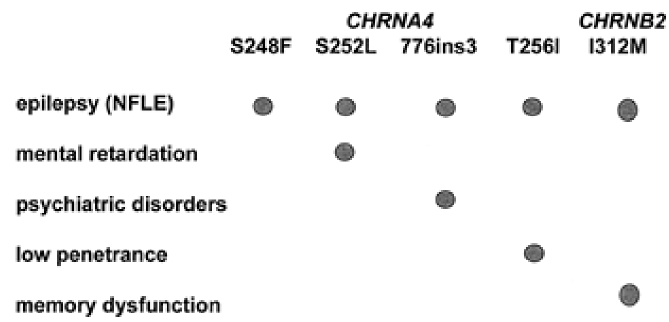

FIGURE 2. Clinical features frequently associated with different nicotinic acetylcholine receptor mutations in autosomal dominant nocturnal frontal lobe epilepsy families. NFLE, nocturnal frontal lobe epilepsy.

Functional analysis carried out with recombinant nAChR receptors in *Xenopus* oocytes or HEK cells, including patch clamp characterization of several known ADNFLE mutations, revealed different biopharmacologic profiles.[11] Co-expression of the S248F mutation and the wild-type *CHRNA4* allele yielded acetylcholine-evoked currents of amplitudes comparable to wild-type receptors but with a higher sensitivity for the natural agonist. Receptors carrying either the 776ins3, S252L, or V287M mutation displayed increased acetylcholine sensitivity but to different degrees compared with the S248F mutation. A reduction of calcium permeability was observed for the mutants S248F and 776ins3 but not for the S252L mutation.[11] Increased acetylcholine sensitivity and therefore a gain-of-function effect is the only functional feature common to all known ADNFLE mutations. It is tempting to speculate that the particular functional signatures of each mutant contribute to the above-described observations of associated neurologic features in ADNFLE, while the gain-of-function effect might be responsible for the epilepsy phenotype. The latter part of this hypothesis is supported by the observation that, compared to wild-type litter mates, mice carrying gain-of-function mutations in the *CHRNA4* gene are dramatically more sensitive to nicotine-induced seizures. Furthermore, nicotine application in these mice resulted in enhanced hippocampal theta rhythms, as demonstrated by in vivo electrophysiologic recordings. This observation would be consistent with a model in which gain-of-function effects in presynaptically located nAChRs activate inhibitory GABAergic interneurons in the neocortex and hippocampus. The enhanced GABA release could then increase network excitability by inhibiting inhibitory pathways. Alternative models for the epileptogenic effect of nAChR mutations could include a disturbance of hippocampal â€œpeacemakerâ€ theta activity due to increased input from septal cholinergic neurons.

Benign Familial Neonatal Convulsions

Benign familial neonatal convulsions (BFNC) is a rare autosomal dominant seizure disorder of the newborn (see also Chapter 223). The disorder is characterized by an age of onset between the first day and, latest, the fourth month of life. The seizures are mostly unprovoked, generalized, or multifocal and of the tonic and/or clonic type. The course of the disorder is often benign and self-limiting, and, with or without pharmacotherapy, in most patients the seizures remit spontaneously within a few days or weeks.[103,137] Later in life seizures can reoccur in up to 15% of the patients, starting mostly at school age or in young adulthood. These so-called late-onset seizures tend to be infrequent and are often provoked, for example, by lack of sleep. Several untypical BFNC patients with a more severe course of the disorder have been described. These patients often show a higher frequency of seizures and seizures still occur after the age of 4 months. Follow-up studies often revealed moderate delays of psychomotor development, and in some patients have a family history positive for epilepsy and mental retardation. Two BFNC families have come to attention in which a mutation carrier developed drug-resistant seizures and/or epileptic encephalopathy shortly after birth, resulting in severe psychomotor retardation. In one of the two severely affected index patients a de novo mutation was found, while the second index patient inherited his mutation from a parent with typical â€œbenignâ€ BFNC.[36,109] It remains unclear if these two patients had a second yet unrecognized condition or if certain risk factors (e.g., perinatal hypoxia) in combination with a BFNC mutation increase the risk for such an unfavorable outcome.

The molecular basis of BFNC is a mutation in the voltage-gated potassium channel genes *KCNQ2* or *KCNQ3* (chromosome 20q13.3 and 8q24, respectively).[13,27,115] Both the *KCNQ2* and *KCNQ3* genes encode ion channel subunits that are composed of six transmembrane domains. The subunits have identical structures including a voltage sensor in transmembrane domain 4, a loop between transmembrane domains 5 and 6 that builds the ion channel pore, and a long C-terminal region of unknown function. The BFNC mutations found so far in *KCNQ2* are either missense mutations located in one of the transmembrane domains or truncating mutations (including nonsense, insertion/deletions, and splice site mutations) located mostly in the C-terminal region. Most mutations are private, meaning that they have not been found in other BFNC families. So far, only three mutations have been found in *KCNQ3*. All known *KCNQ3* mutations are missense mutations located within the vicinity of the pore region.

KCNQ2 and *KCNQ3* encode subunits of the M-channel, a very slowly opening and closing potassium channel that is ubiquitously found in brain.[141] The M-current, first discovered some 20 years ago,[21] is a powerful controller of neuronal repetitive firing. M-currents regulate the number of action potentials of individual neurons by opposing sustained membrane depolarization. M-channels activate at membrane potentials that are more negative than the action potential threshold and at which few other ion channels are active. Therefore, they can be assumed to have a pivotal role in the stabilization of membrane potentials and are likely to control excess neuronal excitability and prevent seizures. Expression studies in *Xenopus* oocytes and HEK cells have shown that BFNC mutations cause only modest reductions (20% to 30%) of potassium currents in reconstitution experiments. It seems, therefore, that even slight alterations of M-channel activity are sufficient to cause seizures.[13]

Exceptions to this haploinsufficiency concept are some rare *KCNQ2* mutations that appear to have a dominant negative effect on channel function, as demonstrated by a >50% reduction in current magnitude. One of these mutations is *KCNQ2*/R207W, which causes the BFNC/myokymia syndrome. The mutation abolishes the third of six positive charges in transmembrane domain 4 that is thought to represent the voltage sensor in the cation channel superfamily. The R207W amino acid exchange was the first *KCNQ2* mutation described that causes a disorder with symptoms outside the central nervous system; it is associated not only with episodic symptoms, but also with continuous symptoms. On the clinical level, heterozygosity for the R207W mutation causes both BFNC and myokymia, a spontaneous and repetitive involuntary contraction of muscle fiber groups.[37] In the BFNC/myokymia syndrome, multifocal or generalized tonicâ€“clonic convulsions typically start around day 3 after birth and disappear spontaneously after a few weeks or months. Electromyographic (EMG) recordings in the patients are initially normal but,

starting in infancy, reveal spontaneous repetitively discharged normal motor unit potentials of 20 to 60 msec in duration. Generalized myokymia with spontaneous finger twitching occurs some years later. The association with both central and peripheral neurologic symptoms might be explained by the unusual electrophysiologic profile of the underlying mutation. R207W causes a loss of K^+ current, whose magnitude depends strongly on the pattern and time course of depolarization. With short periods of depolarization the loss of current is more severe than with other known BFNC mutations. The dominant negative effect is not observed with longer periods of activation. Thus, at long (>1 second) trains of action potentials or during seizure activity, R207W mutant channels may be activated significantly and may even reach wild-type levels. It is possible that the time-dependent dominant negative effect of R207W establishes itself only in the peripheral nervous system and that this might be the reason for peripheral neurologic symptoms like myokymia. This hypothesis rests on the assumption that the neuronal activity of motoneurons is interrupted by longer quiescent periods than is the activity of central neurons whose hyperexcitability triggers seizures. Under such conditions, the dominant negative effect of the R207W mutation would have consequences for motoneurons but not for central neurons.[37]

In mice, *KCNQ2* knockout experiments resulted in early postnatal lethality in homozygous animals, while hemizygous knockout mice developed and behaved normal but showed an increased sensitivity to pentylenetetrazole, an epileptic inducer.[142] Transgenic mice that conditionally express a dominant negative *KCNQ2* pore mutation in the brain only during defined developmental periods demonstrated the critical role of M-channel activity in early postnatal brain development. Suppression of the M-current during the first postnatal weeks was associated with spontaneous seizures, behavioral hyperactivity, and morphologic changes in the hippocampus.[96] These results support the notion that M-currents are critical determinants of cellular and neuronal network excitability. The changes in brain morphology found in transgenic mice also raise the interesting question of whether BFNC caused by *KCNQ2* mutations in humans might be (at least in part) due to submicroscopic structural brain changes (morphologic etiology) rather than exclusively to a reduction of M-currents (functional etiology).

Benign Familial Infantile Convulsions

Benign familial infantile convulsions (BFIC) can be distinguished from BFNCs by a later age at onset[135] (Fig. 3). The autosomal dominant disorder is characterized by the onset of seizures around 6 months of age (range 3 to 9 months). Seizures occur in clusters and respond well to antiepileptic drug treatment. The seizures are partial with secondary generalization and in most patients spontaneous remission has occurred by the age of 12 months. Usually no subsequent neurologic abnormalities develop. Two putative loci were reported, BFIC1 (19q) and BFIC2 (16p12-q12), but no genes have been identified yet.[23,54] Interestingly, three other disorders with overlapping neurologic features map to the same region as BFIC2: The infantile convulsions and choreoathetosis syndrome (ICCA; OMIM 602066),[124] paroxysmal kinesigenic choreoathetosis (PKC; OMIM 128200),[129] and a syndrome comprising rolandic epilepsy, paroxysmal exercise-induced dystonia, and writer's cramp (EPRPDC; OMIM 608105).[53] Therefore, the possibility exists that the four disorders are allelic.

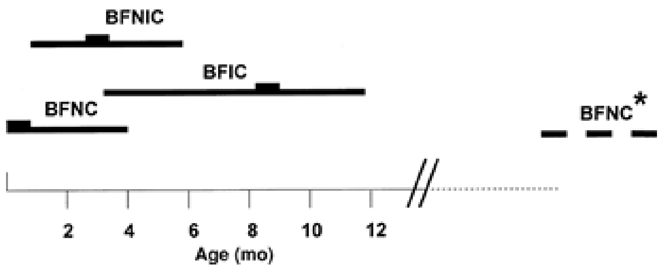

FIGURE 3. Age of onset and remission in benign familial neonatal convulsions (BFNC), benign familial neonatal/infantile convulsions (BFNIC), and benign familial infantile convulsions (BFIC).

A rare seizure disorder with an age of onset intermediate between BFNC and BFIC is benign familial neonatal/infantile convulsions (BFNIC). BFNIC has been shown to be caused by mutations in the voltage-gated sodium channel subunit gene *SCN2A*[9,61] (Fig. 3).

Febrile Seizures

Febrile seizures (FSs) affect 5% to 10% of children under the age of 6 years. Twin and family studies demonstrated the involvement of genetic factors in the etiology of febrile seizures. In most patients an oligo- or polygenic background rather than a monogenic one can be assumed, and a substantial degree of heterogeneity is likely. However, rare families with an apparent autosomal dominant mode of inheritance have been described, and linkage studies identified several putative gene loci, including *FEB1* on chromosome 8q13-q21, *FEB2* on 19p, *FEB3* on 2q23-q24, *FEB4* on 5q14-q15, *FEB5* on 6q22-q24, and *FEB6* on 18p11.2.[64,81,88,90,92,138] In one family with febrile and afebrile seizures, a nonsense mutation (S2652X) was identified in the *MASS1* gene. *MASS1* is part of the large G-protein coupled receptor gene *VLGR1*.[90] The mutation causes a deletion of the C-terminal 126 amino acid residues in the predicted MASS1 protein. If confirmed in independent families, *MASS1* can be regarded as a rare cause for familial febrile convulsions. In another family a missense mutation in the *SCN1A* gene chromosome 2q23-24 has been found to cosegregate febrile seizures, indicating that familial febrile seizures should also be considered a channelopathy.[81]

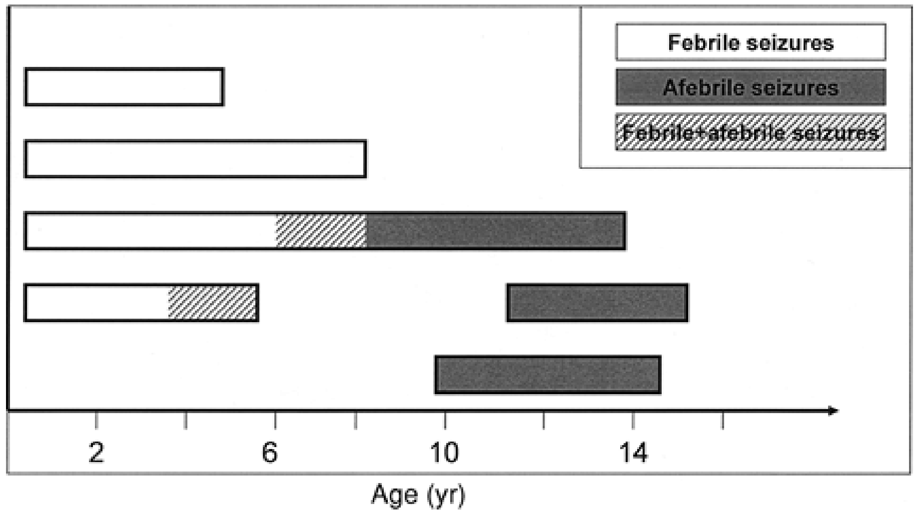

FIGURE 4. Clinical phenotypes in generalized epilepsy with febrile seizures plus (GEFS+). Range of phenotypes found in GEFS+ families is shown. Febrile seizure plus phenotypes include febrile seizures that persist beyond the age of 6 years and/or febrile seizures overlapped or followed by different types of (mostly generalized) afebrile seizures. (Adapted from Baulac S, Gourfinkel-An I, Nabbout R, et al. Fever, genes, and epilepsy. *Lancet Neurol.* 2004;3:421â€“430.)

Generalized Epilepsy with Febrile Seizures Plus and Dravet Syndrome

Febrile seizures are the most common seizure type in families with the recently described syndrome of generalized epilepsy with febrile seizures plus (GEFS+) (see also Chapter 256), followed by febrile seizures plus (FS+; seizures with fever may persist beyond the age of 6 years and/or may be associated with variable afebrile seizures). Afebrile seizure types in affected GEFS+ individuals include generalized tonicâ€“clonic, myoclonic, absence, and atonic seizures or, at least in some families, partial seizures[105] (Fig. 4). Given the highly variable clinical phenotype, it is not surprising that the mode of inheritance underlying GEFS+ is still a matter of debate. Although in some families the trait is likely to be autosomal dominant, in others it is probably better described as oligogenic or as a major gene effect. A genetic concept involving more than one gene would also better fit the clinical variability observed within and between GEFS+ families. The first GEFS+ mutation (C121W) was identified in the *SCN1B* gene on chromosome 19q13.1.

P.199

SCN1B encodes a small accessory subunit of the voltage-gated sodium channel. The mutation C121W can be predicted to disrupt a disulphide bridge and to interfere with the ability of the Î²-subunit protein to modulate the function of the much larger, pore-forming Î±-subunits.[140] Subsequent studies showed that most GEFS+ mutations are located in the gene coding for the Î±1-subunit of the voltage-gated sodium channel, *SCN1A*, on chromosome 2q24.[41] *SCN1A* codes for a large ion channel protein composed of four domains, each containing six transmembrane segments (S1 to S6). Minor GEFS+ genes are *SCN2A*, coding for the Î³2-subunit gene of the voltage-gated sodium channel, or the Î³2-subunit gene of the $GABA_A$ receptor (*GABRG2*).[8,56,66,82,123,139]

Mutations in the *SCN1A* gene have also been identified in the majority of patients with the syndrome of severe myoclonic epilepsy of infancy (SMEI = Dravet syndrome; also Chapter 230) and in some cases of phenotypically overlapping syndromes like borderline SMEI (SMEB) or intractable childhood epilepsy with generalized tonicâ€“clonic seizures (ICEGTC).[31,45] The clinical phenotype of SMEI is characterized by an initially normal psychomotor development, onset of febrile seizures within the first year of life, and subsequent manifestation of various afebrile seizure types including absence, myoclonic, and partial seizures. During the second year of life psychomotor delay becomes evident.

Although caused by the same gene, *SCN1A*, differences in the mutation detection rates and the mutational spectrum present in GEFS+ and SMEI patients are obvious.[87] *SCN1A* mutations are only found in 5% to 10% of GEFS+ patients but are present in 33% to 100% of SMEI patients (the variation is likely to be due to different mutation detection methods and/or patient inclusion criteria). All known GEFS+ mutations are missense mutations that cause amino acid exchanges in the encoded protein, while SMEI mutations are composed of truncating (nonsense or frame shift) mutations (47%), missense mutations (43%), splice site mutations (7%), and deletions (3%). Nearly all reported SMEI mutations (76 of 80) are de novo; only a few of them (4 of 80) were inherited from a parent with a less severe type of epilepsy. Mutations in SMEI tend to be either truncating and/or located in functionally critical parts of the gene. GEFS+ mutations are mostly found in less highly conserved parts of *SCN1A* such as the distal parts of S1 to S4 segments or in the short loops connecting those segments (Fig. 5). It is therefore likely that SMEI and GEFS+ mutations differ with respect to their predicted impact on ion channel function. SMEI mutations can be expected to cause a more severe disturbance of protein function, consistent with the more severe phenotype.

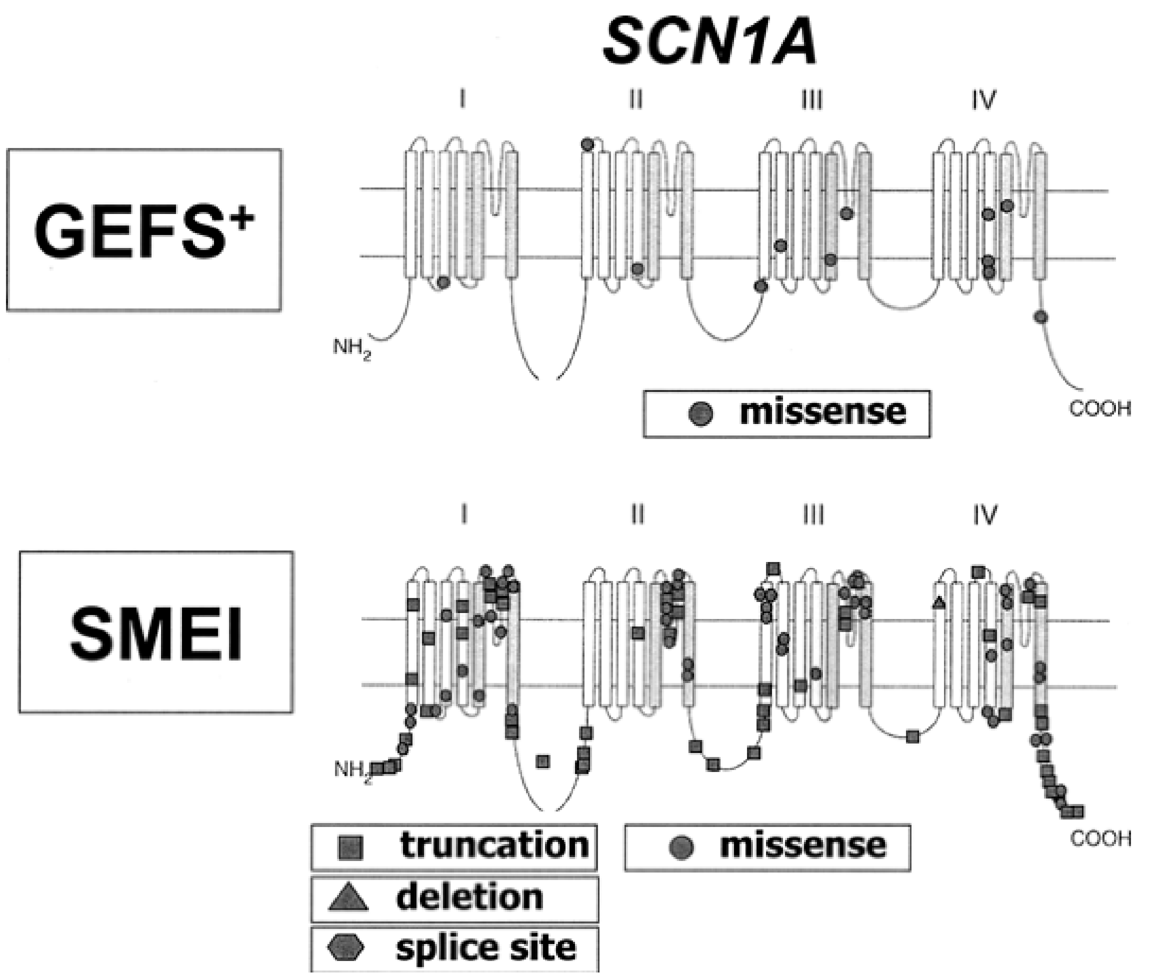

FIGURE 5. Schematic representation of *SCN1A* mutational spectrum in generalized epilepsy with febrile seizures plus (GEFS+) and severe myoclonic epilepsy of infancy (SMEI). All reported GEFS+ mutations are missense mutations. In SMEI different types of mutations are found, and most of these mutations are either truncating mutations or missense mutations affecting functionally important structures like the channel's ion pore. (Adapted from Baulac S, Gourfinkel-An I, Nabbout R, et al. Fever, genes, and epilepsy. *Lancet Neurol.* 2004;3:421â€“430.)

The exact functional effects of SMEI and GEFS+ mutations and their correlations to clinical phenotypes are still unclear. Expression studies of *SCN1A* channels with different SMEI and GEFS+ mutations in *Xenopus* oocytes or HEK293 cells showed a variety of biophysical aberrations including complete loss of function, altered gating properties, and even gain-of-function effects.[77,78,101] These conflicting results can probably partially be explained by different experimental setups, since the biophysical properties of voltage-gated sodium channels strongly depend on the expression system used in the experimental setup. SCN1A channels expressed in HEK293 cells are known to differ from those expressed in *Xenopus* oocytes with respect to their kinetic properties and their sensitivity to Î²-accessory subunits. Furthermore, to be able to compare the different functional studies, the question needs to be addressed whether SMEI and/or GEFS+ mutations alter channel surface expression by affecting gene transcription, mRNA stability, protein folding, or trafficking.

Another syndrome of early childhood epileptic encepha- lopathy that is phenotypically and etiologically related to both SMEI and GEFS+ is ICEGTC. Both GEFS+ and ICEGTC are severe types of early childhood epilepsy that are characterized by fever sensitivity, intractable seizures, and developmental decline after seizure onset. Contrary to GEFS+, myoclonic or absence seizures usually do not occur in ICEGTC patients. *SCN1A* mutations were found in 7 of 10 ICEGTC patients. All mutations were missense mutations that were, similar to SMEI mutations, either located in highly conserved (S4 to S6, pore loop) or, as in GEFS+, less conserved parts of the gene (S1 to S4). Two of the seven published ICEGTC patients inherited their *SCN1A* mutations from a parent with GEFS+-like epilepsy, raising the possibility that additional genetic and/or environmental factors contribute to the more severe phenotype in ICEGTC.[45]

Novel Gene Families in Idiopathic Epilepsy

Most of the genes mentioned above either code for ligand-gated or voltage-gated ion channels (i.e., *CHRNA4/B2*, *GABRG2*, *KCNQ2/3*, *SCN1A/2A*) or for proteins that modulate ion channel function (i.e., accessory channel subunits). Recently, genes of so far unknown function belonging to newly identified gene families were found in some rare idiopathic epilepsies. The first of those was the *LGI1* gene discussed below. These

findings demonstrate that â€œchannelopathiesâ€ are not the only etiologic concept in idiopathic epilepsies, but that other mechanisms might exist.

Autosomal Dominant Lateral Temporal Lobe Epilepsy

The syndrome of autosomal dominant lateral temporal lobe epilepsy (ADLTE, also named autosomal dominant partial epilepsy with auditory features [ADPEAF]) is characterized by simple partial seizures with mainly acoustic and sometimes even visual hallucinations.[144] The age of onset is usually in the second or third decade of life. In some families the seizures tend to start with a brief sensory aphasia without reduced consciousness.[51] In 2002, positional cloning efforts let to the identification of the *LGI1* gene (*leucine-rich glioma inactivated gene 1*) on chromosome 10q24 as the gene responsible for ADLTE/ADPEAF.[44,51,65,85,100] The mutational spectrum includes both missense mutations and truncating mutations, and no mutation hotspot has emerged yet. There are no obvious clinical differences between patients with truncating mutations and those with amino acid exchanges in the *LGI1* gene.

Table 1 Neuronal Ceroid Lipofuscinoses (NCL)

Disorder	Alias	Gene	Locus	Protein	Inheritance
Infantile NCL	CLN1 Santavuori-Haltia disease	*PPT*	1p32	Palmitoyl-protein thioesterase-1	AR
Late infantile NCL	CLN2 Jansky-Bielschowsky disease	*CLN2*	11p15.5	Pepstatin-insensitive lysosomal peptidase	AR
	CLN5 Finnish variant	*CLN5*	13q21.1-q32	nn	AR
	CLN6	*CLN6*	15q21-q23	Linclin	AR

Juvenile NCL	CLN3 Vogt-Spielmeyer disease Batten disease	*CLN3*	16p12.1	nn	AR
Adult NCL	CLN4 Kufs disease, autosomal recessive type	*PPT*	1p32	Palmitoyl-protein thioesterase-1	AR
	CLN4 Kufs disease, autosomal dominant type Parry disease	nn	â€"	â€"	AD

AD, autosomal dominant; AR, autosomal recessive; nn, not known.

So far the function of the *LGI1* gene, which shows a strong expression in neurons within the temporal lobe, is mostly unknown. The LGI1 protein has a distinctive leucine-rich repeat (LRR) motif in its N-terminal end. This motif might be indicative of either receptor function or an interaction with the extracellular matrix. The LRR motif consists of repeated Î²-strands and Î±-helices connected by loops, building a domain that usually serves as a framework for the formation of proteinâ€"protein interactions and is present in a large number of proteins with diverse functions. The C-terminal half of the LGI1 protein contains seven epilepsy-associated repeats (EARs). EARs are characterized by tandem repeats with a core of about 50 residues that probably folds into a Î²-propeller structure.[120] The EARs were also identified in another epilepsy-relevant protein, MASS1/VLGR1, which is mutated in audiogenic epilepsy in mice and in one family with febrile seizures (see above).[91,116] Within the MASS1/VLGR1 protein, the epitempin repeat is part of the ligand-binding ectodomain, suggesting that this repeat, like the LRR domain, might be involved in proteinâ€"protein interactions.

LGI1 was first found to be interrupted by a translocation breakpoint in a glioblastoma cell line and was therefore labeled as a candidate tumor suppressor gene for gliomas.[28] This theory seemed to be supported by the observation that *LGI1* expression is low or absent in high-grade gliomas.[12]

However, it has been demonstrated that *LGI1* is mainly expressed in neurons rather than in glia cells.[52] Therefore, a gradual loss or displacement of neurons during progression toward higher malignancy would be a plausible explanation for the low or absent *LGI1* expression in high-grade gliomas. The absence of *LGI1* expression would then represent a secondary effect rather than a causative event. This interpretation is supported by studies that found fewer *LGI1*-expressing cells in high-grade gliomas compared with low-grade tumors.[12] Furthermore, no evidence was found that the *LGI1* mutations present in ADLTE families increase the rate of brain tumors or other malignancies. It is therefore unlikely that *LGI1* acts as a first step or high penetrance tumor suppressor gene.[20] Nevertheless, experimental evidence exists that *LGI1* plays a role in the suppression of cell migration. For example, experimentally forced expression of *LGI1* significantly reduced the proliferation and migration ability of glioma cells. Invasion assays showed that glioma cells transfected with *LGI1* lost their ability to migrate freely. These results suggest that *LGI1* is involved in cellular control mechanisms concerning migration and invasiveness. Thus, the possibility remains that, although not a bona fide tumor suppressor gene, *LGI1* plays a role in determining the malignancy grade of an already existing tumor.[70] It will be interesting to know if *LGI1* also plays a role in the migration of neuronal cells during embryogenesis. ADLTE/ADPEAF mutations that interfere with such a function could theoretically cause subtle changes in the brain's cytoarchitecture that might cause seizures through abnormal neuronal networks.

Genetic Disorders with Seizures as a Primary Feature

Seizures are an unspecific symptom commonly associated with structural or functional brain damage. It is therefore not surprising that seizures are a predominant feature in a variety of neurogenetic disorders of diverse etiology. Examples are neurodegenerative metabolic disorders, mitochondrial disorders affecting cellular energy metabolism, structural chromosomal aberrations, and neuronal migration disorders. The seizures might be the leading symptom or just one symptom among others. Unlike in the above-discussed idiopathic epilepsies, the seizures are often difficult to control. In some of these disorders the underlying mutations affect the mitochondrial DNA (mtDNA), but most mutations are found in nuclear genes or chromosomes. The modes of inheritance and the recurrence risks depend on the type of mutation, its localization in the genome, and the effect this mutation has on the phenotype.

Neurodegenerative and Metabolic Disorders with Epilepsy

Seizures and myoclonus are common to many neurodegenerative and metabolic disorders (see also Chapter 261). In the following paragraphs some of the disorders in which epilepsy and/or myoclonus constitute a major feature are exemplarily described.

Neuronal Ceroid Lipofuscinoses

There are at least eight human disorders belonging to the group of neuronal ceroid lipofuscinoses (CLN1 to CLN8).[49] The neuronal ceroid lipofuscinoses (NCL) subtypes, which mainly differ with respect to their age of onset, are characterized by progressive visual failure, epilepsy, and myoclonus. Accumulations of an autofluorescent lipopigment in lysosomes of neurons and other cell types are a characteristic feature of NCL. The NCLs are lysosomal proteinoses, and most of them are autosomal recessively inherited. Depending on the subtype and the mutated gene underlying this subtype, the composition of the lysosomal storage material can differ. In the infantile form, mainly sphingolipid activator proteins (saposins A and D) are stored, while in the late infantile and juvenile NCL subtypes mitochondrial adenosine triphosphate (ATP) synthase subunit C is the main storage material. The genes for several NCL subtypes have been identified, but the function of most of them is still unknown[73] (Table 1).

The infantile subtype of NCL, Santavuori-Haltia-Hagberg disease (CLN1), occurs primarily in the Finnish population and is caused by mutations in the gene for palmitoyl-protein

P.202

thioesterase on chromosome 1p32. The age of onset is within the first or second year of life, and the course is characterized by profound mental and motor deterioration, hypotonia, ataxia, myoclonus, epilepsy, and blindness. Death usually occurs at age 8 to 11 years. The mutations in the palmitoyl-protein thioesterase gene render enzyme activity in the brain of patients undetectable, causing intracellular accumulation of polypeptides.[134]

The classical late infantile form of NCL, Jansky-Bielschowsky disease (CLN2), starts at age 2 to 4 years with myoclonus and seizures. Additional clinical features are dementia and blindness with macular degeneration and retinitis pigmentosa. Death occurs by the age of 15 years. CLN2 is caused by mutations in a gene named tripeptidyl peptidase-1 that is likely to code for a lysosomal pepstatin-insensitive carboxypeptidase.[117]

Juvenile-onset NCL (Batten disease, Vogt-Spielmeyer disease) is the most common neurodegenerative disorder of childhood with an incidence of 1 in 25,000 births. Onset begins with visual failure at age 5 to 10 years, followed by epilepsy and mental deterioration. The exact function of the *CLN3* gene, which is mutated in juvenile NCL, is still unknown. Functional studies suggest that the *CLN3* gene product is an integral membrane protein that localizes primarily to the Golgi apparatus and is thought to have a role in neuronal transport pathways.[79,127]

Kufs disease or adult NCL (NCL4) is distinguished clinically from the infantile and juvenile subtypes by onset of progressive myoclonus epilepsy in adulthood and by absence of ocular involvement. The autosomal recessive form of Kufs disease is, in at least one family, caused by mutations in the above-mentioned palmitoyl-protein thioesterase-1 gene. There is also an autosomal dominant variant of Kufs disease for which no gene has been identified yet.[132]

There are at least three disorders that belong to the subgroup of late infantile NCL. These include the Finnish variant (CLN5), a variant of late infantile NCL (CLN6), and the Turkish variant of NCL (CLN8). All three variants are caused by genes of unknown function that probably encode lysosomal proteins or proteins located in or outside the endoplasmic reticulum (ER).[47,104] The *CLN8* gene also causes Northern epilepsy or progressive epilepsy with mental retardation. Northern epilepsy is a recently described novel autosomal recessive epilepsy of childhood onset that is only found in parts of northern Finland. Age of onset is between 5 and 10 years, followed by progressive mental deterioration. Ocular affection has not been reported in those patients, and life expectancy is considerable longer than in other NCL subtypes. The *CLN8* gene encodes a novel transmembrane protein of unknown function. CLN8 protein is probably located outside the ER and might be involved in vesicular neuronal transport mechanism[76] (Table 1).

Juvenile Sialidosis

The cherry redâ€"spot myoclonus syndrome or juvenile sialidosis (sialidosis type 1, mucolipidosis) is an autosomal recessive storage disorder.[39,119] The patients show a slowly progressive reduction of vision and a crippling myoclonus epilepsy. Onset is usually in the second to third decade. A characteristic feature are cherry-red spots in the macula; however, the age of appearance of the spots is extremely variable, and they are therefore not always helpful to establish the diagnosis. Seizures and myoclonus start in the second decade of life. Two different types of myoclonus might appear in patients: A stimulus-insensitive facial myoclonus without a corresponding EEG correlate or a stimulus-sensitive generalized myoclonus with massive jerks associated with EEG spikes. Juvenile sialidosis is caused by mutations in the *NEU1* gene located on chromosome 6p21.3. *NEU1* encodes a neuraminidase and mutations in this gene are suspected to interfere with substrate binding or impaired folding of the enzyme.[110] This consequently leads to progressive lysosomal storage of sialylated glycopeptides and oligosaccharides.[15,94] The excretion of sialic acid covalently linked to a variety of oligosaccharides and/or glycoproteins is a typical feature, but oligosacchariduria is often no longer detectable if diagnosis is delayed into adulthood.

Dentatorubral-Pallidoluysian Atrophy

The autosomal dominant syndrome of dentatorubral-pallidoluysian atrophy (DRPLA) is mostly found in Japan, but reports of several families of non-Japanese ancestry have been published. DRPLA presents with variable combinations of epilepsy, myoclonus, cerebellar ataxia, choreoathetosis, and dementia.[89,118] Three clinical phenotypes are evident in DRPLA; one is dominated by initial ataxia and subsequent choreoathetosis, one is Huntingtonlike with choreatic movements and dementia, and the third is characterized by progressive myoclonus epilepsy. The age of onset is extremely variable and ranges from 6 to 70 years. Anticipation has been reported in several families.[136] These observations can be explained by the fact that DRLPA belongs to the group of trinucleotide repeat disorders and is caused by an expanded CAG repeat in the DRPLA gene on chromosome 12p13.[69] Normal alleles usually have up to 35 repeats, whereas pathologic alleles (full mutation alleles) have 40 to 100 CAG repeats. The full mutation alleles show somatic mosaicism and intergenerational instability. Large increases in repeat length are usually associated with paternal transmission. The repeat size correlates closely with the age of onset and the severity of the disorder. Translated into protein, such expanded polyglutamine stretches have been shown to form aggregates that have a toxic effect on cells. Intracellular accumulation of DRPLA protein and subsequent neurodegeneration are widespread in the central nervous system. The aggregate formation potential of mutated DRPLA protein increases in a CAG-repeat length-dependent manner, explaining the earlier age of onset in patients with larger repeat sizes.[93,113]

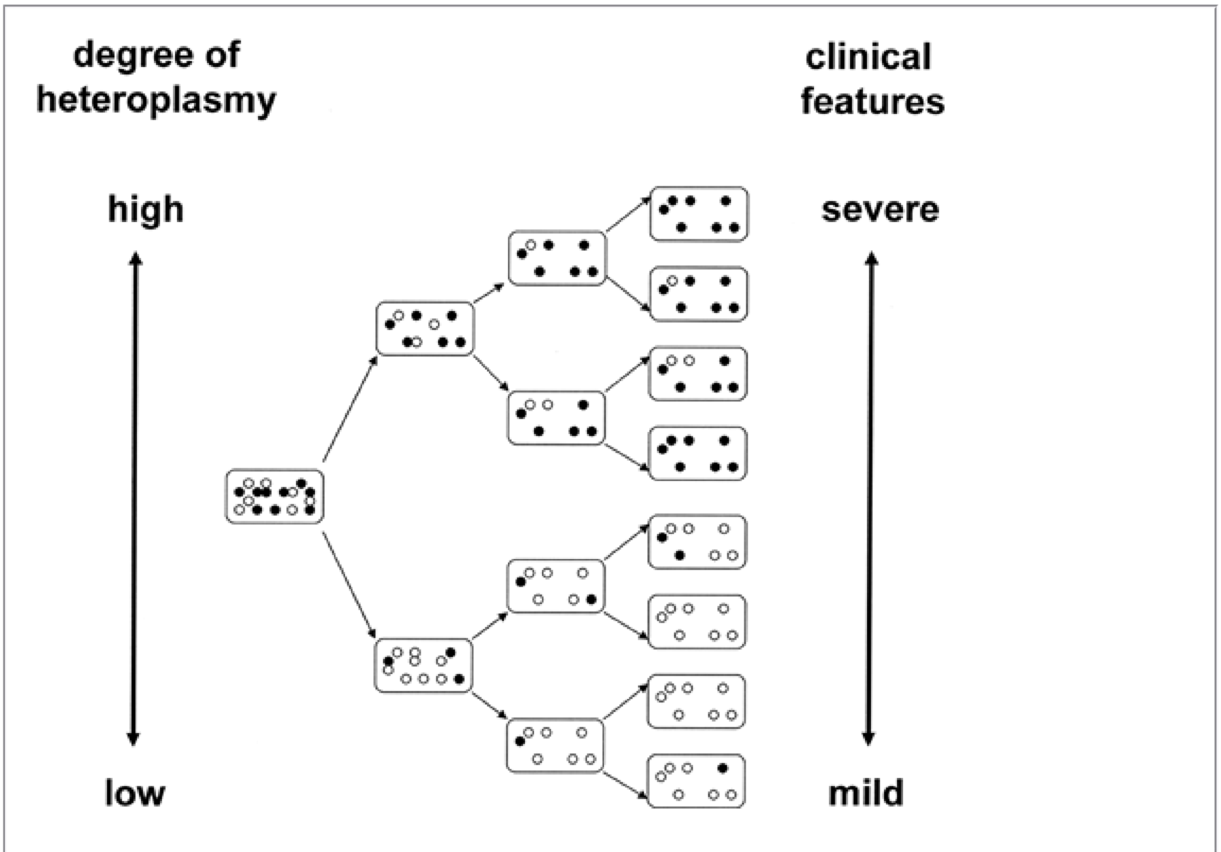

FIGURE 6. Heteroplasmy in mitochondrial inheritance. Cells contain hundreds of mitochondria that behave as semiautonomous organisms and multiply by replication rather than by de novo synthesis. When a cell divides it is a matter of chance which mitochondria will be partitioned in which daughter cell. The resulting mixed population of mutated and wild-type mitochondria is known as heteroplasmy. In heteroplasmy the percentage of mutated mitochondria varies not only from one offspring to the next, but also from tissue to tissue within the same individual. *Filled black circles* indicate mitochondria containing mutated mitochondrial DNA.

Unverricht-Lundborg Disease

Unverricht-Lundborg disease (ULD; also known as Baltic or Mediterranean myoclonus epilepsy) is the most common form of progressive myoclonus epilepsy worldwide. ULD is an autosomal recessive neurodegenerative disorder characterized by progressive stimuli-sensitive myoclonic jerks and generalized tonicâ€“clonic seizures. The age of onset is between 6 and 18 years of age, and the course of the disorder is usually about 10 to 20 years in duration. Mental deterioration, intention tremor, dysarthria, and mild ataxia may develop in later stages of the disorder. Pathologic findings demonstrate a marked loss of Purkinje cells in the cerebellum, neuronal loss in the spinal cord and the medial thalamus, and a proliferation of Bergman glia.[55] Mutations in the *CSTB* gene (cystatin B, also stefin B) on chromosome 21q22.3 have been found in ULD patients. In most patients the disorder is caused by an unstable expansion of a dodecamer repeat located upstream of the initiation codon of *CSTB*.[72] Northern blot analysis demonstrated that tissues from patients carrying the expanded repeat have no detectable *CSTB* mRNA levels. It can therefore be assumed that in these patients ULD is caused by loss of function mutations in the *CSTB* gene. In addition to the repeat mutation, seven other mutations have been identified that can be predicted either to alter the structure of CSTB or to cause alternative splicing. CSTB encodes the cystatin B protein, a widely expressed cysteine protease inhibitor that is thought to have a lysosome-associated physiologic function.[74,95] A major pathophysiologic

P.203

mechanism in ULB is probably the loss of CSTB-mediated protection from protein degrading in neurons.[1] It has also been hypothesized that, at least in a subset of ULD patients, mutated cystatin B protein itself may aggregate and have a toxic effect on the cell.

Lafora Disease

Lafora disease (LD) is an autosomal recessive disorder of adolescent onset that belongs to the group of progressive myo- clonus epilepsies. LD is characterized by severe myoclonus, epilepsy, and rapidly progressive dementia. Death usually occurs within 10 years of onset. Rare forms exist that show a somewhat more benign course of the disorder. The diagnosis can be established by the presence of characteristic periodic acid-Schiff (PAS)â€“positive inclusions, the Lafora bodies, in skin biopsy. Lafora bodies are dense aggregates of abnormally branched glycogen molecules (polyglucosans) that are found in both eccrine duct cells and apocrine myoepithelial cells from LD patients. The Lafora bodies also form in various other tissues and organs like the central nervous system, retina, axis cylinders of spinal nerves, heart muscle, liver cells, and striated muscle fibers.[2,25,57] Recent studies have shown that LD can be caused by mutations in either the *EPM2A* gene (laforin) on chromosome 6q24 or the *NHLRC1* gene (malin) on chromosome 6p22.3.[26,84] A clinical analysis found that LD patients with *NHLRC1* mutations had a slightly longer disease course and later age at death compared to patients with *EPM2A* mutations.[50]

Laforin is a protein tyrosine phosphatase with a carbo- hydrate-binding domain in the N-terminus, while malin is an E3 ubiquitin ligase containing a zinc finger of the RING type in the N-terminal half and 6 NHL-repeat domains in the C-terminal half. It has been demonstrated that laforin is a physiologic substrate of malin. Normally, malin interacts with and polyubiquitinates laforin, leading to its degradation. Mutations in malin found in LD patients diminish this interaction. It has been suggested that laforin's role is to detect polyglucosan appearances during glycogen synthesis and prevent the accumulation of insoluble glycogen molecules resulting from glycogen synthetase overreactivity.[43,75] Thus, one of several possible scenarios would be that the neurodegenerative changes underlying LD occur because loss-of-function mutations in malin cause the accumulation of laforin and lead to suppression of glycogen metabolism. Patients with mutations in laforin would develop LD because laforin would be unable to dephosphorylate a necessary substrate in glycogen metabolism.[48]

Epilepsies with Mitochondrial Inheritance

The chromosomes located in the nucleus are not the only source of coding DNA in our cells. Mitochondria, the reminders of an ancient endosymbiosis between early eucaryotic cells and a proteobacteriumlike ancestor over 1.5 billion years ago, possess their own circular DNA molecule (mtDNA). The original bacterial genome lost most of its genes during evolution, and the few genes that survived on the mtDNA until today can be separated into two groups. Mitochondrial genes either code for proteins that take part in the process of aerobic respiration or code for the mitochondria's transcription/translation system. Mitochondrial inheritance differs from mendelian inheritance in several aspects. The inheritance is strictly maternal, since the sperm mitochondria are selectively eliminated at fertilization. Mutations in mtDNA that seriously harm or abolish the ability of mitochondria to perform their various cellular processes are always heteroplasmic. Heteroplasmic disorders are characterized by a mixed intracellular population of normal and mutated mitochondria. With each cell division it is a matter of chance how many mutated and how many wild-type mitochondria each daughter cells inherits. Hence, heteroplasmy is one of the reasons for the great clinical variability typical for most mitochondrial disorders (Fig. 6).

Myoclonic Epilepsy and Ragged-Red Fiber Disease

Myoclonic epilepsy and ragged-red fiber disease (MERRF) is characterized by progressive myoclonus epilepsy, myopathy, and slowly progressive dementia. Hearing loss and ataxia are common, and patients often develop multiple lipomas or cervical lipomatosis. In most patients ragged-red fibers and abnormal mitochondria with concentric cristae are found in muscle biopsy. Onset ranges from childhood to late adulthood, and, consistent with a heteroplasmic population of mtDNAs, the severity of the disorder can vary considerably, even within one and the same family. In approximately 80% to 90% of patients, MERRF is caused by the T8344C point mutation that affects the $tRNA^{Lysine}$ gene within the mtDNA.[114] Rare MERRF point mutations are T8356C and G8344A, but the syndrome can also be caused by other types of mtDNA mutations including single or multiple deletions. Furthermore, there are several mutations that can cause more than one mitochondrial disorder. An example is the MELAS mutation G8344G that is sometimes found in MERRF patients. The proportion of mutated mitochondria varies between different tissues in MERRF patients. Skeletal muscle frequently has the highest percentage of mutated mtDNAs and correlates best with the clinical severity of the disorder. Muscle biopsy is therefore the first choice for diagnostic mutation analysis.[17]

The G8344A mutation in the $tRNA^{Lysine}$ gene has been shown to inhibit mitochondrial protein synthesis. The translation efficiency and the cytochrome C oxidase activity decline sharply in mutation-carrying mitochondria. Cells with an intracellular percentage of mutated mtDNA that exceeds 85% are extremely sensitive to further damage.[17] It has been speculated that these cells need to accumulate only a few more age-related somatic mtDNA mutations in order to decompensate and cause clinical symptoms. The need for an accumulation of somatic mtDNA mutations in addition to the inherited mtDNA defect would explain the delayed onset and progressive course of the disorder.[34,58,131] Further discussion is available in Chapter 262.

Chromosomal Rearrangements

Cytogenetically visible chromosomal rearrangements often cause the loss or gain of several or many genes. Since approximately 50% of our genes are, at least temporarily, expressed in brain, the resulting cross-genetic imbalance can be expected to cause major structural or functional disturbances in the central nervous system. It is therefore not surprising that seizures are a common finding in these patients.[107] Most chromosomal rearrangements occur de novo in one of the parental germ cells. Thus, even taken into account the rare possibility of a parental germ cell mosaicism, the recurrence risk for siblings is small in these families. Nevertheless, parents need to be karyotyped to exclude the possibility of familial chromosomal rearrangements. Such familial chromosomal rearrangements are mostly balanced translocations where two or more chromosomes exchanged fragments or whole chromosomes are fused together. The carrier of such a balanced translocation is phenotypically normal since he or she has the correct gene copy number, but can have germ cells with an unbalanced chromosomal status. This increases the risk for spontaneous abortions and/or the birth of a severely affected child. Given the number of chromosomes in our cells and size of our genome, the possibilities for individual chromosomal rearrangements are countless. Most of them have been described only in a single or few patients and no typical patterns of clinical features are known. Exceptions are structural rearrangements of certain chromosomal regions that, often due to the presence of repeated DNA elements, have an above-average chance to occur. The underlying mechanism is often a mispairing and incorrect exchange between homologous chromosomes in meiosis. An example that is frequently associated with epilepsy is the inv dup(15) marker chromosome.[30] Additional examples for clinically well-defined syndromes caused by structural chromosomal aberrations are the ring chromosome 20 syndrome, Miller-Dieker syndrome (see also Neuronal Migration Disorders), most cases of Angelman syndrome, Wolf-Hirschhorn syndrome, and the 1p36 deletion syndrome.

Inv Dup(15) Syndrome

The karyotype in individuals with inv dup(15) or idic(15) syndrome is characterized by an extra structurally abnormal chromosome.[35] The supernumerary marker chromosome is formed by the inverted duplication of proximal chromosome 15. Two types of inv dup(15) marker chromosomes with different phenotypic consequences are known. One is a metacentric or submetacentric chromosome that contains mainly heterochromatin and is usually associated with a normal phenotype (karyotype dic[15][q11]). The second type of inv dup(15) (karyotype dic[15][q12 or q13]) is the one that causes the inv dup(15) syndrome. This marker chromosome is considerably larger and contains, among other genes, the Prader Willi/Angelman syndrome critical region.

Functionally, the inv dup(15) syndrome results from gene dosis imbalances due to tetrasomy 15p and partial tetrasomy 15q. The inv dup(15) is the most common of the heterogeneous group of the extra structurally abnormal chromosomes. The estimated incidence at birth is 1 to 30,000. Patients with inv dup(15) syndrome show moderate to profound developmental delay/mental retardation. Physically, muscle hypotonia is the most common clinical feature, whereas other physical findings are rather unspecific. The patients often display an autistic or autisticlike behavior, with gaze and body contact avoidance and no interest toward their peers.[6,16,102] Expressive language may be absent or may remain very poor, and echolalias are common. Stereotypies are frequently seen, including hand flapping, hand wringing, and head turning.

A wide variety of seizures might occur in patients with inv dup(15)-syndrome, with age of onset ranging from 6 months to 9 years. Infantile spasms associated with a hypsarrhythmic EEG have been reported in several cases, while others were diagnosed as having Lennox-Gastaut syndrome or Lennox-Gastaut-like syndrome.[5,143] These patients had tonic/atonic seizures (as head drops or drop attacks), tonicâ€"clonic seizures, and atypical absences with onset between 4 and 8 years of age. Seizures are mostly difficult to control, despite adequate antiepileptic treatment.

Ring Chromosome 20 Syndrome

Ring chromosome 20 (r[20]) syndrome is a rare chromosomal disorder characterized by an indistinct phenotype, epilepsy, mild to moderate mental impairment, and (infrequently) malformation. Most patients are mosaics for the ring chromosome 20; however, the percentage of mosaicism in lymphocytes is not predictive for the severity of the epilepsy or the cognitive problems. All patients have a degree of learning difficulties varying from mild, specific difficulties to severe global learning disability with autistic features. The seizures start between 4 and 6 years of age, and thereafter a slowdown of motor and mental development becomes obvious. Sometimes even deterioration can be observed. Behavioral and adaptation difficulties are frequent, as are emotional immaturity and disturbed fine motor coordination.[19,97] The ictal EEG in ring chromosome 20 patients shows slow theta waves and sharp spikes.[24,68] Long runs of epileptiform activity in the EEG that are not accompanied by confusion or diminished consciousness are characteristic for ring chromosome 20 syndrome. Among other possible mechanisms, ring chromosomes can be formed after breakage in both chromosome arms, loss of the distal fragments, and subsequent

P.205

fusion of the points of fracture. The loss of distal chromosomal material often explains the abnormal phenotype. Interestingly, the subtelomeric end of the long arm of chromosome 20 contains the two known epilepsy genes *KCNQ2* and *CHRNA4*. It is possible that one or two of these genes are deleted in ring chromosome 20 syndrome, contributing to the cause of epilepsy in these patients.

Angelman Syndrome

Angelman syndrome is characterized by severe motor and intellectual retardation, ataxic gait, hypotonia, EEG abnormalities, epilepsy, absence of speech, microcephaly, and facial characteristics including a low forehead, macrostomia, and prominent mandible. The syndrome was first described by Harry Angelman, London, as â€œhappy puppet syndrome,â€[3] a term referring to the often excessive, inappropriate laughter characteristic for patients with Angelman syndrome. The distinctive EEG discharges often start before the onset of seizures. The EEG pattern consists of high-amplitude bilateral spike-and-wave activity that is symmetric, synchronous, and most often monorhythmic with a slow-wave component at 2/s. In about 80% of the patients epilepsy sets in between 6 and 18 postnatal months. Seizure types include absence and myoclonic seizures. Insidious episodes of nonconvulsive or subtle myoclonic status can occur that are easily overlooked as children appear apathetic or in a state of neurologic regression. Seizures are difficult to control by antiepileptic treatment, but seizure frequency tends to decrease in later childhood.[18,71,83]

The genetic etiology of Angelman syndrome is complex, and the majority of cases are due to de novo mutations and are therefore sporadic. In approximately 60% of patients, a cytogenetically detectable deletion of chromosome region 15q11-q13 is found; in another 10% to 15% a submicroscopic deletion of the *UBE3A* gene (ubiquitin protein ligase

E3A)â€"containing critical region for Angelman syndrome can be detected. The chromosome 15 carrying the deletion is always of maternal origin. The paternally inherited Angelman region on chromosome 15 is always inactivated (imprinted); thus, with the loss of the maternally inherited region no active genes remain. A further 3% to 5% of patients have paternal uniparental disomy of chromosome 15 (UPD15). In UPD15, chromosome 15 (or at least the parts of the chromosome containing the region 15q11-q13) is inherited from the father and the patient is missing a maternal copy. A possible mechanism for UPD15 could be a monosomy 15 conception, followed by a postzygotic duplication of the paternal chromosome 15. Familial occurrence of Angelman syndrome is only observed in some of the cases where the disorder is caused by a mutation either in the *UBE3A* gene or in the Angelman region-imprinting center. All types of mutations have the effect that *UBE3A* and other genes expressed exclusively from the maternal chromosome 15 are deleted or functionally silenced. *UBE3A*, although expressed from both alleles in most tissues, is transcribed predominantly from the maternal allele in brain. Another gene that is frequently deleted in Angelman patients is *GABRB3*, the gene coding for the Î²3 subunit of the $GABA_A$ receptor. The exact role of *UBE3A* and *GABRB3* in the etiology of Angelman syndrome is still unknown. A possible mechanism might involve dysregulation of synaptic neurotransmission through the *UBE3A*-related modulation of functional $GABA_A$ receptor complexes.

Wolf-Hirschhorn Syndrome (4p- Syndrome)

Wolf-Hirschhorn syndrome (also known as deletion 4p syndrome or 4p- syndrome) is a contiguous gene syndrome located on the short arm of chromosome 4 in band p16.3. Approximately 87% of the patients carry a de novo deletion, while in the remainder one of the parents is the carrier of a balanced translocation. The characteristic facial features in Wolf-Hirschhorn syndrome include hypertelorism, prominent glabella, epicanthal folds, and cleft lip or palate. Additional features are microcephaly, cardiac defects, growth and mental retardation, and seizures. Epilepsy in Wolf-Hirschhorn syndrome usually starts within the first year of life, and seizures are initially difficult to control but tend to disappear with age. Characteristic are generalized or unilateral myoclonic seizures followed by brief atypical absences. The EEG typically shows centroparietal or parieto-occipital sharp waves, high-voltage waves with superimposed spikes, and bursts of diffuse spikes and waves during drowsiness and sleep, often associated with myoclonic jerks.[111,145]

The theretofore accepted critical region (WHSCR1) is a 165-kb interval on 4p16.3 defined by the loci D4S166 and D4S3327. Recently, Zollino et al.[147] proposed a new critical region for Wolf-Hirschhorn syndrome, and referred to this region as WHSCR2. On the basis of genotype-phenotype correlation analysis, they recommended dividing the Wolf-Hirschhorn syndrome phenotype into two distinct clinical entities, a â€œclassicalâ€ and a â€œmildâ€ form. The exact genotype-phenotype correlations are not fully understood, but it is obvious that the severity of the phenotype strongly correlates with the 4p deletion size. WHSCR2 contains the gene *LETM1* that can be considered as a candidate gene for the seizures observed in most Wolf-Hirschhorn patients. The *LETM1* gene encodes a putative 83.5-kDa protein with a single transmembrane domain, two calcium-binding EF-hand motifs, a leucine zipper, and several Î±-helical structures with high probabilities for forming coiled coils. *LETM1* shows significant amino acid sequence identity to mitochondrial proteins from different species and has been shown to be associated with mitochondrial morphology. The data suggest that the seizures and other neurologic features of Wolf-Hirschhorn syndrome may, at least in part, represent a disorder of mitochondrial dysfunction caused by haploinsufficiency of the *LETM1* gene.[40,108]

Table 2 Genetic Disorders with Generalized Patterns of Abnormal Neuronal M

Type of malformation	Disorder	Gene	Locus	Protein
Lissencephaly type 1	Isolated lissencephaly	*LIS1*(*PAFAH1B1*)	17p13.3	Platelet-activating factor acetylhydrolase, isoform 1b, Î±-subunit
	Miller-Dieker syndrome	Microdeletion including *LIS1, 14-3-3-epsilon*	17p13.3	

	X-linked lissencephaly/double cortex syndrome	*DCX*(*DBCN*)	Xq22.3-q23	Doublecortin
	Norman-Roberts syndrome	*RELN*	7q22	Reelin
Cobblestone dysplasia	Walker-Warburg syndrome	*POMT1* *FCMD* (*FKTN*)	9q34.1 9q31	Protein O-mannosyltransferase Fukut
	Fukuyama congenital muscle dystrophy	*FCMD* (*FKTN*)	9q31	Fukutin
	Muscle-brain-eye disease	*POMGNT1*	1p34-p33	O-mannose Î²-1,2-*N*-acetylglucosaminyltransferas
Heterotopia	X-linked bilateral periventricular heterotopia	*FLNA* (*FLN1*)	Xq28	Filamin-A
	Periventricular nodular heterotopia with microcephaly (periventricular nodular heterotopia type 2)	*ARFGEF2*	20q13.13	Brefeldin A-inhibited guanine nucleotide exchange protein
	Periventricular nodular heterotopia type 3	nn	5p	nn

AD, autosomal dominant; AR, autosomal recessive; nn, not known; XD, X-linked dominant.

1p36 Deletion Syndrome

Terminal deletions of 1p36 occur in approximately 1 in 5,000 live births, making the 1p36 deletion syndrome (also named monosomy 1p36) one of the most common mental retardation syndromes in humans. The clinical features include craniofacial anomalies like tower skull with microcephaly, a prominent forehead, deep-set eyes, and a flat nasal bridge. Additional features are hearing loss, growth retardation, cardiomyopathy, and orofacial clefting. Some patients develop a Prader-Williâ€"like phenotype with obesity and hyperphagia in early childhood. Several patients have been documented to have cerebral atrophy, ventricular asymmetry, hydrocephalus, delayed myelination, or focal cortical dysplasia.[14,112] Seizures occur in about 50% of patients and are of different types, including infantile spasm, simple/complex partial, generalized tonicâ€"clonic, myoclonic, and absence spells. Seizures mostly start during infancy or childhood, and are in most patients well controlled by antiepileptic drugs. EEG abnormalities vary greatly and include focal and multifocal spikes, hypsarrhythmia, and slow-wave activity. Hemizygosity for the 1p36-deleted voltage-gated potassium channel gene *KCNAB2* is associated with a severe seizure phenotype in 1p36 located syndrome.[59,60]

Neuronal Migration Disorders

In the human cortex, neuronal migration starts at approximately 7 weeks of gestation. Neurons originating from the proliferative ventricular zone migrate radially along

specialized glial processes to their final locations. The correct migration depends on several factors, one of the most important being the contact between the migrating neuron and the radial glial fiber. This requires the interaction of adhesion molecules, trophic factors, and guidance molecules, all of them possible candidates for the various disorders of neuronal migration. A second mode of migration has been recently described, in which cells born in the ventricular zone migrate perpendicular to radial glial processes. This nonradial pathway is used by most future inhibitory interneurons. Disturbances of this complicated pattern of cortical development and migration can cause severe neurologic disorders that are often accompanied or characterized by seizures (Tables 2 and 3). Neuronal migration disorders can be noninherited or genetic with distinct inheritance patterns. The malformations found in nongenetic forms are often (but not always) focal, while in the genetic ones the pattern of abnormal neuronal migration is usually generalized. The group of genetic neuronal migration disorders includes different lissencephaly syndromes, disorders with neuronal dysplasia, abnormal neuronal proliferation, and several conditions with heterotopia. Two of the five genes underlying major syndromes with lissencephaly as well as the tuberous sclerosis complex will be exemplarily described here. (See Chapter 259 for further discussion).

Isolated Lissencephaly and Miller-Dieker Syndrome

Classical or type I lissencephaly is histopathologically characterized by four abnormally positioned layers instead of the normal six cortical layers. In magnetic resonance imaging (MRI) the main findings are a smooth brain with a severely thickened cortex and absent (agyria) or simplified (pachygyria) gyri or convolutions. Typical clinical features are global developmental delay, muscle hypotonia, and different seizure types including febrile seizures, absence seizures, and myoclonic jerks. Classical lissencephaly is most commonly caused by mutations in the *LIS1* gene (also named *PAFAH1B1*, platelet-activating factor [PAF] acetylhydrolase, isoform 1B, Î±-subunit) on chromosome 17p13. *LIS1* codes for the noncatalytic *Î²*-subunit of PAF acetylhydrolase, an inactivating enzyme for PAF. PAFs are lipid mediators involved in a variety of biologic and pathologic processes, and *LIS1* is suspected to be involved in different regulatory pathways.[126] Several molecules have already been identified that interact with LIS1 protein. One of them is dynein, a molecular motor responsible for cargo transport in cells that modulate neuronal migration via microtubule organization.[4,125,128] LIS1 has also been implicated in functions like cell adhesion and cytokinesis. Heterozygous *Lis1* mutant mice have been found to display defects in neuronal migration and layering comparable to those found in humans.[22]

Table 3 Genetic Disorders with Focal/Multifocal Patterns of Abnormal Neuronal Migration

Type of malformation	Disorder	Gene	Locus	Protein	Inheritance
Focal subependymal nodular heterotopia	Aicardi syndrome (Aicardi-Goutieres syndrome)	nn	3p21 13q14-21	nn	AR
	Zellweger syndrome		7q21 8q 6q 12 6p 1p36.2 22q11.21	Peroxin-1 Peroxin-2 Peroxin-3 Peroxin-5 Peroxin-6 Peroxin-14 Peroxin-26	AR

Adrenoleukodystrophy (Bronze-Schilder disease, Siemerling-Creutzfeldt disease)	*ABCD1* (*ALDP*)	Xq28	ATP-binding cassette transporter adrenoleukodystrophy protein	XR
Multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria II)	*ETFA* *ETFB* *ETFDH*	15q23-q25 19q13.3 4q32-qter	Electron transfer flavoprotein, Î±-polypeptide Electron transfer flavoprotein, Î²-polypeptide Electron transfer flavoprotein dehydrogenase	AR

AD, autosomal dominant; AR, autosomal recessive; ATP, adenosine triphosphate; nn, not known; XR, X-linked recessive.

Microdeletions including not only *LIS1*, but also genes distal to *LIS1*, are the cause of Miller-Dieker syndrome (MDS). Patients with MDS are characterized by severe psychomotor retardation, failure to thrive, and intractable epilepsy. Typical craniofacial features are microcephaly, bitemporal narrowing, high forehead, small nose, protuberant upper lip, and micrognathia. Death usually occurs before 2 years of age. In most patients the microdeletion is de novo; however, families with balanced translocations and high recurrence risk are known. There is evidence that the greater severity of MDS compared to isolated lissencephaly may be due to deletion of the gene encoding 14-3-3-epsilon protein, which is also involved in cytoplasmic dynein function.[130]

P.207

X-linked Lissencephaly/Double Cortex Syndrome

X-linked lissencephaly (XLIS) and double cortex syndrome (DCX; subcortical band heterotopia) are allelic disorders caused by mutations in the *DCX/XLIS* gene on Xq22.3-q23. XLIS, the male sex-determined manifestation of the two disorders, is characterized by classical lissencephaly, severe epilepsy, and mental retardation. Lethality is high, and family history often reveals multiple miscarriages of male fetus. In females mutations in the *DCX/XLIS* gene usually manifest as a milder phenotype known as double cortex syndrome, named after the typical broad heterotopic zone of neurons visible on MRI scans. *LIS1* and *DCX* mutations differ with respect to their associated pattern of cortical manifestations. Whereas with *LIS1* mutations the clinical manifestation is more severe over the parietal and occipital regions, the *DCX/XLIS* neuronal phenotype is more pronounced over the frontal cortex. The distinct patterns suggest that *LIS1* and *DCX/XLIS* may be part of overlapping, but distinct, signaling pathways that are involved in neuronal migration. It is therefore not surprising that the *DCX/XLIS* protein has been found to be microtubule associated where it is assumed to have a stabilizing function.[99]

Tuberous Sclerosis

Tuberous sclerosis (TS) is an autosomal dominant multiorgan disorder characterized by a great inter- and intrafamilial variation in clinical severity. The phenotypic spectrum of TS includes seizures, mental retardation, renal dysfunction, and dermatologic features such as hypomelanotic macules, facial angiofibromas (adenoma sebaceum), and shagreen patches. Hamartomatous brain lesions, such as cortical tubers, sub- ependymal nodules (SENs), or subependymal giant cell astrocytomas (SEGAs), are typical focal cortical dysplasias found in TS patients. TS results from mutations in either of two genes, *TSC1* on 9q34[133] or *TSC2* on 16p13.[42] The proteins encoded by both genes, hamartin and tuberin, are thought to play important roles in several cell-signaling pathways. Both hamartin and tuberin interact with each other to build the intracellular tuberous sclerosis complex that functions as a guanosine triphosphatase (GTPase)-activating protein (GAP). Important functions of the complex are the enhancement of the intrinsic GTPase activity of Rheb and the inhibition of mTOR signaling.[63] mTOR is a checkpoint kinase (target of rapamycin) that has been linked to numerous human cancers. *TSC1* and *TSC2* regulate the mTOR pathway to control translation and cell growth in response to nutrient and growth factor stimuli. Mutations in either *TSC1* or *TSC2* are likely to cause the cortical dysplasias underlying epilepsy in TS patients at least in part through dysregulation of the mTOR pathway.[36]

Summary and Conclusions

The examples presented in this chapter demonstrate that the different genes underlying epilepsies and syndromes with epilepsy are involved in a broad spectrum of diverse functions and functional pathways. There are gene mutations that cause progressive neurodegeneration as seen in the various subtypes of progressive myoclonus epilepsy including the neuronal ceroid lipofuscinoses, sialidoses, Lafora disease, and Unverricht-Lundborg disease. Mutations in another heterogeneous group of genes interfere with normal brain development and disturb the precisely orchestrated proliferative, migratory, and maturational events needed to form the mature six-layered cortex. Structural chromosomal aberrations that usually affect more than one gene represent a third example for the diversity of genetic mechanisms underlying epileptogenesis. Some of the chromosomal aberrations in which epilepsy is a constant finding have been discussed in this chapter, exemplary

for syndromes in which epilepsy is not caused by the action of a single gene but by the combined action or failure of a number of genes within the aneuploid segment. As shown, one of the most important pathogenetic mechanisms in human epilepsy is based on mutations in various ion channel genes. With a few exceptions, all idiopathic epilepsies with known genes belong to the heterogeneous group of â€œchannelopathies.â€ There are many mechanisms by which mutated ion channels can cause neuronal hyperexcitability, and the ongoing studies of various channelopathies have already contributed much to our understanding of the complexity of pathways that can lead from a single gene mutation to episodic symptoms.

The identification of additional genes and the functional characterization of their gene products will further increase our knowledge about pathogenic mechanisms in epileptogenesis. The growing knowledge will help future generations of neurologists to more precisely classify the epilepsies affecting their patients. It can also be expected to facilitate the development of new antiepileptic drugs for the effective treatment, and perhaps even prevention, of epilepsies.

Chapter 19

Genetic Counseling

Frances Elmslie

Introduction

Genetic counseling has become an integral component of care of many conditions that display mendelian inheritance, and increasingly those that show complex inheritance, such as autism. However, individuals with epilepsy have not been offered genetic counseling in the past, as the genetic contribution to their seizures may not have been recognized or it was felt that little could be offered. As mendelian forms of epilepsy have been described and mutations in the causative genes identified, this situation is beginning to change, and increasing numbers of people with epilepsy are being referred to the genetics clinic. This chapter will summarize the geneticist's approach to the individual with epilepsy and discuss the issues raised by the availability of genetic counseling and genetic testing.

The Process of Genetic Counseling

Genetic counseling may be defined as â€œa communication process that deals with human problems associated with the occurrence, or the risk of occurrence, of a genetic disorder in a family.â€

This process is undertaken in an attempt to help individuals and families:

- Comprehend the medical facts including the diagnosis, probable course of the disorder, and available management.
- Appreciate the way heredity contributes to the disorder and the risk of recurrence in specified relatives.
- Understand the alternatives for dealing with the risk of recurrence.
- Choose a course of action that seems to them appropriate in view of their risk, their family goals, and their ethical and religious standards and act in accordance with that decision.
- Make the best adjustment to the disorder in an affected family member and/or to the risk of recurrence of that disorder.[9]

Until recently, geneticists have not often been involved in the care of women with epilepsy, but as more genes are identified that are implicated in the etiology of epilepsy, the involvement of a geneticist will become more important. It is recommended that any individual who is undergoing genetic testing, particularly when the testing has implications for the family, be seen by the clinical genetics team or an individual who has received training in genetics.

Two main groups of individuals undertake genetic counseling: Clinical geneticists, who are medically trained, and genetic counselors, who come from a variety of different backgrounds, including nursing and scientific. The roles of these two groups are complementary, but different. The primary role of the clinical geneticist is to try to establish a diagnosis, which may or may not be genetic, in order to counsel accurately about offspring risks or risks to other family members. Genetic counselors counsel families in which the diagnosis is established and usually where the condition displays mendelian inheritance. They provide follow-up and support for families in which a genetic diagnosis has been made. In order to be able to counsel an individual accurately, one needs to establish an accurate diagnosis, and in the context of epilepsy, it would be essential to identify predisposing conditions in which epilepsy forms part of the phenotype. Therefore, the clinical geneticist undertakes the genetic management of patients with epilepsy, although a genetic counselor may provide long-term support.

Blandfort et al.[6] established three main reasons why a person with epilepsy may seek genetic counseling:

- An individual with epilepsy may be concerned about the risk of his or her offspring developing epilepsy.
- The parent of a child with epilepsy may be concerned about the risk of future siblings, or an apparently unaffected sibling, developing epilepsy.
- A woman with treated epilepsy may be concerned about the risk of malformation and developmental delay in a child exposed to anticonvulsants in utero.

Until recently, most epilepsy patients seen in the genetics department fell into the second category. The parents of a child with severe epilepsy, often in the context of developmental delay or another neurologic deficit, seek advice about the risk of having another similarly affected child. In addition, the clinical geneticist has a role in confirming or refuting a diagnosis of a fetal anticonvulsant syndrome and in advising about future pregnancies. However, it has only been recently that individuals with a significant family history of epilepsy have been referred to the genetics department, and this comes with the increasing recognition of mendelian forms of epilepsy.

A Framework for Genetic Counseling

One of the primary goals of genetic counseling is to provide information to enable a couple or an individual to make an informed reproductive choice. This is achieved by nondirective counseling, which helps to ensure that decisions are made in the context of the individual's beliefs, values, and background. This differs from some other areas of medicine, in which, for example, a physician may make a specific recommendation about one form of treatment over another. An important component of an individual's ability to make an informed choice is the risk that his or her future children will be affected. It is therefore imperative that the risk given by the geneticist be as accurate as possible and based on knowledge of the family, the specific epilepsy syndrome, electroencephalographic (EEG) and cranial imaging findings, and the presence or absence of a predisposing condition.

P.212

Reproductive decisions are based on the couple's perception of the risk figure given and the burden on the parents if a child is affected. Perception of risk varies enormously from one couple to another. For example, one couple may consider a risk of 2% to be high and another may view it as low, although this will be influenced by the severity of the condition for which the risk is being given.

The Geneticist's Approach to Epilepsy

The Family History

The first component of a genetics consultation is the compilation of the family tree. This should be as detailed as possible, and as a minimum should go back and forward two generations from the consultand. Information on first and second cousins should be included if possible. The amount of information that families share differs from family to family. The accuracy of the family information is a particular problem in epilepsy, in which the phenotype is often age dependent, and may be forgotten, or even hidden. In many families, one or more family member will have or have had epilepsy because of the high prevalence in the general population. Occasionally, the family tree will show clear evidence of mendelian inheritance, most commonly autosomal dominant inheritance. It is possible that some people in such a family do not have seizures, but their siblings and children do. These people are described a nonpenetrant; that is, they carry a mutation in a specific gene but never manifest the disease. All autosomal dominant idiopathic epilepsy genes described to date show incomplete penetrance.

If consanguinity is present, autosomal recessive inheritance should be considered but not presumed. The family history may suggest X-linked inheritance if there is no male-to-male transmission, or if males are more severely affected. Similarly exclusive female transmission may indicate a mitochondrial disorder.

Wherever possible, the diagnoses volunteered by the consultand should be confirmed directly with the treating physician, because accurate information is needed to give accurate risk figures.

Identifying Predisposing Conditions

Conditions that may present with epilepsy have been covered elsewhere. The most important conditions to identify for the purposes of genetic counseling are those that would significantly alter the recurrence risk. A thorough evaluation of the proband would include a full clinical evaluation, including the following:

- Clinical examination including Wood light examination
- Developmental assessment in a child
- EEG data
- Cranial imaging
- Other investigations informed by the clinical presentation (e.g., tests for a suspected metabolic disorder; echocardiography and renal imaging for suspected tuberous sclerosis)

These investigations are most effectively done in partnership with the pediatrician or neurologist who cares for the patient.

An example of an important predisposing condition is that of tuberous sclerosis (TS). Individuals with TS may present with epilepsy at any time from infancy to early adulthood, but approximately 25% of children presenting with infantile spasms will have TS, and therefore all such children should be fully screened for TS. Once a diagnosis of TS is established in a child, the parents should be screened clinically, and if a mutation is identified in the child, by genetic testing. If TS has arisen de novo in the child, the recurrence risk is approximately 2% because of the possibility that one parent carries the mutation in their gonads (gonadal mosaicism), but if a parent has clinical evidence of TS or carries the familial mutation, the recurrence risk is 50%.

Chromosomal analysis would be indicated if the epilepsy occurs in the context of learning difficulties or a physical abnormality. In addition, epilepsy that is difficult to manage (such as that seen in ring chromosome 20 mosaicism) would be an indication for chromosomal analysis. Once a child has been found to have a chromosomal abnormality, it is important to exclude a familial rearrangement in an asymptomatic parent, because this may have implications for future children.

A full metabolic workup is indicated in an infant with early-onset seizures or if there is evidence of regression or precipitating factors such as intercurrent illness.

If cranial imaging reveals a neuronal migration abnormality, further investigations should be performed in an attempt to distinguish between genetic and nongenetic forms.

Identifying the Specific Epilepsy Syndrome

A specific epilepsy diagnosis is important, because family studies have demonstrated that certain epilepsy syndromes show a greater genetic predisposition than others, and this will affect the offspring or sibling risks. Some patients do not know their precise epilepsy diagnosis, and in some instances no attempt has been made to classify their epilepsy, particularly if the diagnosis was made many years ago. Therefore, unless the geneticist has specialist knowledge of epilepsy, the patient will need assessment by a neurologist as well. Factors that are particularly important to consider are the following:

- Age of onset
- Seizure types
- EEG features

- Acute precipitating factors
- Previous history
- Presence of neurologic dysfunction other than seizures

Genetic Risks

Individuals seeking genetic advice fall into two main groups: Those who have epilepsy themselves and want to understand the risk to their offspring, and parents of a child with epilepsy who are concerned about the risk to their future offspring.

Mendelian Epilepsies

When a diagnosis of a mendelian condition has been established, the risk to offspring or siblings is straightforward. In autosomal dominant conditions in which a parent is affected, the risk of a child inheriting the gene mutation is 50%. However, the risk of developing epilepsy will be lower because of nonpenetrance. Genetic studies have shown that penetrance in most autosomal dominant mendelian epilepsy syndromes is of the order of 70%, and therefore the offspring risk of epilepsy can be modified to 35% (0.5 Ã— 70%). If the parents are unaffected and are concerned about a sibling risk, the family history and the results of genetic testing must be taken into account (discussed in more detail below).

Table 1 Recurrence Risks According to Type of Epilepsy and Whether Parent or Sibling Affected

Type of epilepsy	Parent affected	Sibling affected	Reference
Idiopathic generalized epilepsy	2.5%â€“5%	2%â€“5%	3
Childhood absence epilepsy	8%â€“10%	4%â€“6%	3
Juvenile myoclonic epilepsy	6%â€“10%	6%â€“7%	12
Photosensitive epilepsy	6%â€“10%	6%â€“10%	6
Infantile spasms	Unknown	1%â€“2% for infantile spasms (X linkage and tuberous sclerosis excluded)	6
Partial epilepsy	2%â€“3%	2%â€“3%	3
Benign childhood epilepsy with centrotemporal spikes	12%â€“15% (estimate)	12%â€“15%	6

Febrile convulsions	10%	10%â€“20%	6

Modified from Blandfort M, Tsuboi T, Vogel F. Genetic counselling in the epilepsies. *Human Genet.* 1987;76:303â€“331.

Counseling families in which the proband has an established diagnosis of a progressive myoclonic epilepsy including

Unverricht-Lundborg disease, Lafora disease, and the neuronal ceroid lipofuscinoses is straightforward as they are all inherited in an autosomal recessive manner. Therefore, the recurrence risk for a couple that has had one affected child is 25% in each pregnancy. The risk of a person with a progressive myoclonic epilepsy having an affected child depends on the partner's carrier status. If the partner is also a carrier, the risk to the offspring increases to 50%. If he or she is not, then all the offspring will be carriers but will not be affected.

Similarly, in X-linked recessive conditions the sibling risk for an affected male is 25%. X-linked dominant conditions such as that caused by mutations in *DCX* or *XLIS* confer an overall 50% offspring risk, as both males and females can be affected to different degrees. However, some genetic conditions in this group result in male lethality, with the result that the significant offspring risk is for a live-born affected female and is 25%.

However, mendelian epilepsies account for only a small fraction of epilepsy in the general population. Most epilepsy syndromes display â€œcomplexâ€ inheritance, meaning that many genes may be involved or that factors other than genetics play a role in the etiology.

Complex Epilepsies

Numerous family studies have demonstrated that the risk of seizures in the siblings and offspring of a person with epilepsy or febrile convulsions is greater than that of the general population. A number of factors increase the risk of epilepsy in relatives of individuals with epilepsy (summarized in Winawer and Shinnar[24]):

- Gender of the affected parent
- Age of onset
- Idiopathic versus symptomatic epilepsy
- Epilepsy phenotype in the proband
- Presence of EEG abnormalities
- Number of affected relatives

It is well established that there is an increased risk of epilepsy in the offspring of an epileptic woman (approximately 2.9% to 8.7% to age 25) compared with an epileptic man (1% to 3.6%).[3,22] In addition, there is an increased incidence in the daughters of an affected individual compared with sons, and there is a greater incidence among the relatives of an affected woman. The basis of this increased risk is unknown.[16]

Early parental age of onset also influences the risk of epilepsy. Onset of epilepsy before the age of 20 confers a 2.3% to 6% risk to offspring (compared with a background risk of 1% to age 20), whereas onset after 20 gives a 1% to 3.6% risk.[22] Similarly, the sibling risk is greatest when the age of onset is between 0 and 9 years, being 9.5%; the risk is 5.8% for onset between 10 and 24 years and 2.6% for onset between 25 and 39 years.[2] There is no increased risk where the onset of epilepsy has occurred after the age of 35[18]. Idiopathic epilepsies are associated with a greater offspring risk than symptomatic epilepsies (Ottman et al., 1996). However, partial and generalized epilepsies are associated with similar offspring risks, indicating that genetic factors are equally important in the etiology of both groups of epilepsy[16,17]. There is good evidence that childhood absence epilepsy is associated with the greatest offspring and sibling risk of the generalized epilepsies.[17]

The family tree must be taken into account when discussing offspring or sibling risks. The risk of epilepsy in the offspring or siblings of an affected individual increases with increasing numbers of affected relatives.[3] Some families will have a phenotype and family history that fits well with one of the known mendelian epilepsy syndromes such as generalized epilepsy with febrile seizures plus (GEFS+). In others, there may be evidence of mendelian inheritance even though they do not fit any of the well-described mendelian epilepsy phenotypes. Such families may represent â€œnewâ€ epilepsy syndromes. However, it is important to remain conscious of the fact that epilepsy is a common condition with multiple etiologies, and that familial clustering could still have occurred by chance.

If the incidence of epilepsy in the family is higher than that expected for a particular epilepsy syndrome, it would be important to review the diagnosis, or consider whether the family displays mendelian inheritance. In such families it would not be appropriate to counsel a â€œstandardâ€ risk; the risk should be tailored to the family history. Genetic testing may help to clarify the risk in a few families.

A number of twin studies have demonstrated concordance for epilepsy and for the specific epilepsy syndrome, although this relationship is not absolute.[1,5,14] The risk that the affected offspring or sibling of an affected person may not have an identical phenotype needs to be discussed. Estimates of the offspring

and sibling risk figures for complex epilepsy syndromes derived from such family studies are given in Table 1. However, when counseling families, all the factors previously discussed need to be taken into account.

Febrile Convulsions

Febrile convulsions should be considered separately as the general rules for offspring risk do not apply. Febrile seizures affect about 3% of children before the age of 5 years, but higher cumulative incidences have been reported of up to 9% in Japan and 15% in Guam. One third of children with an initial febrile seizure will have a second one, and of these 50% will have a third. However, only a small minority will go on to have afebrile seizures.

It has long been recognized that febrile convulsions run in families. Estimates of the proportion of probands with an affected first-degree relative vary from study to study with figures of between 8%[19] and 49%[22] in siblings and parents being obtained. A number of modes of inheritance have been suggested, but the best evidence indicates that the polygenic model is the most feasible.[19]

Although febrile seizures therefore usually display a complex pattern of inheritance, large pedigrees or groups of families with febrile seizures consistent with autosomal dominant inheritance have been identified. Johnson et al.[13] for example, studied 52 probands and found that the mode of inheritance in multiplex families best fitted the hypothesis of autosomal dominant inheritance with reduced penetrance. A number of gene loci have been mapped in families displaying autosomal dominant inheritance.

Therefore, the family history is of prime importance, as is the nature of the seizures. Some families with atypical febrile seizures may have a diagnosis of GEFS+, particularly if afebrile seizures are also present in the family.

Ethical Considerations in Genetic Testing for Epilepsy

Genetic testing for a number of the mendelian epilepsies is now possible. The value of genetic testing when it helps to establish a diagnosis, to clarify risk, or to enable a prenatal test to be offered in future pregnancies is well established. The progressive myoclonic epilepsies provide a good example of this approach. Genetic testing now forms part of the diagnostic workup of a person with a suspected progressive myoclonic epilepsy. These conditions display full penetrance; that is, individuals who carry two mutations in the causative gene will develop the condition, which ultimately leads to progressive neurologic deterioration and early death. If both mutations are identified in the proband, the diagnosis is established and prenatal diagnosis would be justified in future pregnancies if the parents wish to have it.

However, genetic testing in the idiopathic epilepsies represents more of problem. Genes for the mendelian epilepsies have been identified through the collection of DNA samples from large families after obtaining explicit informed consent. It would be standard practice for the families not to receive results from the research study, although in some cases results will be verified in a diagnostic laboratory and fed back to the family. Those same laboratories may continue to offer testing for a number of months or years in order to build up their knowledge of the genetic mechanisms and functional effects of particular mutations. However, in time, a genetic test may become a diagnostic tool, and it is therefore appropriate for the testing to be done in a diagnostic laboratory.

The ethical implications of testing then need to be considered more carefully. These have been well addressed by Godard and Cardinal.[10] Whether genetic testing is done in a research setting or a diagnostic setting, the results frequently raise issues for the wider family, and these need to be discussed before proceeding with testing. The ethical principles that underlie the practice of medicine that are particularly relevant to genetic testing are as follows:

- Autonomyâ€"respect for the self-determination of individuals and the protection of those with diminished autonomy (i.e., children, or individuals with learning difficulties)
- Beneficenceâ€"maximizing the benefit to health
- Nonmaleficenceâ€"avoiding, preventing, or reducing harm
- Justiceâ€"equity of access

One major way in which genetic testing differs from other forms of diagnostic testing is that the results may have implications for other family members, and therefore these ethical principles need to be considered not only in relation to an individual, but also to the wider family. Testing must take into consideration the cost and efficacy of the test, the duty to warn versus the right not to know, and the possible detrimental effects on other family members.

The Benefits of Testing?

As the genetic basis of more idiopathic epilepsy syndromes is understood, genetic testing is becoming an additional tool to aid diagnosis. This may, in turn, reduce the need for other, more invasive investigations and possibly even affect the choice of treatment. As ongoing studies of drug responsiveness and genotype come to fruition, a genetic test may be used to both determine the most effective drug and anticipate possible adverse drug reactions.

Currently, genetic testing is of greatest benefit when the epilepsy syndrome is severe and life threatening. A good example is severe myoclonic epilepsy of infancy, which is associated with mutations in the gene encoding a sodium channel alpha subunit (SCN1A). Genetic studies have demonstrated that this is virtually always sporadic, and mutations have arisen de novo in most affected individuals.[7] If a mutation has been identified in an affected child that is not present in either parent, it is possible to be very reassuring about the risk to future children. There is a small risk of gonadal mosaicism, and prenatal diagnosis could be offered. More rarely, one parent is shown to carry the mutation, and there is usually a family history of epilepsy. In this case the risk to offspring will be 50%, and the phenotype is likely to be more variable. However, if the parents have had one severely affected child, prenatal diagnosis and termination of pregnancy would be justified.

There is also a potential benefit in familial epilepsy syndromes in which seizures may be misinterpreted, and the diagnosis missed. A good example is that of autosomal dominant frontal lobe epilepsy, in which episodes are frequently misdiagnosed as psychiatric disease, night terrors, etc. If a person at risk had had a genetic test, investigation and treatment of such episodes would be accelerated.

The Risks of Genetic Testing

Many mendelian epilepsy syndromes are benign, self-limiting, or easily treated. In addition, all mendelian epilepsy syndromes

P.215

described to date show incomplete penetrance. Genetic testing in this situation raises particular issues. For example, an individual with autosomal dominant nocturnal frontal lobe epilepsy is found to have a mutation in CHRNA4. She has two children, and asks for them to be tested. At this stage there should be a full discussion about the value of testing with reference to the interpretation of the result. What would a positive result mean for the children? What is their risk of epilepsy? How can this risk be modified? What is the risk to their children? What would a negative result mean? Has the right of the children not to know been taken into account? Have the children understood and given assent? Are there implications for other family members? How will the results be communicated to the individuals being tested and also to the wider family?

After a full discussion, testing goes ahead. One child is found to have the mutation. It is possible that the child will never develop epilepsy, and if he does it is impossible to predict at what age the epilepsy will occur. There is no recognized screening program that can be offered, and the mother may interpret any unusual symptoms as the onset of epilepsy. In addition, the presence of the mutation may jeopardize the child's future insurance prospects, perhaps preventing him from obtaining a driving license or restricting his future choice of occupation. There may also be implications for the child who tested negative. He is still at risk for epilepsy because of the background population risk and may believe himself to no longer be at risk. In addition, he may feel guilty that he escaped the genetic burden of the family, so-called survivor guilt. The particular implications of genetic testing in childhood have been well discussed,[8] and international guidelines for genetic testing proposed.[23]

In the future, genes that cause the complex epilepsies may be identified. It is likely that such genes will cause an increased susceptibility to seizures in a similar way to the increased risk of Alzheimer disease in individuals who carry Apo-E4.[11] The ethics of such testing has not been fully explored, but the principles of beneficence and nonmaleficence will be of particular importance in the future genetic counseling of families with epilepsy.

Summary and Conclusions

Genetic counseling in the epilepsies presents particular challenges, both because of the broad spectrum of potential diagnoses and because of the ethical considerations of genetic testing. This is a rapidly changing field, and these guiding ethical principles must not be forgotten in the enthusiasm to identify new genes.

Chapter 20

Overview: The Neurobiology of Epilepsy

Marc A. Dichter

Introduction

The epilepsies are a complex group of disorders whose common feature is a tendency for hyperexcitability to develop in one or another region of the central nervous system (CNS). Epileptic syndromes and seizure types can be quite variable and may have many causes. Similarly, multiple underlying cellular and molecular mechanisms are likely to be responsible for various epileptiform phenomena. Much research has been, and continues to be, directed at unraveling the mechanisms underlying epileptic events, based on the premise that increased understanding will make it possible to devise either better treatment strategies or better methods to prevent epilepsy.

Neuronal Excitability

The hyperexcitable states that underlie the various forms of epilepsy represent complex functional changes in normal brain anatomy, physiology, and pharmacology. To begin to understand such changes, it is necessary to understand the normal brain substrate on which these alterations are occurring and the developmental patterns that result in the normal functioning. The next 15 chapters in this book are devoted to a systematic discussion of the physiology of normal brain function, organized according to the component parts that may be altered when epilepsy develops. Each chapter focuses on one broad area of neuronal activity, starting with an analysis of normal function at the system, cellular, and molecular levels, and then proceeding to a consideration of where this aspect of physiology might be perturbed to produce epilepsy and how naturally occurring forms of epilepsy might involve this system. Initial focus is on the excitability of individual neurons; detailed considerations of synaptic transmission, both excitatory and inhibitory, and synaptic modulation are then presented, followed by discussions of neuronal circuitry in the neocortex and limbic cortex, and the role of various subcortical structures on CNS excitability. Consideration is also given to the regulation of gene expression by both normal and pathologic activity in CNS pathways and the developmental aspects of CNS function. All this material serves as a basic scientific underpinning for the discussions of experimental seizure models and the human epilepsy syndromes, and also provides potential targets for the actions of antiepileptic drugs.

Experimental Models

To study epileptic phenomena at a network, cellular, or molecular level, model systems are needed. The second half of this section provides detailed analyses of various experimental models used for studying seizures and epilepsy. Such models can be designed to mimic some forms of human epilepsy closely (see Chapters 36,37,38,39) but, as discussed in Chapter 41, no animal model can mimic all the features of any human epilepsy at this time. Alternatively, much simpler models can be developed that allow the isolation of specific individual epileptiform activity in ways that can be analyzed using a reductionist system. In fact, most of what is known about the cellular mechanisms of specific epileptiform events has been derived from studies of simplified systems and acutely provoked seizure activity. These studies were initially performed using in vivo animal models and, as techniques evolved for analyzing CNS tissue in vitro, they were extended to CNS models in acute slice preparations and cell culture. One of the challenges of modern epilepsy research is to extrapolate such findings to the more complex CNS of humans and the more complex problem of chronic epilepsy. The last chapter in this section discusses attempts at conducting such studies in humans, or at least in human tissue.

Epileptogenesis

Most, if not all, forms of epilepsy develop over a defined time period. That is, at some point in time, the brain functions normally (and may be normal), but either after a specific developmental sequence or in response to some form of injury, a new state develops in which the neuronal circuits become hyperexcitable, leading to spontaneous recurrent seizures. This process, referred to as *epileptogenesis*, has been too little studied. Much less is currently understood about the process of epileptogenesis than about the phenomenology of seizures. At a clinical level, not much can yet be done to protect individuals who are known to be at high risk for the development of epilepsy, in comparison with what can be done to suppress seizures once they develop.

Fundamental Mechanisms

What can be said at present about the fundamental mechanisms of different forms of epilepsy? In partial epilepsy, it appears that areas of hyperexcitability are associated with some form of synaptic reorganization that occurs after brain injury. Some areas of brain seem much more susceptible than others, and the limbic structures in the mesial temporal lobeâ€"notably the hippocampus, parahippocampal regions, subiculum, entorhinal cortex, and amygdalaâ€"seem particularly vulnerable. Neurons within epileptic areas in these structures undergo synchronous and paroxysmal depolarizations, and fire bursts of action potentials. These bursts are followed by periods of inhibition. Most often, such events occur singly, and relatively little perturbation of function can be detected. These represent â€œspikesâ€ on the electroencephalogram (EEG). At times, such discharges do not remain confined in either anatomic space or time, and seizures result. More and more neurons are recruited into the hypersynchronous activity, both in local areas and, via synaptic pathways, distant areas subcortically and contralaterally. Why such events occur at all, and why they occur at any

specific point in time remains unknown. After all, even in the most severely affected individuals with epilepsy, seizures occur only intermittently.

It is known that seizure activity involves alterations in the fundamental excitability of neurons and in the synaptic connections between neurons. It is also known that seizures can be produced artificially by altering any of multiple cellular processesâ€"for example, enhancing synaptic excitation or reducing synaptic inhibition. Thus, seizures develop by utilizing slight perturbations in normal cellular excitability or normal synaptic transmission and by utilizing normal anatomic pathways for both control and spread. The recognition of these principles has stimulated epilepsy researchers to lead inquiries into the physiology of normal cortical microanatomy, physiology, and pharmacology, and, most recently, molecular biology.

Primary generalized seizures present a different set of challenges to epilepsy researchers. Unlike the seizures of partial epilepsy, these events appear to start in diffuse bilateral brain areas all at once, and therefore do not provide a focal target for detailed examination by physiologists. In addition, many of the epileptic syndromes involving generalized seizures are the result of genetic alterations in CNS function, several of which are currently being unraveled. For example, studies of thalamic nuclei and thalamocortical circuits have provided dramatic new insights into the fundamental cellular mechanisms underlying some forms of primary generalized seizures. These are discussed in Chapter 31. Moreover, in both mouse and man, single gene mutations that can result in primary generalized epilepsy have been identified. As in the partial epilepsies, small perturbations in the basic cellular mechanisms of excitability and synaptic function are responsible for the underlying abnormal activity.

Most recently, studies of the fundamental mechanisms underlying epilepsy have progressed to the molecular level. Increased understanding of voltage-gated ion channels in excitable membranes, neurotransmitter receptors, neurotransmitter transport molecules, trophic substances, and other neuronal proteins has made it possible for some of the molecular changes associated with the epileptic state to be described. In addition, it is clear that the kind of excess excitability seen during epileptiform events is capable of inducing a number of specific genetic activation patterns in different circuits within the CNS. These are discussed in Chapters 21,22,23,24, 28, 31, 36, 37, and 41. Whether and how these molecular changes contribute to the stabilization of the epileptic state, or whether they are designed to counteract some of the hyperexcitability and suppress seizures remains to be determined. As new techniques in molecular neuroscience are applied to problems in epilepsy, it is likely that at least some of these questions will be answered.

Genetic Studies

Implicit in our understanding of the myriad possible perturbations of normal cellular anatomy, physiology, and pharmacology that can produce seizures in animals is the realization that genetic alterations in any of these processes may produce epilepsy. In fact, many examples of genetically determined epilepsy have been described in a variety of animal species, several of which closely mimic one or another form of epilepsy in humans. Much of this is reviewed in Chapter 37; the human genetic epilepsies are discussed in Chapter 18. Several major principles are emerging from these and other genetic studies, especially those related to the creation of transgenic animals with specific knockouts or abnormalities of single genes. It is clear that full-blown epileptic syndromes can occur in the context of single-gene mutations, but in some cases, other components of the genetic background can influence the phenotypic expression of hyperexcitability. In addition, different components of the epileptic phenotype can be specifically influenced by single genes, for example, EEG patterns. Among the more surprising recent results, however, is the realization that alterations in genes that had not been thought to be specific for brain functionâ€"such as those for enzymes in energy-producing pathwaysâ€"can produce epileptic phenotypes. In fact, seizures are a common and surprising occurrence in many transgenic mice that were developed to study genes whose function was not thought to be related to neurologic diseases. These studies are likely to broaden our understanding of epileptic processes in the CNS and open the analysis of the epileptic state to new approaches, perhaps beyond the usual realm of traditional neuroscience. In turn, these new approaches may lead to new treatment strategies.

Clinical Applications

As mentioned at the beginning of this chapter, a fundamental premise for all this work is that an increased understanding of epileptic processes will result in new treatment strategies or new approaches to prevention. By contrast, until now, essentially all currently available drugs or other treatments for seizures have been discovered by accident or by general screening against seizure models. This is true despite dramatic advances in our understanding of normal brain function and the mechanisms underlying epileptic phenomena over the past 50 years. It appeared that this trend would be reversed when neuroscientists discovered the importance of the inhibitory neurotransmitter Î³-aminobutyric acid (GABA) in epileptiform activity. Drugs could now be targeted for a specific mechanism. This led to the development of two drugs that were specifically designed to enhance the activity of GABA: Vigabatrin, which blocks GABA metabolism, and tiagabine, which blocks the reuptake of GABA after synaptic release. Although each has been demonstrated to be effective in both animal models of epilepsy and in patients with intractable partial seizures, neither drug has proved to be as valuable as first predicted, either because of unexpected toxicity or because of complex relations between different forms of GABA-mediated inhibition in different brain regions in different epilepsy syndromes. Other drugs targeted for the GABA system proved useful, but were then found to *not* act on the GABA system. Similarly, drugs developed specifically to dampen excitatory synaptic function have also been unsuccessful so far. Despite these caveats, however, most epilepsy researchers remain optimistic that, as our understanding of basic mechanisms of epilepsy and epileptogenesis increases, these findings will be directly applied to the clinical problem. Hopefully, within the next 5 to 10 years, new clinical approaches to seizure control and epilepsy prevention will be forthcoming.

Summary and Conclusions

Epilepsy is a complicated disorder involving disturbances of brain function at multiple levels. A variety of experimental models are currently being studied to gain an understanding of the fundamental system-level, cellular, and molecular mechanisms underlying different forms of epilepsy. In addition, human patients with epilepsy can be studied in ways that were not possible only several years ago, utilizing advanced imaging and new electrophysiological tools. Brain tissue from human patients, removed at surgery, can also be used to analyze underlying abnormalities. It is hoped that the increased understanding developed by these approaches will lead to new strategies for the treatment or prevention of epilepsy.

Chapter 21

Control of Neuronal Excitability

Uwe Heinemann

Istvan Mody

Yoel Yaari

Introduction

The behavior of nerve cells is determined by ionic channels. These are transmembrane proteins with a pore that permits ions to pass across the lipophilic membrane. Ion channels may be permanently open or regulated by stretch, voltage, or chemical compounds. Currents flow through these channels in an inward or outward direction dependent on the driving force, which is set by the difference between the actual membrane potential and the equilibrium potential for the given ion(s). An inward current depolarizes the membrane and is carried either by movement of positive charges (Na^+, Ca^{2+}) into the cell or of negative charges (Cl^-) out of the cell. Conversely, outward currents drive the membrane potential in a hyperpolarizing direction and are carried either by cation (K^+) currents out of or anion (Cl^-) currents into the cell. At resting membrane potential, which is negative in all cells, inward and outward currents balance each other. The proteins that encode the water-filled, voltage-dependent ion channels are called Î± subunits. They are often associated with Î², Î³, and other auxiliary subunits. These may modulate properties of the channels, but they also regulate membrane anchoring and trafficking of ion channels. The receptor-gated ion channels usually consist of different Î±, Î², and so on subunits, which all are required to form the ion channel. The nomenclature for ion channels is rather diverse. Physiologists and biophysicists originally named most ion channels according to their ion selectivity and dependence on voltage, ligand binding, or role in cellular function such as stretch, generation of receptor potentials, and so on. A second nomenclature often derives from studies of mutations in the fruit fly *Drosophila*. Scientists who originally cloned ion channels developed yet another nomenclature, and, finally, human geneticists use yet another. This makes reading the original literature difficult and sometimes time-consuming. I find the International Union of Basic and Clinical Pharmacology (IUPHAR) compendia on ion channels rather useful in this respect because it gives all the names used in the literature for all voltage-gated ion channels. I will follow the 2005 nomenclature of ion channels proposed by the International Union of Pharmacological Sciences. The most comprehensive survey of properties of ionic currents and their physiologic meaning is given by Hille.[65]

Receptor-gated ionic channels mediate the information traffic between cells and set the membrane potential as a function of changes in the intracellular milieu such as those of adenosine triphosphate (ATP), pH, or calcium. Voltage-gated ionic channels determine how a neuron integrates synaptic information and propagates it to another neuron or to effector organs. Voltage-gated channels regulate the membrane potential, influence the integrating properties of the dendrites and the discharge mode of a cell, and are responsible for the generation and propagation of action potentials. At the presynaptic terminals, they influence Ca^{2+} loading of the terminals, which is a prerequisite for transmitter release. It is important to note that the distribution of ion channels over the surface of a neuron is not homogeneous. Neurons are polarized cells, which often express in their dendrites other channels than in the soma, the axon, and the presynaptic terminals. Regulation of sorting and direction into axonal and dendritic transport in neurons is much less understood than in epithelial and endothelial cells, which are also polarized. The anchoring of ion channels at distinct sites within and outside the synapse is another important issue because it determines the strength of synaptic coupling and the integration properties of neurons. This has become clear because mutations in stargazing and other anchoring proteins can contribute to epileptogenesis.[102] Similarly, proteins involved in vesicle cycling and other presynaptic functions can contribute to epileptogenesis.[5]

For ionic currents to flow, an electrochemical gradient must be provided, which depends on transport processes across the neuronal membrane. Changes in membrane potentials can be brought about by electrogenic active or secondarily active transport, and such processes frequently influence the responsiveness of neurons. Therefore, in this chapter, I first consider the operation of such ion transport mechanisms. Subsequently, I treat the properties of channels that control the resting membrane potential. I then describe voltage-operated ionic channels that account for neuronal excitability and different discharge modes of neurons. The excitability of neurons is also controlled by low-affinity subsynaptic Î³-aminobutyric acid (GABA), glycine, acetylcholine, and glutamate ionotropic receptors and by high-affinity ionotropic or metabotropic receptors, which are often located at extrasynaptic sites.

Properties of Ion Transporters and Generation of Membrane Potentials

A simple way for ions to cross the plasma membrane is by means of energy-driven pumps, which use the energy from ATP to overcome the barrier imposed by the plasma membrane. Ion pumps are proteins responsible for generating and maintaining the concentration gradients of Na^+, K^+, Ca^{2+}, H^+, and Cl^- ions across the plasma membrane; of H^+ across vesicular membranes; and of Ca^{2+} across the mitochondrial membrane and the endoplasmic reticulum. They bind ions on one side of the membrane, physically transport it across the bilayer, and release it on the other side. Because energy is expended in this process (ATP hydrolysis), it is possible for such active transporters to move ions against a concentration gradient. The energy for this transport comes directly from ATP. It is therefore important that the respiratory chain is intact. The Na,K-ATPase is formed

by Î± and Î² subunits. Four Î± subunits and four Î² subunits have been identified, and two Î± and Î² subunits are necessary for the transport process.[55,145] The ATP-dependent ion transporters affect the electrical behavior of a cell in two ways: They set up the electrochemical ionic gradients that underlie current flow when voltage- or ligand-gated channels are activated. They also affect membrane potential because the transporters are often electrogenic. As an example, Na,K-ATPase transports three Na^+ ions out of a cell in exchange for only two K^+ ions. Hence, the Na,K-ATPase imposes a hyperpolarizing drive on the membrane potential and thereby drives the membrane potential in a negative direction. In fact, the reversal potential for this transporter is quite negative. The membrane potential of neurons and glia would sit very much negative to -100 mV; if not, conductances for Na^+, K^+, and Cl^- would clamp the membrane potential to more depolarized potentials. In fact, it is the Na-K pump that causes K^+ to accumulate within cells and sets up the gradient for Na^+ to enter cells once Na^+-permeable channels are open.[133] Because under resting conditions mostly K^+ channels are open, K^+ ions tend to leave the cells along their chemical gradient. This is prevented by the retaining force set up by negatively charged proteins. Thus, an equilibrium between influx and outflux of K^+ is generated. This equilibrium is described by the Nernst equation. A membrane potential dominated by the K^+ concentration gradient over the membrane would be close to -90 mV. This situation is approached in many astrocytes,[116] which therefore respond to a change in extracellular K^+ concentration more effectively than do neurons.

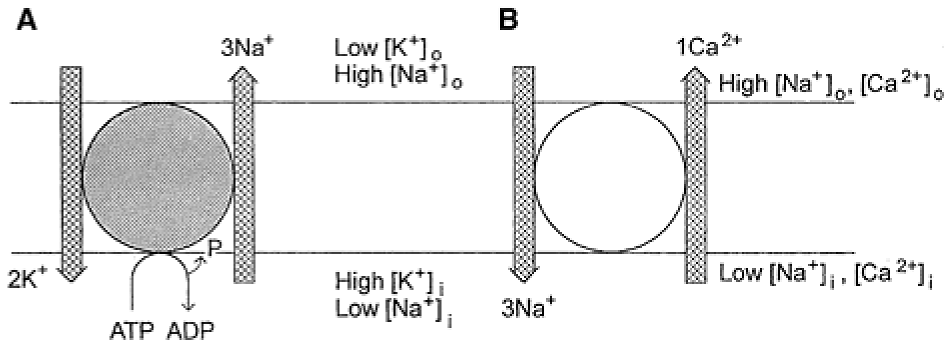

FIGURE 1. A: Active transporter. Principles of action of the electrogenic Na^+,K^+-ATPase. One adenosine triphosphate (ATP) molecule is used to transport three Na^+ ions against the concentration gradient out of the cell, and two K^+ ions are transported against the concentration gradient into the cell. **B:** Secondarily active transporter. In the example of this antiporter, three Na^+ ions are moved along the electrochemical gradient into the cell, and one Ca^{2+} ion is moved against the electrochemical gradient out of the cells. Note that all transporters have a reversal potential. ADP, adenosine diphosphate.

Most neurons and muscle cells have membrane potentials more positive than -90 mV. This is because channels permeable to Na^+ and Cl^- are open under resting conditions. These conductances are much smaller than those for K^+. Nevertheless, the existence of Na^+ leak channels implies that for each K^+ ion that leaves a nerve cell, one Na^+ ion can enter. The cells would slowly depolarize to zero if the Na-K pump did not become activated on intracellular accumulation of Na^+ and thus restore the concentration gradients. Thus, the Na-K pump ultimately is responsible for the generation of the Na^+ and K^+ concentration gradients and the membrane potential. The Na-K pump can be activated by accumulation of both extracellular K^+ and intracellular Na^+.[58] During a seizure resulting from activation of Na^+ and K^+ channels, Na^+ accumulates within the neurons and K^+ in the extracellular space. This leads to activation of the electrogenic Na^+ pump and then to a hyperpolarizing drive. This hyperpolarizing drive contributes to the termination of seizures and is responsible for the long-lasting afterhyperpolarization that follows a single seizure.[61] When Na^+ pumps lose their efficacy, afterhyperpolarizations become smaller, and such loss of efficacy may well underlie episodes of status epilepticus. Indeed, it has been shown that accumulation of intracellular Ca^{2+} can impair the function of the pump.[50] This may be caused by depolarization of mitochondrial membranes, which interferes with the generation of ATP,[89] by consumption of ATP in pumping Ca^{2+} out of cells and into intracellular stores, or by a direct modulation of Na,K-ATPase.

The electrochemical gradient set up by such pumps can be exploited by secondarily active transporters. These use the electrochemical force for inward or outward movement set up by active pumps to transport a second molecule against the concentration gradient. Such transporters import glucose, amino acids, and other agents into the cells as well as export metabolites, calcium, and protons. Often these transporters are not electrically neutral, and thus they can influence the membrane potential (FIGURE 1).

Secondarily active pumps are also involved in regulating the intracellular and extracellular ionic environment. They can use the electrochemical gradient for one ion species to move another ion in the same direction (cotransport) or in the opposite direction over the membrane (antiport). Such transporters do not affect the membrane potential if they are electrically neutral. However, in many cases the transporter is not electrically neutral. For example, the Na^+-Ca^{2+} exchanger in most cases transports three Na^+ ions into the cell against one Ca^{2+} ion out of the cell, thus providing a depolarizing drive to the cell.[13,14]

Secondarily active transporters have a reversal potential. Thus, when the membrane potential moves beyond the reversal potential, the transport direction is also reversed. For example, the reversal potential for the Na^+-Ca^{2+} exchanger is somewhere around -30 mV. This implies that depolarizations beyond this potential would drive Ca^{2+} into the cell, and there is indirect evidence that this occurs during spreading depression and anoxic depolarization.[84] Because the transmembrane ionic gradients strongly change during such conditions, however, the reversal potential also shifts. It is therefore necessary to consider in any of these conditions the actual reversal potential for a given transporter. This also applies to situations in which GABA or glutamate is released by reversed transport from nonvesicular compartments.[2,3]

The intracellular Cl concentration is also affected by secondarily active transporters and in addition by Cl channels. Early during neuronal development, the NKCC1 transporter sets the Cl equilibrium potential above the resting membrane potential of neurons.[119] As a result, inhibitory transmitters such as GABA and glycine produce depolarizations that early during development are sufficient to excite neurons.[28] These GABA-driven giant depolarizing potentials are part of early spontaneous depolarization waves in most neuronal structures.[1] Later in life (in humans, likely during the last trimester of embryonic development[83]), the NKCC1 transporter is replaced by the KCC2 transporter, which extrudes Cl from cells and sets the reversal potential of Cl to values below the resting membrane potential, probably dependent on certain trophic factors.[82] Even then, however, the direction of transport is regulated by the extracellular potassium concentration, and it may reverse

transport direction at about 5.5 mM, resulting in a depolarizing Cl equilibrium potential.[76]

Ion Channels Determining Resting Membrane Potentials

The K channels that most strongly contribute to generation of resting membrane potentials are likely two-pore domain potassium channels consisting of four transmembrane loops with two pores.[57] The K_{2P} channels are encoded by *KCNK* genes, with 11 members so far of the family expressed in the brain. These channels can be influenced by stretch, protons, oxygen tension, and lipids (e.g., arachidonic acid, anadamides), but also by volatile anesthetics and drugs such as riluzole, quinine, quinidine, and bupivacaine, as well as barium at concentrations of 1 to 2 mM.[92] K_{2P} channels are outwardly rectifying and are likely a major route by which potassium is released from cells when they depolarize.

The resting membrane potential is also influenced by potassium inward rectifying (Kir) channels. Seven families of these channels are encoded by *KCNJ* genes.[90] These consist usually of four subunits with two transmembrane segments. These channels rectify because Mg and polyamines block the outflow of potassium through them. Kir channels frequently increase conductance when K accumulates outside the cells. Strongly rectifying Kir 3 family members are activated by G proteins through Î²Î³ subunits and weakly rectifying Kir 6 channels by the ratio of ATP to adenosine diphosphate (ADP). Kir 2 channels are expressed apart from neurons on muscle cells and are involved in vasodilation when K accumulates outside smooth muscle cells.[29] Kir 4.1 channels (perhaps together with Kir 5.1) form the astrocytic K channels involved in spatial K buffering.[74] These channels are very sensitive to Ba in low concentrations. This is in contrast to Kir 7 family members, which are only blocked by Ba at high concentration of about 100 ÂµM. Studies on weaver mice suffering from epilepsy[75] have clarified that mutations in the selectivity filter in the pore-forming loop lead to permeability also for sodium ions and resulting depolarization when Kir 3.3 channels are activated by G proteins.

The ion channels that confer Na and Ca permeability to the membrane at resting membrane potential are not well understood. Some transient receptor potential (TRP) channels may be involved.[30,115] These are rather unselective cation channels with little rectification, which are thought to be involved in receptor potential generation. However, some of them are widely distributed throughout the brain. Thus, all TRPC member channels are expressed in the brain. They are usually activated by the Gq type of G proteins, diacylglycerol (DAG), and also neurotrophic factors. TRPV1â€“4 channels are expressed not only in peripheral, but also in many central neurons. TRPM2â€“4 channels are also expressed in brain and are modulated by arachidonic acid, redox state, and cytokines.

Ion channels that likely also influence membrane resting potential are the cyclic nucleotideâ€“regulated ion channels.[69] They are rather unselective cation channels permeable for both sodium and potassium. They play an important role in phototransduction, but many of them are also expressed in central neurons. They are regulated by intracellular nucleotides such as guanosine 3â€²,5â€²-cyclic monophosphate (cGMP) or cyclic adenosine 3â€²,5â€²-monophosphate (cAMP) and show little voltage dependence. This is in contrast to the hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels, which are also relatively unselective cation channels. These ion channels are activated by hyperpolarization and shift the membrane potential back toward resting membrane potential. The activation curves for these ion channels are regulated by cAMP and cGMP. There are four subunits of these ion channels, all of which are expressed in the brain. They are frequently involved in membrane potential oscillations and are also important for rhythmogenesis in thalamic neurons and other neurons displaying membrane potential oscillations. Cells that express these channels often show resonance properties: This implies that neurons become especially sensitive to specific frequencies of synaptic input usually in the Î¸ and Î± frequency ranges. Upregulation of such channels may be involved in homeostatic plasticity but also following hyperthermia-induced convulsions.[26]

Which chloride channels are contributing to resting membrane potential is unclear. Two calcium-dependent chloride channels have been cloned from rat brain, but their functional role is unclear. Whether-volume activated chloride channels are expressed in neurons is unclear, but such channels could be involved in osmoregulation of astrocytes.

Voltage-Gated Ionic Channels

These channels determine the excitability of neurons, the different firing modes, the integrating properties of dendrites, and the mechanisms that lead to transmitter release from presynaptic terminals. Except for voltage-dependent chloride channels, most voltage-gated ion channels belong to one superfamily.[160] They all build on a pore-forming unit contained in the Î± subunits. Voltage-regulated Na and Ca channels consist of four homologous motifs with six transmembrane Î± helices termed S1 to S6 with a membrane reentrant loop between S5 and S6. The voltage-gated potassium channels consist of four Î± subunits, which combine to form a voltage-regulated potassium channel. As in voltage-gated Na and Ca channels, the ion-conducting pore and selectivity filter are formed by the S5 and S6 segments and the reentrant pore loop between them. Four subunits are also used to form cyclic nucleotideâ€"gated (CNG), HCN, and TRP channels. Heteromeric assembly of different subunits, combinations with different auxiliary subunits, RNA editing, and splicing confer very different properties to these channels.

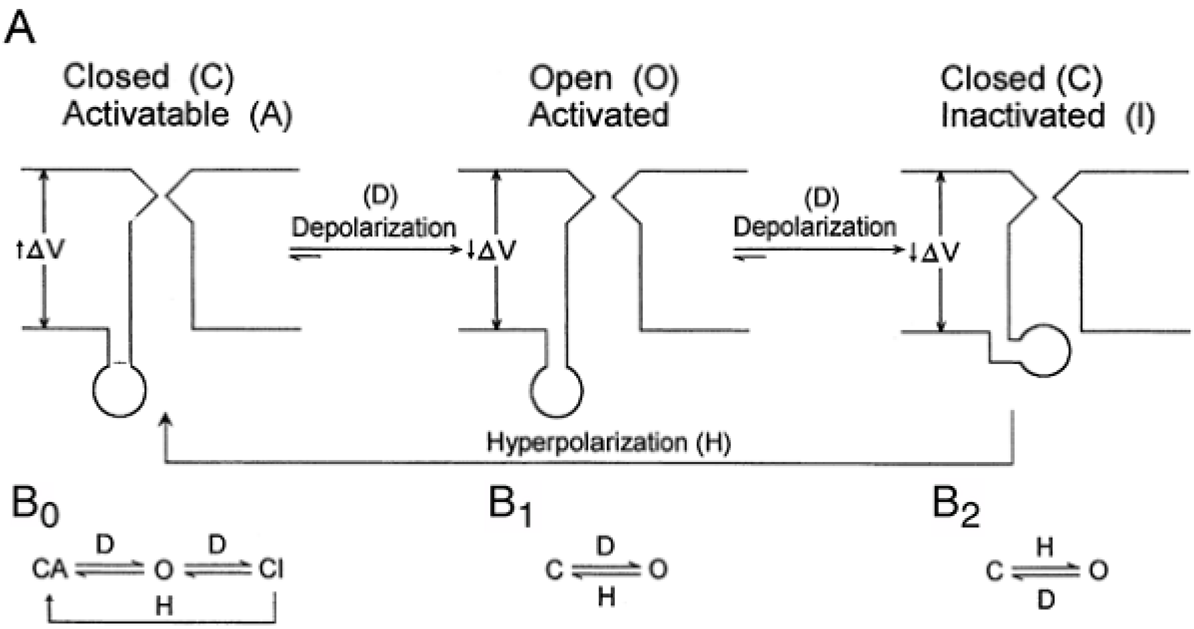

FIGURE 2. Reaction schemes of voltage-gated channels. **A:** Principle of action of transient Na^+ or K^+ channels.

At rest, the channel is closed by the position of a gate in the outer mouth of the channel (closed, activatable). On depolarization, the channel proteins change their conformation, permitting passage of ions. The conformation change is controlled by a voltage sensor that measures the potential difference across the neuronal membrane. On further depolarization, an inner, ball-like structure moves into the inner mouth of the channel, obstructing the passage of ions (closed, inactivated). Hyperpolarization is required to change the conformation from the inactivated state to the activatable state. **B0, B1, B2:** Summary of typical reaction schemes of voltage-operated channels. C, closed; CA, closed activatable; CI, closed inactivatable; D, depolarization; H, hyperpolarization; O, open.

Voltage-gated ionic channels are thus membrane-spanning proteins that form a pore; the opening and often also the closing of the pore are regulated by the transmembrane voltage gradient. The voltage sensor is contained in the S1-to-S4 segment of the Î± subunits, forming the channel, which is absent in Kir and K_{2P} channels. Voltage-gated ionic channels usually have auxiliary subunits.[160] The voltage-gated sodium channels possess only four Î² subunits, which modulate channel activation and regulate membrane surface expression. Therefore not only mutations in Î± subunits but also those in Î² subunits can lead to epilepsy. Voltage-gated Ca channels are regulated by Î², Î³, and Î±2Î´ subunits. The four Î² subunits are all intracellular proteins that regulate channel gating and surface expression. Mutations in Î² subunits can thus also lead to channelopathies, including epilepsy. There are eight Î³ subunits including stargazing,[102] which link the Ca channels to other transmembrane proteins, including Î±-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)-type glutamate receptors. The Î±2Î´ subunits are binding sites for anticonvulsants such as pregabalin and gabapentin.[39]

Voltage-regulated K channels have different types of auxiliary subunits.[93] K_V1 channels are associated with Î²1â€“3 subunits; K_V4 channels with Kchip 1â€“4; and K_V3, 4, 7, 10, and 11 channels with the five members of mink-like subunits.[160] The Î² subunits in the K_V1 channel family influence channel closing. Kchips belong to the superfamily of Ca sensor proteins and regulate channel kinetics and channel membrane surface expression. The mink-like subunits are also important regulators

P.222

of channel dynamics. Finally, the K_V2 family is modulated by K_V5, 6, 8, and 9 modifier/silencer subunits.

The gating of these ionic channels occurs preferentially at a defined membrane potential at which the probability of channel opening increases strongly. However, because the sensor for the gating is located within the membrane, it recognizes the voltage difference between the inside and outside leaflets of the membrane. On both sides of the membrane, there are negative surface charges that attract preferentially Ca, Mg, and H ions. Consequently, changes in H^+, Ca^{2+}, and Mg^{2+} and proton concentration can influence the gating properties.[66] Occasionally, these ions can also modify permeability properties. Well-known examples are cation channels, which can become activated during rapid decreases in Ca^{2+} concentration.[63,156]

In addition, ionic channels can be influenced by intracellular metabolism. For example, certain K channels are rather sensitive to the ATP content of a cell. At physiologic ATP levels, these channels are closed, whereas depletion of ATP leads to opening of K channels and consequently to hyperpolarization. Block of such channels can induce seizures.[7] Some ionic channels possess redox sites such as voltage-gated K channels and K_{2P} channels, which react to the formation of free oxygen radicals or are sensitive to arachidonic acid and its derivatives.[103] Most ionic channels change their properties on phosphorylation, and many protein kinases and some phosphatases can therefore affect the opening and closing of voltage-gated channels. In some cases, such modulations give the cells distinctly different discharge modes, whereas in others, there is a continuum of modifications in the reactivity of a given neuron. In addition, the intracellular level of Ca^{2+} can cause activation and occasionally inactivation of ionic channels.

Based on permeability of the pore, the resulting transmembrane currents are differentiated as Na^+, K^+, Ca^{2+}, and Cl^- currents. Proton currents have also been described and are a prerequisite for formation of radical oxygen species released from activated microglial cells.[43] Within these different species of ionic currents, a distinction is made between persistent and transient currents. Most of the persistent channels open on depolarization and some on hyperpolarization of the membrane potential with respect to the resting membrane potential. Such channels behave according to the reaction schemes illustrated in FIGURE 2B. When persistent ionic currents are activated, the channels open and close, with an increased probability of being open for the whole period of time that the membrane potential is above the threshold for channel opening.

Transient currents show a time-dependent variation of probability of being open when the membrane potential is above that required for channel gating. Their reaction scheme can be formally described as in FIGURE 2A. In these channels, the open probability strongly decreases with time. This time-dependent inactivation is often mediated by a ball formed by the intracellular end of transmembrane proteins. These balls move into the inner mouth of the channels, thereby preventing further passage of ions. This type of inactivation is designated chain-and-ball inactivation and resides at the N terminal of the channel protein.[66] By contrast, there is also a C-type inactivation, which depends on conformational changes in the channel itself. Inactivation of either type makes the channel temporarily refractory and induces a time-dependent short-term memory into channel properties. The conditions and time it takes to remove inactivation are usually studied in paired pulse experiments. Removal of inactivation in sodium channels is typically delayed when anticonvulsants such as carbamazepine or phenytoin are applied.[118] Besides the kinetics of an ion channel, the steady-state behavior also is used to describe the channel properties.[68] Steady-state inactivation curves are determined by current measurements with pulses evoked from different membrane potentials to a potential at which the current is maximal. Conductances are then derived from Ohm's law by taking into account the driving force for the ion species and the measured current amplitude. Normalized conductance curves are then plotted and give the percentage of ion channels that can be maximally opened as a function of resting membrane potential. The steady-state activation curve describes the relative conductance as a function of the membrane potential achieved during a voltage step. A leftward shift of the steady-state

inactivation curve then indicates that at a given membrane potential a fewer channels are available for current generation. Such leftward shifts of steady-state inactivation curves contribute to effects of anesthetics and anticonvulsants. A leftward shift of the steady-state activation curve indicates that more channels can contribute to an ionic current and for the sodium channel would indicate a lower threshold for the generation of action potentials.

Thus, voltage-gated ionic channels can frequently be modulated by drugs. These often affect membrane fluidity, changing the energy barriers that a channel protein must overcome to change its conformation from a closed to an open state. Moreover, drugs can bind to channel proteins, stabilizing a given conformation and changing its threshold for activation. Especially interesting are drugs that are use dependent, that is, they bind to a channel protein only when it is activated. Such drugs often enter the open mouth of an ionic channel and then move very slowly through the channel, preventing further current flow. In some cases, they affect the transition from an inactivated to an activatable state and thereby also produce a use-dependent effect. On the other hand, some drugs and toxins impede the inactivation process, changing a transient into a persistent current.

Voltage-Gated Sodium Currents

The fast transient Na^+ currents are mainly involved in the generation of action potentials, first described by Hodgkin and Huxley.[67] The rapid upstroke of the action potential is the result of a voltage-dependent increase in membrane Na^+ conductance. The threshold for action potential generation is defined as the membrane potential at which Na (and Ca) conductances equal those of K (and Cl) conductances. This implies that Na channels must also be active in the subthreshold range. In most central neurons, the threshold of activation for the fast Na^+ current is about -60 mV.[23] The currentâ€“voltage relationship of this current is characteristically a U-shaped curve, for which the maximum of current amplitude is usually reached at about -20 mV. The fast transient Na^+ currents inactivate rapidly. The inactivation behavior of the current has been described with time constants of 2 to 4 msec in most neurons studied. The Na channel can only reactivate when inactivation is removed. This is a voltage-dependent and time-dependent process often involving two time constants.[118] Rapid removal of inactivation is typical for interneurons, which therefore can fire in higher frequencies than most glutamatergic neurons. By means of electrophysiologic and biochemical techniques, several toxins have been identified as blocking Na^+ channels. After it was found that tetrodotoxin (TTX) acts in nanomolar concentrations as a selective blocker of most neuronal Na^+ channels, it became a useful chemical tool for studying properties of these channels in more detail.[80] In addition to TTX-sensitive channels, TTX-resistant Na^+ channels have been detected.[159] Acutely isolated neurons from the medial entorhinal cortex of the rat exhibit a TTX-resistant Na^+ current in addition to the TTX-sensitive Na^+ current.[154] Like TTX, saxitoxin and Âµ-conotoxin are able to block Na^+ conductance by either occluding the channels or causing conformational changes.[31] Moreover, a number of lipid-soluble alkaloid toxins, including batrachotoxin, veratridine, aconitine, and grayanotoxin, can shift the voltage dependence of activation in a hyperpolarizing direction and prevent current inactivation, resulting in persistent channel activation at normal membrane potentials.[24] The voltage dependence of Na^+ currents is also changed by the application of Î²-scorpion toxins, which cause enhanced activation. Brevetoxins and ciguatoxins can cause repetitive firing of nerve cells by shifting the activation curve of Na^+ currents to more negative potentials.[24] Toxins such as veratridine and brachatoxin can therefore readily induce convulsant activity.[107]

Sodium currents are encoded by nine different Î± subunits, which combine with four different Î² subunits. Na_V1.1â€“1.3, 1.5, and 1.6 are expressed in central neurons. Na_V1.1 (*SCN1A*) channels associate with Î²1 to Î²4 subunits.[24] Na_V1.1 channels are highly expressed in hippocampal interneurons, and deletion of this channel leads to reduced firing of interneurons in the hippocampus, which explains some of the hereditary epilepsies associated with mutations in these channels such as generalized epilepsy with febrile seizures plus (GEFS+) and myoclonic epilepsy. The Î²4 subunit in this and other channels accelerates removal of inactivation, permitting high-frequency generation of action potentials, as is typical for many interneurons. Na_V1.2 (*SCN2A*) can also interact with all Î² subunits. It is highly expressed in axons of central neurons. Mutations in these channels have also been linked to epilepsy.[143] Na_V1.3 channels are highly expressed during development but are also expressed on somata in adult brain cells. These channels are upregulated after nerve injury and, due to rapid removal of inactivation, can be involved in high-frequency axonal discharges. This implies that the action potential frequency in somatic recordings may not necessarily be the same in axon terminals. They interact with Î²1 and Î²3 subunits. Na_V1.5 channels (*SCN5A*) are insensitive to TTX and, besides heart muscle cells, are also expressed on subgroups of central neurons. They can interact with all four Î² subunits. Finally, Na_V1.6 (*SCN8A*) channels are expressed in central neurons and mostly on the somatodendritic region of output cells in the cerebral cortex, hippocampus, and cerebellum. It is thought that these ion channels contribute at least partially to persistent sodium channels.

The Î² subunit 1 occurs with different mutations, leading to GEFS+ and also to temporal lobe epilepsy (TLE).[73] Persistent noninactivating Na^+ current has been found in a number of neurons.[4,6,48] Its activation threshold was determined at potentials more negative than that of the fast transient Na^+ current, at about -70 mV. Because of activation near the resting membrane potential of neurons and the loss of inactivation, this current can contribute to subthreshold membrane potential oscillations and resonance, playing an important role in the genesis of the Î¸ rhythm in these cells.[4] It is likely that also some metabolites can remove inactivation and thereby permit generation of persistent sodium currents. Another possibility is that persistent sodium channels are due to window currents. When the steady-state activation and inactivation curves are considered, they often overlap and generate a voltage range in which a portion of these channels is frequently open.

Voltage-Gated Calcium Currents

Calcium currents play a major role in neuronal excitability, directly by their contribution to membrane depolarization and indirectly through the elevation of the intracellular concentration of free Ca^{2+}. Voltage-dependent Ca^{2+} conductances in neurons contribute to the generation of dendritic spikes, slow somatic depolarizations, and related burst discharges.[22] Influx of Ca^{2+} through voltage-gated Ca^{2+} channels can activate Ca^{2+}-dependent K^+ channels and regulate many intracellular Ca^{2+}-dependent processes. Calcium channels are also responsible for rapid delivery of Ca^{2+} to trigger transmitter release.[46,150]

Voltage-gated Ca^{2+} channels consist of Î±1 subunits with which Î² subunits, Î±2Î´, and Î³ subunits can be associated.[25] In the classic studies of sensory neurons by Carbone and Lux,[19] they showed that voltage-gated Ca^{2+} channels could be differentiated into two major categories: (a) low-voltage-activated (LVA) and (b) high-voltage-activated (HVA)

P.224

channel types. The Î±1 subunits of Ca channels can be differentiated into three families: (a) Ca_V1, (b) Ca_V2, and (c) Ca_V3 members.[25] The Ca_V1 family shares high threshold of activation, no voltage-dependent inactivation, and sensitivity to dihydropyridines, and these are often referred to as L-type Ca channels. In the central nervous system (CNS), only Ca V 1.3 (Î±1c, *CACNA1C*) channels are expressed on somata and dendrites of neurons, with little effect on regulation of transmitter release. The Ca_V2 subfamily (Ca_V2.1â€"2.3) has three members, which are all insensitive to dihydropyridines. Ca_V2.1 (Î±1A, *CACNA1A*, or P/Q-type) channels are involved in transmitter release but are also found in many neurons expressed on dendrites. They are sensitive to Ï‰-agatoxin IVa. The Ca_V2.2 (Î±1B, *CACNA1B*, or N type) channels are also expressed presynaptically and on dendrites. These channels show time-dependent inactivation and are blocked by Ï‰-conotoxin GVIA. Like Ca_V1 channel members, these two channels require high levels of depolarization to become activated. Ca_V 2.3 channels (Î±1E, *CACNA1E*, or R-type channels) require less strong depolarization for activation, are expressed on somata and dendrites, and are sensitive to the peptide SNX-482. They can be involved in epilepsy.[144] Low-voltage-activated channels contain Ca_V3.1 to 3.3 members (Î±1G, H, I; *CACNA1G*, H, I), are rather sensitive to low concentrations of Ni, and form the T-type Ca channels. In most neurons, these channels activate at potentials positive to -70 mV. Inactivation of the T-type Ca^{2+} channels develops monoexponentially within tens of milliseconds and shows a strict dependence on voltage. Unlike in L-type Ca channels, the inactivation kinetics is independent of Ca^{2+} influx through the channel.[20,21] No specific high-affinity antagonist has so far been identified for the T-type Ca^{2+} current, although antiepileptic drugs used to treat petit mal, such as ethosuximide and dimethadione, reduce T-type Ca^{2+} currents in thalamic neurons and dorsal root ganglion cells.[35]

The behavior of voltage-gated Ca currents is influenced by different subunits. The intracellular Î² subunit consists of four known isoforms Î²1 to Î²4 (*CACNB1*â€"*CACNB4*). Mutation in Î²4 subunits also are involved in ataxia and epilepsy in mice and humans.[18] The Î² subunits regulate current density by controlling the amount of Î±1 subunit expressed at the cell membrane. In addition to this trafficking role, the Î² subunits regulate the activation and inactivation kinetics and shift the voltage dependence for activation of the Î±1 subunit pore in the hyperpolarizing direction.

The Î±2Î´ subunits are formed from a distinct gene. The Î±2 subunit is the extracellular glycosylated subunit that interacts the most with the Î±1 subunit. The Î´ subunit has a single transmembrane region with a short intracellular portion, which serves to anchor the protein in the plasma membrane. There are four Î±2Î´ genes: *CACNA2D1* to *CACNA2D4*. Coexpression of the Î±2Î´ enhances the level of expression of the Î±1 subunit and causes an increase in current amplitude, faster activation and inactivation kinetics, and a hyperpolarizing shift in the voltage dependence of inactivation.[146] Some of these effects are observed in the absence of the Î² subunit, whereas in other cases the coexpression of Î² is required. The Î±2Î´-1 and Î±2Î´-2 subunits are the binding sites for at least two anticonvulsant drugs, gabapentin and pregabalin, which also find use in treating chronic neuropathic pain.[39]

The Î³ subunits are associated with only some of the Î±1/Î² complexes. The Î³ subunits do not affect trafficking and for the most part are not required to regulate the channel complex. There are eight genes for the Î³ subunit: *CACNG1* to *CACNG8.* The Î³1 subunits are expressed in skeletal muscle, and the Î³2 and Î³3 subunits may be associated with the P/Q- and N-type channels. Some Î³ subunits (Î³3, Î³4, and Î³8) and particularly stargazing (Î³2) associate Ca channels with AMPA-type glutamate receptors.[148,149]

Voltage-Gated Potassium Currents

Whereas voltage-gated sodium and calcium channels are formed by a distinct subgroup of proteins forming the Î± subunit, most voltage-dependent potassium channels are formed by four subunits.[60,160] The first cloned potassium channels were detected in *Drosophila* and named shaker (K_V1.1â€"1.8; *KCNA1â€"7*, *KCNA10*), followed by shab (K_V2.1 and 2.2; *KCNB1.2*), shaw (K_V3.1â€"3.4; *KCNC1â€"4*), and shal (K_V4.1â€"4.3; *KCND1â€"*3) related subunits. The M-type potassium channels modulated by muscarine were originally detected in sympathetic ganglia and form the K_V7 family with five members (*KCNQ1â€"5*). The identification of the voltage-dependent potassium channels forming the K_V10 to 12 families (eag, erg, and elk; *KCNH1â€"8*) was based on the identification of the ether-a-go-go channel in *Drosophila*. In the different families, the same subunits can form homomeric potassium channels, or different subunits can combine to form heteromeric channels. Heteromeric channel formation is well documented for K_V1, K_V7, and K_V10 families but likely also occurs in other families of voltage-gated potassium channels. The combination of subunits in heteromeric channels frequently confers different properties to the ion channels than those expected from the characteristics of homomeric potassium channels in a given family. The diversity of potassium channels is further increased by silencer and modifier subunits belonging to the K_V5, 6, 8, and 9 families. These subunits do not form conducting channels but can combine with members of the K_V2 family to form functional channels with different properties than those observed in homomeric K channels from this family. As with Na and Ca channels, Î² subunits have been identified that can combine with members of the K_V1 and K_V2 families to provide for altered channel properties but also likely are involved in channel trafficking and surface expression. Kchip1 can associate with K_V4 family members and modify their properties. Calmodulin interacts with K_V10 members and minK proteins with Kv11 family members. In addition, alternative splicing confers different properties to K channels.

Thus a wide variety of K^+ currents exists in excitable cells, and potassium channels represent the most diverse type of voltage-gated ion channels known, comparable only to $GABA_A$ receptors. Apart from their genetic identity, potassium currents can be distinguished by their voltage sensitivity, kinetics of activation and inactivation, single-channel behavior, and pharmacologic modulation. With respect to these properties, macroscopic voltage-gated K^+ currents found in neurons can be subdivided into two types: (a) outward delayed rectifying K^+ currents and (b) (fast) transient K^+ currents.

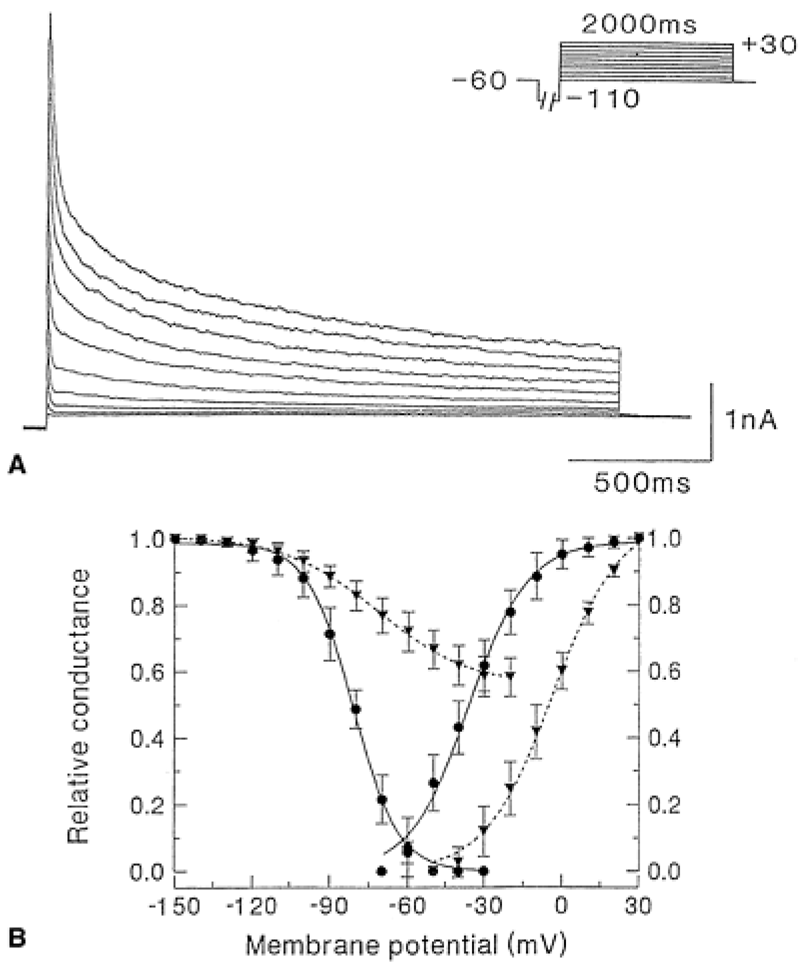

FIGURE 3. Outward K^+ currents activated by depolarizing voltage changes preceded by a hyperpolarizing prepulse. Currents were recorded in an acutely isolated entorhinal cortex cell. **A:** Currents were evoked by application of depolarizing voltage commands from the holding potential of -60 mV to potentials

between -60 and -30 mV for 200 msec following a hyperpolarizing prepulse to -110 mV for 1,000 msec. **B:** Steady-state activation and inactivation curves for isolated fast transient A-type currents (*closed lines*) and delayed rectifying currents (*dotted lines*). Overlap of steady-state inactivation and activation curves indicates the voltage range in which channels open and close permanently. Note that around resting membrane potentials A-type currents can contribute to the stabilization of membrane potential.

Most of the delayed rectifying K^+ currents (I_K) have a relatively high activation threshold. The currents activate at potentials more positive than -40 mV.[47,68,132] Therefore, I_K seems to activate only during action potentials, not in the subthreshold voltage range. Hence, I_K contributes to spike repolarization.[139] In addition, I_K may be partly responsible for spike broadening during repetitive firing, due to slow accumulating current inactivation. In many neuronal preparations, time constants of 2 to 5 seconds have been determined to describe the inactivation behavior of this current (FIGURE 3).[8,105] Pharmacologically, these currents are sensitive to tetraethylammonium (TEA). Delayed rectifier currents can be encoded by most members of the K_V1 family, which are all expressed in the central nervous system except for $K_V1.7$. Except for $K_V1.4$, they all encode for delayed rectifier-like ion channels. Members of the $K_V1.1$ and 1.2 families share a relatively high sensitivity to kaliotoxin and to dendrotoxin. In addition, $K_V1.6$ is sensitive to dendrodotoxin. Delayed rectifier channels can also be encoded by K_V2 family members, which are modulated by a number of accessory

subunits. Their pharmacology is relatively sparse. They are sensitive to TEA and show only low sensitivity to 4-aminopyridine (4-AP). It is interesting that $K_V2.2$ is sensitive to phencyclidines, which are generally known to cause open channel block in *N*-methyl-D-aspartic acid (NMDA) receptors, and otherwise are used for studies on NMDA receptors.[49] Finally, members of the K_V3 and K_V4 families can encode delayed rectifier currents. K_V3 family members encoding delayed rectifier currents are rather sensitive for 4-AP, whereas K_V4 family members show low sensitivity. The K_V3 family members are all expressed in central neurons except for $K_V3.3$. It is interesting that $K_V3.1$ and 3.2 encode for delayed rectifier currents in many interneurons. They are sensitive to relatively low levels of TEA and 4-AP. On one hand, these drugs prolong action potentials in interneurons, but on the other hand, they strongly reduce firing frequency and thereby GABA release. It is believed that these effects contribute to the convulsivogenic effects of TEA and 4-AP in low concentrations.

Fast transient A-type currents (I_A) markedly differ from I_K in their kinetics; they show a fast activation following depolarization and inactivate rapidly, within tens of milliseconds.[47,86,104] Their threshold of activation is at about -45 to -60 mV, that is, at a more hyperpolarized level of membrane potential than that of I_K[71] and below the threshold for action potential generation. Moreover, at membrane potentials more positive than -50 to -30 mV, A-type currents cannot be activated because they show a strong steady-state inactivation behavior. In most neurons, half-maximal inactivation for A currents was determined at potentials between -85 and -70 mV.[106] The pharmacologic sensitivity of I_A is also different from that of I_K. The A-type current is selectively blocked by 4-AP in the micromolar (K_V1 and K_V3 family members) to millimolar concentration range (K_V4 family members), but it is relatively insensitive to TEA. In hippocampal neurons, the I_A can also be blocked by low concentrations of the snake toxin dendrotoxin.[100]

It has been shown that I_A plays an important role in determining the onset of discharge in response to a depolarizing stimulus and in the regulation of repetitive firing.[32,104] In addition, I_A seems to be involved in repolarization of the action potential because the spike is broadened when I_A is blocked by 4-AP.[141]

In a few reports, a K^+ conductance (I_D) has been characterized that activates rapidly within milliseconds, like I_A, but inactivates slowly over several seconds.[59,140] In contrast I_K, this current is insensitive to TEA, but it is very sensitive to 4-AP and dendrotoxin. These potassium conductances seem to be responsible for a longer delay in the onset of firing in response to long-lasting depolarizing stimuli. Because I_D activates rapidly on depolarization, it tends to keep the cell from depolarizing further. Only as I_D slowly inactivates does the cell reach threshold and fire after delay, which can have a duration of up to about 15 seconds.[141] The rapid activation of I_D suggests that it may also participate in spike repolarization.

In the K_V1 family (*KCNA1â€"7*, *KCNA10*) only $K_V1.4$ (*KCNA4*) encodes for an A-type current. $K_V1.4$ is highly expressed on mossy fibers and axons, and it is believed that $K_V1.4$ alone or in combination with $K_V1.2$ controls presynaptic transmitter release in many central neurons. Indeed, 4-AP in relatively low concentrations increases presynaptic Ca uptake in Schaffer collaterals and mossy fiber terminals. For pharmacologic studies of effects of Ca channel blockers, it is noteworthy that many members of the K_V1 family are also moderately sensitive to L-type Ca channel blockers. One family member ($K_V1.2$) is also sensitive to picrotoxin. The A currents can also be encoded by K_V3 and K_V4 family members.

Whereas $K_V3.1$ and 3.2 genes (*KCNC1*, *KCNC2*) encode for delayed rectifier currents, that for 3.4 encodes for transient potassium currents with a relatively high sensitivity to TEA and for A-type potassium currents in hippocampal granule cells. The genes for the K_V4 channel family members (*KCND1â€“3*) all encode for A-type potassium currents with low sensitivity to 4-AP. They seem to be expressed in the somatodendritic region of pyramidal cells and regulate backpropagation of action potentials and modulate excitatory input to dendrites.[77] The expression of these channels is modulated by Kchip subunits, which also influence their kinetics.

The M-type current (I_M) is encoded by *KCNQ* genes and belongs to the K_V7 family. I_M is a small, subthreshold, voltage-dependent outward K^+ current that is activated at more hyperpolarized potentials (positive to -60 mV) than the delayed rectifying current. The current activates and deactivates slowly and does not inactivate.[15] Thus, as the only K^+ current that both activates below the spike threshold and does not inactivate, I_M can play a unique role in the control of cell excitability. In addition, I_M contributes to the resting membrane potential in many neurons.[34,38,96] It also seems to contribute to the early spike-frequency adaptation and is involved in generation of the medium afterhyperpolarization, an up-to-100-msec undershoot that follows an action potential or a spike train.[141] The M current can be completely suppressed by muscarinic agonists and by specific blockers such as XE-991 or linopiridine. It is encoded by family members of the K_V7 family, also named KCNQ channels. It is of interest that heteromultimers of $K_V7.2$

and 7.3 are usually expressed in central neurons and their axons. In addition, $K_V7.5$ also is expressed in central neurons. The expression of these channels is particularly high during development, when the expression of K_V1, 2, and 3 members is still low. This implies that K_V7 deletions or mutations in mice are often lethal. Recently a transgenic mouse has been made in which the expression of KCNQ channels can be downregulated at desired time points. These animals all develop epilepsy.[112] This channel family has been gaining in interest because relatively specific agonists such as retigabine are available that are powerful anticonvulsant drugs.[40,122] K_V7 channels are strongly involved in rhythmogenesis and in resonance phenomena.[112]

Based on the *Drosophila* ether-a-go-go channels, three families of voltage-gated potassium channel families have been detected, most of which are also expressed in the brain.[16,60] These belong to the K_V10 (*KCNH1* and *KCNH5*; *EAG1* and *EAG2*), K_V11 (*KCNH2*, *KCNH5*, and *KCNH7*; *erg1* to *erg3*), and K_V12 (*KCNH8*, *KCNH3*, and *KCNH4*; *elk3*, *elk2*, and *elk1*) families. Most of the family members are expressed in brain except for perhaps $K_V12.3$. Some of the family members are activated at very low membrane potentials and therefore can contribute to resting membrane potential. Their activation can be very slow. $K_V10.1$ is a potassium channel that is also permeable for calcium ions and is blocked by calcium/calmodulin.[17] $K_V10.2$ is also blocked by intracellular calcium. It activates at â€“100 mV. The K_V10 family members are blocked by imipramine and by astemizole.[52] The K_V11 members can form heteromeric channels. Because of the involvement of one of their members in the long-QT syndrome in heart disease, there is a wealth of pharmacologic agents available with which it should be possible to learn more about their functional role in central neurons. K_V12 channels activate at hyperpolarized membrane potentials with rather slow kinetics and are insensitive to 4-AP and TEA but sensitive to barium.

Calcium- and Sodium-Activated Potassium Channels

With respect to their kinetic properties and their sensitivity to various pharmacologic agents, at least three different types of Ca^{2+}-activated K^+ currents have been distinguished in neurons of the central nervous system. A Ca^{2+}-activated K^+ current of large single-channel conductance (150 to 300 pS) has been detected in most neurons studied.[91] This current is also voltage dependent and contributes to spike repolarization and fast afterhyperpolarization. The channel is constituted by a $K_{Ca}1.1$ Î± subunit encoded by the *KCNMA1* gene. These channels associate in the brain with one of three Î² subunits, Î²2 to Î²4. The Î²2- and Î²3-containing $K_{Ca}1.1$ channels are sensitive to charybotoxin and iberotoxin, and the Î²4-containing channels are not but are potentiated by 17Î²-estradiol. Î²2 and Î²3 subunits confer inactivation to these channels. It is of interest that a number of other activators exist for these channels that may have potentially anticonvulsant effects. These include drugs such as NS 1608, NS 1619, and BMS 204352.[153] Mutations in the Î²3 subunit have recently been associated with susceptibility to idiopathic epilepsies.

The second class of Ca-activated K currents belong to the $K_{Ca}2$ family (*KCNN1*â€“*KCNN3*), which has three members.[153] These SK channels are exclusively regulated by intracellular Ca and are not voltage dependent. Voltage-clamp studies have suggested that they encode medium-duration Ca^{2+}-activated K^+ currents with a single-channel conductance of 20 to 60 pS, which can contribute to the medium afterhyperpolarizations during spike trains and to afterhyperpolarizations that last for about 200 msec.[111,138] These channels are blocked by bicucullin methiodide and may contribute to the epileptogenic action of bicuculline. It is interesting that the SK-type channels can be activated by drugs such as EBIO, NS 309, and riluzole.[110] The $K_{Ca}3.1$ channel (*KCNN4*) is not expressed on neurons but is expressed strongly on microglial cells and may contribute to neuronal damage during status epilepticus.[125] Blocking these channels prevents activation of inducible nitric oxide synthase (iNOS)- and nitric oxide (NO)-dependent neuronal damage.[81] These channels are also activated by methylxanthines such as caffeine and theophylline.

A prominent Ca-dependent K current (I_{AHP}) accounts for the late afterhyperpolarizations that contribute to afterhyperpolarization following seizures. These currents are blocked by cAMP and consequently by norepinephrine through Î² receptors, dopamine through D1-like receptors, and through other agents that upregulate cAMP.[62] These currents are resistant to TEA and also to other K_{Ca} channel-blocking toxins. Their molecular nature has not been identified.

Closely related to Ca-activated potassium channels are Na-dependent K channels named K_{Ca} 4.1 (*SLACK*, *SLOW2.2*, *KCNT1*) and K_{Ca} 4.2 (*SLICK*, *SLOW2.1*, *KCNT2*). These channels are already active at physiologic intracellular sodium concentration and Cl concentrations and can form heteromultimers in which the $K_{Ca}4.2$ subunit is dominant. These ion channels are regulated by $G_{Î±q}$-type receptors, which activate protein kinase C. This is of interest because mGluR1 and muscarinic M1 receptors use this pathway. The two subunits are differently regulated. Whereas $K_{Ca}4.2$ is suppressed by muscarinic agonists, $K_{Ca}4.1$-mediated currents are increased. Therefore these ion channels may contribute to the differential effects of muscarinic and mGluR receptorâ€“mediated effects in different neurons. The sodium-dependent K conductances are only blocked by very high concentration of Ba and quinidine.[153]

A further, not yet genetically identified ionic channel underlies cation currents activated by elevation in intracellular Ca concentration.[109] These so-called CAN channels are sensitive to flufenamic acid, which in hippocampal neurons was shown to affect depolarizing afterpotentials and paroxysmal depolarizations during seizure-like events.[124] The molecular identity of these ionic channels is not known, but it is likely that TRP channels are involved in these currents.

Finally, a cation current can be activated by lowering the extracellular Ca concentration, which may contribute to epileptogenesis because sometimes the extracellular Ca concentration drops to very low levels during seizure-like events.[63,64,157]

Bursting Behavior

Spontaneous generation of seizures seems frequently to depend on the presence of burster cells. These are neurons that, when excited, produce an all-or-none response, consisting of a depolarizing envelope that triggers a burst of action potentials. Such burster neurons have been described in the neocortex,[33] hippocampal areas CA3 and CA1,[155] and the subiculum.[11] The area most abundantly equipped with burster neurons is the subiculum, where about 50% of pyramidal cells have bursting properties. In the neocortex, the hippocampus, and the subiculum, the bursting behavior is caused by a persisting Na^+ current, whereas in CA1 pyramidal cells of epileptic animals, the bursting behavior seems to depend on T-type inward Ca^{2+} currents.[158] The notion that persistent Ca^{2+} currents are involved in ictogenesis is supported by the observation that Ca^{2+}-channel blockers possess anticonvulsant properties. In the concentration ranges in which these agents have anticonvulsant effects, however, they may no longer be specific for Ca^{2+} channels.[135] On the other hand, many anticonvulsant drugs

not only affect the kinetics of fast Na channels, but also block persistent Na channels and some Ca channels.[120]

Membrane Potential Oscillations and Resonance Behavior

Voltage-gated currents are also involved in the synchronization of neurons, which is necessary for the generation of epilepsy. The finding that drugs that suppress primarily generalized nonconvulsive seizures, such as absences, block T-type Ca^{2+} currents has made this very clear.[34] This phenomenon is discussed in Chapter 31.

A second current apparently involved in synchronization is I_Q (I_H, I_F), which is encoded by *HCN* genes. This current is activated on hyperpolarization and deactivates very slowly. Therefore, a depolarizing sag develops during hyperpolarization that depolarizes a cell toward resting potential and causes an afterdepolarization following a hyperpolarizing event.[108] Under appropriate conditions, such currents cause bursting in subicular neurons and also in CA1 and CA3 neurons. These currents, together with M -type potassium currents and persistent sodium currents, are frequently involved in membrane potential oscillations, which occur already at rest or close to action potential threshold.[70,72,112] These membrane potential oscillations have been observed in neocortical neurons and are readily induced in perirhinal and entorhinal cortex cells.[128] They also occur in certain interneurons.[113] These types of ionic currents also induce resonance behavior.[45,129] In cells that express these currents, the input resistance changes as a function of frequency of current input to the neurons. Resonant cells frequently have the largest impedance at frequencies between 4 and 15 Hz. This implies that these cells integrate synaptic input more effectively when it occurs at resonance frequencies. Such mechanisms are important in determining oscillatory activity preceding seizures, contribute to Î¸ and Î³ activity, and are also involved in Î± rhythm activity. It is expected that such mechanisms are altered in epilepsy.

Voltage-Gated Currents and Epilepsy

There is considerable evidence that voltage-gated currents contribute to the generation of seizure. This evidence stems from various observations. It has been shown that toxins that prolong Na^+ channel opening cause seizures.[51] Similarly, drugs that prevent activation of K^+ currents also induce seizures. These include muscarinic receptor agonists, which reduce M-type currents, certain Na-dependent K conductances and EAG channel activity, and 4-AP, which can block K^+ currents. Surprisingly, TEA, which affects many K^+ currents, is a much less potent convulsant agent than 4-AP. Because A-type currents are rapidly inactivated during depolarization, it is unlikely that they contribute much to epileptogenesis. When TEA is applied in a concentration of 2 mM, which reduces I_K in a similar way as 4-AP at a concentration of 50 to 100 ÂµM, short recurrent discharges with a frequency of 0.1 Hz are induced in entorhinal cortex and hippocampal slices, whereas 4-AP induces convulsion-like events. Because 4-AP augments presynaptic uptake of Ca^{2+} much more than TEA, it is likely that augmented transmitter release causes the seizures.[54,78] The second line of evidence comes from experiments with transgenic mice. Many of the potassium-channel-knockout animals develop epilepsy. Mutations in ion channels have also been found in inherited epilepsies in mice and rats. These studies are often also supported by studies of human inherited epilepsies in which Na channel mutations, Ca channel mutations, and K channel mutations have all been identified as causes of epilepsy.

It is of interest that epilepsies can also be accompanied by acquired channelopathies. Thus, it was shown in a number of convincing studies that bursting behavior of neurons is upregulated in different acquired epilepsies.[142] The best-studied channels in this respect are HCN channels, which are upregulated following hyperthermia-induced seizures.[27,130] Upregulation of these channels has also been seen after repetitive stimulation of a kind that induces neither long-term potentiation nor long-term depression, and it was suggested that they are involved in homeostatic plasticity.[151] Changes in expression of K currents have been described in a model of temporal lobe epilepsy in which downregulation of the A-type-encoding $K_V4.2$ channel has been described.[12] This channel is involved in limiting backpropagation of action potentials and in reducing the transfer of excitatory postsynaptic potential (EPSPs) from apical dendrites into the soma. It is interesting that in the same model upregulation of T-type Ca channels also has been described, resulting in increased bursting behavior of hippocampal neurons.[142] For acutely isolated hippocampal neurons of the CA1 region, it was shown that the amplitude of voltage-gated Ca^{2+} currents of the HVA type is increased after kindling.[88] Enhancement of Ca^{2+} currents persisted for at least 6 weeks without further tetanic stimulation. Whole-cell patch-clamp recordings of acutely dissociated granule cells from the dentate gyrus of kindled adult rats demonstrated a markedly enhanced Ca^{2+}-dependent inactivation of Ca^{2+} currents, which was correlated with lack of the cytoplasmic Ca^{2+}-binding protein calbindin-D_{28K} during kindling-induced epilepsy.[87,88]

Many of the voltage-gated currents are targets for antiepileptic drugs. The effects on Na^+ currents of some of the antiepileptic drugs, such as phenytoin and carbamazepine, are well known.[95,120] Agents that act on presynaptic uptake of Ca^{2+},[39] or that activate K^+ currents, are of considerable interest. Thus, it has been shown that drugs that activate ATP-dependent K^+ currents, M currents, and Ca-activated K currents can have antiepileptic effects.[7,9,10,53] More recently, some interest has developed in the properties of Na^+ currents in epileptic tissue of patients with drug-resistant epilepsy. It may well be that transient Na^+ currents in the tissue of such patients have a reduced sensitivity to phenytoin and carbamazepine.[117]

Ligand-Gated Ionic Channels

Ligand-gated ionic channels open when a neurotransmitter binds to a receptor. These channels also comprise various subunits. Ligand-gated channels open fast, in the range of milliseconds, and are therefore used in fast synaptic transmission. The most important inhibitory ligands are GABA and glycine; they open a Cl^-- (and HCO_3^--) permeable channel.[79] Depending on membrane potential and the reversal potential for Cl^-, this results in either depolarization or hyperpolarization. The Cl^- reversal potential depends on the activity of a Cl^- pump.[94] If this is inwardly directed, mediated by the NKCC1 transporter, the Cl^- equilibrium potential is above the resting membrane potential, and consequently a depolarizing GABA or glycine potential results. When the Cl^- transporter is outward mediated by the KCC2 transporter, the Cl^- potential is hyperpolarizing with respect to the resting membrane potential, and hyperpolarizing inhibitory postsynaptic potentials are generated on binding of the agonist to the receptor. In addition to NKCC1 and KCC2, the carbanhydrase activity also plays a role, which determines the bicarbonate reversal potential.[119,152]

Depending on subunit composition, the GABA-operated ion channel is also permeable to bicarbonate. Because the bicarbonate equilibrium potential is depolarizing with respect to

resting membrane potential, bicarbonate-permeable ion channels exert a depolarizing drive, and the resulting GABA-mediated potentials are depolarizing. In fact, after an initial hyperpolarization, prolonged activation of GABA channels lead to a depolarization that is sensitive to carbanhydrase inhibitors. The subunit composition also determines whether GABA-gated channels respond to furosemide, zinc, benzodiazepines, and Î²-carbolines. In general, barbiturates seem to prolong the mean open time of GABA-gated Cl^- channels (see Chapter 23). A subgroup of GABA receptors does not fit the pharmacologic sensitivity of GABA receptors. These receptors contain Ï subunits. Their role in synaptic mechanisms is not fully understood.

GABA receptors containing Î´ subunits[137] have a high affinity for GABA and therefore sense ambient GABA levels. These receptors mediate tonic inhibition.[134] Recent evidence suggests that tonic inhibition is very sensitive to neurosteroids.[97] It is likely that tonic inhibition is affected in epilepsy.[56,85,131]

A potentially important second mechanism providing for tonic inhibition relies on activity-dependent editing of glycine receptors with a subsequent manifold increase of glycine receptors to glycine, making them sensitive to ambient levels of glycine and taurine.[99] Preliminary evidence suggests that this occurs also in human temporal lobe epilepsy.

Acetylcholine, when bound to nicotinergic receptors, and glutamate, when bound to AMPA, kainate, or NMDA receptors, are ionic channels permeable to small cations such as Na^+ and K^+ and to a variable degree also to Ca^{2+} ions (see Chapter 22). These ionic channels mediate fast excitatory synaptic transmission. In addition, serotonin can bind to receptors that gate an ion channel directly. The 5HT3 receptors are predominantly expressed on interneurons. Nicotinergic receptors are also important, however, as shown by the recent discovery that a mutation in an Î± subunit of the nicotinergic receptor accounts for a genetically determined type of epilepsy in humans.[85,136]

For excitatory synaptic transmission in the central nervous system, the glutamate receptors are most important. The duration of excitatory postsynaptic potentials in the central nervous system is largely regulated by a fast desensitization,[42,114] whereas the duration of inhibitory postsynaptic potentials is regulated by GABA uptake into presynaptic terminals and glia.[41,44]

Metabotropic Receptors

Receptors are said to be *metabotropic* when the binding of a ligand does not directly lead to a conformational change of an ion channel. Instead, the receptors interact with G proteins. These can directly influence membrane channels, particularly Ca^{2+} channels,[121] or the activation of enzymes can lead to the production of second messengers such as inositol-1,4,5-triphosphate (IP3), cyclic adenosine monophosphate (cAMP), and diacylglycerol, which activate protein kinases (see Chapter 27). These affect voltage- and ligand-gated channels in the membrane. The effects are rather slow and therefore account for slow depolarizations or hyperpolarizations. Activation of metabotropic receptors often produces long-lasting effects, in that phosphorylation of an ion channel persists until the channel is used; the information conveyed by an appropriate stimulus also affects later synaptic potentials and the integration properties of neurons for subsequent signals. Finally, second messengers can activate gene-regulating peptides and thereby affect the production of proteins, a process involved in the formation of long-lasting memory traces.

Three classes of ionotropic transmitters (GABA, glutamate, and acetylcholine) interact with metabotropic receptors. Whereas changes in metabotropic $GABA_B$ receptors and mGluR receptors have been well studied in different epilepsy models, less is known on the alterations in muscarinergic receptors and the cholinergic signaling pathway. Neuromodulators such as serotonin, norepinephrine, dopamine, and histamine also interact with metabotropic receptors. Finally, most neuroactive peptides act via G proteins.

The activation of metabotropic receptors leads to different cellular effects that can be either excitatory or inhibitory. This depends on the type of G protein activated, the intracellular second messenger, and the target in a given cell as well as in a given neuronal network. Thus, glutamate can probably activate three different classes of metabotropic receptors.[37,98] Potassium channels are activated by GABA via $GABA_B$ receptors, but GABA also inhibits Ca^{2+} currents. Acetylcholine and glutamate often block K^+ channels via metabotropic receptors. The same applies to serotonin (5-HT) and norepinephrine. These agents, however, can also activate K^+ currents. In general, metabotropic receptors are likely future targets for anticonvulsant drugs.[101]

Presynaptic Receptors

As initially demonstrated in the spinal cord, it is now well established that presynaptic terminals express both ionotropic and metabotropic receptors. These can be autoreceptors, in which the released transmitter binds to the presynaptic membrane and then interferes with further transmitter release. They can also be heteroreceptors, in which the released transmitter diffuses to terminals in the surrounding area. In the spinal cord and brainstem, presynaptic terminals are themselves innervated by afferent fibers. There, ionotropic GABA receptors can impose a depolarization on the axon terminal, which blocks Na^+ currents through depolarization, thereby interfering with synaptic transmission.[126] In cortical structures, inhibitory effects of $GABA_B$ receptors on presynaptic GABA release have been frequently demonstrated.[36,147] Glutamatergic nerve endings also possess presynaptic autoreceptors, however, which often differ from postsynaptic receptors in their binding properties, including those for kainate[127] and mGluR receptors.[123] Presynaptic receptors modulating transmitter release have been described for adenosine and many neuromodulators and neuropeptides as well. Their physiologic and pathophysiologic function is little understood. However, such presynaptic receptors may be suitable targets for new classes of antiepileptic drugs (FIGURE 4).

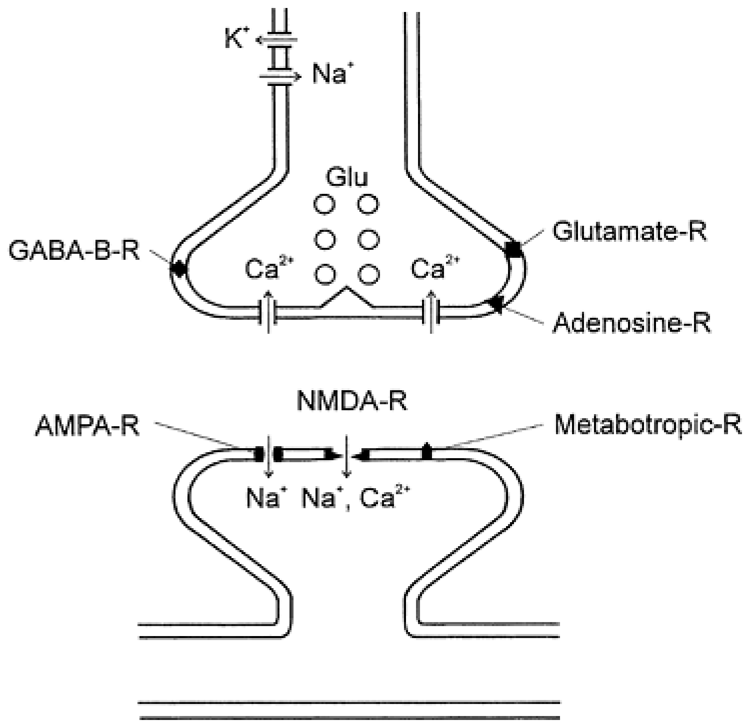

FIGURE 4. Location of different presynaptic and postsynaptic transmitter receptors. Receptors for Î³-aminobutyric acid B ($GABA_B$), adenosine, and glutamate can regulate transmitter release. AMPA, Î±-amino-3-hydroxy-5-methyl-4-isoxazolepropionate; NMDA, *N*-methyl-D-aspartic acid; R, receptor.

Summary and Conclusions

The trafficking of information in the central nervous system depends critically on voltage- and transmitter-gated ionic channels. Storage of information and adaptation to metabolic needs probably depend on metabotropic receptors, which process short-term information into longer-lasting modifications of neuronal transfer of information and may even alter the preferred state of neuronal firing. Through activation of gene-regulatory peptides, they appear to be involved in long-term storage of information of physiologic or pathologic significance.

Any transfer of information leads to a perturbation of ionic gradients, which requires the functioning of ion transporters. Thus, ion pumps are involved not only in regulating membrane potential and loading the â€œbatteryâ€ for activation of voltage- and transmitter-gated currents, but also in setting up ionic gradients for the uptake of nutrients and the outward transport of metabolites. Ion transporters are usually not electrically neutral and so contribute to the electrical behavior of neurons and glia.

P.229

Through modern techniques of molecular biology, information about the binding properties of voltage- and transmitter-gated channels is expanding, and new approaches to the development of region-specific toxins and drugs are being undertaken. These will soon offer more-specific tools for manipulating neuronal activity. Increased knowledge of the presynaptic terminal, with its autoreceptors and heteroreceptors and various amino acid transporters, offers new possibilities for the development of antiepileptic drugs. Better understanding of the role of metabotropic receptors and their individual functions may even make it possible for drugs to be designed that interfere with the epileptogenic process itself.

Chapter 22

Excitatory Synaptic Transmission

Karen S. Wilcox

Peter J. West

Marc A. Dichter

Introduction

Information processing throughout the central nervous system (CNS) occurs through synaptic transmission between neurons coupled via chemical synapses. Excitability at chemical synapses is controlled by both the amount of excitatory neurotransmitter released and by the way in which the postsynaptic neuron responds to the released transmitter. Multiple regulatory mechanisms exist within the CNS to maintain a controlled and focused level of excitability and to prevent excess excitation. These include mechanisms intrinsic to excitatory systems and mechanisms extrinsic to these systems; regarding the latter, direct inhibition and indirect modulation are noteworthy. Excess activation of excitatory pathways in specific circuits can lead to epileptic activity, neuronal damage, and even cell death. This chapter discusses what is known concerning the inotropic and metabotropic glutamate receptors that underlie excitatory synaptic transmission and the role(s) that they play in epilepsy.

Excitatory Neurotransmitters

A variety of endogenous compounds have been identified as agonists at excitatory amino acid (EAA) receptors. However, the two EAAs that are thought to be the most likely neurotransmitter candidates are L-glutamate and L-aspartate. Both compounds act as agonists at all subtypes of inotropic glutamate receptors. Other endogenous compounds present in the CNS that act as agonists at EAA receptors and can depolarize neurons include *N*-acetylaspartylglutamate (NAAG), quinolinic acid, and the sulfur-containing amino acid analogs of glutamate: Cysteic acid, homocysteic acid, cysteine sulfinic acid, homocysteine sulfinic acid, and S-sulfocystein.[28] Whether any or all of these act as neurotransmitters at specific synaptic sites remains to be determined.

Glutamate Synthesis and Uptake Mechanisms

Glutamine and Î±-ketoglutarate are thought to be the major precursors for glutamate, which is subsequently packaged into vesicles for future release into the synaptic cleft. Glutamine is taken up into the presynaptic terminal via an active, sodium (Na)-dependent uptake protein. It is then transported to mitochondria, where it is converted via phosphate-activated glutaminase to glutamate and ammonia. Î±-Ketoglutarate is also actively taken up into the presynaptic terminal, where it is transaminated into glutamate. The glutamate anion in the terminal is then actively taken up into vesicles for future release. Upon release into the cleft, the glutamate either is actively taken back up via a neuronal glutamate transporter and repackaged, or it diffuses away from the cleft and glial glutamate transporters, most often excitatory amino acid transporter (EAAT)-2, internalize the extracellular glutamate.[17]

Once in astrocytes, the glutamate can either be (a) released again into the synaptic cleft via a calcium-dependent vesicular release,[13] (b) metabolized via glutamine synthetase into glutamine, or (c) metabolized into Î±-ketoglutarate by either glutamate oxaloacetate transaminase or glutamate dehydrogenase.

This glutamine and Î±-ketoglutarate is then actively transported out of the glial cells and back into the presynaptic terminals for subsequent resynthesis of glutamate (Fig. 1).[51] Recent work by a number of groups suggests that patients with temporal lobe epilepsy (TLE) may have a deficiency in glutamine synthetase in the astrocytes of sclerotic tissue. This reduced glutamine synthetase may underlie the elevation in extracellular glutamate often associated with TLE[47,155] by reducing the rate of glutamineâ€"glutamate cycling.[119]

Clearly, glutamate uptake molecules perform a vital function in maintaining large precursor levels for glutamate synthesis and low extracellular concentrations of glutamate. To date, five high-affinity glutamate transporter proteins have been cloned.[17,66,67,120,145] All five transporter proteins have been shown to be sodium-dependent, and they are preferentially located in neurons, astrocytes, or other types of glial cells. The recent development of highly specific antagonists of these glutamate transporters will prove quite valuable in ascertaining the contribution these transporters make to neurotransmission at excitatory synapses.

Ionotropic Excitatory Amino Acid Receptors

Three pharmacologically distinct classes of inotropic glutamate receptors (iGluRs) have been identified. The names of these iGluR subfamilies are based on the synthetic agonists that bind to the specific receptor subtypes and selectively open the associated ion channels: The Î±-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor, the kainic acid (KA) receptor, and the *N*-methyl-D-aspartate (NMDA) receptor. This initial pharmacologic classification was supported by the subsequent identification of separate gene families whose sequence similarities were correlated with their affinity for the agonists previously described: GluR1 through GluR4 (which encode AMPA receptor subunits); GluR5 through GluR7; KA1 and KA2 (which encode low- and high-affinity KA receptor subunits, respectively); and NR1, NR2A through NR2D, and NR3A and NR3B (which encode NMDA receptor subunits). Two orphan receptor subunits, GluRÎ´1 and GluRÎ´2, have also been identified.[69]

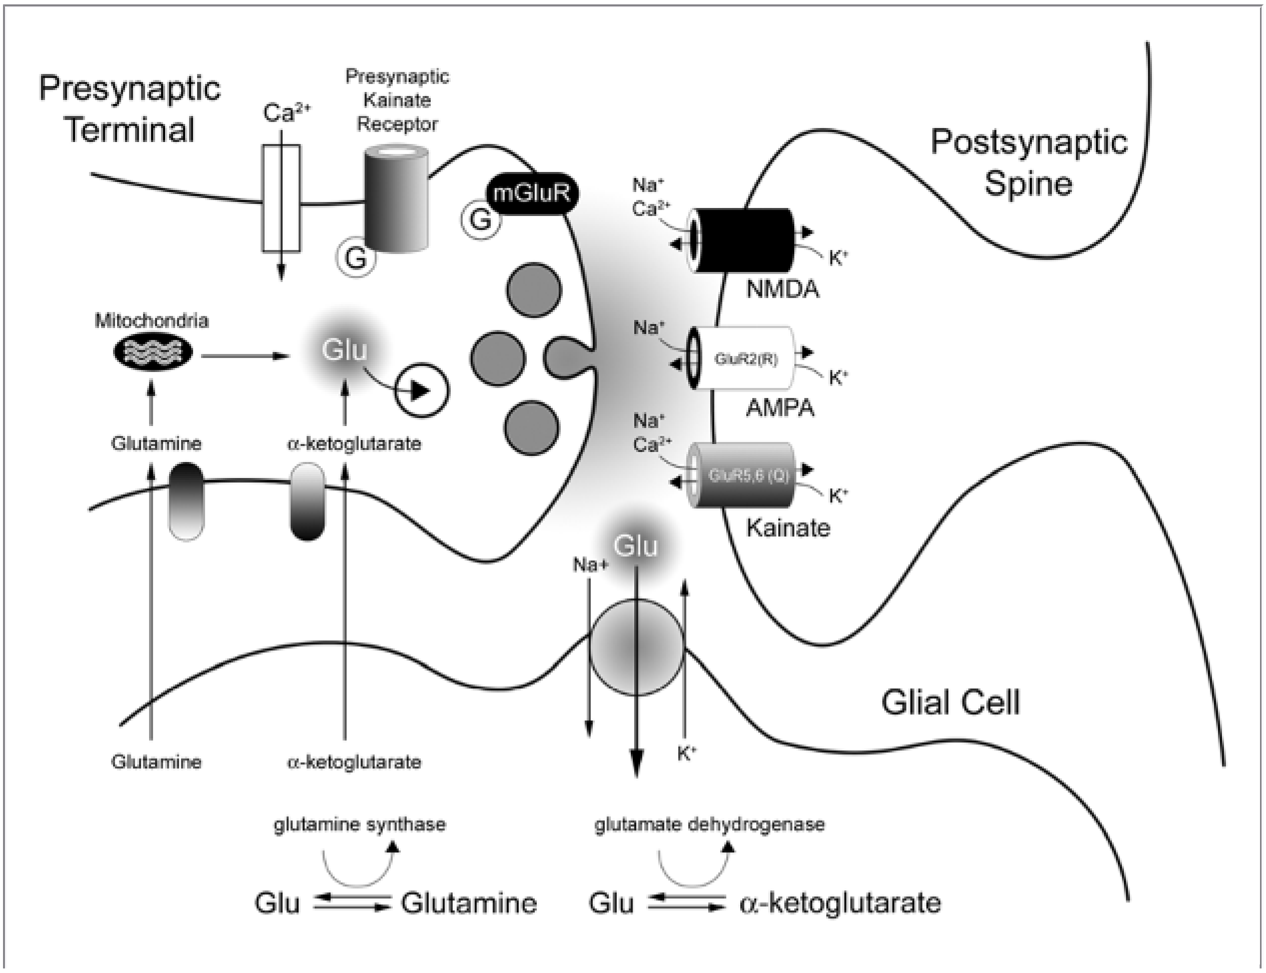

FIGURE 1. Schematic diagram of a model excitatory synapse.

All iGluR subunits have an extracellular N-terminus, an intracellular C-terminus, three transmembrane domains (M1, M3, M4), and a membrane re-entrant loop (M2) that forms the pore (Fig. 2). The ligand binding domain of iGluRs is formed by

stretches of amino acids in the N-terminal domain (S1) as well as the linker between M3 and M4 (S2). This ligand binding domain has been crystallized in various functional conformations, and has provided insight into key features of glutamate receptor agonist affinities, activation, desensitization, subunit association, and receptor assembly. Several articles offer excellent in-depth review of this topic.[86,92,93] Functional receptor-gated ion channels are formed when subunits within, but not between, families come together to form homo- or hetero-oligomers. Although the precise subunit stoichiometry of iGluRs was debated for some time, recent studies now suggest that these receptors are composed of four subunits.[91] The reader is directed to several excellent reviews on this topic.[42,69,139]

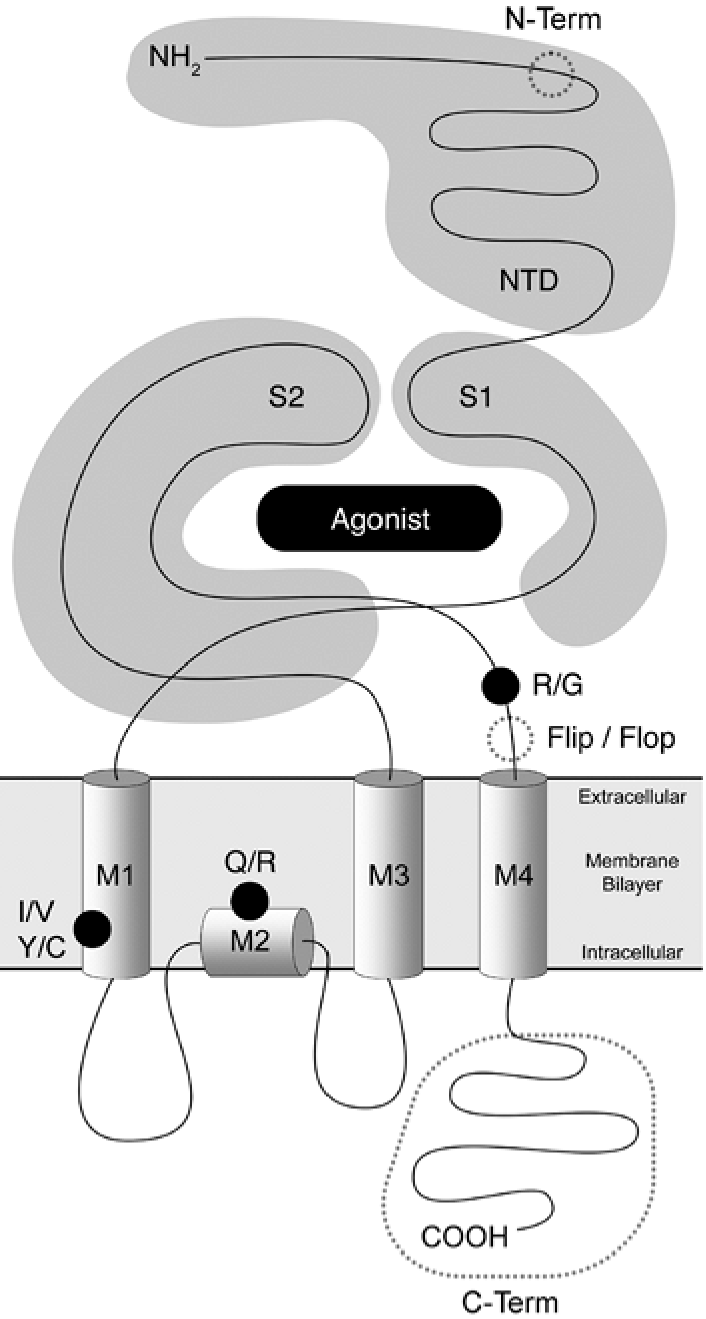
AMPA Receptors

Molecular Biology

Post-transcriptional Modification.

The AMPA receptor subunits GluR1 through GluR4 are each comprised of approximately 900 amino acids and share approximately 70% sequence homology. Additional diversity among the subunits can be generated by post-transcriptional modifications (alternative splicing and RNA editing). All four AMPA receptors undergo alternative splicing of a 38-amino acid sequence in the extracellular domain between M3 and M4. This gives rise to two splice variants, â€œflipâ€ and â€œflop.â€[141] These receptors exhibit differing biophysical and pharmacologic characteristics; the flip variant tends to desensitize more slowly and to a lesser extent than do flop variants, which can influence the amplitude of the AMPA receptor responses.[104] Flip variants also have a greater sensitivity to the allosteric modulator cyclothiazide than do the flop variants. Expression levels of these variants are regulated developmentally, regionally, and in a cell-typeâ€“specific manner, and are also modified by disease states such as epilepsy.

In addition to the flip and flop splice variants, the GluR1, GluR2, and GluR4 AMPA receptors can undergo alternative splicing of their C-termini. This splicing results in isoforms with â€œlongâ€ and â€œshortâ€ cytoplasmic C-terminal domains, and these variants are named as such. Variation in the length of these receptors' C-terminal domains can influence their interactions with cytoplasmic proteins through the presence (â€œshortâ€ C-termini) or absence (â€œlongâ€ C-termini) of a PSD-95/Disc-large/ZO-1 (PDZ) binding domain.[39]



Alternative Splicing

	N-term	C-term	Flip / Flop
AMPA		GluR2, GluR4	GluR1-4
Kainate	GluR5	GluR5-7	
NMDA	NR1	NR1	

RNA editing

	Q / R	R / G	I / V & Y / C
AMPA	GluR2	GluR2-4	
Kainate	GluR5, GluR6		GluR5, GluR6
NMDA			

FIGURE 2. Schematic diagram of iGluR structure within membrane.

It has been observed that homomeric or heteromeric AMPA receptors that lack the GluR2 subunit are permeable to calcium and exhibit a voltage-dependent block by intracellular polyamines that results in an inwardly rectifying current-voltage (IV) relationship. The ability of the GluR2 subunit to influence these AMPA receptor properties resides in a single amino acid substitution (the genomically encoded glutamine is converted to arginine) in the pore forming M2 segment. This Q/R substitution is the consequence of post-transcriptional editing of premessenger RNA.[142] AMPA receptors that contain edited GluR2(R) are impermeable to

calcium, have a low single-channel conductance, and have linear IV relationships.[147] Most neurons in the adult CNS have been shown to possess AMPA receptors with these qualities, and this suggests that the GluR2(R) subunit is a constituent of most native AMPA receptors. One notable exception to this rule is receptors expressed in various interneurons that appear to be calcium permeable, inward-rectifying, and are therefore believed to lack the GluR2 subunit.[73]

A second known post-transcriptional modification to AMPA receptors via RNA editing is the substitution of the genomically encoded arginine (R) for glycine (G) in GluR2, GluR3, and GluR4. This R/G site is located just before the flip/flop cassette in the extracellular domain between M3 and M4. Generally speaking, homomeric and heteromeric assemblies of edited (G) receptors have faster kinetics for recovery from desensitization (resensitization) than do their unedited (R) counterparts. Variations also occur in the kinetics of desensitization in edited (G) versus unedited (R) receptors, with a tendency toward slower desensitization rates. Akin to the other post-transcriptional splice variants and RNA-edited forms of AMPA receptors, the R/G edit progresses with brain development in a subunit and splice variant-dependent manner.[42]

Post-translational Modifications.

As another way to generate additional diversity, AMPA receptors also undergo post-translational modifications in the forms of glycosylation and phosphorylation. All AMPA receptors contain extracellular glycosylation sites but different subunit combinations appear to be affected differently by the presence or absence of bound oligosaccharides. For example, with the exception of GluR2, the lectin concanavalin-A potentiates AMPA receptorâ€“mediated currents by binding to these carbohydrates and inhibiting desensitization.[50] Although it is not entirely clear what the function of glycosylation is in these receptors, it is thought that this modification is involved in the maturation and transport of receptors and possibly the protection of AMPA receptors from degradation.[116]

Additionally, AMPA receptors have been shown to be phosphorylated basally or in response to varying types of synaptic activity. Although commonalities exist, the particular phosphorylated amino acid residues and kinases responsible for these modifications vary on a subunit basis. Phosphorylation of these residues leads to alterations in the receptor-gated channel properties. One of the most extensively studied instances of this phenomena is the phosphorylation of specific residues in the C-terminal domain of GluR1. GluR1 subunit phosphorylation potentiates receptor activation and leads to an increase in channel conductance and open probability,[7,38,124] and these modifications have been shown to be involved in forms of plasticity such as long-term potentiation (LTP) and long-term depression (LTD).[76] A complete description of this work is beyond the scope of this review, and the reader is directed to an excellent review.[116]

Structure and Function of AMPA Receptors.

The structure of the ligand-binding core of AMPA receptors, as well as other iGluRs, has been determined through the application of X-ray diffraction, and this has led to considerable insight into the molecular mechanisms of receptor activation and desensitization.[56] By using a water-soluble construct of the li- gand binding domain (S1 and S2), the structure was determined to have a hinged clamshell shape, in which the agonist binds in the cleft between each shell. In the absence of agonist, the clamshell is mostly open, whereas in the presence of agonist, the clamshell closes to varying degrees depending on the particular agonist. The degree of closure was shown to correlate with the degree of receptor activation (in which kainate, a partial agonist for AMPA receptors, caused an intermediate degree of closure relative to the full agonists AMPA and glutamate). Furthermore, competitive antagonists like 6,7-dinitro-quinoxaline-2,3(1H,4H)-dione (DNQX) were shown to stabilize the open conformation of the ligand-binding clamshell. Finally, the observation that these receptor fragments tended to favor crystallizing as dimers led to hypotheses and subsequent studies examining the tetrameric stoichiometry of these receptors (a dimer of dimers), as well as the conformational changes that are necessary for the closing of the clamshell

P.236

binding pocket to translate to opening of the channel and desensitization of the receptor complex.

Electrophysiology

As noted earlier, the ligand-binding pocket of iGluRs consists of a bilobed â€œhinged clamshellâ€ structure that adopts differing conformations in the absence or presence of agonist. Upon binding of the full agonists glutamate or AMPA, the cleft between the two lobes (S1 and S2) closes by approximately 20 degrees relative to each other, whereas binding of the partial agonist kainate induces a cleft closure of approximately 12 degrees.[56,86] In either event, this cleft closure is coupled to receptor activation and ion channel opening. In most natively expressed receptors, the ion channel is equally permeable to Na^+ and potassium (K^+), and the resulting current has a depolarizing effect on the neuron by driving the membrane potential toward an equilibrium potential of approximately 0 mV. However, in AMPA receptors that either lack the GluR2 subunit, or in which the GluR2 subunit is unedited, there is also a significant permeability to calcium (Ca^{2+}).

Electrophysiologic studies using single-channel recordings of recombinant AMPA receptors have shown that homo- and heteromeric channel assemblies display multiple conductance levels whose amplitudes vary in a subunit-dependent manner, as well as in response to post-transcriptional and post-translational modifications.[38,129,147] For example, homomeric receptors composed of the unedited GluR4(Q), as well as heteromeric receptors composed of unedited GluR4(Q) and GluR2(Q), have single-channel conductance between 20 and 30 picosiemens (pS). On the other hand, inclusion of edited GluR2(R) into these heteromeric assemblies reduces the conductance to approximately 10 pS, and homomeric assemblies of GluR2(R) have conductances in the femtosiemens (fS) range.[147] Native AMPA receptors in a variety of neurons have single-channel conductance similar to those reported for recombinant receptors. For example, cultured cerebellar granule cells have AMPA receptors that fall into three categories based on their single-channel conductance: Highâ€"conductance (10â€"30 pS), low-conductance (5â€"10 pS), and femtosiemens channels (<1 pS).[35,162]

One of the most dramatic features of this receptor, relative to the NMDA receptor, is the rapid desensitization observed when the receptor is exposed to the full agonists AMPA or glutamate.[151,154] After rapid application of an agonist, the channel opens. However, in the continued presence of the agonist, the amount of current flow is rapidly reduced, with a time constant of decay of <10 msec. If the agonist application is terminated and then reapplied, the current is again quite large, so that desensitization does not last long in the absence of agonist. Electrophysiologic studies have led to the conclusion that desensitization probably contributes, at least in part, to the rapid decay of excitatory postsynaptic currents (EPSCs) observed during neurotransmission at excitatory synapses.[151,152]

Pharmacology

AMPA receptors are responsible for most of the rapid excitatory neurotransmission within the vertebrate CNS. When compared to NMDA receptors, AMPA receptors have a relatively low affinity for glutamate, the endogenous amino acid that represents the most likely candidate in mediating neurotransmission at both these receptors.[117] In addition to AMPA and glutamate, AMPA receptors can be activated following the binding of quisqualic acid, derivatives of willardiine, and natural toxins such as domoic acid. However, as mentioned earlier, the most potent selective agonist for this class of EAA receptor is AMPA[67a]. As noted earlier, binding of agonists to AMPA receptors often results in various degrees of desensitization, and the desensitization observed appears to be agonist-specific. Little to no desensitization occurs when a partial agonist, such as kainate, is used to induce a current. However, AMPA, quisqualic acid, glutamate, and many other full agonists result in a desensitizing current at this receptor.

Both competitive and noncompetitive antagonists of AMPA receptors have been described. Competitive antagonists of this receptor include 5-cyano-7-nitroquinoxaline-2,3-dione (CNQX) and other analogs of the quinoxalinedione family such as 1,2,3,4-tetrahydro-6-nitro-2,3-dioxo- benzo[f]quinoxaline-7-sulfona- mide (NBQX), DNQX, and 1,4,7,8,9,10-hexahydro-9-methyl-6-nitropyride[3,4-f]quinoxaline-2,3-dione (PNQX).[60] This family of antagonists has limited utility in discriminating between AMPA and kainate receptors. Fortunately, noncompetitive antagonists that have a sufficiently higher affinity for AMPA than kainate receptors have been developed; 2,3-benzodiazapines, such as GYKI 52466 and 53655, are relatively selective for AMPA receptors and have allowed for the functional examination of kainate receptors (see below).[69]

Regulation of AMPA Receptor Subunit Expression and Function

Anatomic Distribution.

The anatomic distribution of AMPA receptors in the CNS has been determined by in situ hybridization, receptor autoradiography, and immunocyto-chemistry.[69] These receptors are widely present in projection neurons and interneurons throughout the brain, although regional differences exist in the relative amounts of each of the receptor subunits. For example, whereas GluR1, GluR2, and GluR3 are rather ubiquitously expressed throughout the CNS, GluR4 expression is limited to select regions of the thalamus and cerebellum. In addition, whereas principal neurons utilize AMPA receptors including the GluR2 subunit, interneurons are more likely to express AMPA receptors lacking GluR2 and are thus permeable to Ca^{2+}. AMPA receptors are thought to be located primarily postsynaptically, although some evidence suggests that presynaptic AMPA receptors are present in some neurons and can influence neurotransmitter release.

In addition to neurons, AMPA receptors are also found in glia, where they are thought to be able to sense nearby neuronal activity.[156] With regards to epilepsy, the functional properties of these receptors may be modified by changes in the expression levels of individual subunits and/or their pre- and post-translational modifications. For example, it has been demonstrated that GluR1 receptors expressed in hippocampal astrocytes have an elevated flip-to-flop ratio in tissue from humans with pharmacoresistent TLE.[135,136] This increase in the flip isoform could result in receptors with slower desensitization and enhanced depolarizations in astrocytes.

Developmental Regulation.

GluR1, GluR2, and GluR3 are all present and expressed at birth in the rat, whereas the GluR4 subunit is not expressed until approximately postnatal day 14. There is considerable developmental regulation of the splice variant forms of the AMPA receptor, and these changes over time can dramatically impact the function of the receptor and ultimately the excitability of the neuron.[102] In general, in the adult animal, most AMPA receptors contain the flop form of the receptor subunits. This results in receptors that are generally impermeant to calcium and desensitize rapidly. However, in the young brain, a greater flip-to-flop ratio is present, which results in receptors that are more permeant to calcium and open for longer durations. This contributes greatly to the hyperexcitability observed in the young brain.

Trafficking and Associated Proteins.

Interestingly, it is thought that AMPA receptors are not initially present at excitatory synapses, although NMDA receptors are present at postsynaptic sites at birth. Furthermore, transcription as well

P.237

as insertion of AMPA receptors into postsynaptic sites is tightly regulated and, for some forms of the receptor, is activity dependent. Recent work has dramatically increased the understanding of AMPA receptor trafficking at synapses, and the reader is encouraged to see some excellent recent reviews on this extensive topic.[111,116]

Briefly, AMPA receptors are assembled in the endoplasmic reticulum, transported through the Golgi, and targeted to the dendrites. The exact mechanisms whereby the receptors are targeted to dendrites and delivered there are currently under investigation. However, because AMPA receptors lack motor components, it is believed that associated proteins are involved in propelling the receptors along cytoskeletal tracks to the dendrites. For GluR2 and GluR3 receptor subunits, interactions with the C-terminus with glutamate receptor interacting protein/AMPA binding protein (GRIP1/ABP) is thought to be necessary for proper dendritic delivery, whereas the interaction of the C-termini of the GluR1 and GluR4 receptors with protein 4.1N seems to be essential for proper delivery of these subunits.[16,49,111,138] Although cytoplasmic vesicles are responsible for initial delivery of AMPA receptors, it is unclear whether they deliver them to the postsynaptic or extrasynaptic sites. Indeed, a number of studies indicate that extrasynaptic receptors are free to diffuse to synaptic sites, where they are then anchored in place by a number of scaffolding proteins.

Once at the dendrite, GluR2- and GluR3-containing receptors are free to rapidly cycle between the postsynaptic sites and intracellular compartments constitutively in an activity-independent fashion. Thus, it is thought that these receptors help to maintain a constant level of receptors at the synapse. In contrast, AMPA receptors containing GluR1 and GluR4 subunits are tightly regulated at the synapse in an NMDA- and activity-dependent fashion. It is believed that this activity-dependent regulation of receptor number at the synapse results in both LTP and LTD (see Chapter 35).

Critical to the ability of AMPA receptors to be inserted into the postsynaptic membrane is the presence of the transmembrane AMPA receptor regulatory proteins, or TARPs. These auxiliary proteins have been found to be important for the selective delivery of AMPA receptors to extrasynaptic regions. In addition, TARPs have now been shown to regulate the activity of AMPA receptors. For example, the first TARP to be examined, stargazin, has been shown to increase the affinity for glutamate at the AMPA receptor and also decrease desensitization and deactivation rates.[121,134,153] An interesting aside to this story is that the stargazin gene has been implicated in absence seizures observed in the stargazer mouse, although the seizures appear to be linked to the proteins' interaction with voltage-gated calcium channels in the thalamus.[82,83]

Different AMPA receptor subunits combine with different combinations of auxiliary proteins that can oversee a myriad of functions of AMPA receptors. In general, the associated proteins fall into one of two categories: PDZ domainâ€"containing proteins and non-PDZ domainâ€"containing proteins. A thorough description of all associated proteins is well beyond the scope of this chapter, and the reader is referred to several recent reviews.[116] However, as we learn more about the assembly, targeting, and regulation of function of AMPA receptors, a number of potential therapeutic targets for the treatment of a variety of seizure disorders will no doubt emerge.

AMPA Receptors and Seizures

Clearly, excitatory synaptic transmission is involved in many aspects of synchronization and seizure generation, and there is no doubt that AMPA receptor number and function are critically involved in these mechanisms. Not only are there alterations in excitatory circuits in some forms of epilepsy (most notably mossy fiber sprouting in TLE), but a number of studies have demonstrated that following seizures, changes occur in a number of cell types with regards to the type of AMPA receptor subunits that are expressed. Changes in subunit expression have been observed in both animal models of epilepsy as well as in human epilepsy.[37,43,57,61,90,122,131,143] Clearly, these alterations in subunit expression have important ramifications with respect to the function and regulation of excitatory synaptic transmission, and these alterations are just beginning to be understood at the circuit level. Many of these changes in excitatory synaptic transmission are addressed in a number of other chapters in this book and will not be elaborated upon here.

Kainate Receptors

Molecular Biology

Cloning studies have revealed the existence of five kainate receptor (KAR) subunits: The low-affinity subunits GluR5, -6, and -7, and the high-affinity subunits KA1 and KA2. (This topic has been reviewed.)[42,80] Multiple alternative splice variants have been identified for GluR5 through GluR7. Additionally, post-transcriptional editing occurs in GluR5 and GluR6 at the glutamine/arginine (Q/R) site, but this does not occur in the GluR7, KA1, or KA2 subunits. GluR5 through GluR7 can form functional homomeric KARs in expression systems, whereas the KA1 andKA2 subunits cannot. However, KA1 and KA2 subunits can assemble with GluR5, -6, and -7 to form functional heteromeric receptors. Clearly, this inherent molecular diversity can lead to the assembly of a sizeable number of different KARs with distinct stoichiometries. As was the case for AMPA receptors, subunit assembly can dictate the functional properties of the resulting receptor-gated ion channels, including permeability, conductance, and pharmacology. For example, homomeric assemblies of GluR5 or GluR6 that possess an arginine at the Q/R site are functionally different from receptors composed of subunits possessing a glutamine.[10] These edited, arginine-containing receptors have a reduced calcium permeability, a linear or slightly outward rectifying current-voltage relationship instead of an inward or double rectifying relationship, a single low conductance state as compared with multiple conductance states, and an increased chloride permeability.

Electrophysiology

Postsynaptic Kainate Receptors.

Functional postsynaptic KARs are present in a variety of cell types. Examples include cerebellar granule cells and Golgi cells[18,140]; retinal bipolar cells[40]; neurons of the superficial dorsal horn,[84] lateral superior olive,[158] and motor and somatosensory cortex[2,45,71]; and a variety of neurons in the hippocampus and amygdala.[22,31,32,52,53,54,58,127,157,160] As originally described in CA3 neurons of the hippocampus, KAR-mediated EPSCs are defined as being resistant to inhibition by the AMPA receptor-selective 2,3-benzodiazepine GYKI 53655 (or GYKI 52466), but sensitive to inhibition by CNQX.[22] Furthermore, KAR-mediated EPSCs are smaller than their AMPA receptor-mediated counterparts, have significantly slower rise and decay kinetics, and are not potentiated by cyclothiazide.[22,157] Even though the KAR contribution to combined AMPA/kainate-mediated EPSCs is relatively small, postsynaptic KARs participate in synaptic transmission and may even be segregated to their own synapses.[31] Data using glutamate uptake blockers suggests that the KARs' slow kinetics are due to intrinsic characteristics[18,71] and may impose unique integrative properties to neurons.[53]

P.238

Presynaptic Kainate Receptors.

Presynaptic KARs have been found to modulate the release of glutamate at a variety of synapses in the CNS and peripheral nervous system (PNS).[24,29,55,65,68,70,128,132,133] One of the best studied examples of this is the mossy fiberâ€"CA3 synapse in the hippocampus. At this synapse, presynaptic KARs modulate glutamate release in a bidirectional manner; low KAR agonist concentrations in the nM range increase glutamate release, whereas larger concentrations in the ÂµM range depress the synaptic response. Furthermore, these kainate autoreceptors may sense synaptically released glutamate and play a role in frequency-dependent facilitation.[29,75,133] The hippocampal CA3-CA1 is another excitatory synapse modulated by presynaptic KARs. KAR agonist application reduces glutamate release at this synapse by metabotropically inhibiting calcium influx at the terminal.[24,29,55] Depolarization of the presynaptic terminals is not necessary for the reduction in glutamate release. This appears to be in contrast to the actions of presynaptic KARs at the mossy fiberâ€"CA3 synapse. This has led some to suggest that modulation of transmitter release by KARs could obey different mechanisms and rules at different synapses.[78]

Presynaptic KARs have also been found to modulate the release of Î³-aminobutyric acid (GABA).[3,9,14,30,62,85,99,109,125,126,127,137] KAR agonists depress evoked inhibitory postsynaptic currents (IPSCs) and reduce the frequency of miniature IPSCs as recorded in CA1 PYR neurons of the hippocampus.[125] Pertussis toxin can prevent this effect, which suggests that depression of GABA release at this synapse may occur via presynaptic KARs acting through a G-proteinâ€"coupled cellular cascade.[126] However, KARs do not always act to depress the release of GABA. In the CA1 interneurons of the hippocampus, activation of a separate population of KARs that are likely to be localized to the soma or axon can increase spontaneous GABA release by increasing action potential firing frequency.[32,52,54,106,127] Additionally, the activation of presynaptic KARs at synapses between inhibitory interneurons enhances GABA release.[30] Furthermore, presynaptic KARs have been found to exert a concentration-dependent bidirectional control of GABA release in the rat amygdala.[15]

This effect is similar to the aforementioned bidirectional control of glutamate release. These effects of presynaptic KARs on GABA release can be mediated by glutamate released from neighboring excitatory terminals under normal physiologic conditions.[99] Taken together, the control of GABA release by KARs may be heterogeneous, again ultimately depending on the properties of the GABA-releasing synapse.[78]

Pharmacology

The distinction between AMPA and kainate receptors was initially somewhat blurred because both AMPA and KA can activate both types of receptors. However, there are differences in the potency of each agonist at the different receptor subtypes. Whereas the order of agonist potency at AMPA receptors is: Quisqualate > domoic acid ~AMPA > glutamate > KA, the order for at least some molecular forms of the kainate receptor is: Domoic acid > KA > glutamate > AMPA.

Advances in the development of AMPA and KAR selective antagonists, along with the development of KAR knockout mice, have recently and dramatically increased our understanding of the structure, function, regulation, and pharmacology of these subtypes of iGluRs. In particular, the 2,3-benzodiazepines have been found to be fairly selective for AMPA receptors, and the use of these compounds have helped to reveal the functional expression of KARs on a variety of neuronal cell types. In addition, a number of decahydroxyisoquinoline carboxylate molecules have recently been developed and serve as subunit-selective KAR antagonists. However, these antagonists, (e.g., LY382884 and LY294486) are somewhat selective within the KAR family and mostly block GluR5 subunits. Thus, their utility is somewhat limited to those receptors containing the GluR5 subunit. With regard to epilepsy, a novel anticonvulsant, topiramate, in addition to its other actions on GABA receptors and sodium channels, has been found to effectively block GluR5-containing receptors in the amygdala.[58]

Many neurons that are subject to cell death following KA-induced status epilepticus also have an abundance of postsynaptic KA receptors. Perhaps the most studied synapse to date in this regard is the mossy fiberâ€"CA3 synapse of the hippocampus. CA3 pyramidal cells are highly susceptible to seizure-induced cell death in human and animal models of TLE, and have a prominent postsynaptic KAR component to the EPSC. Additionally, mossy fiber also contains presynaptic KARs. Activation of these receptors can enhance glutamate release and further contribute to excitotoxicity of CA3 cells during periods of excessive activation, as seen during seizure activity. In addition, knockout mice with targeted deletions of the GluR6 subunit are not as susceptible to the deleterious effects of kainate.[105] The CA3 neurons have a greatly reduced sensitivity to the exogenous application of kainate, and the mice are resistant to systemic KA-induced seizures and do not exhibit the same cell death patterns or astrogliosis as the littermate controls. Therefore, it is becoming increasingly clear that KA receptors play an important role in epilepsy.

Regulation of KA Receptor Subunit Expression

Anatomic Distribution.

In situ hybridization and immunohistochemical studies have led to the discovery of different distributions throughout the brain for mRNA encoding GluR5 through GluR7. In contrast to GluR5 and -6, GluR7 is not found in most of the hippocampus, although it has been found in the granule cells of the dentate gyrus.[11,12,46] GluR7 mRNA is also quite abundant in the caudate-putamen, but GluR5 is absent from this region. Of particular interest is the finding that mRNA for both GluR6 and -7 is present in high abundance in brain regions that have been found to be profoundly sensitive to destruction following KA treatment. These areas include the hippocampus, cortex, and reticular thalamic regions.

KA1 is expressed at high levels in only CA3 pyramidal cells and dentate granule cells, whereas KA2 is found in virtually all brain regions. Some evidence supports the hypothesis that the KA2 receptor is co-expressed in some areas with GluR6 and -5, and that KA1 may be coexpressed with GluR6 in the hippocampus.

KARs have been found at both postsynaptic and presynaptic locations. At many postsynaptic sites, KARs have been found to contribute substantially to the overall EPSC, thus suggesting that these receptors are colocalized with both AMPA and NMDA receptors. Activation of KARs at presynaptic sites can regulate neurotransmitter release. Activation of the receptor can open the ion channels as well as signal the G-protein, and it has recently been shown that the KA2 subunit is necessary for the G-proteinâ€"mediated effects of receptor activation at the mossy fiberâ€"CA3 synapse.[130]

Developmental Regulation.

Protein for all five KAR subunits has been identified as early as embryonic day (E)14 in the rat brain, and in situ hybridization studies have demonstrated that each of the subunits of the KAR can undergo specific changes in expression levels throughout the brain over the course of development. There is widespread and heterogeneous distribution of the receptor subunits in the adult animal, and the stoichiometry of the receptors in individual cell types is diverse and still under investigation. The GluR5 subunit is expressed at lower levels in the adult brain than in the young animal, and is ultimately found in dorsal root ganglion cells, the septum, subiculum, and a variety of cortical regions.

The GluR6 subunit is found at its highest levels in the cingulate cortex, granule cells, and CA3 and CA1 pyramidal cells in the hippocampus. GluR7 subunit expression also decreases throughout the course of development, but can be found in the striatum and throughout the cortex and hippocampus. KA1 subunit expression also decreases throughout development and is found ultimately in the CA3 pyramidal cells and subiculum. Finally, KA2 is highly expressed throughout the brain throughout development.[77]

At thalamocortical synapses, postsynaptic KARs are present early on in development, whereas postsynaptic AMPA receptors develop a little later and ultimately comprise the majority of thalamocortical synapses after postnatal day (P)7.[8] KARs have also been found on migrating axons, and the activation of these presynaptic receptors can either increase or decrease axonal motility, depending on the concentration of kainate.[77] Therefore, early expression of presynaptic KARs may have functions other than the regulation of transmitter release.

Trafficking and Associated Proteins.

Following assembly of dimers in the endoplasmic reticulum (ER), KARs are sorted and delivered to various locations within the cell. KA2 and GluR5c will remain in the ER unless paired with other subunits due to an ER retention sequence on the subunit. The C-termini of many of the KARs have PDZ-domain binding sites, which suggests that PDZ proteins such as PSD-95, GRIP/ABP, and protein interacting with C kinase 1 (PICK1) may also be involved in trafficking of these receptors to the plasma membrane and postsynaptic sites. GluR6a, GluR5b, and GluR5c contain PDZ-binding domains and, although deletion of that portion of the C-terminal does not interfere with the delivery of the receptors to the plasma membrane, it does prevent the proper insertion into the synapse.[79]

KA Receptors and Seizure Activity

Many iGluR subunits have been found to be altered in specific cell types and in selective brain regions from patients with epilepsy. Therefore, it comes as no surprise that this has been shown to be the case for KARs as well. For example, Kortenbruck and colleagues have demonstrated that there is a significantly increased editing efficiency at the Q/R site for both GluR5 and -6 receptors in patients with TLE.[74]

Recent work from Ben-Ari's laboratory[48] demonstrated that mossy fiber sprouting in the KA model of TLE results in excitatory synapses in granule cells that utilize KARs, a situation not found in the control, unsprouted granule cells. It is not clear what role in seizure generation these new synapses play, but nonetheless, the new appearance of postsynaptic KARs in pathophysiology further links these receptors to epilepsy.

NMDA Receptors

Molecular Biology

As with the non-NMDA receptors, cloning of a variety of NMDA receptor subunits has revealed a great diversity of receptors. Three subfamilies of NMDA receptors have been identified: NR1, -2, and -3. Eight splice variants of the NR1 receptor (with the presence of three inserts) have been identified, whereas NR2 has four separate subunits (Aâ€"D) encoded by four separate genes.[59] Two subunits of the NR3 family of NMDA receptors have been identified and found to be expressed in the CNS: NR3A and NR3B.[25,146]

Homomeric channels formed from the expression of NR1 mRNA are fully functional, having the typical pharmacology of NMDA receptors. That is, they require the presence of glycine for activation, and a voltage-sensitive block by extracellular magnesium ions (Mg^{2+}) occurs. However, the currents observed from homomeric channels are quite small; this has been interpreted to mean that native receptors likely have additional subunits.[41,103]

Unlike homomeric NR1 receptors, homomeric NR2 receptors do not form functional ion channels. When each of the four NR2 receptors, Aâ€"D, are individually co-expressed with the NMDA receptor (NMDR)-1 receptor, functional channels are observed with large conductances and appropriate pharmacology. Variations in both NR1 and -2 subunits have profound effects on NMDA receptor pharmacology and physiology. For example, one splice variant of NR1 confers sensitivity to polyamines. In addition, heteromeric receptors are sensitive only to the stimulating effect of polyamines if they are composed of NR1A (lacking the N-terminal insertion) and NR2B.[161] Similarly, sensitivity to the coagonist effects of glycine and Mg^{2+} are quite subtype-specific. These factors could have great implications in considering the roles of NMDA receptors in epileptogenesis and in trying to target these receptors for the development of new antiepileptic drugs.

Expression studies in human embryonic kidney (HEK)-293 cells have demonstrated that the NR3A subunit requires the expression of the NR1a subunit for proper assembly and insertion into the membrane. In addition, the presence of the NR3A subunit in combination with the NR1 and NR2A subunit results in a decrease in the single-channel conductance of the NMDA receptor.[25,36,118,146] Consistent with this finding, studies in mice lacking the NR3A gene have demonstrated that whole-cell currents induced by the exogenous application of NMDA are increased. In addition, mice lacking the NR3A subunit were also found to have an increase in dendritic spine density in cortical neurons, suggesting that the NR3 subunit can play role in the development of postsynaptic structures.[36]

Even less is known about the NR3B subunit, which has only recently been cloned.[112] This subunit is expressed in motor neurons located in the spinal cord and some brainstem nuclei. Functional channels containing this subunit occur only when both the NR1 and NR2a subunits are expressed. In a manner similar to NR3A, expression of NR3B results in a decreased conductance through the NMDA receptor.[112] Thus it would appear that the presence of either NR3 subunit will downregulate current flow through the NMDA receptor-gated ion channel. It is currently unknown whether the NR3 receptor subunits are expressed at native synapses.

Electrophysiology

At hyperpolarized membrane potentials, activation of the NMDA receptor does not result in current flow through the channel. This is because, at hyperpolarized potentials, extracellular Mg^{2+} will block the channel.[114] However, at more depolarized potentials, Mg^{2+} will be expelled from the channel, and both monovalent and divalent cations (most notably, calcium), can flow through the channel. The permeability of the channel to calcium underlies the great interest in this EAA receptor. The entry of calcium through this channel signals a biochemical cascade, resulting in the development of both LTP and LTD at many synapses (see Chapter 35). The increasing activation of the NMDA channel at depolarized membrane potentials serves as a positive feedback mechanism or amplification mechanism at excitatory synapses. As a postsynaptic cell is depolarized, more current will flow through the NMDA receptorâ€"channel and, therefore, more depolarization will result.

The behavior of the activated NMDA receptorâ€"channel complex differs dramatically from that of the non-NMDA receptors. Activation of the channel is much slower, with the time to the peak current being often tens of milliseconds. Desensitization at NMDA receptors during the exogenous application of agonist takes several hundred milliseconds to develop, whereas desensitization at AMPA receptors occurs within

P.240

5 to 10 msec. The mechanism of desensitization of this receptor (and the determination of whether the receptor desensitizes at all during synaptic events) has been controversial. Desensitization has been attributed to the absence of glycine, such that when glycine is present in high concentrations, desensitization is

prevented.[94] Other evidence, however, suggests that glycine plays no role in desensitization.[63] In addition, a calcium-dependent desensitization has also been described.[26]

Another difference between non-NMDA and NMDA receptors is the voltage-sensitive block of Mg^{2+} at the NMDA receptor. The IV relationship of NMDA receptors has a region of negative slope resistance at hyperpolarized potentials, whereas the IV relationship for non-NMDA receptors is linear. In addition, single-channel experiments have revealed that once agonist has bound to the NMDA receptor, the channel can open and close repeatedly for up to several hundred milliseconds, resulting in long-lasting currents.[81] Single-channel experiments have also revealed that the primary conductance state for NMDA channels is approximately 50 pS, although transitions to lower conductance states have been observed.[34,35]

Pharmacology

The NMDA receptor has been studied extensively, especially once it was determined that activation of this EAA receptor underlies different forms of synaptic plasticity in a number of systems. Agonists at the NMDA receptor include NMDA, glutamate, and a variety of other EAAs. As with AMPA and kainate receptors, NMDA receptors possess two agonist-binding sites.[27] Specific antagonists at the glutamate-binding site include DL-2-amino-5-phosphonovalerate (APV) and its family, as well as 3-([Â±]-2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP) and its structurally related family. Of particular interest to the NMDA receptors is the fact that it is the only EAA receptor that has an absolute requirement for a coagonist, glycine.[64,72] If the glycine site on the receptor is blocked or unoccupied, binding of glutamate to the receptor will not result in the channel opening. In addition, it seems that, at least in adult rat forebrain, the glycine site of the NMDA receptor is not always saturated, depending on the subunits expressed and the location of the synapse in question.[23,159] Therefore, regulation of glycine concentrations may be critical to the regulation of excitatory synapses. In addition to its coagonist requirement, the NMDA receptor has been shown to be modulated by Mg^{2+}, H^{+}, Zn^{2+}, polyamines, steroids, and an oxidationâ€“reduction site.[114,144,150,161] Modulation at all these sites represent potential therapeutic targets for the symptomatic treatment of epilepsy.

It was hoped that novel anticonvulsants could be developed to selectively target subunits of NMDA receptors. However, NMDA receptor antagonists are not generally well tolerated, exhibiting a number of adverse effects. Of the newer-generation anticonvulsants, only felbamate has been found to partially block NMDA receptors. However, felbamate is a broad-spectrum compound with multiple modes of action, so it is not felt that the NMDA antagonism can directly explain the efficacy of felbamate.

Regulation of NMDA Receptor Subunit Expression

Anatomic Distribution and Cellular Localization.

In situ hybridization studies have demonstrated that mRNA encoding the NR1 subunit is expressed in almost all neurons in the CNS, although the individual splice variants tend to be more localized.[101,103] However, the various NR2 subunits (Aâ€“D) are more differentially localized to specific brain regions. For example, the NR2A and -2B subunits are highly expressed in cortical and hippocampal regions, whereas the NR2C subunit is not expressed in these regions. The NR2D subunit is preferentially expressed in olfactory bulb and lower brainstem regions, whereas NR2C is found in the cerebellar granule cell layer.[101]

Developmental Regulation.

Although the NR1 subunit is ubiquitously present at birth, considerable developmental regulation of NR2 subunits has been described. In rats, the NR2B receptor subunit is present at birth, whereas the NR2A subunit is not expressed until sometime after the second postnatal week. The NR3A subunit has also been shown to be developmentally regulated. Expression of this subunit is high throughout the rat brain during the first few weeks of postnatal life, although in the adult animal, expression occurs only within specific nuclei of the thalamus, amygdala, and lateral olfactory tract.[25,146]

Trafficking and Associated Proteins.

Tremendous advances have recently been made in our understanding of the regulation of NMDA receptor trafficking and, not surprisingly, many of the same basic processes in play for AMPA and KARs are involved in trafficking NMDA receptors as well. Following assembly in the ER, proteins with PDZ-domain binding sites interact with the NR2 subunits to traffic the receptor to the membrane. In particular, PSD-95 is thought to bind the NMDA receptor and, through an interaction with kinesin, deliver the assembled receptors to the membrane. Delivery of the receptor appears to be NR2 subunitâ€"dependent, with NR2B subunitâ€"containing receptors delivered and inserted to extrasynaptic regions and NR2A-containing receptors delivered and inserted into the synapse. NR2B-containing receptors are free to diffuse to the synapse as needed, and the rate of exocytosis and endocytosis of these receptors is substantially higher than for receptors containing NR2A subunits.[123]

Although a vast number of proteins have been identified that directly interact with the NMDA receptor, perhaps one of the most important of the associated proteins is calmodulin-dependent protein kinase II (CamKII). Activation of this kinase is critically important for long-term plasticity to occur at excitatory synapses, and it is directly linked to signaling mechanisms involved in regulating AMPA receptor number at the synapse. The regulation of second-messenger signals subsequent to activation of NMDA receptors and Ca^{2+} influx is continuing to be studied with great interest, and future therapies for seizure disorders may ultimately involve the regulation of proteins associated with iGluRs, rather than direct modulation of the receptorâ€"ion channel complexes.

NMDA Receptors and Seizure Activity

The importance in NMDA receptors for the initiation of long-term changes in various models of synaptic plasticity, along with the ability of NMDA antagonists to block seizure activity in many animal models, has led to the suggestion that excessive activation of these receptors can underlie seizure generation. In addition, the presence of NR2B subunits at synaptic sites can lead to prolonged EPSPs with substantial calcium influx, contributing to hyperexcitability in the developing brain. Therefore, the role of the NMDA receptor in epilepsy has been extensively explored.

Recently, several groups have identified a number of changes in NMDA receptor expression and function in human tissue resected from patients with cortical dysplasia. Alterations in NMDA receptors have also been identified in several animal models of cortical malformations, leading to the hypothesis that, in some cases, altered excitatory synaptic function in these cortical circuits could contribute to the observed hyperexcitability.[4,21,33,107] Likewise, a number of alterations in NMDA receptor expression and function have been identified following kindling and in resected human tissue from patients with TLE. How these changes ultimately result in seizure activity remains to be determinedâ€"indeed, whether these changes are either compensatory or contributory still must be established. However, future work will undoubtedly contribute to our understanding of the role of the NMDA receptors to seizure activity.

Metabotropic Excitatory Amino Acid Receptors

The EAAs are also capable of activating a group of receptors that are coupled via second-messenger systems to biochemical pathways and ion channels. These have been called metabotropic glutamate receptors (mGluRs). Based on sequence homology, coupling to different second-messenger systems, and the pharmacology of presently available agonists and antagonists, three separate groups of mGluRs have been established: Groups I, II, and III. These receptors, unlike their inotropic counterparts, are not comprised of subunits that form an integral ion channel; instead, they are comprised of polypeptides that have a putative seven-transmembrane spanning domain with a large extracellular NH2 terminal region. When an agonist binds to the mGluRs, activation of a variety of G-proteins occurs. This G-proteinâ€"coupled activation then results in a diverse biochemical cascade that can result in the modulation of a variety of cellular functions, such as current flow through voltage-gated ion channels. Within the three groups of receptors, eight subtypes of the mGluRs have been cloned, and these correspond to a novel gene family of G-proteinâ€"coupled receptors.[59,110,113] In addition, a number of splice variants have been identified for mGluR1, -4, -5, -6, -7, and -8, leading to a great diversity of potential mGluRs.

Activation of this class of glutamate receptors has been implicated in a variety of CNS functions, including different forms of synaptic plasticity and excitotoxicity. However, until recently, mGluRs have been difficult to study due to the overall lack of and/or availability of specific receptor antagonists and agonists. As was the case for iGluRs, the physiologic functions of the mGluRs are beginning to be deciphered as transgenic animals become available.

This section summarizes what is presently known concerning the pharmacology, anatomic distribution, and role of the three groups of these G-proteinâ€"coupled EAA receptors in synaptic transmission, plasticity, and epilepsy. However, for more in-depth coverage of these topics, the reader is encouraged to see some excellent recent reviews.[69,113]

Group I mGluRs

Group I receptors include the mGluR1 and mGluR5 receptors. The mGluR1 receptor is further characterized by the existence of six splice variants; there are two splice variants for the mGluR5 receptor. Selective agonists, with the ranking of the relative potency, include quisqualate > glutamate > ibotenate > trans-1-aminocyclopentane-1,3-dicarboxylate (tACPD).[59] Upon binding of the ligand to the receptor, inositol triphosphate (IP3) and diacylglycerol (DAG) formation is increased, intracellular calcium is mobilized, and arachidonic acid is released. The G-proteins that couple the receptor to the effector mechanisms are pertussis toxinâ€"sensitive for mGluR1.[1,5,69]

In situ hybridization studies have revealed that the mRNA encoding for Group I mGluRs is highly abundant in the CA2 and CA3 cell layers of the hippocampus. However, although mRNA for mGluR1 is found to be highly expressed in Pur- kinje cells of the cerebellum, mGluR5 is not present at all in these cells. Likewise, although CA1 cells of the hippocampus have mGluR5 mRNA, these same neurons have virtually no detectable mRNA for mGluR1.[1,89] Although both mGluR1 and -5 are coupled to the same effector system, only activation of mGluR5 results in the induction of hyperexcitability and epileptiform activity in hippocampal brain slices. However, activation of both mGluR1 and -5 is required to maintain this electrographic behavior. It is intriguing to note that antago-nists of both mGluR1 and -5 can act as anticonvulsants[100] in a variety of animal models as well.[96,97,98]

Group II mGluRs

Group II mGluRs include the mGluR2, -3, and -8 subtypes of the receptor family. Unlike Group 1 receptors, activation of Group II mGluRs results in the suppression of forskolin-stimulated cyclic adenosine monophosphate (cAMP) accumulation.[148,149] The agonists, in the relative order of potency for this group, include: Glutamate > tACPD = ibotenate > quisqualate.[59] The actions of all members of this group are blocked by pertussis toxin. Activation of receptors in this group, as well as those of Group III, often results in a decrease in neurotransmission at both glutamatergic and GABAergic synapses. A rather specific antagonist at both Group II and Group III receptors has been identified: $^{+}$-Î±-methyl-4-carboxyphenyl-glycine (MCPG).[44] This antagonist can block the decrease in neurotransmission observed in the presence of tACPD.[87] Although somewhat controversial, it is believed that activation of tACPD-sensitive receptors may play a role in the development of both LTP and LTD in various regions of the brain.

In situ hybridization studies have determined that the mGluR2 receptor is abundantly expressed in Golgi cells of the cerebellum and granule cells in the accessory olfactory bulb. This receptor type is also abundant in the neocortex and hippocampus. The mGluR3 mRNA is also highly expressed in the neocortex and hippocampus.[149] In a developmental model of epilepsy, recent work using a novel Group II agonist, (2R,4R)-4-aminopyrrolidine-2,4-dicarboxylate (2R,4R-APDC), has demonstrated that the activation of these receptors can be both neuroprotective and anticonvulsant.[149]

Group III mGluRs

The mGluRs considered members of Group III include mGluR4, -6, and -7.[69,108] As with the activation of Group

II receptors, activation of those in this group results in a reduction of forskolin-stimulated increase in cAMP production.[69] However, these receptors are specifically activated by the selective agonist L-2-amino-4-phosphonobutyrate (L-AP4). These receptors are also activated following binding of both glutamate and tACPD. MCPG acts as a potent antagonist at these receptors. mGluR4-mediated activation of G-proteins is blocked by pertussis toxin, but mGluR6-mediated activation is not.

mGluR6 mRNA is found exclusively in the retina, and evidence suggests that mGluR4 is present in both the retina and cerebellum. mGluR7 is widely distributed throughout the brain. mGluR6 is involved in signal transduction from photoreceptors to on-bipolar neurons in the retina, whereas mGluR4 and -7 may be involved in regulating neurotransmitter release.[115,148] Indeed, recent evidence also suggests that agonists of mGluR4 can also be useful for protection against seizure activity.[88]

Role of mGluRs in Epileptic Activity

Many, if not all, neurons in the CNS appear to have mGluRs on axon terminals, where they mediate presynaptic modulation. In addition, activation of postsynaptic receptors may cause direct depolarization and modulation of intrinsic currents. Activation of mGluRs most often results in presynaptic inhibition and postsynaptic excitation and, thus, the net effect may be variable, brain site-specific, and may depend on the distribution of the various receptor subtypes and their cellular locations. It is not surprising, therefore, that activation or inhibition of these

receptors may modulate epileptiform activity. Data suggests that mGluRs may be involved in the transition between interictal and ictal behavior in the amygdala[6] and in the maintenance of interictal activity in the hippocampus.[95] In the neocortex, mGluR activation may have both suppressive and stimulatory effects, presumably based on different receptor subtypes, and this may also be developmentally regulated.[19,20] As more is learned about the pharmacology of these receptors, as subtype-specific agonists and antagonists and as transgenic animals with targeted deletions of the mGluRs become even more available, it is possible that a new class of antiepileptic drug could emerge that would selectively enhance the suppressive effects or inhibit the stimulatory effects of mGluR activation.

Summary and Conclusions

Synaptic excitation plays a critical role in essentially every function that the CNS is designed to perform. Small transient perturbations in the efficacy of excitatory transmission or in the balance between excitation and inhibition can lead to a seizure. Permanent changes in excitatory synaptic efficacy, or changes in local recurrent excitatory circuitry, can lead to a hyperexcitable state that we call epilepsy. The molecular mechanisms that underlie excitation at the biophysical and pharmacologic levels are beginning to be unraveled. Individual AMPA, kainate, and NMDA receptorâ€"channel complexes can be analyzed, and their subunits characterized. Metabotropic glutamate receptors and their associated G-proteins, which appear to serve as modulatory elements at both excitatory and inhibitory synapses, are also being identified. The circuits within which all these receptors play their critical roles are being characterized, and changes that occur in epileptic brains are being identified. Each of these areas holds the potential for developing new strategies either to prevent the development of epileptic circuits or to target highly specific agents to interfere with the development of epileptic events, even if an epileptic propensity exists in an injured tissue.

Chapter 23

GABA$_A$ and GABA$_B$ Receptor-Mediated Inhibitory Synaptic Transmission

Robert L. MacDonald

Istvan Mody

Introduction

The neurotransmitter Î³-aminobutyric acid (GABA) is the most abundant inhibitory neurotransmitter in the central nervous system (CNS). GABAergic inhibition is the primary form of fast inhibition in the forebrain, and can mediate both presyn- aptic and postsynaptic inhibition. GABA-mediated presynaptic inhibition occurs when GABAergic nerve terminals release GABA onto presynaptic nerve terminals, resulting in a reduction of neurotransmitter release. In contrast, GABAergic postsynaptic inhibition is mediated by the interaction of the neurotransmitters with specific postsynaptic receptors. GABA binds to two distinct types of GABA receptor, GABA$_{A,C}$ receptors and GABA$_B$ receptors, to produce neuronal inhibition. GABA$_A$ and GABA$_C$ receptors are ligand-gated chloride ion (Cl^-) channels from the cys loop family of receptors, and GABA$_B$ receptors are seven-transmembrane domain receptors from the G-proteinâ€"coupled receptor (GPCR) family. Reduction of GABAergic inhibition because of mutation of GABA$_A$ receptors has been shown to be associated with several types of idiopathic generalized epilepsies, including childhood absence epilepsy, generalized epilepsy with febrile seizures plus, and juvenile myoclonic epilepsy.[70,71] Enhancement of GABAergic inhibition is the basis of action of a number of antiepileptic drugs (AEDs).

Î³-Aminobutyric Acid

GABA is synthesized in and released from the presynaptic terminals of GABAergic neurons. Glucose is the primary precursor of GABA, but pyruvate and other amino acids can also serve as precursors when metabolized in the Krebs cycle.[79] The immediate precursor of GABA is glutamate, which can be produced from glutamine by glutamate synthetase or from Î±-ketoglutarate. Glutamic acid is then decarboxylated to form GABA. GABA is degraded by the enzyme GABA transaminase. GABA transaminase converts GABA into succinicsemialdehyde. This reaction involves removal of an amine group from GABA and transformation of Î±-ketoglutarate into glutamate. Therefore, as the GABA is degraded, its precursor molecule is formed, ensuring precursor availability for further synthesis. Succinicsemialdehyde is then degraded by the enzyme succinicsemialdehyde dehydrogenase (SSADH) to form succinic acid. This synthetic and catabolic pathway is called the *GABA shunt*. The shunt is thought to operate by an interaction with adjacent glia. GABA is released presynaptically and is taken up by high-affinity GABA transporters in nerve terminals and glia. In glia, GABA is degraded to succinicsemialdehyde, thus generating glutamate. Glutamate is then converted to glutamine by glutamine synthetase. It is believed that glutamine can then diffuse from the glia into nerve terminals, where it then again converted by glutaminase into glutamate, thus providing a substrate for GABA synthesis. GABA transaminase and SSADH are thought to be bound to mitochondria, whereas glutaminase and GAD are free in the terminal cytoplasm. Glutamine synthetase occurs free in the glial cytoplasm.

GABA$_A$ Receptors

GABA$_A$ receptors are macromolecular proteins from the cys loop family of ligand-gated ion channels that include the nicotinic acetylcholine receptor (nAChR), glycine receptor, and serotonin 5â€“HT$_3$ receptor. GABA$_A$ receptors contain multiple specific binding sites including sites for GABA, antagonists such as bicuculline and picrotoxin, AEDs including barbiturates and benzodiazepines, and the anesthetic steroids. GABA$_A$ receptors form a Cl$^-$-selective channel.[73,90]

GABA$_A$ Receptor Molecular Biology

GABA$_A$ receptors are hetero-oligomeric pentamers that form a transmembrane Cl$^-$channel. Seven GABA$_A$ receptor subunit families (Î±, Î², Î³, Î´, Ï€, Îµ, Î¸) have been identified,[90] and each subunit family is composed of one or more subtypes: (Î±1â€“Î±6), (Î²1â€“Î²3), (Î³1â€“ Î³3), (Î´1), (Îµ1), (Ï€1), and (Î¸1). In addition, several splice variants have been reported. An additional subunit, the Ï subunit, is highly homologous to the GABA$_A$ receptor subunits but primarily forms retinal receptors that have been classified as GABA$_C$ receptors. Members of the same GABA$_A$ receptor family share approximately 70% to 80% sequence homology, whereas members of different families share 30% to 40% sequence identity. The number of potential GABA$_A$ receptor isoforms that could be formed from the 12 Î±, Î², and Î³ subtypes alone is staggering. However, it has been demonstrated that not all potential subtype combinations assemble to create functional GABA$_A$ receptors,[3,4] and the Î±1Î²2Î³2 receptor is likely the dominant native benzodiazepine-sensitive isoform. The stoichiometry of native GABA$_A$ receptors has shown to be 2Î±2Î²1Î³, with an assembly pattern of Î³-Î²-Î±-Î²-Î±, as seen from the synaptic cleft.[6,26,57,110]

GABA$_A$ Receptor Structure

GABA$_A$ receptor subunits are about 450 amino acids in length and have a large N-terminus of approximately 200 amino acids that is shaped by the signature cysteine disulfide bridge and is likely an extracellular domain. The GABA binding site is at the two Î±/Î² subunit interfaces.[101] Hydropathy analysis predicted four transmembrane-spanning domains (M1â€“M4) of about 20 amino acids in length, which have the highest degree of amino acid sequence homology across subunit

families and across the cys loop family in general. The M2 domain is thought to form the GABA$_A$ receptor channel pore.[26] A short (eight amino acids) cytoplasmic segment (M1â€“M2 linker) connects M1 and M2, and a slightly longer extracellular segment (M2â€“M3 linker) connects M2 to M3. Also, a highly variable large cytoplasmic loop spans between M3 and M4 and contains consensus sequences for protein phosphorylation and proteinâ€“protein interaction that vary among subtypes. This domain is important for receptor trafficking and surface clustering through interactions with cytoplasmic proteins.

GABA Binding Site

Detailed structural information is available for the extracellular domain of cys loop receptors based on homology with the acetylcholine binding protein (AChBP),[100] which has been crystallized and solved.[21] The acetylcholine-binding pocket is formed at AChR subunit interfaces by three loops (Aâ€“C) from the positive side and three Î²-strands (Dâ€“F) from the negative side of the protomer. Using mutagenesis and the substituted cysteine accessibility method (SCAM) approach,[1,15,48,86,120] the GABA$_A$ receptor binding pocket has been shown to be similar to that of the AChBP binding pocket.

GABA$_A$ Receptor Conduction Pathway

M2 likely lines the channel, and the amino acids lining the pore are likely Î± helical[126] as is the nAChR M2.[82] Using electron microscopy of crystalline postsynaptic membranes, the nAChR channel has been shown to be tapered, as viewed from the synaptic cleft, and is formed by five Î±-helical segments.[82] The pore has a minimum diameter in the middle of M2 at residues L251 and V255, and this region has been identified as the channel gate.[82] GABA$_A$ receptors also have a 9â€²L in the middle of M2, and mutation of the M2 9â€²L causes destabilization of the closed state,[13] similar to the nAChR. Thus, the GABA$_A$ receptor gate is likely to be similar in location to that of the nAChR.

Coupling of GABA Binding to Channel Gating

Recent insights have emerged into the coupling of binding of GABA to GABA$_A$ receptors and subsequent gating of the channel. The extracellular N-terminal domain is directly connected to the membrane by M1; however, evidence from several sources has suggested that the N-terminal domain also interacts with the extracellular M2â€“M3 linker. Several disease mutations in the M2â€“M3 linker have been identified. In the nAChR, these mutations are associated with congenital myasthenic syndromes[38]; in the GABA$_A$ receptor, they are associated with a generalized epilepsy[7,14]; and in the glycine receptor, these mutations are associated with hyperekplexia.[61] All these mutations decreased receptor current, suggesting a disruption in the coupling of agonist binding to channel gating. Based on the AChBP, it was suggested that loop 2 (and possibly loop 7) interact with the M2â€“M3 linker to couple GABA binding to gating.[54] Using SCAM, gating was shown to induce a conformational change in and/or around the N-terminal half of the M2â€“M3 linker.[9] Using mutagenesis of pairs and triplets of amino acids in the nAChR Î± subunit, a network of interacting amino acid residues have been shown to connect the preM1 region, loop 2, and the M2â€“M3 loop.[64] Thus, coupling of agonist binding to channel gating may involve both direct (pre M1) and indirect (loop 2) pathways that connect to the M2â€“M3 loop. The gating process has been further clarified using electron microscopy of nAChRs.[82,116] Loop 2 of both Î± subunits is positioned such that it contacts the distal M2, just before the beginning of the M2â€“M3 loop. Binding of ACh induces both loop 2s rotate by 15 degrees about an axis passing through the disulfide bridge, normal to the membrane. The loop 2 rotations are associated with M2 rotations, which are translated down M2 to the gate, presumably causing the gate to open. Thus the major transduction of binding to gating appears to pass in the Î± subunits from loop 2 to the distal M2 and then to the M2 gate.

GABA$_A$ Receptor Desensitization

Receptor desensitization occurs when agonist-evoked current declines during continued agonist application. No clear structural basis exists for desensitization of cys loop receptors. Desensitization of nAChRs has been studied using the SCAM technique.[124] The â€œdesensitization gateâ€ was suggested to include the closed gate, but to extend further (more toward the extracellular portion) into M2. GABA$_A$ receptor subunit composition influences current desensitization rates.[37,97,117] In glycine receptors, desensitization is influenced by amino acids at the distal end of M1, leading to the hypothesis that this region and the M1â€“M2 linker served as a hinge involved in the gating of the channel.[69] Using subunit chimeras constructed with N-terminal Î´ sequence spliced to Î³2L sequence at various points within M1 and M2, and using rapid agonist application, fast desensitization was demonstrated to depend on the structure of M1 and proximal N terminus.[12]

GABA$_A$ Receptor Pharmacology

GABA$_A$ receptor pharmacology has been shown to be quite complex.[73,90] To fully activate the receptor, two molecules of GABA are required to bind to two independent sites on the GABA$_A$ receptor channel at the two Î±/Î² interfaces. In addition to GABA, a number of GABA analogs can activate the receptor, including the plant alkaloid muscimol and the synthetic GABA agonist tetrahydroisoxazolopyridinol (THIP). GABA$_A$ receptor currents can be competitively antagonized by the convulsant drug bicuculline and noncompetitively antagonized by the convulsant drug picrotoxin. GABA$_A$ receptor current can also be noncompetitively reduced by the convulsant antibiotic penicillin, which enters the GABA$_A$ receptor channel to produce a fast open-channel block. The antiepileptic benzodiazepines and barbiturates enhance GABA$_A$ receptor currents, but through different binding sites on the GABA$_A$ receptor. In contrast, the convulsant Î²-carbolines, such as methyl 6,7â€“dimethoxy-4â€“ethyl-Î²-carboline-3â€“carboxylate (DMCM), decrease GABA$_A$ receptor current. A number of compounds, including CL 218872, inverse agonist Î²-carbolines, and imidazolpyridines (zolpidem), bind to the benzodiazepine site. In addition to binding benzodiazepine receptor agonists, such as diazepam, and inverse agonists, such as DMCM, the receptor binds a benzodiazepine receptor antagonist, flumazenil, which binds to the receptor and antagonizes the actions of benzodiazepine receptor antagonists and inverse agonists but has little intrinsic activity. In addition to the preceding allosteric regulators, certain anesthetic and naturally occurring neuro- steroids, including alfaxalone, pregnenolone, and androsterone, alter GABA$_A$ receptor current. Most of these anesthetic steroid compounds bind to a specific site on the GABA$_A$ receptor to enhance current.

GABA$_A$ Receptor Physiology

GABA binds to GABA$_A$ receptors and evokes openings that occur in bursts.[74] When the channel opens, it opens to a main conductance level of 27 pS and to two smaller, subconductance levels.[16] GABA$_A$ receptor channels are permeable to a number of anions and exhibit a conductance sequence of Cl^->Br^->SCN^->F^-. GABA$_A$ receptor channels are almost exclusively Cl selective, with a permeability ratio of potassium (K) to Cl ions smaller than 0.05. The permeability sequence for large polyatomic anions suggests that open

P.247

GABA$_A$ receptor channels have effective pore diameters of about 5.6 Ã….

Rapid application of GABA to outside-out patches from hippocampal neurons or to HEK293 cells expressing Î±1Î²3Î³2L receptors evokes rapidly rising (1â€"2 msec) currents that then decay over three to four phases of desensitization.[14,25,45] Following GABA application, the currents deactivate over two phases. GABA$_A$ receptor subunit composition influences current desensitization rates.[14,37,97,117] For example, addition of the Î´ subunit to Î±1 and Î²3 subtypes significantly reduced both the rate and extent of desensitization relative to Î±1Î²3Î³2L receptor currents.[45]

Ensemble currents (whole cell or macropatch currents, inhibitory postsynaptic currents [IPSCs]) observed experimentally represent the summed behavior of individual channels. A complete mechanistic understanding of GABAergic inhibition requires analysis at the level of single channels. GABA$_A$ receptor single channels exhibit complex patterns of activity. GABA increases the probability of channel opening and, after the channel opens, it closes and rapidly reopens in bursts of openings. Increasing GABA concentration increases average open and burst durations. Detailed kinetic analyses of channel behavior have been obtained for native[74,87,115,122] and recombinant[23,39,45] GABA$_A$ receptors, demonstrating multiple open and closed states occurring in bursts. Kinetic models were proposed to account for these properties, with connections of discreet kinetic states (Markov modeling) and incorporating two sequential GABA binding sites, three open states, and ten closed states.[115]

Recombinant Î±1Î²Ï‡Î³2 receptors also exhibit multiple open and closed states.[3,39,45] However, Î±1Î²1Î´ GABA$_A$ receptors have different gating properties, with only two open states that are similar to the two briefest open states of native and Î±1Î²Ï‡Î³2 GABA$_A$ receptors. The model was used to interpret actions of modulators of GABA$_A$ receptor function, including benzodiazepines, barbiturates, neurosteroids, picrotoxin, penicillin, and Î²-carbolines.[111,112,113,114] Using rapid application of GABA to outside-out patches from hippocampal neurons, Celentano and Wong[25] demonstrated three desensitization phases. Jones and Westbrook[52] demonstrated that GABA$_A$ receptors entered long closed states and subsequently reopened, suggesting that desensitized states prolong currents evoked by brief, synaptic-like GABA applications. The combination of single-channel properties and macroscopic kinetic properties, not easily extractable from single-channel recordings (such as activation, desensitization, deactivation), led to a comprehensive GABA$_A$ receptor model.[45]

Channel gating and desensitization have also been shown to affect GABA binding. GABA is locked onto GABA$_C$ and GABA$_A$ receptors by channel opening[27] and, once bound to Î±1Î²3Î³2L GABA$_A$ receptors, GABA is â€œtrappedâ€ by open, preopen, and desensitized states.[14] This trapping of GABA on the receptor prolongs currents following brief GABA application, as occurs during IPSCs.[52] In contrast, it has been reported that ACh is not locked on nAChRs by open states.[43]

GABA$_A$ Receptor Anatomic Distribution and Development

The widespread and overlapping distribution of GABA$_A$ receptor subunit cDNAs identified using in situ hybridization[65,125] and the large number of subunits suggests that GABA$_A$ receptors exist in vivo in multiple isoforms. However, the colocalization of subtype mRNAs does not provide information on subunit assembly. Immunoprecipitation has been used to determine subtypes that coassemble in vivo.[50,89,94,95,108] In the cerebellum, the most likely isoforms are Î±1Î²Ï‡Î³2, Î±6Î²Ï‡Î³2, Î±1Î±6Î²Ï‡Î³2, Î±6Î²Ï‡2Î´, and Î±1Î±6Î²Ï‡Î´ receptors. The Î´ subunit is likely to combine with the Î±6 subtype in the cerebellum and with the Î±4 subtype in the thalamus, and based on coexpression, it may also combine with the Î±1 subtype in the cortex, thalamus, hippocampus, and olfactory bulb. Characterization of GABA$_A$ receptor subunit expression patterns using in situ hybridization has been reported in the developing[63] and adult[62,125] rodent brain. A detailed immunohistochemical study identified general anatomic patterns as well as cell-type specificity within regions and gross subcellular localization (soma versus neurite membranes).[94]

$GABA_B$ Receptors

$GABA_B$ receptors are seven-transmembrane proteins and are coupled to calcium (Ca) or K ion channels via guanosine triphosphate (GTP) binding proteins.[17,18,19] $GABA_B$ receptors are located on presynaptic terminals and on postsynaptic membranes. When activated by GABA presynaptically, $GABA_B$ receptors reduce synaptic transmitter release by decreasing presynaptic calcium entry; when activated postsynaptically, $GABA_B$ receptors produce slow postsynaptic inhibition by increasing K conductance.

$GABA_B$ Receptor Molecular Biology, Structure, and Trafficking

Two different $GABA_B$ receptor subunits have been cloned, the $GABA_{B1}$ and $GABA_{B2}$ subunits.[51,56,59,80,88,123] These subunits have an approximate length of 950 residues, and the $GABA_{B2}$ subunit has two splice variants, $GABA_{B1a}$ and $GABA_{B1b}$.[55] At the amino acid level, $GABA_{B1}$ and $GABA_{B2}$ subunits have approximately 35% identity and 55% similarity, and $GABA_B$ receptors are heterodimers composed of both $GABA_{B1}$ and $GABA_{B2}$ subunits. $GABA_B$ receptors are members of the GPCR superfamily; they have seven membrane-spanning domains and a long extracellular chain at the N terminus. Heterodimerization is required for successful trafficking of $GABA_B$ receptors to the cell surface and for effective agonist-induced activation.[24,42,77,92] The $GABA_{B1}$ subunit appears to be necessary for agonist activation, whereas the $GABA_{B2}$ subunit is involved in trafficking of the heterodimer to the cell surface. When exposed, a C-terminal arginine-based endoplasmic reticulum (ER) retention/retrieval signal, RSRR, results in the retention of unassembled $GABAB_{B1}$ subunits in the ER and prevents surface trafficking of heteromeric receptors. Interaction of C-terminal coiled-coil domains mask the RSRR retention signal motif in the $GABA_{B1}$ subunit and permit cell surface trafficking.[10,77,92] Agonist binds to the $GABA_{B1}$ subunit and produces a conformational change that permits the $GABA_{B2}$ subunit to activate G-proteinâ€"coupled signaling.

$GABA_B$ Receptor Pharmacology

$GABA_B$ receptors were initially defined as sites that were GABA sensitive but were not blocked by the $GABA_A$ receptor antagonist bicuculline.[17] Although GABA is undoubtedly the natural ligand for this receptor, a drug used to treat spasticity, Î²-p-chlorophenyl GABA (baclofen) was shown to be virtually inactive at $GABA_A$ receptors but stereo- specifically active at $GABA_B$ receptors. The active form of baclofen is the minus isoform. Since the identification of baclofen as a specific $GABA_B$ receptor agonist, a number of closely related analogs of baclofen and GABA also have been shown to be agonists. These compounds include Î²-hydroxy GABA, muscimol, 3â€"aminopropopolyphosphinic acid (3APPA), 3â€"aminopropyl (methyl)-phosphinic acid (3AMPA), and CGP44532. The phosphinic acid analogs are the most potent $GABA_B$ receptor agonists, often having affinities 10 to 100 times higher than baclofen.[4] Because $GABA_A$ receptor agonists

such as bicuculline and picrotoxin were inactive at $GABA_B$ receptors, it became important to develop specific $GABA_B$ receptor antagonists to study the effects of synaptic GABA interaction with $GABA_B$ receptors. The first GABA antagonist was the phosphonic derivative of baclofen, phaclofen. Although phaclofen is a very weak $GABA_B$ receptor antagonist, it is selective. In addition, a number of other $GABA_B$ receptor antagonists have been introduced (CGP 35348, CGP 36742, CGP 55845A, CGP 62349, and SCH50911).

$GABA_B$ Receptor Physiology

$GABA_B$ receptors have several different effector mechanisms, including the adenylate cyclase system and Ca and K channels. The actions of $GABA_B$ receptor agonists on these effectors are blocked by pertussis toxin, suggesting that $GABA_B$ receptors couple to their channel targets via a $G_{iÎ\pm}$- or $G_{oÎ\pm}$-type G protein (especially $G_{i2Î\pm}$). $GABA_B$ agonists inhibit basal and forskolin-stimulated adenylate cyclase in the brain through a G-proteinâ€"dependent pathway to reduce intracellular cyclic adenosine monophosphate (cAMP). $GABA_B$ receptor agonists also decrease voltage-gated Ca channels. Multiple high-threshold and low-threshold Ca channels have been reported.[40,81] High-threshold channels include N-type, L-type, P-type, and R-type channels. The low-threshold channel is a T Ca channel. These channels differ in the voltage range of activation and in rates of inactivation. $GABA_B$ receptor agonists have been demonstrated to reduce current flow through P/Q- and N-type Ca channels.[81] If this effect occurred at presynaptic terminals, this would result in decreased presynaptic Ca entry and, therefore, decreased release of neurotransmitter. The effect appeared to provide a basis for GABA-mediated presynaptic inhibition. These effects of $GABA_B$ receptor agonists have been shown in the peripheral nervous system and have been shown to inhibit excitatory synaptic transmission between hippocampal neurons.[98,103,109,127] It is likely that the effect of $GABA_B$ receptor agonists on reducing high-threshold transient Ca currents accounts for the reduction in synaptic transmission produced by these compounds. Activation of $GABA_B$ receptors has been shown to reduce the excitatory synaptic transmission presumably mediated by glutamate, but $GABA_B$ receptors have also been identified on presynaptic terminals of GABAergic neurons, and thus produce autoinhibition of GABA release from GABAergic nerve terminal. Thus $GABA_B$ receptors appear to be involved in the regulation of GABA release from nerve terminals and to affect the regulation of release of both excitatory and inhibitory neurotransmitters. In addition to regulation of presynaptic Ca channels, $GABA_B$ receptor agonists have postsynaptic action to enhance Kir3â€"type K conductance.[68] In a number of brain regions, including the hippocampus, cerebral cortex, thalamus, septum, and medulla, activation of GABAergic neurons produces biphasic IPSPs. A rapid early bicuculline-sensitive component is followed by a phaclofen- and CGP 35348â€"sensitive slow component. The fast component of the IPSP has been shown to be Cl-mediated, whereas the late slow phase is K-mediated.

Although all $GABA_B$ receptors appear to be heterodimers composed of $GABA_{B1}$ and $GABA_{B2}$ subunits, the role of the $GABA_{B1}$ splice variants has been unclear. Recently this issue has been clarified by the demonstration of differential compartmentalization and functions of dimers containing either the $GABA_{B1a}$ or $GABA_{B1b}$ splice variant. In hippocampal CA3â€"to-CA1 and layer 1 somatosensory cortical dendritic synapses on layer 5 pyramidal neurons, presynaptic glutamate release is inhibited by activation of $GABA_B$ receptors containing the $GABA_{B1a}$ splice variant, whereas activation of $GABA_B$ receptors containing the $GABA_{B1b}$ splice variant mediates postsyn- aptic inhibition.[93,119]

$GABA_B$ Receptor Anatomic Distribution

$GABA_B$ receptors have a widespread distribution in the central and peripheral nervous systems.[17] As has been described earlier, $GABA_B$ receptors exist on the synaptic terminal of excitatory/inhibitory neurons and on the cell bodies of neurons. In the CNS, an uneven distribution of receptors occurs, as measured by receptor autoradiography. This regional heterogeneity undoubtedly is of great importance for understanding the function of $GABA_B$ receptors. The location of $GABA_B$ receptors does not correlate with the presence of $GABA_A$ receptors. There are locations where primarily $GABA_A$ receptors are present and other locations where primarily $GABA_B$ receptors are present. The highest density of $GABA_B$ receptor binding sites appears to occur in the cerebral cortex, certain thalamic nuclei, cerebellum molecular layer, interpeduncular nucleus, and spinal cord dorsal horn.[20,29] Moderate densities of $GABA_B$ receptor sites are also present throughout the hippocampal formation. In addition, $GABA_B$ receptor binding sites have been located in the globus pallidus, habenula nucleus, superior colliculus, and amygdala. In the hippocampus, there is moderate density of binding in the stratum radiatum, dentate gyrus molecular layer, and stratum pyramidale in CA1. In contrast, there is a low level of binding in the subiculum. In the cerebral cortex, a nonhomogeneous pattern of binding is found, with high levels of binding in layers 1 to 3, and moderate levels of binding in layer 4. Thalamic binding is high in the medial geniculate and dorsal lateral geniculate, and low in the ventral lateral geniculate. In the superior colliculus, high binding occurs in the superficial gray layer and low binding in the intermediate gray layer.

Frequency-Dependent Plasticity at Inhibitory Synapses

The magnitude of the conductance change produced by a neurotransmitter or the amplitude of the synaptic potential is referred to as the *strength of synaptic transmission*. In general, the strength of synaptic transmission at most synapses is not invariant; synaptic strength may increase or decrease, commonly because of previous synaptic activity.[75,128] Alterations in the strength can be short-term increases (facilitation) or decreases (depression), or they can be long-term increases (long-term potentiation [LTP]) or decreases (long-term depression [LTD]). GABAergic synaptic inhibition is no exception, except that primarily use-dependent depression is seen at inhibitory synapses. For example, in hippocampus, inhibitory synaptic strength decreases during repetitive stimulation.[8] The basis for use-dependent depression in inhibitory synapses is unclear but could be multifactorial. The most likely mechanisms may involve postsynaptic desensitization of $GABA_A$ receptors, reduction in driving force due to Cl redistribution, and a loss of the transmembrane Cl gradient or feedback inhibition of GABA release mediated by presyn- aptic $GABA_B$ receptor autoreceptors. When modest stimulation protocols are employed, such as paired pulse stimulation, it is thought that the primary mechanism of GABAergic synaptic depression is due to feedback inhibition of GABA release mediated by presynaptic $GABA_B$ autoreceptors.[35,84] However, it is unlikely that the activation of $GABA_B$ autoreceptors is the sole explanation of synaptic depression at inhibitory synapses because not all GABAergic terminals contain $GABA_B$ autoreceptors.[11,60] For example, in inhibitory synapses in area CA3 of the rat hippocampus, both $GABA_B$ autoreceptor-dependent and autoreceptor-independent components of paired-pulse depression have been described. Activation of $GABA_B$ autoreceptors produces *fast* paired-pulse

depression that lasts for less than 1 second, whereas a second $GABA_B$ autoreceptor-independent mechanism persists for several seconds. The $GABA_B$ receptor-dependent fast paired-pulse depression was shown to require activation of several presynaptic inhibitory neurons, whereas $GABA_B$ receptor-independent paired-pulse depression occurred at single inhibitory synapses.[60] Thus, although GABAergic inhibition is essential for maintaining an appropriate level of excitability in synaptic circuits, under those conditions in which multiple GABAergic pathways are stimulated, GABAergic synaptic strength can be decreased by $GABA_B$ receptor-dependent as well as $GABA_B$ receptor-independent mechanisms, thus producing frequency-dependent depression. This phenomenon undoubtedly has significance in the acute disinhibition that may precede the development of epileptiform discharges.

Disinhibition and Epilepsy

Epilepsy is associated with hypersynchronous activation of large populations of neurons, and considerable interest has been focused on the possibility that reduction of inhibition, or *disinhibition*, is associated with the pathogenesis of some forms of epilepsy. The primary genesis for the hypothesis that modified GABAergic inhibition produces epileptiform discharge has been based on the experimental evidence that drugs that block GABAergic inhibition produced paroxysmal bursting in isolated neurons and produced partial seizures in experimental animals when the convulsants are applied topically to the cortex or hippocampus.[99] Application of GABA antagonists, including penicillin, picrotoxin, or bicuculline, produces large depolarizations because of combined giant excitatory postsynaptic potentials, thus producing paroxysmal depolarization shifts (PDSs), which are the interictal manifestation of an epileptiform event. It is thought that production of these epileptiform events requires a combination of reduced GABAergic inhibition, feed-forward excitation, and bursting properties of individual neurons.[125] It is likely that local paroxysmal bursting can spread to involve large areas of the hippocampus or generalize to the cortex when inhibition is further weakened and when other synchronizing factors occur, such as altered extracellular K and Ca concentration.

The ultimate form of disinhibition in epilepsy may be considered to be the conversion of a well-behaved GABA-mediated hyperpolarizing inhibitory event into a malicious depolarizing excitatory potential. Depolarizing or shunting inhibition has long been known to exist is neurons[2] and, depending on the threshold for action potential generation of the innervated cell, it can be inhibitory or excitatory.[106] The latter action is mainly confined to the passive phase of the synaptic potential.[44] The sign of the voltage change evoked by GABA is solely dependent on the reversal potential of the permeant ions (Cl^- and HCO_3^-) through the channel. Early on during development, most cells are loaded with Cl^-, causing GABA effects to be depolarizing[91] and thus playing a major role in shaping the development of the neurons by activating the influx of the second-messenger cation Ca^{2+}. The depolarizing action of GABA does not last into the adulthood because, at a given stage in development, the activation of various pumps and exchangers make sure that permeant ions become extruded from the cell.[96] However, adult epilepsy is an exception. It seems that, perhaps because of the malfunctioning of some of the anion extrusion mechanisms in the epileptic brain, some principal cells become depolarized by GABA to the extent at which interictal spiking can be induced as if GABA were an excitatory transmitter.[31]

Conclusive evidence that alteration of GABAergic inhibition is involved in the pathogenesis of idiopathic generalized seizures has come from the identification of several $GABA_A$ receptor subunit point mutations in the Î±1, Î³2, and Î´ subunits; these reports have been reviewed.[70,71] The Î³2 subunit mutations include Î³2(R43Q) associated with febrile seizures (FS) and childhood absence epilepsy (CAE),[121] Î³2(K289M) associated with generalized epilepsy with febrile seizures plus (GEFS+,[5], Î³2(Q351X) associated with GEFS+,[47] Î³2(Q1X) associated with severe myoclonic epilepsy of infancy (SMEI),[47] and Î³2(IVS6 + 2T â†' G) associated with GEFS+[53]. The Î±1 subunit mutation, Î±1(A322D), is associated with juvenile myoclonic epilepsy (JME).[32] Two Î´ subunit variants, Î´(R220H) and Î´(E177A), were identified as susceptibility genes associated with GEFS+ and JME.[36]

Inhibition and Synchrony

It would be extremely simplistic to regard GABAergic neurons in the brain as only â€œinhibitory.â€ It has become exceedingly clear over the past decade and a half that the vast anatomic heterogeneity of these cells corresponds to an equal functional diversity.[41,78,83,104] It is also evident that the activity of highly specific subsets of interneurons can entrain various oscillatory rhythms in neuronal networks.[23,41,58,104] Does this action of interneurons amount to â€œinhibitionâ€? Certainly not.

One of the most elegant demonstrations of synchronization through inhibition was done in recordings from two pyramidal cells innervated by a single inhibitory basket cell.[30] If the basket cell was activated during the random and asynchronous firing of the two pyramidal cells, the two cells were both simultaneously inhibited, but started firing together for a few cycles upon their recovery from the inhibition.[30] More recent findings show that depolarizing (shunting) inhibition can serve as a â€œhomogenizerâ€ of diverse firing rates, thus greatly enhancing oscillatory activity in the Î³-frequency range.[118] In light of such synchronizing action of interneurons, the role of inhibition in epilepsies becomes much more complex than initially thought. Depending on which inhibitory interneuron survives in the epileptic tissue, and which GABA receptors suffer from plasticity, the outcome of the inhibitory changes can be pro- or antiepileptic. The general consensus seems to be that perisomatic inhibition, the type of inhibition generally thought of as being responsible for the synchronization of principal cells, is preserved in epileptic brain.[76] In contrast, the interneurons innervating the dendrites of principal cells and of other interneurons show considerably more morphologic plasticity. These GABAergic cells, which also contain various neuropeptide, are lost, sprout, and alter their synaptic contacts, thus leading to a much altered diversity of innervation in epilepsy.[76] The functional significance of these plastic changes are not well understood; one also needs to keep in mind that the morphologic plasticity is accompanied by altered $GABA_A$ receptor expression and molecular composition in epileptic brain.[67,105]

If inhibitory postsynaptic events can lead to synchrony, it is not surprising to find enhanced synaptic activation of $GABA_A$ receptors in some models of epilepsy.[7,33,89] In some epilepsy models, such as FS, the synchronizing effect of an enhanced inhibition is augmented by an increase in other voltage-gated conductances. The parallel increase in the hyperpolarization activated I_h current helps the simultaneous recovery of the principal cells from inhibition and promotes their bursting.[28]

Antiepileptic Drug Action and $GABA_A$ Receptors

There are a number of AEDs whose actions are mediated by an interaction with GABA receptor system.[72] Postsynaptic $GABA_A$ receptor currents are enhanced by barbiturates and benzodiazepines. Presynaptic GABA release is likely modified by the AED vigabatrin. The uptake of GABA has been shown to be modified by compounds such as tiagabine. Finally, valproic acid has been suggested either to enhance the

P.250

release of GABA or to enhance postsynaptic GABA responses. Gabapentin was designed specifically to be a GABA analog that penetrated into the CNS. Although there are some suggestions that gabapentin may react with the GABA system to enhance GABAergic inhibition, evidence remains uncertain. Blockage of the low-threshold T Ca channelâ€“mediated Ca spike evoked by GABAergic IPSPs from the nucleus reticularis thalami (NRT) may be a mechanism of action of many drugs effective against generalized absence seizures.[34] Spike-and-wave discharges in experimental animals are blocked by $GABA_B$ receptor antagonists,[49,66,102] but the relevance of this observation to treatment of generalized absence seizures in humans remains uncertain.

Finally, felbamate has been demonstrated to enhance GABAergic inhibition, although this result requires confirmation.

Summary and Conclusions

It is quite clear that a focal reduction of GABA-mediated inhibition will produce partial epilepsy and, when produced systemically, will cause generalized seizures. Conversely, drugs that enhance GABAergic inhibition are antiepileptic. Alterations in GABAergic inhibition may be produced by several mechanisms. First, changes could occur in the morphology, axonal arborization, number, excitability, or innervation of inhibitory interneurons. Second, there could be modification of GABA release produced from individual synaptic terminals due to alterations in GABA stores or modifications of GABA-synthesizing or GABA-metabolizing enzymes. Third, a change could occur in the number, distribution, or composition or properties of postsynaptic $GABA_A$ receptors, and of the reversal potential of the permeant ions through these receptors. Fourth, mutations may be present in $GABA_A$ receptor subunits that alter the trafficking or and/or function of $GABA_A$ receptors. Finally, modified forms of GABAergic inhibition are present during development, suggesting the possibility that altered GABAergic inhibition not only is important in epilepsy but may have differential importance during development. The functions of GABAergic system are complex; they include inhibition, excitation, and synchrony. Therefore, in situ, it is difficult to predict how specific alterations in the function of GABAergic mechanisms, some of them genetically determined,[85,107] will produce epilepsy. Nevertheless, newly developed techniques for studying the specific identity of GABA receptors, properties of native GABA receptors, and behavior of GABAergic neurons and synapses should allow a more detailed understanding of the role of GABA-mediated synaptic transmission in epilepsies.

Chapter 24

Voltage-Gated Ion Channels: Molecular Biology and Role of Mutations in Epilepsy

Dimitri M. Kullmann

Stephanie Schorge

Introduction

Voltage-gated ion channels have long been known to be central to the excitability of the brain. However, the recent discovery of several ion channel mutations in patients with seizure disorders (the â€œepileptic channelopathiesâ€) has led to an appreciation of the importance of the molecular mechanisms underlying ion channel function in epilepsy. These experiments of nature have provided a unique insight not only into the mechanisms of seizure initiation and propagation but also into the fundamental molecular biology of ion channel synthesis and function.

What needs to be explained?

A parsimonious description of an epileptic channelopathy attempts to account for lowered seizure threshold on the basis of whether the mutation enhances or reduces the current carried by the channel (gain or loss of function, respectively). However, it is also important to explain the inheritance pattern associated with the mutation. Most of the known mutations associated with seizure disorders are either dominantly inherited or arise de novo in sporadic cases or in the parental germ line. This finding does not necessarily mean that recessive mutations do not occur: It could simply reflect the difficulty of identifying causative genes in kindreds with recessive inheritance.

Some seemingly monogenic epilepsies show extensive variability of clinical manifestations in different members of an affected family (Chapter 18). This variability is apparent as incomplete penetrance, or as phenotypic heterogeneity within a family carrying a particular mutation. Perhaps the best example of this phenomenon is seen in the genetics of a type of epilepsy associated with mutations in genes encoding sodium (Na^+) channels. An important advance came with the demonstration that an extremely pleomorphic epilepsy syndrome, generalized epilepsy with febrile seizures (FS) plus (GEFS+), could be associated with a single mutation in a Na^+ channel subunit[109] (see the section Ion Channel Mutations in Epilepsy). GEFS+ is not a syndrome in the conventional sense because it cannot be diagnosed in an individual. Instead, it describes a spectrum of manifestations of abnormal central nervous system (CNS) excitability in different members of a family, ranging from uncomplicated FSs to malignant forms of epilepsy that can lead to profound mental and physical disabilities and premature death. At present, little is known about the relative importance of genetic and environmental factors in this variability. However, some recent efforts to identify modifying genes, summarized at the end of this chapter, provide a possible way forward.

Diversity of Voltage-Gated Ion Channels

Given the central role of ion channels in controlling neuronal excitability, and their roles as targets of several antiepileptic drugs (AEDs), it has long been speculated that inherited dysfunction of such channels may account for some of the heritability of epilepsy. Indeed, the first mutations discovered to cause epilepsy inherited in a Mendelian fashion were found in genes encoding subunits of voltage- and ligand-gated ion channels.[5,7,14,91,99,108,109] Even though monogenic epilepsies are individually rare, they have now been associated with a wide range of ion channel gene mutations. One or two new channel genes responsible for monogenic epilepsy have been reported in each of the last few years (Chapter 18).

Voltage-gated ion channels underlie both the resting and action potentials of neurons. With the exception of the chloride (Cl^-) channel CLCN2, which was recently implicated in epilepsy,[44] the voltage-gated ion channels that underlie neuronal excitability all contain pore-forming subunits that share a common motif. Indeed, the genes encoding the essential core of ion channels are all thought to be related to a common ancestral prokaryotic potassium (K^+) channel, and together comprise the third largest family in the human genome.[112] The central feature of this family is a pair of transmembrane helices joined by an extracellular loop that plunges back into the membrane and contributes to the ion-conducting pore. Most K^+ channels are composed of four such subunits, so that permeating ions travel through a tunnel lined by four symmetrical peptide chains. Among K^+ channels the largest group consists of subunits that have four additional transmembrane helices, making a total of six membrane-spanning segments, with cytoplasmic tails at either end of the peptide chain (Fig. 1). The crystal structure of a representative voltage-gated K^+ channel has now been solved[67] and is invaluable to efforts to understand the functional impact of missense mutations.

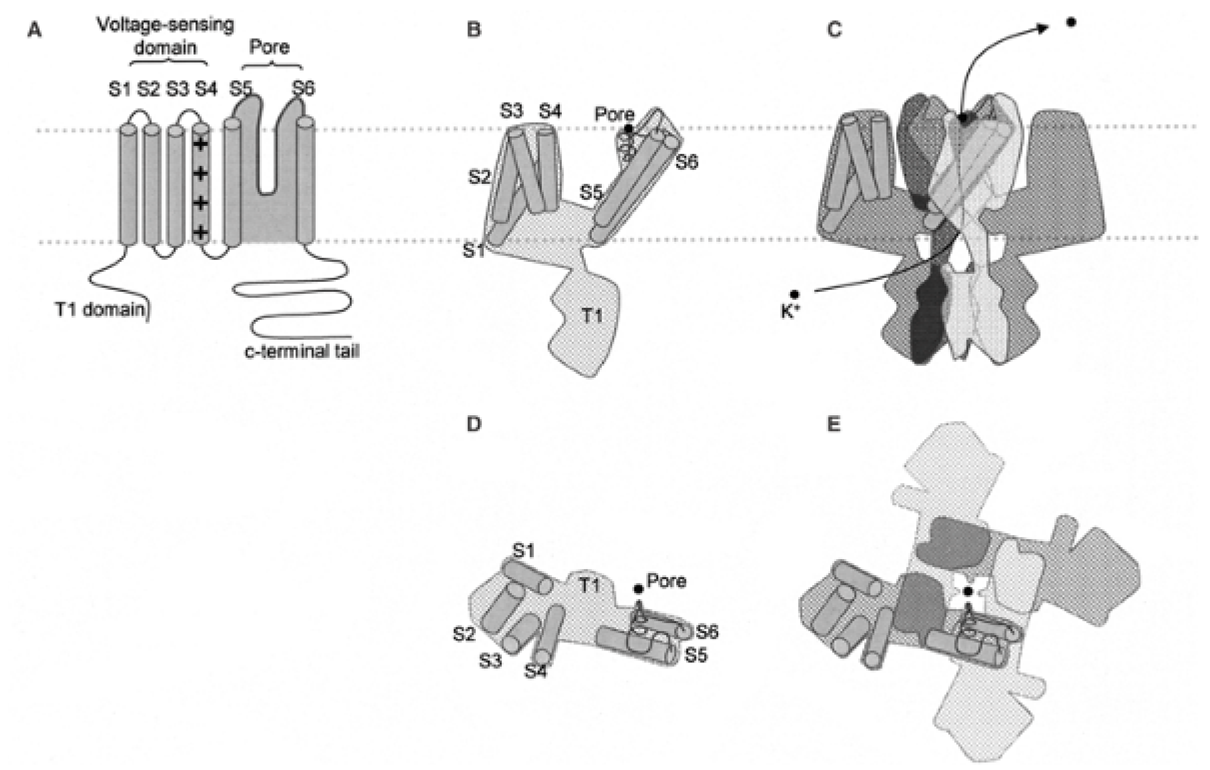

FIGURE 1. Structure of voltage-gated K^+ channels. **A:** A simplified depiction of the peptide chain of a voltage-gated K^+ channel showing the six transmembrane segments (*cylinders*) in the membrane (*dotted gray lines*). The position of the voltage sensor is indicated (+ *signs*). The loop between S5 and S6 forms the pore and selectivity filter (*shaded gray*). The outside of the cell is up, and the intracellular side is down. **B:** A representation of a single subunit of a voltage-gated K^+ channel based on the recent crystal structure.[67] The approximate positions of the helices are indicated along with the pore loop and a single potassium ion in the selectivity filter (*black circle*). The T1 domain is comprised of the N-terminal tail of the subunit and is thought to be important for subunit assembly.[85] **C:** Four subunits arranged to make a channel in the membrane. The helices are only shown in one subunit for clarity. The usual path of a K^+ ion through the lower side of the channel, and out the center of the top is indicated. **D:** A single subunit rotated and viewed from outside the cell, with the positions of the transmembrane domains indicated as in **B**. **E:** Four subunits forming the pore of a voltage-gated K^+ channel viewed looking down at the surface of a cell. The structure

determined by Long et al.[67] largely confirmed the membrane topology represented in **A**, but surprisingly, showed that the voltage-sensing domain (S1â€“S4) is offset to the side of the pore-forming segments (S5â€“S6) when the channel is viewed from above the surface of the membrane (looking into the pore of the channel). The black dot represents a K^+ ion in the pore of the channel.

The typical pore-forming subunit of a Na^+ or calcium (Ca^{2+}) channel is thought to have evolved via twofold duplication of a six-transmembrane domain (6-TM) K^+ channel gene, giving rise to a single protein containing four domains, each of which contains six transmembrane helices (Fig. 2). Although these channels exhibit distinct ion selectivities, they have the same overall topology, pore structure, and fourfold symmetry as the 6TM family of K^+ channels. The different ion selectivities exhibited by K^+, Ca^{2+}, and Na^+ channels are accounted for by a few amino acids in the pore loop. These channels also share a common mechanism of voltage sensing, which involves positively charged amino acids in the fourth transmembrane segment of each subunit (in the case of 6TM K^+ channels) or domain (in the case of Na^+ and Ca^{2+} channels). A complete native ion channel also contains one or more auxiliary subunits, which belong to a far more heterogeneous family of proteins, some of which are entirely intracellular while others contain membrane-spanning segments. These modulate the function of the pore-forming subunits, as well as helping to target them

P.254

to their correct destination in the neuron and linking them to scaffolding and signaling proteins.

In addition to their different ion selectivities, which relate the direction of ion flux to the chemical and electrical gradients across the membrane, channels have several other important features that account for their distinct roles in neuronal excitability. Notably, they activate (that is, undergo a conformational change that opens the ion-conducting pathway) at different rates and over different transmembrane voltage ranges. Many channels also inactivate in the presence of sustained depolarization, via a conformational change that is not simply the inverse of the activation event. The fast activation and inactivation kinetics of Na^+ channels, along with the positive reversal potential of Na^+ ions, underlies the upstroke of fast action potentials in almost all mammalian neurons. K^+ channels, which tend to hyperpolarize cells when they open, are largely responsible for setting the resting potential of the cells, as well as curtailing action potentials and shaping the frequency and pattern of repetitive firing. Ca^{2+} channels mediate slow action potentials in some neurons (particularly in the thalamus) but also couple depolarization with intracellular signaling, in the form of Ca^{2+} entry. One of the most important functions of Ca^{2+} channels is to trigger neurotransmitter release at synapses.

This overview of voltage-gated ion channels provides the backdrop summarized for further understanding the specialization and diversity of K^+, Na^+, and Ca^{2+} channels. Each class may be further subdivided into distinct subtypes, encoded by different genes, different splice variants, and different combinations of auxiliary subunits. This variability produces a functionally diverse population of channels with distinct patterns of expression in brain areas, among neuronal populations, and within cell compartments such as dendrites, axons, and pre- synaptic membranes.

Relating Gain or Loss of Function to Epilepsy

A simplistic view of epileptic channelopathies is that gain-of-function mutations of Na^+ or Ca^{2+} channels (that is, mutations that enhance the Na^+ or Ca^{2+} current flow when the membrane is depolarized) should enhance the excitability of neurons and circuits and therefore lower seizure threshold. Conversely,

P.255

P.256

loss-of-function mutations of K^+ channels should destabilize resting membrane potentials and predispose the brain to seizure. This view is supported, for example, by the fact that several AEDs (phenytoin, carbamazepine, and lamotrigine) are thought to act by stabilizing Na^+ channels in an inactivated state, thus rendering them more reluctant to open upon depolarization.[81] As will be seen, this view is far from providing a full account of how ion channel mutations give rise to epilepsy.

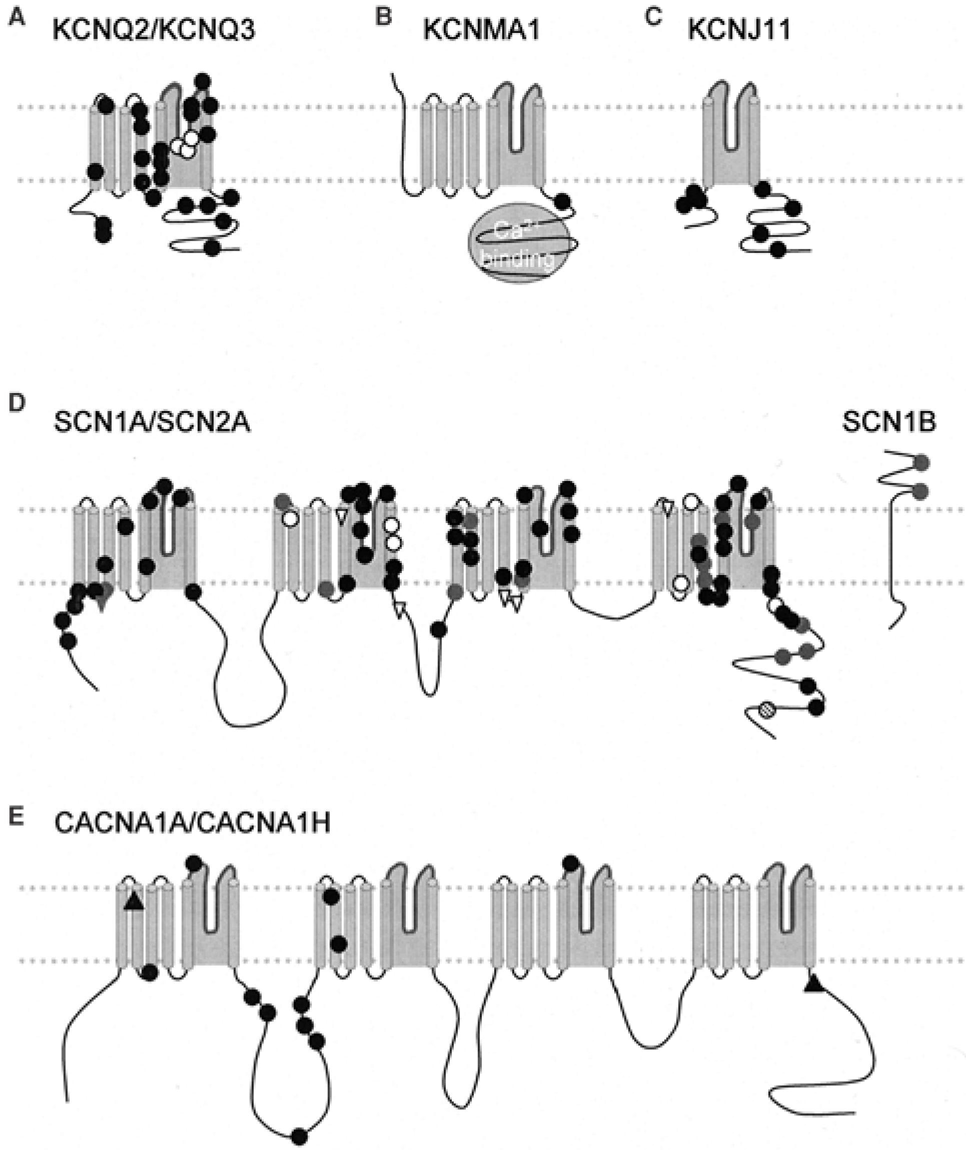

FIGURE 2. Missense mutations associated with epilepsy in voltage-gated channels. **A:** The subunits underlying the M current, the Kv7.2 and Kv7.3 subunits, encoded by KCNQ2 and KCNQ3, respectively. These subunits share the overall six-transmembrane topology of the archetypical K^+ channel shown in FIGURE 1A. Mutations in KCNQ2 are black circles, and KCNQ3 are white circles. (Adapted from Turnbull J, Lohi H, Kearney JA, et al. Sacred disease secrets revealed: the genetics of human epilepsy. *Hum Mol Genet*. 2005;14(Spec No. 2):2491â€“2500, with permission.[104]) **B:** The BK channel KCNMA1. This channel contains an extra TM domain before the conserved voltage-sensing domains, traditionally called S0. In addition, the channel contains a conserved Ca^{2+} binding domain (*gray circle*). The approximate position of the mutation associated with epilepsy is indicated by a black circle. Adapted from Du W, Bautista JF, Yang H, et al. Calcium-sensitive potassium channelopathy in human epilepsy and paroxysmal movement disorder. *Nat Genet*. 2005;37(7):733â€“738, with permission.[24] **C:** The approximate positions of missense mutations in KCNJ11 (Kir6.2) linked to DEND syndrome (*black circles*). The two transmembrane segments KCNJ11 are homologous to the S5 and S6 transmembrane segments in the K^+ channel shown in FIGURE 1A. Although KCNJ11 does not have a voltage-sensing domain, it is a member of the voltage-gated channel superfamily and likely shares an evolutionary ancestor with 6TM channels. Functional Kir6.2 channels are associated with the SUR receptor, a multitransmembrane protein. Adapted from Hattersley AT, Ashcroft FM. Activating mutations in Kir6.2 and neonatal diabetes: new

clinical syndromes, new scientific insights, and new therapy. *Diabetes*. 2005;54(9):2503â€"2513. with permission.[43] **D:** Missense mutations in Na channels linked to epilepsy. The pore-forming subunit of Na channels contains four domains each with six transmembrane segments homologous to those in the 6TM voltage-gated K^+ subunit. Missense mutations in SCN1A are associated with SMEI (*black circles*), GEFS+ (*gray circles*), intractable childhood epilepsy with generalized tonicâ€"clonic seizures (ICEGTC) (*white circles*), and infantile spasms (*hatched circle*). Missense mutations in SCN2A are linked to GEFS+ (*gray triangles*), and benign familial neonatal-infantile seizures (BFNIS) (*white triangles*). The two mutations in SCN1B linked to GEFS+ are also shown (*gray circles*) along with the membrane topology of that subunit. Many further mutations linked to SMEI are nonsense mutations; these are not shown here because they would be likely to trigger NMD, and thus their approximate position in the protein may not be relevant. Adapted from Meisler MH, Kearney JA. Sodium channel mutations in epilepsy and other neurological disorders. *J Clin Invest*. 2005;115(8):2010â€"2017, with permission.[72] **E:** Mutations in Ca^{2+} channels linked to epilepsy. The overall structure of the voltage-gated Ca^{2+} channels is similar to that of Na^+ channels, but conserved amino acid substitutions in the pore lead to selectivity for Ca^{2+} ions. Missense mutations/polymorphisms in CACNA1H (T-type Ca channel) linked to epilepsy (*black circles*), from Chen Y, Lu J, Pan H, et al. Association between genetic variation of CACNA1H and childhood absence epilepsy. *Ann Neurol*. 2003;54(2):239â€"243, with permission.[16] Mutations in CACNA1A (P/Q type Ca channel) linked to epilepsy (*black triangles*).[49,52] The mutation in the intracellular carboxyl tail of the channel is a nonsense mutation, but may escape degradation from the NMD pathway, and is therefore included with missense mutations.

Currently, missense mutations are the most common type of mutation found in voltage-gated ion channel genes associated with epilepsy. This may however be an artefact of sequencing efforts that focus on coding exons, while ignoring the introns and regulatory sequences within a gene. It may also reflect the potentially more severe impacts of nonsense mutations or mutations that disrupt the regulation of ion channels. Some mutations may not be compatible with fetal viability or with survival to adulthood.

Ion Channel Mutations in Epilepsy

K^+ Channels

For mutations of one type of K^+ channel, the simple view that relates a reduction in seizure threshold to loss of function appears to hold. Kv7.2 and Kv7.3 subunits, encoded by KCNQ2 and KCNQ3, co-assemble to form a slowly activating K^+ channel that shows little inactivation with prolonged depolarization. The subunits are widely expressed in the gray matter of the brain, including Î³-aminobutyric acid (GABA)ergic and dopaminergic neurons of the thalamus and basal ganglia.[19] The heteromeric channels consisting of Kv7.2 and Kv7.3 have the biophysical properties of the so-called *M current,*[110] which is active in many neurons close to the resting potential and is profoundly modulated by muscarinic and other G-proteinâ€"coupled receptors. The molecular identity of this conductance was only resolved with the discovery of the KCNQ2 and KCNQ3 genes. These were identified through a positional cloning effort to elucidate two loci for benign familial neonatal convulsions (BFNC) (see also Chapter 223).[7,14,91] Infants affected by this condition have brief generalized and partial seizures, with otherwise normal brain development and behavior; this topic has been reviewed.[62] The convulsions generally resolve spontaneously by the age of 6 weeks, although they can persist into adulthood in a minority of cases. All the missense mutations in KCNQ2 and KCNQ3 associated with BFNC impair K^+ flux when measured in heterologous expression experiments, mainly by reducing current density.[50,92] Loss of function can be expected to apply for the splice site, frameshift, and gene deletion mutations that have also been reported.

These findings underline the importance of the M current for setting the resting potential and firing rates of neurons that have a strategic role in seizure initiation and/or propagation.[20,63] Furthermore, the reasonably straightforward link between mutations that decrease the M current and the development of epilepsy has led to renewed interest in the experimental AED retigabine, which relatively selectively increases M currents; two reviews on this topic have been published.[20,103] Why infants carrying KCNQ2 or KCNQ3 mutations â€œoutgrowâ€ neonatal convulsions is unexplained. Because the mutations are dominantly inherited, only one allele of one of the two constituent subunits of the heteromeric channels is potentially defective in affected individuals, so there is some degree of redundancy. Moreover, a developmental increase in seizure threshold may occur during the first few weeks of life, or there may be a gradual increase in expression of the remaining, unaffected KCNQ2/3 alleles, such that a small reduction of K^+ flux may become insufficient to manifest as spontaneous convulsions. Interestingly, one missense mutation, associated with a broader syndrome that includes myokymia in adulthood, as well as neonatal convulsions, alters a voltage-sensing residue of KCNQ2.[23] This mutation produces a slowing of activation that persists upon coexpression of wild-type KCNQ2 and KCNQ3, suggesting a dominant effect on heteromeric channels.

In striking contrast to mutations in KCNQ2 and KCNQ3, mutations found in two other classes of K^+ channels associated with epilepsy lead to a gain of function. The KCNMA1 gene, which encodes the pore-forming subunit of a voltage- and Ca^{2+}-sensitive K^+ channel, has recently been linked to a syndrome characterized by generalized epilepsy and paroxysmal dyskinesia.[24] The large-conductance Big K^+(BK) channel encoded by KCNMA1 is widely expressed in the CNS. It contributes to fast neuronal repolarization following action potentials and to the early part of the afterhyperpolarization. It is also present presynaptically, where it may curtail neurotransmitter release. Surprisingly, the KCNMA1 mutation identified by Du et al.[24] in a single large family increases the open probability of these channels when expressed in vitro, such that they mediate a larger K^+ flux than wild-type channels over a range of transmembrane voltages or intracellular Ca^{2+} concentrations. A possible explanation for the occurrence of seizures and dys- kinetic paroxysms is that accelerated repolarization allows cells to fire repetitive action potentials. This is consistent with the effect of experimental deletion of an auxiliary subunit in the mouse, which paradoxically enhances BK channel function and is associated with temporal lobe seizures.[9]

Gain-of-function mutations in the KCNJ11 gene, which encodes the adenosine triphosphate (ATP)-sensitive inwardly rectifying K^+ channel Kir6.2, are associated with neonatal diabetes. Although this channel is abundant in the pancreas, where it gates the release of insulin, it is also widely expressed in the brain. Interestingly, some mutations that dramatically reduce the sensitivity of the channel to intracellular ATP (which normally closes the channels) are, in addition, associated with developmental delay, muscle weakness, and epilepsy (the DEND syndrome).[37,78,79] Mutant Kir6.2 channels tend to be open at the resting potential, so they are unlikely to lead to neuronal hyperexcitability. Why, then, are they associated with seizures? It has been suggested that ATP-sensitive K^+-channel subunits (and the sulfonylurea receptors associated with them in the native channel complex) are expressed to a greater extent in inhibitory interneurons than in pyramidal cells, and the disproportionate inhibition of interneurons by mutant Kir6.2 subunits may lead to seizures; see Ashcroft[4] and citations within.

Na^+ Channels

Many heterozygous Na^+ channel mutations are associated with epilepsy. The first missense mutation identified in a GEFS+ kindred affects the Î²1 auxiliary subunit encoded by SCN1B (see also Chapter 256). This subunit has a single transmembrane segment, and the mutation disrupts a cysteine bond within the extracellular portion of the protein, preventing it from modulating the function of the pore-forming subunit.[109] Although this represents loss of function for the SCN1B gene, the effect on Na^+ currents appears to be a net gain of function, because one of the normal roles of Î²1 is to accelerate fast inactivation. Impairment of fast inactivation represents a striking parallel with mutations in SCN4A, which encodes the pore-forming subunit of the skeletal muscle Na^+ channel, associated with hyperkalemic periodic paralysis and paramyotonia.[55] Impaired fast inactivation of muscle Na^+ channels gives rise to a persistent Na^+ current, which leads to depolarization and repetitive firing of muscle fibers.

P.257

Several mutations in SCN1A, encoding the pore-forming subunit of the brain $Na_V1.1$ channel, have since been identified in other families with GEFS+[27]; reviewed in Lerche et al.[63] Some of these have also been reported to impair fast inactivation.[69] This parallel between muscle and neuronal Na^+ channel mutations has, however, been challenged by several observations. First, detailed biophysical examination of several SCN1A mutations reveals effects on activation threshold and other parameters that imply that at least some of them result in loss rather than gain of function.[1,68,96] That is, depending on the pattern of membrane potential changes imposed on mutant $Na_V1.1$ channels, they may be more reluctant to open than wild-type channels. Second, disruptive mutations of SCN1A are a frequent cause of severe myoclonic epilepsy of infancy (SMEI, or Dravet syndrome).[18,100] This intractable pediatric epilepsy syndrome includes febrile and afebrile generalized and partial seizures, and is associated with episodes of status epilepticus, developmental arrest and regression, and mortality in childhood. It is generally sporadic, although it also occurs in families with a history of FSs. Indeed, an overlap occurs between GEFS+ and SMEI.[87] SCN1A mutations associated with SMEI are frequently de novo, and are typically nonsense, splice site, and frame shift mutations, although missense mutations also occur. Many of these mutations are expected to lead to complete loss of function (see later discussion). Finally, missense mutations in SCN1A have also been shown to occur in a milder pediatric syndrome, intractable childhood epilepsy with generalized tonicâ€“clonic seizures (ICEGTC),[34] with a variety of effects on activation and inactivation kinetics.[83] Notwithstanding the continued uncertainty about whether impaired Na^+ channel inactivation found in some GEFS+ mutations outweighs the other kinetic alterations, there is general agreement that the severe end of the GEFSâ€“SMEI spectrum is consistently associated with loss of function SCN1A mutations. In keeping with this, lamotrigine, which promotes Na^+ channel inactivation, can aggravate SMEI.[40]

The controversy surrounding gain versus loss of Na^+ channel function in GEFS+ calls for an improved understanding of the normal role of the Î²1 subunit and of $Na_V1.1$ channels in neuronal excitability. Î²1 is ubiquitously expressed and co-assembles not only with the pore-forming subunit encoded by SCN1A but also with several other Na^+ channels, including $Na_V1.2$ encoded by SCN2A. Interestingly, $Na_V1.1$ and $Na_V1.2$ have complementary expression profiles in many neocortical neurons, with $Na_V1.1$ predominantly expressed in the soma and dendrites, whereas $Na_V1.2$ is mainly located in the axons. Recently, heterozygous SCN2A mutations were identified in association with another pediatric seizure disorder, benign febrile neonatal/infantile convulsions (BFNIC).[45]

A possible explanation for the association of loss-of-function mutations of Na^+ channels with epilepsy is that they are more important for the firing of inhibitory interneurons, although this remains to be tested. Alternatively, Na^+ channel mutations might result in unexpected compensatory alterations in the expression of other channels, resulting in a hyperexcitable state. Genetic mouse models may provide an important insight into the consequences of deletion or missense mutations of Na^+ channels. The homozygous SCN1B knockout has seizures and ataxia, and exhibits subtle morphologic abnormalities in myelinated axons.[15] Interestingly, $Na_V1.3$ expression is increased in some neurons, providing some support for the hypothesis that epilepsy arises from compensatory alterations in other channels. The phenotypes of SCN1A knockin and knockout mice have not yet been reported.

Ultimately, we need to know how Na^+ channels behave in situ in people affected by these mutations. Although brain tissue is not accessible to detailed biophysical analysis, Bostock and colleagues have developed transcutaneous stimulation and recording methods that yield an insight into the conductances underlying action potential generation and refractoriness in peripheral nerves.[8] Neither SCN1A nor SCN2A are thought to be expressed in peripheral nerve. However, Î²1 subunits are found in motor axons. A comparison of controls and subjects with the original SCN1B mutation associated with GEFS+ reveals changes that imply a loss of excitability[59] consistent with a decreased number of Na^+ channels expressed in the nodes of Ranvier, rather than with a change in channel gating.[15] This again points to a loss-of-function effect, leaving unexplained the occurrence of seizures if the same phenomenon occurs in the brain.

Ca^{2+} Channels

T-type Ca^{2+} channels are unusual among Ca^{2+} channels in that they activate with relatively small membrane depolarization from resting potentials, but are also readily inactivated with maintained depolarizations. These properties mean that they mediate a transient Ca^{2+} conductance, revealed by briefly depolarizing neurons from a relatively negative potential. This can be demonstrated in thalamic neurons, which express T-type channels. These cells can be induced to fire rhythmic bursts of Na^+ action potentials riding on a slower T-type Ca^{2+} action potential. As each Ca^{2+} action potential terminates upon inactivation of the T-type channels, the neuron hyperpolarizes (especially if it receives a concurrent inhibitory synaptic input), following which the cycle repeats itself as the T-type channels recover from inactivation and begin a new Ca^{2+} action potential. Because of their association with rhythmic burst-firing, T-type channels have long been suspected to play a central role in spike-and-wave epilepsy, which manifests as excessive synchronous oscillations in the thalamocortical loop.

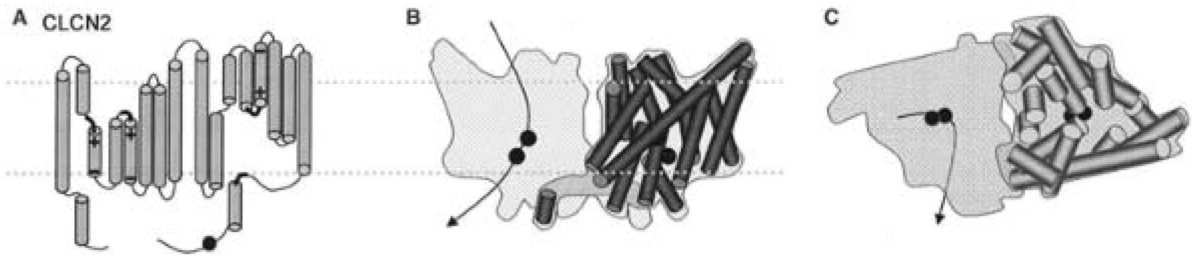

FIGURE 3. Structure of voltage gated Cl^- channels. **A:** The simplified membrane topology of ClC channels. They are composed of 12 helical segments of varying lengths and have no evolutionary relationship to the voltage-gated cation channels. The pore of ClC channels is assembled from charged helices (*indicated by + and â€" signs*) and amino acids in the loops between selected helices (*thick black lines*). The approximate position of the missense mutation in the Cl^- channel ClC-2 (CLCN2) associated with IGE is indicated (*black circle*).[44] **B:** The predicted assembly of a ClC channel as resolved from crystal structure (from Dutzler R. The structural basis of ClC chloride channel function. *Trends Neurosci*. 2004;27(6):315â€"320, and Dutzler R, Campbell EB, Cadene M, et al. X-ray structure of a ClC chloride channel at 3.0 A reveals the molecular basis of anion selectivity. *Nature*. 2002;415(6869):287â€"294, with permission[25,26]). Two subunits, each containing a pore, assemble to create a functional channel. Not all helices cross the membrane, and most are tilted to give an overall rhomboid shape. Helices are only shown in only one of the two subunits for clarity, and the path of a Cl^- ion into a cell is indicated with two ions shown inside each curved pore. **C:** A ClC channel viewed from outside the cell, looking down at the pores. The positions of four Cl^- ions are shown inside the subunits (from Dutzler R. The structural basis of ClC chloride channel function. *Trends Neurosci*. 2004;27(6):315â€"320, and Dutzler R, Campbell EB, Cadene M, et al. X-ray structure of a ClC chloride channel at 3.0 A reveals the molecular basis of anion selectivity. *Nature*. 2002;415(6869):287â€"294, with permission[25,26]).

The pore-forming subunits of three distinct subtypes of T-type channels ($Ca_V3.1$, $Ca_V3.2$, and $Ca_V3.3$) are encoded by CACNA1G, CACNA1H, and CACNA1I, respectively.[76] Their characterization led to confirmation that ethosuximide, effective in spike-and-wave epilepsy, is a T-type Ca^{2+} channel blocker. This, together with their role in thalamic burst-firing, led to the prediction that gain-of-function mutations in T-type channels may occur in idiopathic generalized epilepsy. Several heterozygous CACNA1H polymorphisms have been identified in patients with childhood absence epilepsy (CAE).[16] However, the relationship to epilepsy requires confirmation in other populations: Some polymorphisms identified in Australian families did not segregate with epilepsy.[46] Functional characterization of the mutations in vitro has revealed several effects on activation and inactivation kinetics, which in most cases imply an increase in T-type currents.[57,58,106] However, some mutations had no detectable effect or even showed loss of function. Because some of the effects were subtle, and the polymorphisms do not cosegregate with disease in most cases, CACNA1H may be a susceptibility gene rather than a causative gene for CAE and other forms of idiopathic generalized epilepsy. Interestingly, when two polymorphisms were introduced into the CACNA1H gene, they sometimes gave rise to biophysical alterations that were not seen with either mutation on its own.[106] This calls for further work to elucidate the full impact of combinations of polymorphisms in CACNA1H and other genes encoding Ca^{2+} and other channel subunits to determine what changes in neuronal excitability are necessary to induce the disease. For the moment, as with the constellation of mutations in Na^{+} channels linked to GEFS+, the link between T-type channel function and epilepsy remains incompletely understood.

High-threshold neuronal Ca^{2+} channels also exist as a triplet of subtypes ($Ca_V2.1$, $Ca_V2.2$, and $Ca_V2.1$). Of these, $Ca_V2.1$ (also known as the P/Q type channelâ€"a terminology that reflects its somewhat variable pharmacologic and biophysical properties and abundant expression in cerebellar Purkinje

neurons) is a major mediator of the presynaptic Ca^{2+} influx that leads to neurotransmitter release both in the CNS and at the neuromuscular junction. Mutations in the CACNA1A gene encoding the pore-forming subunit of the $Ca_V2.1$ channel have been linked to episodic ataxia type 2, familial hemiplegic migraine, and spinocerebellar ataxia type 6 (reviewed by Kullmann[61]). Recently, two human CACNA1A mutations have been shown to be linked to ataxia accompanied by spike-and-wave epilepsy.[49,52] One of these is a missense mutation, which leads to a radical amino acid substitution in a highly conserved transmembrane segment.[49] In this case, the main effect seems to be a decrease in total P/Q-type Ca^{2+} current in cells expressing the mutant. The location of the missense mutation in a transmembrane segment, and the reduced ability of heterologously expressed mutant channels to reach the plasma membrane, suggest that this mutation may lead to the disease not merely by a change in channel kinetics, but by a change in the folding and trafficking of the channels.

Why epilepsy should accompany loss-of-function CACNA1A mutations is far from clear. Mutations associated with episodic ataxia type 2 without epilepsy also give rise to various degrees of loss of function. Thus, it is possible that modifying genes or environmental/developmental factors also play a role in determining whether epilepsy occurs or not. Some clues as to the possible reason why seizures occur come from examining mice with $Ca_V2.1$ mutations. Several inbred strains of mice with a combination of ataxia and spike-and-wave epilepsy harbor mutations in CACNA1A and genes encoding auxiliary subunits of $Ca_V2.1$ channels.[30] Some of these mice also have unexpected increases in T-type currents in thalamic neurons, possibly as a developmental compensation.[1]

Cl_- Channels

The ClC family of voltage-gated Cl_- channels is not related to the voltage-gated cation channel superfamily. It belongs to a distinct family of channels containing two pores and consisting of two identical subunits (Fig. 3).[51] The importance of voltage-gated anionic currents in epilepsy is underscored by the discovery of five mutations in families with idiopathic generalized epilepsy (IGE) in one of these unrelated voltage-gated channel genes (CLCN2).[22,44] ClC channels are thought to have a variety of functions in many tissue types but, in neurons, they are implicated in maintaining the Cl_- gradient required to make GABAergic synapses hyperpolarizing.[51] Two of the predicted mutant sequences failed to produce any current when expressed in vitro,[44,74] and thus may reduce the inhibitory effects of GABA currents, leading to hyperexcitability. A third mutation changes a single amino acid in the CLCN2 mRNA and was shown to lead to a depolarizing shift in the voltage dependence of the current.[44] A separate study reported that this mutation changed the modulation of the channel by intracellular nucleotides.[22] Further complicating the analysis of these mutations is the presence of multiple, functionally different, alternatively spliced transcripts of the CLC2 gene,[10,17] some of which affect sequences adjacent to the missense mutation. The mutation may have different effects on different splice variants, and it is not clear which variants are expressed in neurons and which are restricted to other cell types.

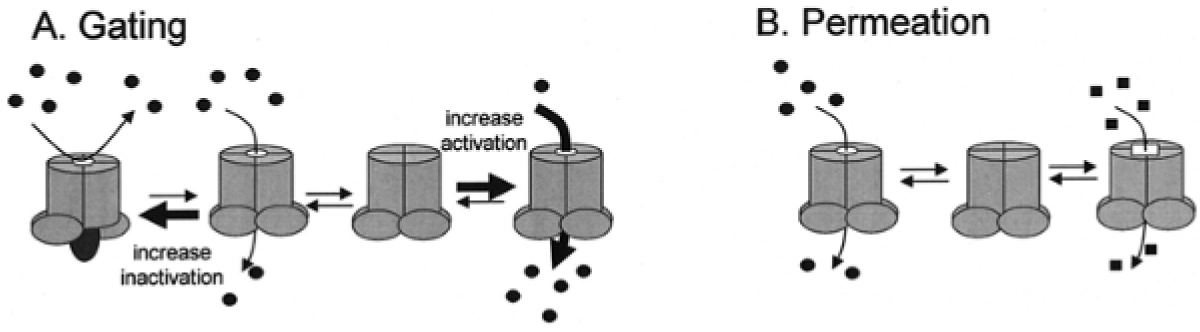

FIGURE 4. Possible effects of missense mutations on the behavior of channels. **A:** Missense mutations may change the likelihood of opening or of shutting once opened, and thus lead to increased or decreased ion conduction. In addition, missense mutations may change the rate of inactivation. **B:** Mutations may change the selectivity or permeation of channels, without changing the rate of opening. These sorts of changes are rare. More often a mutation will reduce permeation through the pore without changing the ion selectivity.

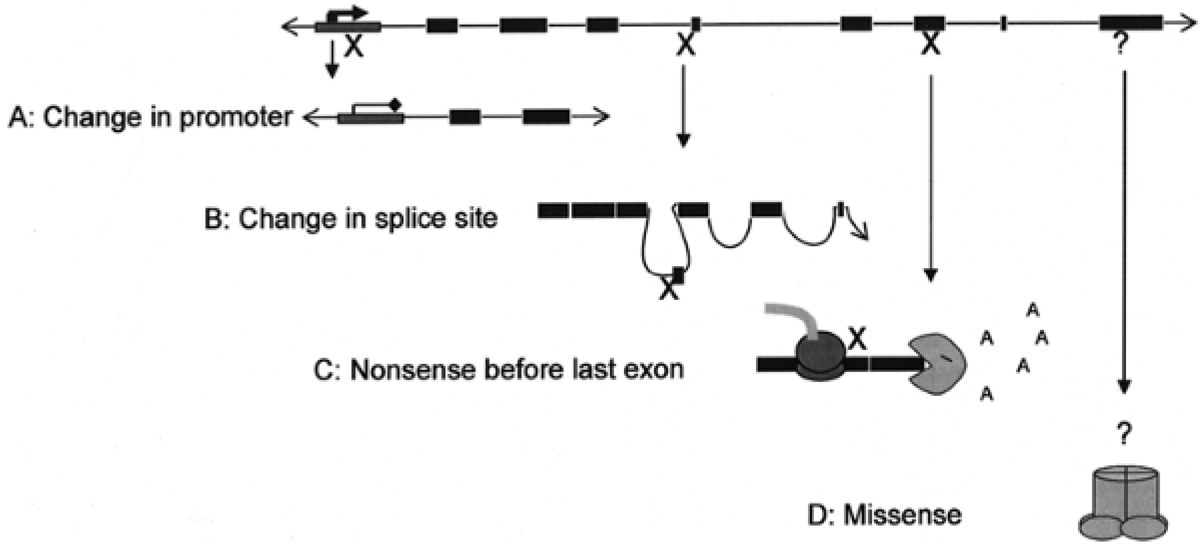

FIGURE 5. Mutations that disrupt DNA and mRNA processing. **A:** Mutations in the promoter of a gene may decrease or increase the amount of transcription from that gene, or the amount of mRNA made. **B:** Mutations in splice sites may destroy the ability of the spliceosome to recognize and excise an intron. This leads to the translation of intronic sequences and often results in nonsense and frameshift mutations. **C:** Nonsense mutations lead to nonsense-mediated decay so long as they are before the last exon/exon splice boundary. The first ribosome to translate an mRNA pauses on a nonsense codon and, unless all exon/exon boundaries have been crossed, that mRNA is destroyed by RNAses in the cell before further translation occurs. **D:** Missense mutations can have varying effects on the behavior of channels (see Fig. 4).

Ion Channel Biogenesis

The heterologous expression of mutant channel genes makes it relatively straightforward to characterize the consequences of individual mutations for the kinetic parameters of the channels (although extrapolation to clinical manifestation remains speculative, as noted earlier). However, many human channelopathies are not linked to simple missense mutations that change the gating of channels (Fig. 4). They are instead associated with mutations that have their effect on ion channels before they even reach the membrane. Mutations that disrupt the biogenesis of ion channels are much more difficult to study experimentally.

This section addresses the stages of biogenesis, starting with gene transcription (Fig. 5). Although direct evidence that all these processes are disrupted in human epilepsy is lacking, we argue that they are essential to understanding the molecular

and cellular consequences of many of the genetic defects identified in seizure disorders.

Transcription

Because DNA transcription is under the control of promoters, which play a central role in regulating the neuronal expression of ion channel genes, mutations within promoter regions might be expected to be an important disease mechanism.[84] For example, a mutation that prevents a copy of SCN1A from being transcribed might lead to the same phenotype as seen in mutations that disrupt channel biogenesis at a later stage, such as truncation. Perhaps surprisingly, no mutations in CNS ion channel promoter regions have been unequivocally associated with inherited disorders. However, this might reflect the poor understanding of promoter structures and the priority given to searching for mutations in coding regions.

Although there is very little evidence on the genetic causes of altered ion channel transcription in human disease, considerable attention has recently been given to acquired changes. Notably, axon damage can lead to changes in the transcription of several Na^+ channel genes, possibly accounting for a lowering of threshold for action potential initiation, and therefore contributing to neuropathic pain.[42] This phenomenon, called â€œtranscriptional channelopathy,â€ is reviewed by Waxman.[111] Experimental epilepsy models have been reported to alter Na^+ channel expression in vivo[66] as well as in vitro.[2] The mechanisms underlying altered transcription are poorly understood, and the consequences unpredictable. Moreover, a related

phenomenon may explain why some genetic defects are associated with the altered expression of other genes. Thus, it is possible that SCN1A mutations that should, on their own, lead to Na^+ channel haploinsufficiency could indirectly drive other promoters enough to lead to an excess of related Na^+ channel transcripts.

Mutations Leading to Faulty mRNA Processing

The importance of mRNA processing in neurologic disease is highlighted by the fact that many disease-associated mutations fall not in the coding exons, but in regions that disrupt mRNA splicing. Such mutations can result in exon skipping, or in an aberrant sequence (arising when an intronic sequence is included in the mature mRNA) and premature stop codons. Factors that regulate the stability of an mRNA or its translation can also have dramatic impacts on the level of a protein expressed. Sequences in introns and intronâ€“exon boundaries, which are not a part of the final protein and which are still poorly understood, can regulate alternative splicing and mRNA turnover and thus have an effect on the function or amount of protein produced.[35,64]

Nonsense-Mediated Decay

Mutations that insert premature termination codons in mRNAs have been estimated to account for 30% of inherited human genetic disorders.[33,107] These premature termination codons may be inserted either by a nonsense or frameshift mutation within a coding exon, or by abolishing a splice site, thus leading to translation of an intron or a frameshift in the transcript (see the section Alternative Splicing).

Most mutations that harbor premature termination codons probably do not produce a truncated protein but instead target the nascent mRNA for rapid degradation by the nonsense-mediated decay (NMD) pathway.[71,88] In some human genetic diseases, frameshifts, premature termination, and aberrant splicing often result in relatively mild defects in heterozygotes, probably because the mRNA from the mutant allele is destroyed before any potentially disruptive protein is produced. However, this generalization does not always hold: Many of the mutations linked to SMEI give rise to premature stop codons. To date, there is no direct evidence on the role of the NMD in human ion channel truncation mutations, but this may be largely because mRNA from affected tissues is not readily available for investigation.

In some cases, mRNAs containing premature stop codons can escape the NMD. An mRNA that contains a premature termination codon within about 50 bases of the final splice site fails to trigger NMD pathway and, as a result, a truncated protein is produced.[107] Similarly, a premature stop codon occurring in a gene that is transcribed from a single exon is also predicted to escape NMD and lead to translation of a truncated peptide. An example is a nonsense mutation in the KCNA1 gene, which has only one exon and encodes the Shaker-type K^+ channel Kv1.1. Mutations in this gene are associated with dominantly inherited episodic ataxia type 1 (EA1)[11] and a spectrum of related disorders ranging from muscle cramps to epilepsy.[28] A nonsense mutation in the C-terminus of the protein causes a severe drug-resistant form of the disease.[28] Expression studies show that, when the mutant allele is translated in heterologous expression systems, it exerts a dominant-negative effect on the wild-type allele.[70,82]

There are some hints that even transcripts that contain premature stop codons in exons 5â€² to the last exonâ€“exon junction can, under some circumstances, escape degradation and give rise to translated peptides. For example, radically truncated channels corresponding to fewer than the four homologous domains of neuronal Ca^{2+} channel subunits have been detected in several tissues, including the brain.[54,90] It has been argued that at least some of these peptides arise from alternative splicing rather than from posttranslational cleavage, and this might represent part of the normal variability of gene products rather than a pathologic phenomenon. Unexpectedly, experimentally truncated Ca^{2+} channels can have a dominant negative effect on full-length channels when they are co-expressed in vitro.[80] It is not known what function truncated channels may have in vivo.

Alternative Splicing

The recent completion of the human genome project has shown that humans have many fewer genes than expected on the basis of protein diversity in the brain.[41] This discrepancy is to a great extent explained by alternative splicing of mRNAs (Fig. 5). Through alternative splicing, a final gene product can contain (or lack) any of several distinct alternative amino acid sequences that confer distinct properties to the entire protein. Thus, depending on posttranscriptional splicing, individual genes can encode a range of proteins with subtle variations in function (reviewed in Lipscombe[65]). Genetic variability in splice donor or acceptor sites that control this form of mRNA processing can bias the relative proportions of the protein variants. Tate et al.[102] recently studied a common single nucleotide polymorphism falling in the splice site of an alternatively spliced exon of SCN1A, the Na^+ channel gene implicated in GEFS+ and SMEI. This polymorphism was highly significantly correlated with the maximal dose of phenytoin or carbamazepine (both of which act upon $Na_V1.1$) prescribed in a large cohort of people with epilepsy. Although the polymorphism did not appear to be correlated with the development of epilepsy per se, it appeared to have an effect on its treatment. Whether the differences in maximal dose reflected differences in seizure control or in tolerability was not determined. Interestingly, epilepsy per se also appears to affect splicing at the same site in Na^+ channels.[3,36,102] This raises the possibility that drug responsiveness and possibly biophysical properties of $Na_V1.1$ channels are affected both by inheritance and by epilepsy itself, by converging upon alternative splicing.

The mRNAs of many of the ion channels linked to epilepsy are subject to extensive alternative splicing. As yet, little is known about the expression levels of different splice variants in different cell types, and about the impact of splice variants on the function of channels. It is possible that, depending on the splice variant background, individual genetic polymorphisms may have dramatically different effects.

mRNA Editing

RNA editing in mammalian ion channels was first reported for ionotropic glutamate receptor subunits.[95] In some neurons, nearly 100% of the glutamate receptor subunit GluR2 mRNA is edited after transcription to change a single amino acid in the pore region of the channel from a glutamine to arginine. This change has profound effects on the biophysical properties of the channel,[101] as well as on its tetramerization[38] and export from the endoplasmic reticulum (ER).[39] Recently, it has been reported that genes encoding many other CNS signalling proteins undergo mRNA editing,[48] although generally to a lesser degree than does GluR2. RNA editing requires a conserved complementary sequence to form base-pairs with the region that is targeted for change. Mutations in this sequence might

be buried deep within long introns and yet could have an impact on the coding sequence of the target exon. Thus, it is possible that mutations that do not change the amino acid sequence directly still have an effect on a channel by interfering with RNA editing.

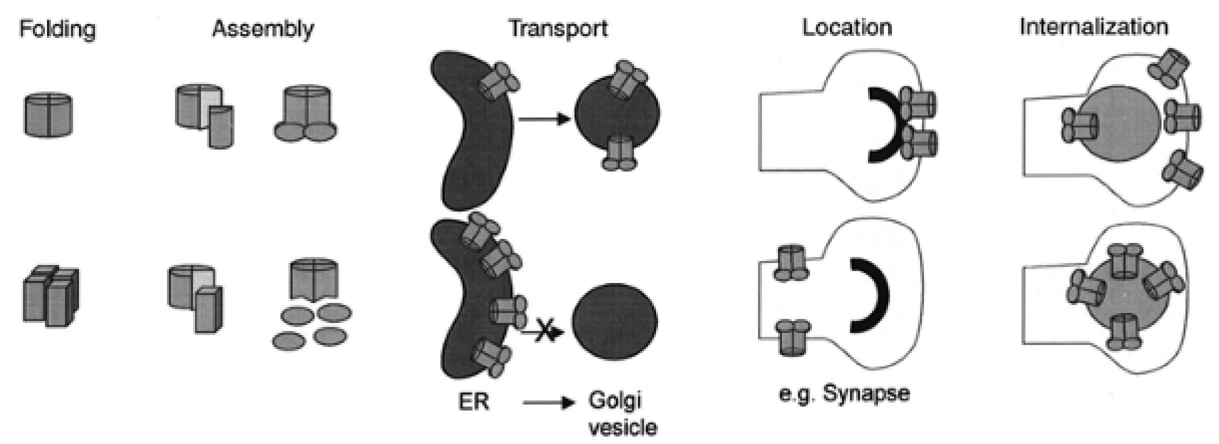

FIGURE 6. Mutations affecting protein processing. Mutations in regions that are structurally important can disrupt the folding of subunits. This can lead to the failure of subunits to assemble, the failure of accessory subunits to bind, and may trigger UPR and reduced translation and transcription. In addition, failure to assemble may prevent channels from leaving the ER or reaching the surface or the correct region of the cell. Finally, mutations may affect how long channels remain in the membrane before they are targeted for internalization and degradation.

RNA editing occurs in the human KCNA1 gene, which, as mentioned above, encodes Kv1.1,[48] a K^+ channel linked to episodic ataxia and myokymia, as well as epilepsy[28] RNA editing switches isoleucine to valine at a site in the S6 transmembrane domain lining the cytoplasmic pore that is important in fast inactivation. This residue acts as a receptor for cytoplasmic inactivating peptides that plug the pore of the channel upon sustained depolarization.[115] Interestingly, missense mutations affecting two neighboring pore-lining valine residues that also act as receptors for the inactivating peptide have been found in families with EA1.[28] Other editing sites have been reported in the N-terminus of the squid ortholog of Kv1.1, where they have a profound effect on channel assembly.[85] These observations imply that it may be important to consider an impact on RNA editing for seemingly conservative genetic variants linked to epilepsy.

Translation, Folding, and Trafficking

Some missense mutations may cause haploinsufficiency by preventing channels from reaching the surface of the cells (Fig. 6). Some SCN1A missense mutations associated with SMEI and GEFS+ have been shown to produce no current when expressed in vitro.[68] The amount of surface expression of these mutants has not been measured, so it is not known whether they reach the plasma membrane, but some channels have been shown to be retained in the ER until folded and assembled properly (see the section Subunit Assembly). Interestingly, two of the three different mutants shown in Lossin et al.[68] not to produce current were associated with GEFS+, whereas the third was associated with SMEI, a more severe clinical phenotype; yet, in the heterologous system, their effect was identical. This raises the possibility that the different mutants are processed differently in the brain, in a fashion not duplicated in vitro, such that the impact of the mutations associated with the less severe phenotype is attenuated.

Translation depends not only on the integrity of the mRNA and the ribosome apparatus but also on the ER. Misfolded proteins can jeopardize the entire cell. High concentrations of unfolded proteins can trigger stress responses implicated in the cell death associated with several neurologic disorders, including Alzheimer disease.[32] Under conditions of ER stress transcription in general is suppressed, most translation is inhibited, and protein degradation is increased[113]; collectively, these changes are known as the unfolded protein response (UPR). This provides a possible explanation for an otherwise puzzling observation: As mentioned earlier, some Ca^{2+} channel truncations, which closely mimic naturally occurring mutations associated with episodic ataxia and epilepsy, have a dominant negative effect on the wild-type allele even when no direct evidence suggests an interaction between the peptides.[52,75,80] If, as has been proposed, ion channels are in a class of â€œdifficult-to-foldâ€ proteins, a mutation in one allele that leads to an accumulation of unfolded proteins in the ER may disproportionately target other channel subunits waiting to be folded for degradation, including those encoded by the wild-type allele.

Subunit Assembly

Mutations can also potentially affect channel assembly. A cluster of missense, frameshift, and truncation mutations of KCNQ2 associated with BFNC occur in or near a C-terminal domain that affects assembly of heteromeric channels.[21,89,92] The truncation mutations are in or very near the end of the mRNA, and so are unlikely to trigger NMD. Instead, they are most likely to produce truncated or frame-shifted proteins. This C-terminal region of the subunit is located in the intracellular space and is thought to be important in subunit interactions.[89] Biochemical analysis of one KCNQ2 mutation that dramatically changes this C-terminal end of the protein has shown that the mutant subunits cannot produce current on their own, possibly because they are rapidly degraded.[94] When these mutants are allowed to co-assemble with KCNQ3 subunits, they are stabilized and able to produce currents with normal kinetics.[94] It is becoming evident that the fate of many ion channel subunits depends on their ability to assemble with the correct mixture of partners to form a complete channel.

In some cases, the subunits that are disrupted by mutations are not essential for channel function, but instead are important for modifying channel kinetics. An important example is the SCN1B mutations associated with GEFS+. SCN1B encodes the Î²1 subunit of Na^+ channels, which accelerates fast inactivation. The first mutation identified in GEFS+ disrupts a cysteine bond in Î²1, and probably leads to degradation of the subunit.[109] The consequence is slowed inactivation, which could be interpreted as a gain of Na^+ channel function (see the earlier section Na^+ Channels). The simple disruption of subunit binding seems to be sufficient to cause epilepsy. In fact, it was a mutation associated with epilepsy in SCN1A that disrupted binding to the SCN1B subunit that first identified the sequence in SCN1A that mediates this binding.[97] This underscores what may be a theme in the study of channelopathies: In many cases, information from genetic disorders reveals how ion channels function, rather than the other way around.

Decay and Degradation

As we have seen (in the section on Subunit Assembly), mutations that disrupt subunit assembly can also lead to dramatic changes in channel decay rates. In the case of KCNQ2, subunits that are unable to assemble into channels seem to be targeted for decay in the proteasome. Indeed, proteasome inhibitors have been shown to prolong the half-lives of mutant channels in vitro.[94] It is quite possible that the mechanisms driving decay in heterologous systems are different from those in neurons, and consequently less sensitive to mutations affecting channel half-life. However, as yet, little is known about those factors that regulate the half-life of membrane proteins or the pathways that control their decay, either in neurons or in heterologous systems.

Modifiers of Severity: Single Nucleotide Polymorphisms (SNPs) or Mutations?

One prominent and enigmatic feature of the channelopathies associated with epilepsy is the variability of their inheritance. Mutations associated with GEFS+, for example, can lead to widely varying clinical manifestations in individuals harboring the same Na^+ channel variant.[73,98] Further illustrating this principle, a mutation found in two brothers with SMEI was also identified in their father, whose only symptom was FS.[60] A major puzzle is to determine the genetic or environmental factors that can modify the impact of a mutation so dramatically.

The importance of modifier genes is best illustrated in model animals, in which genetic backgrounds can be directly compared by selective breeding. The severity of an identical mutation in SCN2A has been shown to differ in two inbred strains of mice, with one strain developing fewer seizures later in life and living longer than another strain carrying the identical mutation.[6] Recently, a mutation that disrupts splicing in a Na^+ channel gene and causes a chronic movement disorder in one strain of mice was shown to be lethal in a second strain.[12] The difference in impact was traced to a mutation in a hitherto unknown splice factor in the second strain that reduced the amount of correctly spliced Na^+ channel below the threshold for viability.[12]

As exemplified by the CACNA1H mutations reported in CAE, polymorphisms that are not thought to be directly linked to epilepsy may affect the biophysical consequences of other genetic variants.[106] Several sequencing efforts are now underway to identify common polymorphisms in ion channels that may impact the severity of disease-causing mutations.

Relating Channel Function to Clinical Syndrome

Even when the functional consequence of a mutation in an ion channel gene is understood, explaining the phenotype and inheritance pattern can present some challenges. Clearly, it is necessary to know where the ion channel is normally expressed, its role in neuronal excitability, and the effect of perturbing signaling within a population of neurons on the behavior of the whole organism. However, several potential pitfalls exist on the road to â€œexplainingâ€ how a mutation in an ion channel can lead to a clinical syndrome, including redundancy within ion channel gene families, variations in RNA splicing, and effects of perturbed signaling on brain development.

A potentially powerful approach is to examine animal models of human channelopathies. Three types of mouse model are beginning to give significant insights. First, a number of mouse strains with spontaneous recessive mutations in ion channel genes have phenotypes that overlap with human disorders linked to the same gene (for example, CACNA1A and the glycine receptor gene GLRA1).[13,29,86] Second, targeted deletions can shed light on the consequences of nonsense mutations in channel genes.[31,53,93] And third, human mutations can be introduced into the mouse ortholog of a gene, which offers a direct test of the effects on neurons, circuits, and systems. This approach has been applied to a KCNA1 mutation associated with episodic ataxia[47] and to a CACNA1A mutation associated with familial hemiplegic migraine.[105] Although it can be highly informative, the approach suffers from the limitation that a missense mutation in a human gene might have different effects on ion channel function than the same mutation in the mouse ortholog. For example, a patient with intractable epilepsy and mental decline was found to have a heterozygous nonsense mutation in SCN2A[56]; however, mice heterozygous for a targeted knockout of SCN2A had no noticeable abnormalities, whereas the homozygotes died as neonates without obvious seizures.[77] Moreover, some genes known to be key in epilepsy, such as SCN1A, are not processed in the same way in mice and humans. The alternate exon found in human SCN1A, which contains a polymorphism that is correlated with a change in the maximal dose of AEDs is not functional in mice and rats (SS, unpublished observation). So, although mouse models may prove most helpful for exploring some of the mechanisms of ion channel mutations leading to diseases, ultimately human sequences will have to be consulted. A further limitation of mouse models is that, because of their short lifespan, subtle disorders that only manifest in adult life may not be apparent in heterozygous animals. Indeed, seizures and other neurologic disorders have generally only been reported in homozygous animals, whereas most of the human disorders are dominantly inherited.

Future Work

Although genetic studies have linked a large number of polymorphisms in ion channel genes to epilepsy, caution is advised in extrapolating from genotypes to phenotypes in humans. In most cases, it is not possible to directly examine the effects of ion channel gene polymorphisms in human neuronal tissues. However, every effort should be made to discover in what context a gene is transcribed, when transcription would be expected to result in rapid mRNA degradation or production of a truncated peptide, what splice variants and subunits are likely to be present, and how a polymorphism could affect the targeting and even removal of an ion channel. We are leaving the stage when heterologous expression of mutant cDNA is sufficient to establish the effects of the mutations on neurons. In the future, heterologous expression should be combined with

expression studies in vivo, especially when animal models might not reflect human pathologies. In the meantime, genetic studies, which have already provided a wealth of information about the functional domains of ion channels, might also lead to valuable information about the processing of mRNAs and peptides.

Summary and Conclusions

The list of voltage-gated ion channel genes harboring mutations in patients with epilepsy will no doubt continue to grow. With advances in understanding of the stages of ion channel biogenesis it will be important to focus not only on those exons which encode the protein but also on non-coding regions, in particular promoters and intronic and untranslated sequences that affect RNA processing. As the cost of DNA sequencing falls, and a larger number of ion channel genes can be sequenced, it is likely that variants will be identified where it is unclear whether they are rare non-causative polymorphisms or disease-causing mutations. Determining the functional impact of these variants will require increasingly subtle understanding of the molecular and cell biology of ion channels and neurons. Genetic variations identified in individuals may also be susceptibility factors, contributing to, but not determining fully, the risk of developing epilepsy. By extrapolation, it will be important to determine how such genetic factors contribute to the overall heritability of epilepsy in the population.

Chapter 25

Inflammation

Annamaria Vezzani

Jukka Peltola

Damir Janigro

Introduction

Immune and inflammatory reactions have been described in the central nervous system (CNS) in various neurologic diseases, including epilepsy. In particular, several cytokines and activated proinflammatory signaling pathways have been measured in the brain, cerebrospinal fluid (CFS), or blood after seizures induced in experimental models and in clinical cases of epilepsy (for review see Vezzani[101]).

Inflammatory reactions in the CNS appear to arise from the activation of both branches of the immune system, namely, innate and adaptive immunity. In the rodent brain, inflammatory mediators are produced during epileptic activity by microglia, astrocytes, and neurons as part of innate immune mechanisms. In human epileptic tissue, evidence suggests that both innate and adaptive immunity contribute to the induction and perpetuation of inflammation in the brain.[63] The bloodâ€“brain barrier (BBB) appears to play a crucial role in modulating the functional communication between innate and adaptive CNS immunity by tightly regulating the entry of blood-borne immune cells, antigens, and antibodies into the brain.[79]

A crucial question is whether, in the brain, inflammation is a component of the etiology of epilepsy, a consequence of seizures and cell damage, or both, and if inflammation can contribute to the progression of the disease.[76]

In the attempt to address these questions, preclinical investigations in experimental models of seizures focused first on the time-course of specific proinflammatory events occurring in the rodent brain after the induction of seizures.[101] Much effort has been devoted to describe the regional distribution and cell-specific expression of proinflammatory molecules and their signaling in brain, vis-Ã -vis the patterns of seizure spread and the associated neuronal cell loss. Second, functional and pharmacologic studies have shown that cytokines can decrease the threshold for seizure induction and/or prolong the duration of seizures. Moreover, cytokines and downstream inflammatory mediators affect neuronal survival to injury, induce glial cell proliferation, modify BBB permeability to blood-borne molecules and cells, and inhibit neurogenesis.[2] Pharmacologic evidence demonstrates that some anti-inflammatory treatments reduce seizures in experimental models and, in some instances, in clinical cases of epilepsy. All these findings support the hypothesis that inflammation in the brain plays a role in ictogenesis and, in some instances, also in neuronal cell loss, while also predicting its contribution to epileptogenesis. Direct proof for the latter is still lacking.

Several experimental findings have highlighted a dichotomous role for immune/inflammatory events in the CNS. Thus, these reactions can be also neuroprotective, and they thus constitute an adaptive, beneficial endogenous response to injury, similar to the classical immune/inflammatory responses to infection.[2,63,92] In general, the deleterious effects of cytokines or other inflammatory mediators on neuronal excitability and cell survival appear to be mediated by their ability to provoke an extracellular rise of glutamate by actions on mechanisms of neurotransmitter release and/or reuptake, to potentiate the function of ionotropic glutamate receptors, and to enhance the production of mediators of oxidative stress (i.e., arachidonic acid and nitric oxide).[2] However, cytokines can also induce the synthesis of nerve growth factor, ciliary neurotrophic factor, and insulin-like growth factor from astrocytes, all involved in brain repair.[2] Other potential mechanisms of neuroprotection induced by cytokines include stimulation of antioxidant pathways and enhanced expression of manganese superoxide dismutase or calbindin, leading to an attenuated elevation of intracellular calcium (Ca^{2+}) induced by tissue injuries. In summary, the final outcome of inflammation on brain function is highly dependent on the extent to which inflammatory mediators are produced, the length of time the tissue is exposed to inflammation, and the balance between the neurotrophic and inflammatory factors produced by the competent cells. It is also possible that the peripheral versus central origin of the cells and molecules involved in inflammation may play a role.

In this chapter, we review experimental and clinical evidence supporting the hypothesis that inflammation in brain may be a common thread playing a pro-epileptogenic role in various forms of epilepsy of different etiologies. Although the initial trigger of an inflammatory response in the brain remains still speculative (when the original description of the disease does not include the presence of specific pathogens), a large variety of insults that induce inflammation in the brain often result in the occurrence of seizures, and eventually in the onset of epilepsy, suggesting that an injury, even if subtle, occurring at birth or during lifetime may initiate a cascade of chronic inflammatory events in the CNS that contributes to the basis for the late onset of epilepsy (Fig. 1).

Understanding and awareness of the role of inflammation in epilepsy will increase our knowledge of the mechanisms underlying the etiopathogenesis of seizures and might open new perspectives for their pharmacologic treatment.

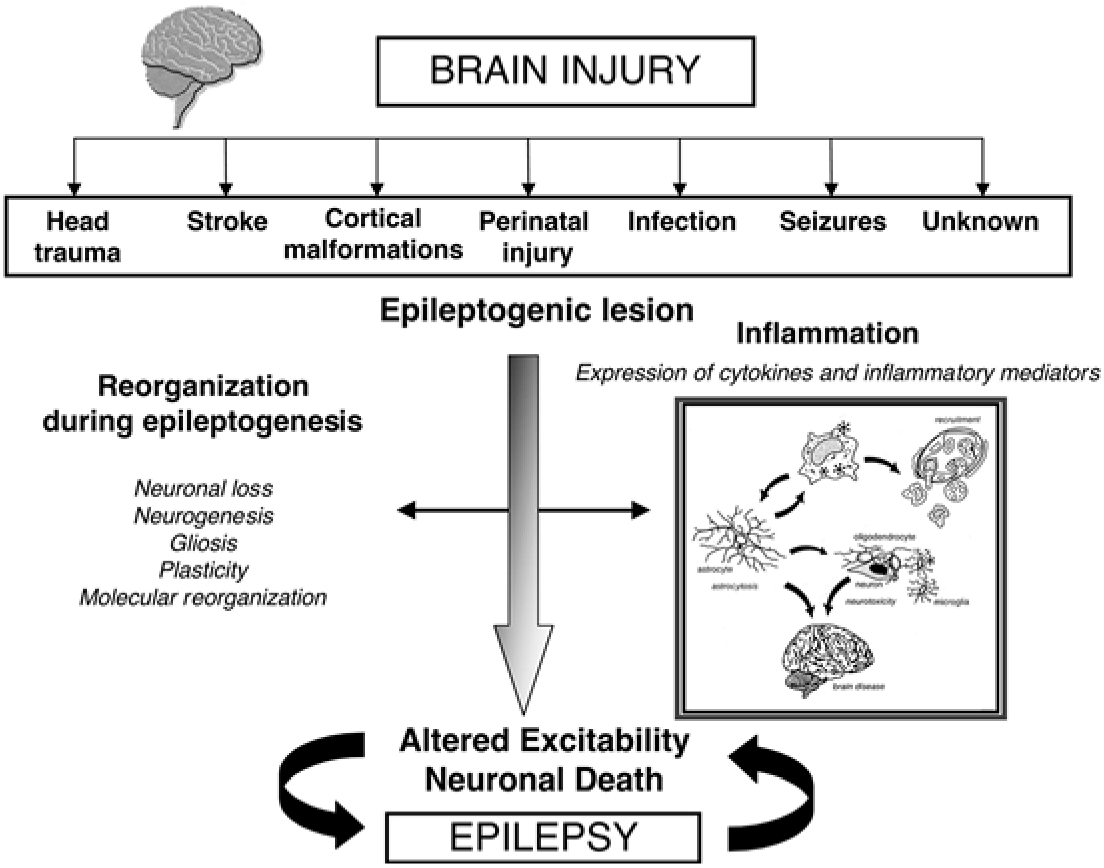

FIGURE 1. Schematic representation of the cascade of events that may be triggered by brain injury, eventually resulting in epilepsy. A large variety of injuries, even if subtle, occurring at birth or during a lifetime, may initiate anatomic, molecular, and synaptic reorganizations as well as a cascade of chronic

inflammatory events in the brain that contribute to the late onset of epilepsy. Both innate and adaptive immune responses may play a role in initiating and consolidating inflammation in brain (exemplified in the boxed cartoon). The BBB is crucially involved in mediating the recruitment of cell components of the adaptive immune system, and alterations of the barrier properties may predispose the brain to the occurrence of seizures (see text for details).

Experimental Models of Seizures

Expression Studies

During systemic infections (mimicked in rodents through the administration of lipopolysaccharide [LPS], a component of the gram-negative bacterial wall), the brain triggers an inflammatory response mounted to protect the host against infectious microorganisms. This phenomenon consists of an early inflammatory response (innate immunity) that can eventually progress to an adaptive immune response mediated by activated lymphocytes recruited from the blood.[63,81] The CNS shows a well-organized innate immune reaction in response not only to infection but also to a variety of brain injuries. In particular, cytokines such as interleukin (IL)-1Î², tumor necrosis factor (TNF)-Î±, and IL-6, although expressed at very low levels in healthy brain tissue, are rapidly induced there following

ischemic, traumatic, and excitotoxic damage and seizures (for review see Allan[2] and Vezzani[101]). Status epilepticus (SE), or recurrent seizures induced in rodents by electrical stimulation or application of chemoconvulsants, induces a rapid increase of proinflammatory cytokines and various markers of the innate immunity (e.g., nuclear factor [NF]-ÎºB system, prostaglandins and their pathway enzymes, Toll-like receptors, chemokines, complement system) in glia and in neurons[19,60,66,97] (Fig. 2). Increased production of inflammatory molecules in the brain has also been reported in genetic models of audiogenic seizures and in kindling.[26,77] Markers of inflammation increase specifically in those brain regions involved in seizure onset and spread.

The inflammatory response observed in mouse brain following pilocarpine-induced seizures differs from that described after systemic injection of LPS[63,81,97,101]: Thus, inflammatory molecules are first and predominantly expressed after endotoxemia in circumventricular organs, the choroid plexus, the leptomeninges, and along brain microvessels whereas microglia are involved to a minor extent and with a delay of several hours. Moreover, neurons do not typically express inflammatory markers after endotoxemia. Seizures induce a massive inflammatory response in parenchymal microglia and neurons (NF-ÎºB and cyclooxygenase [COX]-2 are significantly expressed by neurons). Moreover, changes induced by endotoxemia are relatively short-lasting when compared to those observed after seizures. These observations suggest that inflammation induced by seizures in the brain results from complex neurophysiologic events that differ in their duration and in the cell populations involved from classical immune reactions triggered by infection.

The long-lasting stimulation of the innate immune response and related inflammatory reactions observed after seizures may eventually promote infiltration of lymphocytes and the establishment of acquired immunity in the CNS. Whether this phenomenon occurs is still controversial in animal models: There is indication of a late penetration of $CD45^+$ monocytes into the brain parenchyma after seizures; however, Turrin and Rivest[97] recently reported that markers of adaptive immunity, such as the production of IL-12 and interferon (IFN)-Î³ by activated T cells, are undetectable in the brain of pilocarpine-treated mice at least up to 72 hours after seizure induction. Accordingly, immunostaining for T cells, B cells, and natural killer (NK)-cells was negative in the brain of kainic acidâ€"treated rats, although granulocytes and macrophages/monocytes were detected.[21]

The Role of Inflammation in Seizures

To address the functional consequences induced by inflammatory reactions on seizures and neuronal cell death, two main experimental approaches have been taken: (a) the intracerebral or systemic application of pro- and anti-inflammatory stimuli, and (b) the use of transgenic mice overexpressing proinflammatory cytokines in glia.

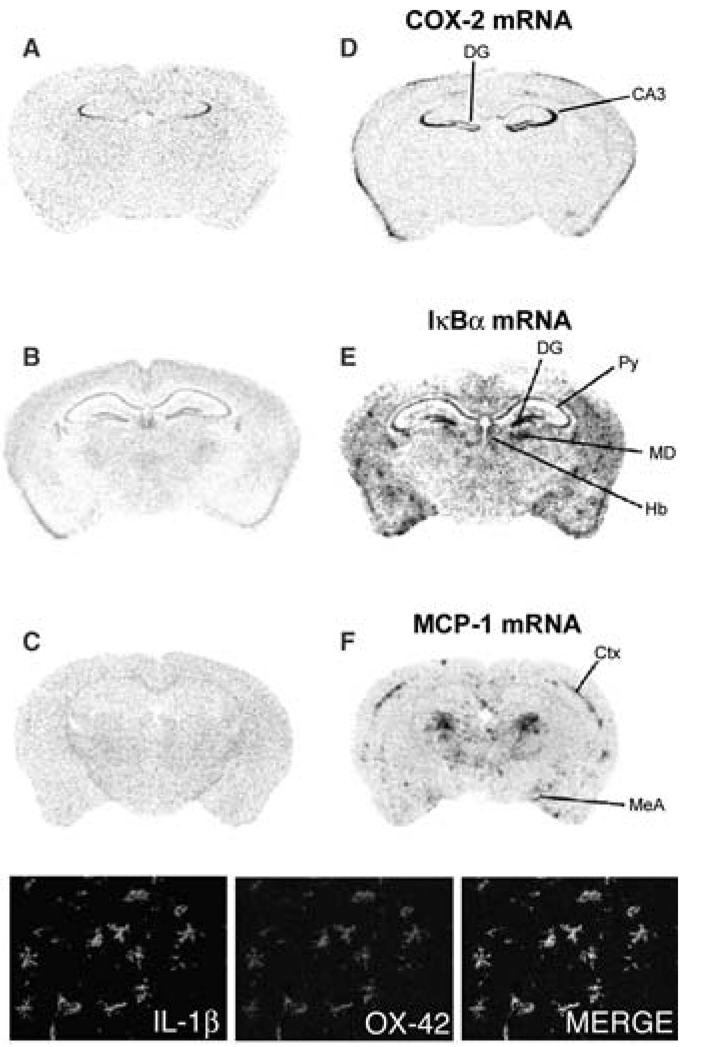

FIGURE 2. Seizure-induced expression of genes encoding proinflammatory molecules in rodent forebrain areas after seizures. Panels **D** through **F** show the increased hybridization signal of COX-2, IkBÎ±, (an index of NFÎºB activation), and the chemokine monocyte-chemoattractant protein (MIP)-1, 24 hours after seizures induced by pilocarpine in mouse forebrain sections (adapted from Turrin NP, Rivest S. Innate immune reaction in response to seizures: Implications for the neuropathology associated with epilepsy. *Neurobiol Dis.* 2004;16:321â€"334, with permission). Very low or nondetectable expression was found in basal conditions (saline-injected mice), as depicted in corresponding panels **A** through **C**. The phenotype of the expressing cells was identified using selective markers: The majority of cells expressing these inflammatory mediators were infiltrating monocytes and parenchymal microglia; in some instances also endothelial cells were positive. Neurons also overexpressed COX-2 and IÎºB mRNA. Micrographs in bottom row depict IL-1Î² and OX-42$^+$ microglia and their merged image, respectively. Ctx, cortex; CA3, pyramidal layer regions; DG, dentate gyrus; Hb, habenular nucleus; MD, mediodorsal thalamic nucleus; MeA, medial amygdala; Py, pyramidal cell layer. (See the color insert.)

IL-1Î² significantly exacerbates seizure activity when intra-cerebrally injected in rodents shortly before the induction of

P.269

hippocampal seizures or SE.[19,100,102] On the contrary, IL-1RA, a naturally occurring molecule that antagonizes the effect of endogenous IL-1Î², has powerful anticonvulsant activity,[103] and IL-1RAâ€"overexpressing mice display a reduced susceptibility to seizures.[102] These findings strongly suggest that an increase in brain levels of IL-1Î² has proconvulsant effects.

Recent data highlight the possibility that IL-1Î² signaling contributes critically to the hyperexcitability underlying febrile seizures (FS). Thus, intracerebroventricular injection of IL-1Î² reduces seizure threshold in 14-day-old mice subjected to hyperthermia[22] or in immature rats exposed to LPS-induced fever[31]; IL-1Î² receptorâ€"deficient mice or IL-1RAâ€"injected rats were resistant to the induction of this kind of seizures.

It is important to note that changes in seizure threshold or duration induced by components of the IL-1Î² system are independent of alterations in core temperature.[31] Hyperthermia-induced seizures can cause long-term effects on brain excitability in the absence of irreversible neuronal cell loss,[9] therefore highlighting the possibility that the IL-1Î² system may be critically involved in fever-induced epileptogenesis.

Biochemical studies have shown that IL-1Î² can increase glutamatergic neurotransmission, and this action may mediate its effects on seizures: IL-1Î² enhances the calcium influx induced by *N*-methyl-D-aspartate receptor stimulation in pyramidal hippocampal cells by inducing the phosphorylation of the NR2B subunit of this receptor complex[106]; IL-1Î² inhibits glutamate reuptake by astrocytes[111] and decreases the peak magnitude of Î³-aminobutyric acid (GABA)-mediated currents in cultured hippocampal neurons.[108]

The effect of TNF-Î± on seizures depends on its brain levels and the receptor subtypes primarily involved: Relatively low doses of TNF-Î± reduce seizure activity by interacting with TNF-Î± p75 receptors,[8] whereas mice overexpressing high amounts of TNF-Î± in glia show age-dependent spontaneous seizures and degenerative changes possibly mediated by p55 receptors.[1] A direct interaction between TNF-Î± and Î±-amino-3-hydroxy 5-methylisoxazole 4-propionate (AMPA) receptors has been recently demonstrated in hippocampal neurons: This cytokine acting on p55 receptors regulates the cellular trafficking of AMPA receptors by inducing their membrane expression in a molecular conformation that amplifies the glutamate responses but reduces $GABA_A$ membrane receptors.[91]

Transgenic mice overexpressing IL-6 in glia show a profound increase in their sensitivity to glutamate-induced seizures, and neuronal loss of GABA- and parvalbumin-positive neurons was constitutively found in the hippocampi of these animals.[84] Findings in transgenic mice suggest that a preexisting chronic inflammatory condition in the brain can predispose to the occurrence of seizures and promote neurologic dysfunctions. Accordingly, systemic administration of LPS to adult mice decreases their threshold to seizure induction, and this effect was blocked by anti-inflammatory drugs.[86] IL-1Î² and TNF-Î± also play an important role in the sensitization of CNS to infection-related seizures in rodents caused by *Shigella dysenteriae* or *Streptococcus pneumoniae.*[59,112]

Table 1 Inflammatory markers and anti-inflammatory treatments in experimental models of seizures

		Pharmacologic treatments	
Exp models	**Inflammatory markers**	**Anticonvulsant**	**Proconvulsant**
Chemoconvulsants	Cytokine and their receptors	Low corticosterone	High corticosterone
	Signalling pathways (NFkB;P38MAPK)	TNF-Î±/p75 receptor	High IL-1Î²

	COX-2, mPGES	IL-1RA	COX-1/2 inhibitors
	Adhesion molecules	Caspase-1 inhibitor	Aspirin (10 mg/kg)
	Chemokines	NSAID	
		Aspirin (â‰¤15 mg/kg)+	
		lipoxygenase inhibitor	
FS	IL-1Î²	IL-1RA	IL-1Î²
Infection	IL-1Î²,TNFÎ±		IL-1Î², TNF-Î±
MES	n.d.	Aspirin (100â€“500 mg/kg)	COX-1/2 inhibitors
Audiogenic seizures	IL-1Î±		
Kindling	Cytokine and their receptors	Low IL-1Î² Immunoglobulins	

Chemoconvulsions were provoked by kainic acid, bicuculline methiodide, penicillin, pentylenetetrazol, or pilocarpine. In general, the inflammatory markers were enhanced by seizures in glia and, in some instances, in neurons and in brain regions involved in the initiation and generalization of epileptic activity (see text for details). FS, febrile seizures; MES, maximal electroshock test; PTZ, pentylenetetrazol; mPGES, membrane/microsomal prostaglandin E synthase. After FS or infection, the cytokines were measured in plasma only; n.d., not determined; NSAID, nonsteroidal anti-inflammatory drugs.

Limited information exists on the role in seizures for other cytokines such as fibroblast growth factor (FGF), IL-2, IL-3, or interferon (see Vezzani[101] for details). Finally, sequential intrahippocampal infusion in rats of individual proteins of the membrane attack pathway of the complement system induced both seizures and neurotoxicity,[110] implying that complement activation in the brain may contribute to seizures and cell death in diseases such as Rasmussen encephalitis.

Anticonvulsant Effects of Anti-inflammatory Strategies

Table 1 summarizes the data available on the effects of anti-inflammatory strategies on seizures. Nonsteroidal anti-inflammatory drugs (NSAIDs) can attenuate seizures; in particular, ibuprofen and indomethacin reduced penicillin-induced electrocorticographic and motor seizures in rats[107]; a similar effect was observed with paracetamol. Aspirin also protected mice from maximal electroshock (MES)- and pentylenetetrazol-induced seizures and potentiated the anticonvulsant action of diazepam and sodium valproate.[90] In general, conflicting data are available on the effect of COX-1

and -2 inhibitors on seizures since prostaglandins can either reduce or promote seizures and affect neuronal cell survival differently depending on their specific type and receptor subtype interactions.[6,14,101]

Glucocorticoids (GCs) are potent inhibitors of the transcription of genes encoding most of the proinflammatory molecules, thus representing a critical endogenous negative feedback system with anti-inflammatory properties. Accordingly, a GC receptor inhibitor increased the inflammatory reactions induced by LPS in brain and enabled IL-1Î² and TNF-Î± to unveil neurotoxic effects. However, prolonged elevation of GCs (corticosterone) in the high physiologic range may induce a catabolically vulnerable state in neurons and result in an exacerbation of excitotoxic damage.[85] This dichotomy may explain also the paradoxical proconvulsant effects of corticosterone and dexamethasone on seizures.[51]

Interestingly, valproate inhibits the LPS-induced activation of NF-ÎºB and the subsequent production of TNF-Î± and IL-6 in monocytes and glioma cells. Carbamazepine was shown to decrease the LPS-induced production of prostaglandins and the activation of phospholipase A in rat glial cells.[39,58] This evidence suggests that part of their anticonvulsant effects may be mediated by nonconventional anti-inflammatory actions.

Inflammation and Neuronal Cell Survival

When administered individually, cytokines do not directly lead to cell death but they can have synergistic effects (e.g., IL-1 plus TNF-Î±) that result in neurotoxicity involving both necrotic and apoptotic mechanisms. IL-1 exacerbates excitotoxic injury in vivo, whereas IL-1RA reduces excitotoxic, traumatic, and ischemic brain damage.[2] Moreover, the extent of damage in the hippocampus after an excitotoxic insult appears to correlate significantly with the antecedent inflammatory cell infiltration and microglial activation, suggesting that neuronal damage can be at least in part caused by the preceding inflammation.[21]

Another cytokine effect that links them to epilepsy-related events is their inhibitory action on neurogenesis. In particular, neurogenesis is reduced by inflammation induced by radiation injury or LPS, whereas it is restored by indomethacin or inhibition of microglia activation by minocycline.[23,61]

Bloodâ€“Brain Barrier and Inflammation

During the past several years, increasing interest has arisen in the role of the BBB in epilepsy.[65] Advances in radiology have enhanced our ability to image and study the human BBB, and further developments in the research of metabolic deficiencies linked to seizure disorders, neuroinflammation, and multiple drug resistance to antiepileptic drugs (AEDs) have amplified the significance of the BBB relationship to epilepsy[5,28,42,57] (Fig. 3). Finally, a growing body of evidence has shown that inflammatory mechanisms may participate in the pathologic changes observed in the epileptic brain, with increasing awareness that blood-borne cells or signals may participate in epileptogenesis by virtue of a leaky BBB.

An indisputable correlation exists between BBB disruption and seizures. Seizures and epilepsy are commonly observed in conjunction with stroke, traumatic brain injury, and CNS infections, all conditions known to result in compromised BBB function.[7,34,83] In addition, regional patterns of BBB breakdown during epileptiform seizures induced in animal models by various convulsive agents have been quantified.[64] Unfortunately, whereas several microangiographic models are available to study the BBB in animal models, a suitable (i.e., microscopic, quantitative, and minimally invasive) technique for evaluating BBB integrity in humans does not exist. Compounded by insufficient means of investigation, a point of debate is whether (a) the BBB fails before, during, or after seizures; (b) the compromised integrity of the BBB is a component of the etiology of epilepsy or a consequence of seizures; and (c) drugs that preserve or restore BBB function (e.g., steroids or NSAIDs) can have beneficial effects.[95]

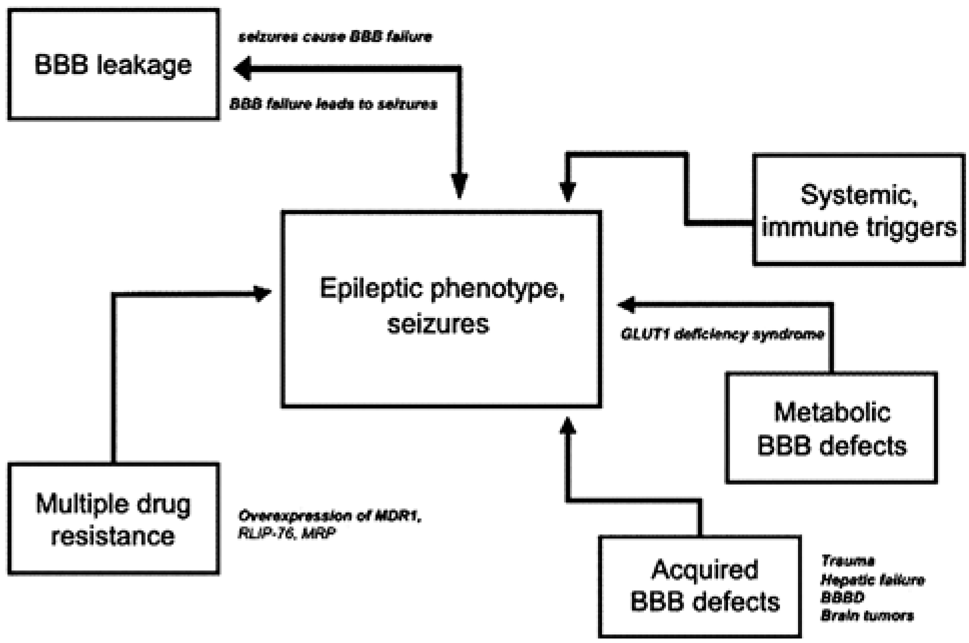

FIGURE 3. A contemporary view of the BBB's role in epileptogenesis, multiple drug resistance, metabolic epilepsies, and inflammation. See text for a review of these concepts.

BBB disruption after acute head trauma is a well-known pathologic finding in both animal studies and humans.[12,16,47]

P.271

This disruption may persist for weeks to years after the injury, and may be associated with abnormal electroencephalographic (EEG) activity.[47] Whether this abnormal activity develops into epilepsy is currently unknown, but observations have suggested that BBB disruption in conjunction with a slowing in EEG activity may be a precursor to seizures.[70]

Thus, strong evidence exists that BBB leakage may result in the development of seizures, but a clear-cut relationship and the exact nature of the offending mechanisms have remained elusive. This is likely due to the complexity of disease conditions associated with BBB leaks. These include concomitant hemodynamic disturbances (intracerebral hemorrhage or embolic stroke); loss of autoregulation of cerebral blood flow (e.g., in traumatic brain injury); and changes in intracranial pressure due to edema, inflammation, and the like. Furthermore, the lack of EEG data may actually underestimate the true impact of BBB failure on the breakdown of neuronal control.

BBB openings have been mapped for a variety of convulsive agents with different mechanisms of action (e.g., impairment of GABA transmission, increased glutamate neurotransmission, direct excitatory action).[4,41,64,78,94] Furthermore, with increased arterial blood pressure, the BBB becomes permeable to macromolecules under induced epileptiform seizures.[4,94] A direct link between the mechanism of action and the region where BBB breakdown was observed is not obvious. However, a few brain regions are easily affected by seizure activity irrespective of the means of induction.[4,41,68,70,78,94] Other regions of the brain show BBB breakdown only under the influence of specific convulsants.[64]

The results by Seiffert et al.[88] suggest that neurons tend to fire abnormally when exposed to molecules that extravasate through a leaky BBB. We studied the abnormal vasculature of rats exposed prenatally to the angiogenic inhibitor thalidomide in light of their results.[29] Abnormal neuronal development in these rats was associated with vascular malformations and a compromised BBB. Similar findings were reported by Marchi et al. for methylazoxymethanol (MAM)-treated rats.[56] A brief exposure to *intravascular* fluorescein isothiocyanate

(FITC)-albumin allowed for exploration of the integrity of the BBB and resulted in a significant accumulation of albumin in neuronal (but, surprisingly, not glial) cells. Thus, it appears that the leakage of the BBB observed in these animals was sufficient to cause extravasation of serum albumin to levels that allowed significant intraneuronal accumulation. Neuronal hyperexcitability was commonly associated with regions of abnormal cortical development characterized by protein extravasation. It is therefore possible that the altered neuronal properties of thalidomide- and MAM-treated rats are due to a combined â€œcircuitry effectâ€ (e.g., abnormal wiring of neurons) and a concomitant effect of molecules that are normally segregated into peripheral blood.

Neuroinflammation has been traditionally seen as a CNS-specific branch of immunology. Thus, a great deal of effort has been made to find immunocompetent or inflammatory cells in the brain (or spinal cord) parenchyma. It is now clear that virtually every class of brain cell has some potential or propensity to replicate immunologic or inflammatory processes. This emerging field was recently reviewed elsewhere.[99,101]

In addition to intrinsic inflammatory mechanism, it is increasingly clear that the peripheral immune system may, under certain circumstances, provoke havoc in the CNS. This is a rare occurrence, however, thanks in part to a BBB mechanism that (a) impedes or hampers cell migration across the endothelial cell monolayer and (b) prevents or reduces chemoattraction of potentially harmful macrophages. The flip-side of this is that CNS-specific antigen may be considered as non-self and thus lead to autoimmunity. Again, even when this happens, the BBB minimizes the risks associated with the presence of offending effector cells in the peripheral circulation.

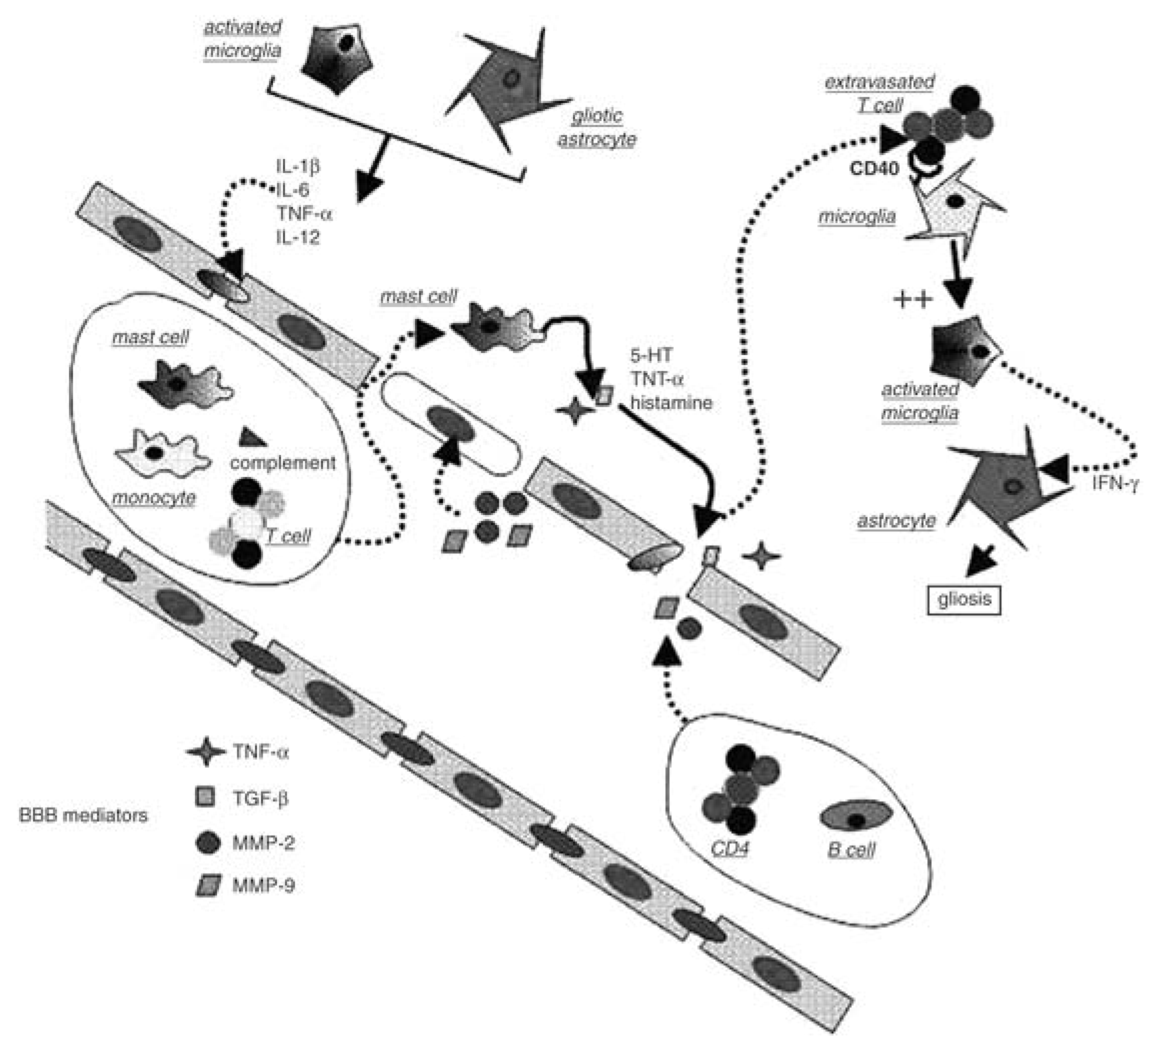

FIGURE 4. Schematic representation of the events that may link intraluminal inflammatory responses to

parenchymal proepileptogenic changes. Note that BBB failure is initiated by intravascular release of proteases that lead to a digestion of the endothelial cells that separate the brain parenchyma from the blood. This leads to subsequent extravasation of cellular and molecular players that ultimately may lead to abnormal epileptogenic activity.

Several potential explanations exist for the sometimes conflicting results obtained with animal models and direct comparisons to the human pathology. One of the issues that has not been fully explored is whether the increased or decreased levels of inflammatory mediators are a consequence of or are prodromic to the seizures. In addition to the temporal sequence of cause and effect, the cellular origin of inflammatory mediators is also important. It is commonly assumed that â€œbrainâ€ cytokines derive in fact from brain cells, whereas quantitatively, white blood cells are the main source of interleukins. In fact, the release of inflammatory mediators by blood cells results in focal BBB failure, and this may facilitate the extravasation of substantial quantities of cytokines.[48,49] This is likely followed by binding to CNS receptors, with a plethora of downstream effects. FIGURE 4 summarizes some of these events. An additional confounding factor is the type, duration, and intensity of seizures. All these combined may well produce opposite effects on the activation of cells either present in the brain or

transmurally influenced by a number of hemodynamic changes that are associated with seizures.

In conclusion, a number of variables including the BBB must be considered and experimentally controlled before the exact nature and consequence of inflammation in animal models of seizures can be understood. In any case, as in the case of more obvious neurologic disorders based on immune overreaction (e.g., multiple sclerosis), the BBB status is likely to play an important role.

Stress and Inflammation

Seizure activity is associated with strong activation of the stress axis. Stress induces the release of corticotropin-releasing hormone (CRH), leading to the secretion of GC, which strongly influence immune and inflammatory reactions.[62] In turn, immune molecules including cytokines, stimulate CRH secretion and thus activate the hypothalamus-pituitary-adrenal axis. The secretion of CRH can affect inflammatory reactions both by activation of GC or by direct interaction with its own receptors on immune cells and in the CNS.[10] Although stress has been regarded as mainly immunosuppressive, stress hormones can have complex effects,[21,85] including the regulation of T-cell differentiation, which leads to inhibition of cellular immunity while favoring humoral immunity.[24]

Human Studies

Immunogenetics

There are several reports on the association between IL-1Î² 511 allele polymorphism and temporal lobe epilepsy (TLE). An increased frequency of homozygotes for allele 2 was described in patients with TLE with hippocampal sclerosis (TLE+HS) compared with healthy controls or TLE patients without HS.[44] In an extension study, allele 2 was most frequent in patients with a history of prolonged FS and TLE+HS.[45] However, subsequent investigations in a population of patients of European ancestry suggested that an association between the IL-1 gene variation and TLE+HS may not exist.[15,32]

Table 2 Evidence for immune activation in human epilepsy

Epilepsy type	Autoantibodies	Immune genetics	Cytokine network
Newly diagnosed epilepsy	aPLâ†'	NA	SS IL-6â†' CSF/serum SE IL-6â†'â†' CSF/serum
Well-controlled epilepsy	aPL Â±, AGA Â±	NA	NA
Febrile seizures	NA	IL-1Î² polymorphism	IL-6â†' CSF, IL-1Î² CSF
Refractory epilepsy	GADâ†', aPLâ†'	IL-1Î² polymorphism	IL-6â†' serum interictally
	GM1â†'	IL-1Î² polymorphism	Brain IL-1Î²â†'
TLE+HS	GluR3â†'	HLA DQ2â†'	NFÎºBâ†'
Rasmussen's encephalitis	AGAâ†'	NA	NA
Cortical dysplasia	GluR3â†'	NA	Brain IL-1Î²â†'
	NA		

APL, antiphospholipid antibodies; NA, not available; SS, single seizure; CSF, cerebrospinal fluid; SE, status epilepticus; Â±, similar to controls; AGA, antigliadin antibodies; GAD, antibodies against glutamic acid decarboxylase; GM1, antibodies against GM1; GluR3, antibodies against GLUR3.

In a Finnish study, the distribution of IL-1Î± and IL-1Î² alleles was different in patients with severe localization-related epilepsy compared with control subjects; moreover, the patients who were noncarriers of the IL-1RA allele 2 were significantly more likely to be carriers of the IL-1Î² allele 2.[73] The IL-1Î² allele 2 is associated with increased production of IL-1Î², and the IL-1RA allele 2 is known to be associated with a high secretion of IL-1RA.[37] At present, the data on IL-1 polymorphism are conflicting, but new studies also demonstrate an increased frequency of haplotypes of human leukocyte antigen (HLA)

P.273

such as HLA DQ2, classically associated with autoimmune disorders, in patients with mesial TLE.[67] Taken together, these findings suggest that patients with severe localization-related epilepsy may have a genetically determined predisposition for an augmented immune response (high IL-1Î² production with decreased production of IL-1RA). An increase in the frequency and the carriage of IL-1Î² allele 2 was observed also in pediatric patients with FS compared with healthy blood donors.[104]

The Activation of the Cytokine Network in Human Epilepsy: Febrile Seizures

Because IL-1Î² is both the most potent endogenous pyrogen[27] and lowers seizure threshold in animal models (see previous paragraphs), its production may be associated with the hyperexcitability underlying FS. Other cytokines such as IL-6 may also induce fever and affect seizure parameters.

Helminen and Vesikari[33] reported a significant increase in IL-1Î² production in monocytes stimulated by LPS from children with FS compared with cells from children with bacterial or viral infections without convulsions, or those with no infection, thus suggesting that peripheral cells of the immune lineage from children prone to seizures may produce more proinflammatory cytokines. A different study showed increased production of IL-6 and IL-10 by peripheral blood mononuclear cells in response to LPS in pediatric patients with previous FS compared with a control population, whereas IL-1Î² production did not differ.[93] These contradictory results on IL-1Î² are most likely due to variations in cell-stimulation protocols (Table 2).

Conflicting results were also reported when measuring cytokine levels in the CSF and blood of epileptic patients. In this respect, no significant differences were observed between mean IL-1Î² levels in the CSF and blood of patients with FS as compared with children with febrile illnesses without seizures,[50] or in the CSF and plasma concentrations of IL-6.[38] Accordingly, no differences in plasma levels of IL-1Î² were found between patients with FS and febrile controls,[105] whereas the same study showed that the plasma IL-1RA-to-IL-1Î² ratio and plasma and CSF IL-6 levels were significantly higher in FS patients. In disagreement with the above-reported studies, the mean concentration of IL-1Î² was found to be significantly increased in the CSF of patients with FS, without any changes in the corresponding IL-1Î² serum levels.[30] The discrepant findings are most likely explained by differences in the time elapsed from sample collection and the last seizure, and by the different sensitivity of the assays used for cytokine measurements. Increased levels of proinflammatory cytokines in nonfebrile conditions have been reported in patients with West syndrome.[53]

The Activation of the Cytokine Network in Human Epilepsy: Adult Patients

Activation of the cytokine network has been demonstrated after single seizures in patients with new-onset seizure disorders. Among the cytokines studied, a robust increase occurred in soluble IL-6 concentrations both in CSF and plasma, and a trend of increased IL-1RA concentrations, whereas IL-1Î², TNF-Î±, or nerve growth factor (NGF) concentrations were not changed.[72,75] The type and duration of seizures seem to determine the extent of the increase in IL-6.[52]

Although ample experimental evidence confirms the activation of the IL-1 system in the brain during seizures, clinical studies failed to consistently report changes in peripheral or CFS levels of IL-1Î², although upregulation of IL-1RA appeared to occur. This may be due to the lack of strict correspondence between the brain changes in IL-1Î² and its CFS concentrations. Thus, the autocrine/paracrine effects of IL-1Î² can be produced by very low quantities of this cytokine, but may not result in measurable changes in its CSF concentration.[87] The increase in IL-1RA and IL-6 concentrations in CSF is an indirect evidence of the activation of the IL-1 system in human epilepsy, because IL-1Î² is the most potent activator of IL-1RA, and IL-6 is also one of the best markers of enhanced IL-1Î² activity.[20]

Additional evidence for the CNS origin of the cytokines is provided by studies on therapy-resistant patients showing that, during the interictal state, plasma levels of IL-1RA and IL-6 are modified in the absence of changes in the production and secretion of cytokines from blood mononuclear cells.[36] However, at variance with this evidence, an earlier study showed a greater production of IL-1Î±, IL-1Î², and IL-6 from peripheral blood mononuclear cells in response to proinflammatory stimuli in patients with epilepsy but without seizures for 6 months preceding blood collection, compared with control subjects.[69]

Still limited but convincing evidence demonstrates the presence of active inflammation in surgically removed hippocampi from epileptic patients. Increased production of IL-1Î± has been reported in the microglia in human TLE specimens,[89] and an enhanced release of inflammatory cytokines has been measured from hippocampal slices of epileptic tissue.[18] Overexpression of NFÎºB, a transcriptional factor mediating inflammatory

cascades, has been reported in hippocampal neurons and glia in TLE+HS patients.[17] Increased expression of cytokines and elevated levels of NFÎºB, TNF-Î±, and other proinflammatory markers have been described in brain samples from tuberous sclerosis; inflammatory markers have been found in dysplastic neurons and giant cells in tubers, thus suggesting that they may be related to the intrinsic hyperexcitability of cortical malformations and contribute to epileptogenesis.[54] Interestingly, high expression of IL-1Î² and its receptors, and IL-1RA was recently found in surgically resected specimens from focal cortical dysplasia and glioneuronal tumors. The number of IL-1Î² and IL-1RI$^+$ cells was positively correlated with the frequency of seizures, whereas the expression of IL-1RA was negatively correlated with the duration of epilepsy prior to surgery.[80] Other studies also document the presence of activated microglia and astrocytes in TLE.[13]

These findings indicate the activation of inflammatory cascades in human epileptic brain tissue that may be induced by recurrent seizures or even precede the onset of active epilepsy, or both.

Autoantibodies and Epilepsy

The role autoantibodies mediating inflammation in epilepsy has raised increasing interest since the first description of anti-GluR3 antibodies in Rasmussen encephalitis.[82] In subsequent studies, these antibodies have also been described in some other severe localization-related epilepsies.[55,109] Autoantibodies have also been implicated in refractory epilepsy, but their pathogenetic significance is less well established. In this respect, an increased prevalence of antiphospholipid antibodies was demonstrated among patients with epilepsy without any connective tissues disease.[3,25,71,98] Another class of antibodies with possible etiologic significance are those against GM1-gangliosides, which are a component of synaptic membrane and major regulators of ion currents. GM1 antibodies have shown to be epileptogenic in experimental studies,[46] and they have been measured in patients with therapy-resistant, localization-related epilepsy.[11] Antibodies to glutamic acid decarboxylase (GAD), an enzyme that catalyzes the conversion of L-glutamic acid to GABA, were found in patients with refractory focal epilepsy.[74] Recently, antibodies against the dietary protein gluten (contained in grains of wheat, rye, and barley) measured in patients with HLA DQ2 or DQ8 positivity were linked to TLE+HS.[43]

Treatments

In selected human epilepsies and experimental models, evidence suggests an anticonvulsant efficacy of intravenous administration of high-dose immunoglobulins (for review see Hirayama[35] and Vezzani[101]). The exact mechanisms of this action are not well established, but the modulation of circulating soluble factors, such as cytokines and antibodies, may be involved.[40] The anticonvulsant actions of adrenocorticotropic hormone (ACTH) and steroids are better documented in West syndrome and other epileptic encephalopathies (for review see Vezzani[101]). Finally, there is also evidence of anti-inflammatory actions of some antiepileptic drugs, as reported in the previous paragraphs.[39,58]

Summary and Conclusions

The hypothesis that chronic inflammation in the brain may be implicated in the etiopathogenesis of seizures is supported by experimental studies in rodent models of seizures showing that increased levels of inflammatory mediators have pro-ictogenic effects and can contribute to cell loss and BBB damage. Clinical studies support an activation of the cytokine system and downstream inflammatory events in the brain and, in some instances in blood and CSF, in pediatric and adult patients with epilepsy of various etiologies. Moreover, in some instances, anti-inflammatory or immunosuppressant treatments control seizures in otherwise drug-resistant epileptic patients.

Several issues await further investigations, including the nature of initial trigger(s) of an inflammatory response in the brain that may lead to the onset of epilepsy; to what extent seizure activity and/or injured cells may contribute to perpetuate inflammatory processes; the relative contribution of parenchymal brain cells, endothelial cells of the BBB, and peripheral immune cells to the increased levels of inflammatory mediators in the brain; and when during the epileptogenesis process these different sources of inflammatory molecules play a role.

If a relationship between inflammation and the etiopathogenesis of seizures were proven, this may suggest novel anticonvulsive treatments and possibly an innovative strategy for retarding or arresting epileptogenesis.

Acknowledgments

The authors wish to acknowledge Fondazione Mariani Onlus, Foundazione Monzino and Negri-Weizmann (A.V.) and the National Institutes of Health (NIH-NS43284, NIH-HL51614, NIH-NS46513, NIH-NS049514, and NIH-NS38195) (D.J.) for supporting part of these studies.

Chapter 26

Astroglial Mechanisms in Epilepsy

Christian SteinhÃ¤user

Philip G. Haydon

Nihal C. de Lanerolle

Introduction

Currently available anticonvulsant drugs and complementary therapies are not sufficient to control seizures in about a third of epileptic patients. Thus, there is an urgent need for new treatments that prevent the development of epilepsy and control it better in patients already inflicted with the disease. A prerequisite to reach this goal is a deeper understanding of the cellular basis of hyperexcitability and synchronization in the affected tissue. Epilepsy is often accompanied by massive reactive gliosis. Although the significance of this alteration is still poorly understood, recent findings suggest that modified astroglial functioning may have a role in the generation and spread of seizure activity. In the following sections we detail properties of astrocytes as well as their changes that can be associated with epileptic tissue. Our goal is to provide an understanding of the working knowledge of this cell type with the long-term view of providing a foundation for the development of novel hypotheses about the role of glia in seizure disorders.

Basic Physiology of â€œNormalâ€ Astrocytes

Before discussing details of membrane physiology of astrocytes, it is important to note that it is likely that there are different types of cells with astroglial properties within a given brain region, and that astrocyte properties may vary in different subregions. However, at this time we have only little understanding of the different properties of these cells and how heterogeneous these cell types are. In rodents, the majority of astrocytes express the astrocyte-specific protein, glial fibrillary acidic protein (GFAP); have a high resting K^+ conductance; are coupled in a syncytium through gap junctions, and have linear current/voltage relationships. A second type of cells, which we will also call astrocytes or astroglial cells, contains GFAP mRNA, but expresses a plethora of voltage-gated ion channels and are not coupled in a gap junction syncytium. It is likely that the functional impact of these two subtypes of cells with astroglial properties is distinct. For example, in the hippocampus the former cells express glutamate transporters, while the latter express Î±-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)-type glutamate receptors.[80,125]

Membrane Physiology

Astrocytes express almost the same set of ion channels and receptors as do neurons,[67,108,120] although the relative strength of expression varies between the two cell types. For example, in astrocytes, K^+ channel density by far exceeds that of Na^+ channels, preventing generation of glial action potentials. Nevertheless, a glia-specific, or at least preferential expression, has been elucidated for some of these channels and carriers. Among them is Kir4.1, a subunit belonging to the family of inwardly rectifying K^+ (Kir) channels. In the central nervous system (CNS) this channel is predominantly localized at distant astrocyte processes surrounding synapses or capillaries.[58] Recent work suggests a colocalization of Kir4.1 with the water channel aquaporin-4 (AQP4), which in the brain and spinal cord is also expressed by astrocytes but not neurons. Increasing evidence indicates that a coordinated action of both channels is required for the astrocytes to maintain K^+ and water homeo-stasis in the CNS.[89,121] As illustrated in the following sections, dysfunction of these astroglial transmembrane channels appears to play a key role in epilepsy.

In contrast to the majority of mature neurons, astrocytes are usually coupled through gap junctions to form large intercellular networks. Astrocytic gap junctions are mainly formed by connexins 43 and 30 (Cx43 and Cx30) in a cell-type specific fashion. Through these networks astrocytes can dissipate molecules, such as K^+ or glutamate, a process considered important to prevent their detrimental extracellular accumulation.[116] Recent data suggest that the capacity of K^+ clearance is only partially disturbed in the absence of astrocyte gap junctions, presumably because of the existence of â€œindirectâ€ coupling of elongated astrocytic processes.[126] Connexins also contribute to the propagation of intercellular Ca^{2+} waves, presumably by enhancing adenosine triphosphate (ATP) release, rather than by providing an intercellular pathway for signal diffusion.[87] However, the pathologic impact of disturbed astroglial gap junction expression is not well understood yet.[110,110a]

Another main function of astrocytes is removal of neurotransmitters released by active neurons. Uptake of glutamate is accomplished by two glia-specific transporters, EAAT1 and EAAT2 (in rodents termed GLAST and GLT-1), the activity of which may shape the kinetics of receptor currents at some synapses.[11,32] Compelling evidence suggests that disturbed glutamate uptake by astrocytes is directly involved in the pathogenesis of epilepsy, as discussed in the following sections.

However, astrocytes can also release neuroactive agents, including neurotransmitters. Several studies revealed that such a release is critically dependent on an increase of astroglial $[Ca^{2+}]_i$. Astrocytes express a plethora of neurotransmitter receptors that are coupled through G proteins (G_q) and phospholipase C to the release of Ca^{2+} from internal stores.[56] Stimulation of neuronal afferents induces Ca^{2+} elevations within astrocytes,[33,98] which can spread to neighboring astrocytes, demonstrating the presence of an astrocyte-to-astrocyte network.[28,111] Thus, although astrocytes are electrically inexcitable, these glial cells contain a chemically based form of excitability that is bidirectionally linked to

P.278

neuronal activity.[56] Though initially discovered in 1994,[92] the past decade has seen many studies demonstrating that astrocytes release chemical transmitters (â€œgliotransmittersâ€), including glutamate, ATP, and D-serine.[56,124] Although the mechanisms underlying astroglial transmitter release are open to debate, at least part of the release seems to occur through regulated, Ca^{2+}-dependent exocytosis, a mechanism that in the CNS was previously thought to be exclusive to neurons.

What is the impact of transmitter release from astrocytes? Several reports suggested that gliotransmitters may activate receptors in neurons to modulate the strength of inhibitory and excitatory synaptic transmission[13,50,66,93,94,132,135] (reviewed by 124). Importantly, because with their fine terminal processes single astrocytes reach tens of thousands of synapses simultaneously,[25] the release of gliotransmitters may lead to the synchronization of neuronal firing patterns.[6,49] The different gliotransmitters that are released from astrocytes have quite distinct functions. Glutamate, the first identified gliotransmitter,[92] is able to modulate neuronal excitability[6,49,117] through actions on the *N*-methyl-D-aspartate (NMDA) receptor, as well as to modulate synaptic transmission.[50] D-serine is a coagonist of the NMDA receptor. Released D-serine can bind to what has been termed the glycine-binding site of the NMDA receptor and, as a consequence, enhance NMDA receptor function. In the hypothal-amus, the amount of astrocyte-derived D-serine supplied to synapses can regulate which forms of synaptic plasticity occur. In conditions where little of the coagonist is supplied a long-term synaptic depression can result, whereas when D-serine is locally supplied to the synapse long-term potentiation results.[91] The release of ATP from astrocytes can have a variety of functional actions. In cultures it has been shown that the release of ATP is important for mediating components of Ca^{2+} waves that propagate between astrocytes: During a Ca^{2+} elevation ATP is released from an astrocyte, which then has paracrine actions on neighbors, which induces further Ca^{2+} signals and ATP release.[53] Because cell surfaces express a plethora of ectonucleotidases, once ATP is released it is rapidly hydrolyzed to adenosine. As a consequence, ATP that is released from astrocytes leads to synaptic modulation mediated by adenosine.[94] In the hippocampus high-frequency activity of groups of synapses causes Ca^{2+} signals in neighboring astrocytes, which then release ATP, and after the hydrolysis to adenosine, cause a presynaptic inhibition of neighboring synapses.[94] In this manner the astrocyte coordinates the strength of synaptic signaling. As illuminating as these studies have been, we still await an understanding of the functional consequences of gliotransmission on neural network function, processes such as learning and memory and ultimately behavior. Rapid forms of neuronâ€“glia interactions seem also to be involved in the regulation of local blood flow as demonstrated in cortical brain slices where neuronal stimulation led to glutamate release, activation of metabotropic glutamate receptors (mGluRs) in astrocytes, and regulation of the tone of vessels contacted by processes of the stimulated astrocyte.[86,112,136] Emerging evidence suggests that disturbances of these mechanisms are involved in the pathogenesis of epilepsy, as discussed below.

Several important aspects of neuronâ€“glia interactions are not yet understood. Thus, as outlined above, recent studies corroborated the finding that astrocytes are heterogeneous with respect to antigen profiles and functional properties, but it is still unclear which type(s) of astroglial cells are activated and are capable of releasing transmitters, which transmitters can be released by astrocytes, which mechanisms these cells use for the release, and whether the efficiency of neuronâ€“glia signaling changes during development. Intriguingly, a recent report presented evidence that a subtype of cells with astroglial properties even receives direct synaptic input from glutamatergic and Î³-aminobutyric acid (GABA)-ergic neurons.[62] The physiologic impact of this type of interaction remains to be clarified.

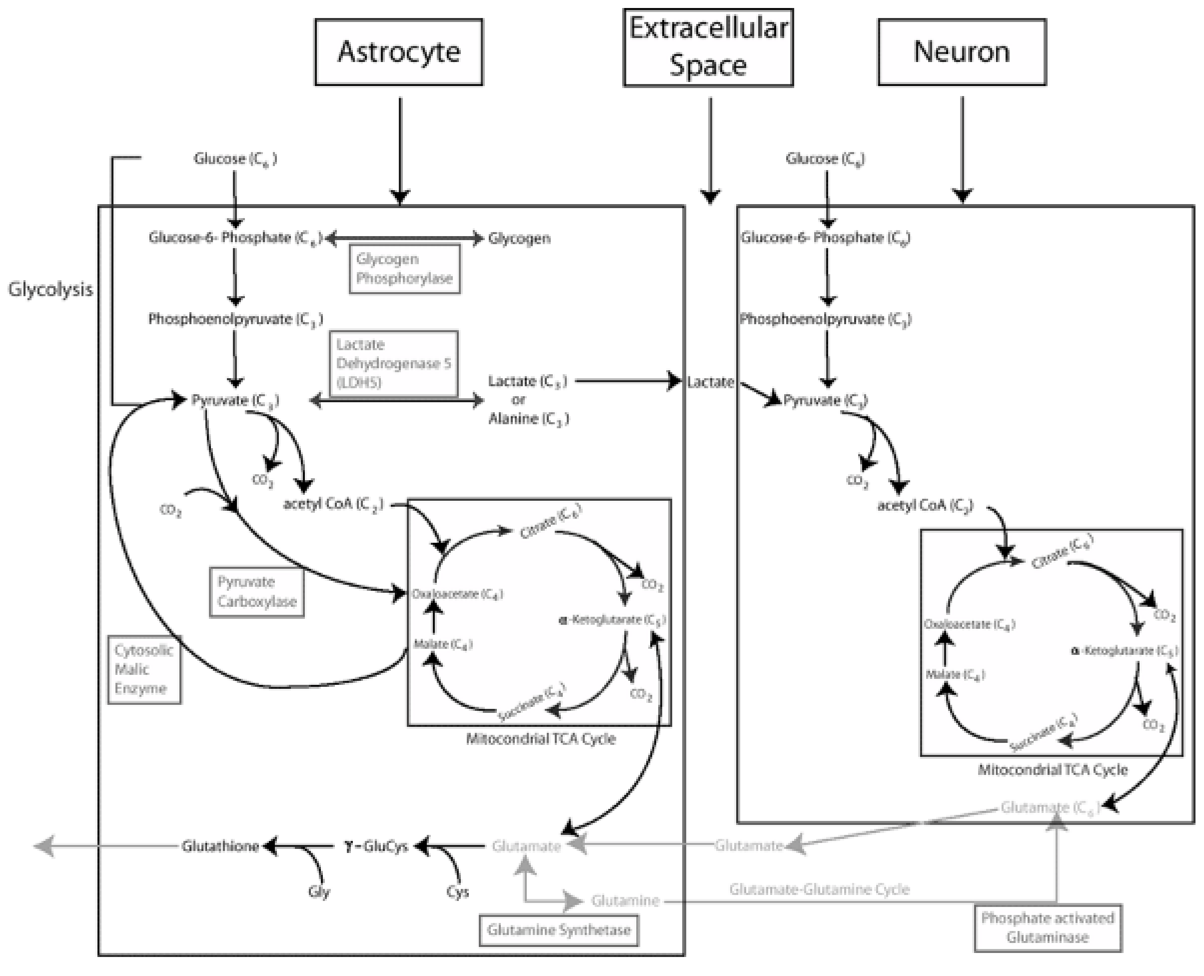

FIGURE 1. Shown schematically are similarities and differences of the energy metabolic pathways in astrocytes compared to neurons. Note the distinctive enzymes found in only in astrocytes (*in boxes*).

Astrocyte Metabolism

Astrocytes play an important role in the metabolism of the brain through their unique degradation of both glucose and glutamate.[57] The astrocyte's importance for these processes lies in their possession of some key enzymes not normally found in neurons. These enzymes are glutamine synthetase, pyruvate carboxylase, and cytosolic malic enzyme.

Glucose is the main energy source of the brain. It is a six-carbon chain molecule that is degraded to its end-products, carbon dioxide and water. The metabolism of glucose takes two stages. Glycolysis in the cytosol yields two ATP molecules and can occur in the presence or absence of oxygen, whereas oxidative metabolism in the mitochondria yields 36 ATP molecules per molecule of glucose through its conversion to acetylcoenzyme A (acetyl-CoA) and breakdown in the tricarboxylic acid (TCA) cycle.[57] Astrocytes, like neurons, are capable of metabolizing glucose through both pathways. The TCA cycle is limited by the fact that its intermediates continuously leave: Neuronal glutamate is lost to glia, glutamate is used for glutathione synthesis in astrocytes, and glutamine is used for GABA synthesis in GABAergic neurons.[57] Such a loss of carbon skeletons without replenishment can impair neuronal ability to produce amino acid transmitters and the rate of oxidative metabolism. Astrocytes alone are capable of replenishing carbon skeletons because they, rather than neurons, possess the enzyme pyruvate carboxylase, which can de novo carboxylate each molecule of pyruvate to a molecule of oxaloacetate (four carbon atoms) that can be inserted into the TCA cycle to replenish it.

The glutamate released by neurons during excitatory synaptic activity is largely removed from the synaptic cleft by astrocytic glutamate transporters (cf. above). Once in the astrocyte, glutamate is converted to glutamine by the addition of ammonia, a reaction catalyzed by the enzyme glutamine synthetase that is found in astrocytes (and oligodendrocytes) but not neurons. The glutamine thus produced is released into the extracellular space where it accumulates in high concentrations (~0.25 mM)[54] and is returned to neurons. In the neuron, glutamine is hydrolyzed to glutamate, the reaction being catalyzed by the enzyme phosphate-activated glutaminase (PAG). Several lines of evidence show that glutamine produced by astrocytes is essential for the production of neuronal glutamate.[57] This exchange of glutamate and glutamine between neurons and astrocytes is described as the glutamateâ€“glutamine cycle.

Conversion to glutamine is not the only fate of astrocytic glutamate. With high levels of extracellular glutamate, some of the glutamate taken up by astrocytes can be deaminated or transaminated to Î±-ketoglutarate and then metabolized in the TCA cycle.[82] Under conditions of high extracellular glutamate, Î±-ketoglutarate may also leave the TCA cycle as malate to be converted in the cytosol to pyruvate, catalyzed by the cytosolic malic enzyme, which is restricted to glia.[83] Pyruvate can either be reintroduced into the TCA cycle via acetyl-CoA or be converted into lactate and exported to neurons.

Glial cells, especially astrocytes, also have a prominent capacity to produce lactate in the presence of normal oxygen levels.[127] This process, also called aerobic glycolysis, is stimulated on exposure of astrocytes to glutamate.[95] Further, mobilization of glycogen reserves in astrocytes by various neurotransmitters has been shown to result in enhanced lactate release.[41] The presence of the lactate dehydrogenase 5 (LDH5) isoform in astrocytes favors conversion of pyruvate to lactate. Lactate is released into the extracellular space and used as an energy source by neurons. Thus, astrocytes act as a lactate source inside the brain, especially during enhanced synaptic

P.279

activity, and the concept of an astrocyte-neuron lactate shuttle has been proposed.[96] In vivo dialysis studies in sclerotic hippocampi have demonstrated increased levels of lactate along with glutamate during seizures.[43]

Astrocytes, rather than neurons, contain the cystineâ€“glutamate exchanger.[32] This transporter helps astrocytes to accumulate cystine, which is reduced to cysteine for the production of astrocytic glutathione.[40] Synthesis of glutathione occurs primarily in astrocytes. In the process of glutathione formation, astrocytes release glutathione into the extracellular space, which is essential for providing neurons with the glutathione precursor L-cysteinyl glycine, formed from glutathione by the coenzyme Î³-glutamyl transpeptidase.

These distinctive metabolic pathways in astrocytes are summarized schematically in FIGURE 1.

Astrocytes in the Pathology of Epileptic Foci

Neurons have been the primary focus of attention in the study of the pathology of the epilepsies, because ictal activity is generated by neurons. It is, however, becoming clear that glial cells, in particular astrocytes, may play a major role in the excitability generated at seizure foci.[110a,117] With this finding in mind, re-examination of the pathology of seizure foci may indicate a significant astrocytic component in many seizure foci.

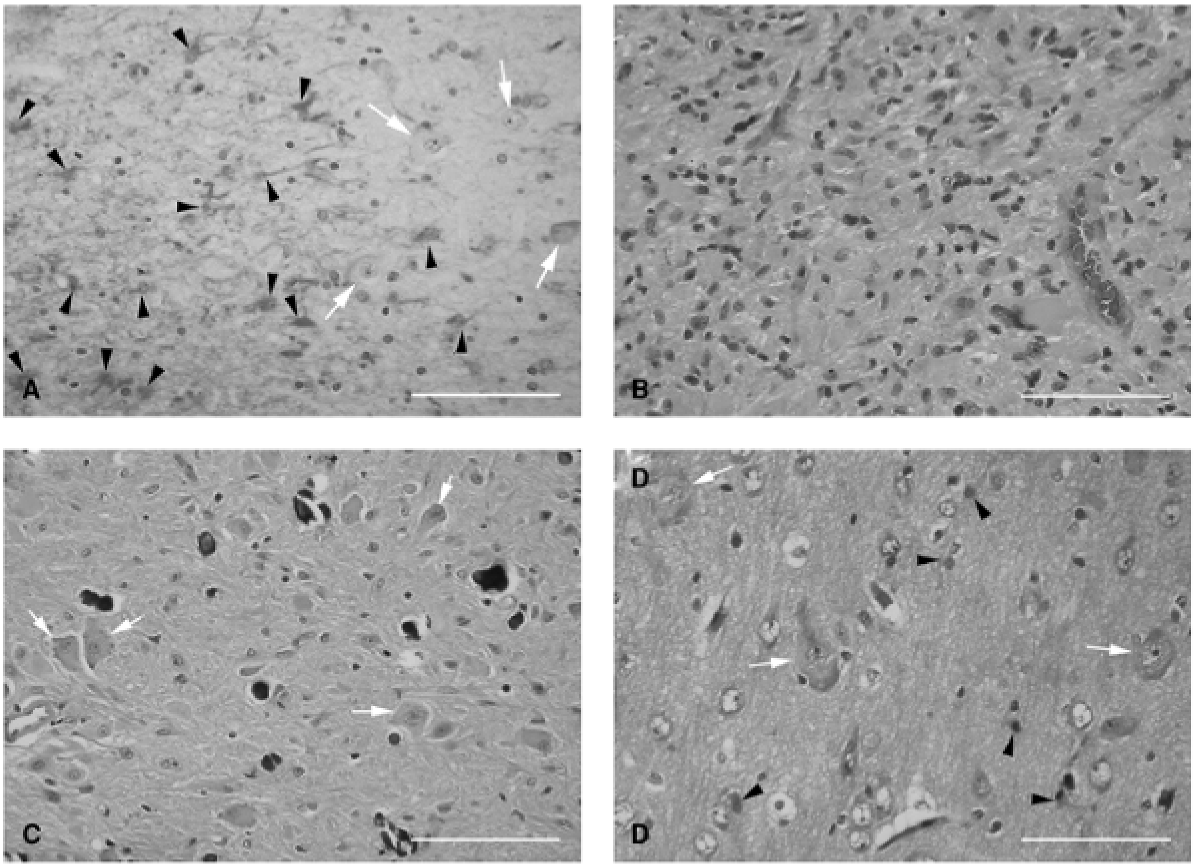

FIGURE 2. Photomicrographs of four human neuropathologic conditions associated with seizures in which astrocytes are a prominent component of their cellular composition. **A:** Hippocampal sclerosis: A portion of the hippocampus immunostained for glial fibrillary acidic protein (GFAP; peroxidase-DAB) and Nissl counterstained. The right third of the picture is area CA2 of the hippocampus showing some remaining neurons (*white arrows*). The left two thirds represent area CA1 that shows an almost complete loss of neurons, with GFAP immunopositive astrocytes (*black arrowheads*). **B:** Astrocytoma: A hematoxylin and eosinâ€“stained section of an astrocytoma showing neoplastic astrocytes with considerable variation in size and shape of individual nuclei. **C:** Tuberous sclerosis: A portion of a cortical tuber stained with hematoxylin and eosin, showing abnormal neurons (*white arrows*) in a background matrix of fibrillary gliosis. Calcification is seen as scattered black structures. **D:** Hemimegalencephaly: A hematoxylin and eosinâ€“stained portion of cortical neuropil showing large, highly anomalous neurons (*white arrows*) and astrocytes (*black arrowheads*). Scale bars, 100 Âµm. (Picture provided by kind courtesy of Dr. Jung H. Kim, Neuropathology, Yale School of Medicine.)

Temporal Lobe Epilepsy

Perhaps the most prominent seizure focus with a major astrocytic component is the sclerotic hippocampus in mesial temporal lobe epilepsy (TLE). Hippocampal sclerosis has been associated with TLE, and the prevalence of this pathology has been variously estimated. Early autopsy studies found between 30% and 58% of TLE cases presenting with hippocampal sclerosis.[20,77,109] Examination of specimens from patients who had undergone surgery for the control of medically intractable TLE showed a similar proportion. Falconer reported that about 43% to 47% of his patients suffered from Ammon horn sclerosis (AHS)[23,47]; the UCLA series of temporal lobectomies for TLE found hippocampal sclerosis in 65% of the cases.[78] In the latter two studies, patients with hippocampal sclerosis had a better surgical outcome than those without it. Careful analysis of the pathology and electrophysiology of 151 hippocampi removed in the Yale surgical series revealed that about 60% of the specimens presented with AHS.[34] After surgery, 84%

of AHS patients had an excellent (Engel class I), seizure-free outcome.

What is most striking about the sclerotic hippocampus is that it is significantly depleted of its neuronal populations but has an increased population of glia, especially astrocytes (Fig. 2A) and microglia. Anatomic and physiologic studies published to date[35,110,110a] indicate that astrocytes in the sclerotic hippocampus display many unusual characteristics compared to those of nonsclerotic hippocampi. However, neither the extent of the molecular uniqueness of astrocytes in the sclerotic hippocampus nor the molecular processes underlying their genesis and function are currently understood.

Mass Lesions

Seizures are a major clinical manifestation also of intracranial tumors, being observed in about 35% of cases.[68] The majority of primary brain neoplasms are derived from glial cells and are collectively called gliomas. Gliomas are the most common among epilepsy-related tumors and are predominantly low grade. Among the epileptogenic gliomas, astrocytomas (Fig. 2B) are most frequent, being found in 50% to 70% of cases.[68] Regardless of their type or grade, surgical removal of gliomas result in excellent seizure control (citations in 68). In hemimegalencephaly, a rare disorder closely associated with seizures, there is often diffuse proliferation of astrocytes in the cortex as well as subcortical white matter in addition to cortical neuronal abnormalities (Fig. 2D).

Tuberous Sclerosis

Tuberous sclerosis complex (TSC) is a disease that is manifested due to mutations in the TSC1 and TSC2 genes of the human genome. Epilepsy occurs in about 90% of affected individuals.[31] The pathologic substrates of TSC are also associated with astrocytes. Brain lesions of TSC are of three types: Cortical tubers, subependymal nodules, and subependymal giant cell astrocytomas (SEGAs). Cortical tubers show abnormal cortical lamination and are characterized by the presence of a proliferation of astrocytes in addition to dysmorphic neurons and eosinophilic giant cells (Fig. 2C).[37,52] Subependymal nodules are also composed predominantly of dysplastic astrocytes and mixed-lineage astrocytic or neuronal components,[37] giant cells, and, sometimes, calcium depositions.[64] SEGAs also display astrogliosis, dysmorphic neurons, and giant cells. Thus, all three pathologies are associated with astrogliosis. Even the giant cells have astrocytic properties. Yamanouchi et al.[131] divided giant cells into two subtypes: â€œNeuronlike giant cellsâ€

and â€œindeterminate giant cells.â€ The majority of the latter were positive for GFAP, vimentin, and nestin, markers expressed by astrocytes, and rarely contained neurofilaments. In conclusion, brain lesions of TSC, in addition to other alterations, also seem to be associated with defects in astrocyte biology.

Astrocyte Dysfunction Contributes to Seizure Generation in Temporal Lobe Epilepsy

The hippocampal seizure focus in TLE has been studied the most, compared to other seizure foci in the brain. Through these studies there is rapidly emerging a picture of astrocytes at the sclerotic hippocampal seizure foci as having unique structural and functional characteristics. In this section these characteristics are reviewed to exemplify some of the mechanisms through which they may contribute to seizure generation and compare them to what is known of astrocytes at other seizure foci (see Astrocyte Dysfunction at Other Seizure Foci section).

Voltage-Gated Na^+ and Ca^{2+} Channels

Information about changes in Na_v channel expression in experimental or human epilepsy is inconsistent. Comparative patch clamp analyses were performed in hippocampal specimens with and without significant astroglial sclerosis, surgically removed from patients with intractable TLE. Two papers reported enhanced Na^+ current densities in human astrocytes from sclerotic specimens[17,18] (Fig. 3), while no increase was found in another human study[59] and in the hippocampus of kainate-treated rats, an animal model of TLE.[61] It is conceivable that this apparent discrepancy reflects subregional differences because the latter two studies investigated astrocytes in the CA1 region while the aforementioned focused on the hilus.

During seizure activity, the extracellular Ca^{2+} concentration decreases at the site of the seizure focus. Low $[Ca^{2+}]_o$, in turn, generates spontaneous epileptiform activity. In this regard it is worth considering the observation that depletion of external Ca^{2+} can induce Ca^{2+} oscillations in astrocytes. Increase in $[Ca^{2+}]_i$ is known to induce the release of the excitatory amino acid glutamate from astrocytes, a process that seems to contribute to seizure generation (see Ca^{2+} Signaling in Astrocytes: A Source of Glutamate section). Although decreases in $[Ca^{2+}]_o$ probably arise from Ca^{2+} influx into neurons, Ca^{2+} channels in astrocytes might also contribute to the depletion. Notably, immunostaining revealed an up-regulation of astrocyte L-type Ca^{2+} channels both in the kainate model of epilepsy and sclerotic hippocampal specimens from TLE patients,[38,128] suggesting enhanced glial uptake of Ca^{2+} in the lesioned CNS (Fig. 3). Besides a rapid and direct contribution to seizure generation via depletion of $[Ca^{2+}]_o$, enhanced astroglial Ca^{2+} influx is likely to stimulate synthesis and release of transmitters, cytokines, and growth factors, which may modify the architecture and activity of neural circuitry on a long term.

K^+ Channels and Water Channels

Seizure activity in vivo is characterized by elevations of $[K^+]_o$ from 3 mM to a ceiling level of 10 to 12 mM, while on the other hand, high $[K^+]_o$ levels are sufficient to trigger seizurelike events in acute brain slices. Because of its presumed importance in the regulation of excitability, properties of astroglial Kir channels have been investigated in experimental and human epilepsy. Evidence of an involvement of Kir channels in impaired K^+ buffering in sclerotic human hippocampus came from measurements of $[K^+]_o$ with ion-sensitive microelectrodes and patch clamp studies. Heinemann's group compared the effect of Ba^{2+} on stimulus-induced changes in $[K^+]_o$ in the CA1 region of hippocampal brain slices obtained from TLE patients with (AHS) or without sclerosis (non-AHS). In non-AHS tissue, Ba^{2+} significantly augmented rises in $[K^+]_o$, while this effect was not observed in AHS specimens. Since Ba^{2+} is a blocker of Kir channels, these findings suggested impaired function of these channels in the sclerotic tissue.[69] Indeed, direct evidence for a down-regulation of Kir currents in the sclerotic human CA1 region of epilepsy patients came from a comparative patch clamp study.[17,59] Together, these data indicate that in the sclerotic condition, impaired K^+ buffering through reduced expression of functional Kir channels contributes or even initiates seizure generation (Fig. 3). Preliminary data suggested an involvement of the Kir4.1 subunit in this process.[104]

Recent studies revealed a spatial overlap of Kir (subunit Kir4.1) and water channels (aquaporins) in astroglial end-feet contacting capillaries[58,89] and suggested that buffering of K^+ via Kir channels depends on concomitant transmembrane flux of water in the same cell. These parallel water fluxes are thought to be necessary to dissipate osmotic imbalances due to K^+ redistribution. In agreement with this hypothesis, clearance of extracellular K^+ is compromised upon reduction of the perivascular pool of astroglial AQP4,[4] and impaired K^+ buffering in concert with prolonged seizure duration is observed in AQP4-/- mice.[16] Hence, dysfunction of the bloodâ€"brain barrier (BBB) seems to be involved in seizure generation (see also Astrocytes and Bloodâ€"Brain Barrier Modifications at Seizure Foci section). In the sclerotic hippocampus of TLE patients, AQP4 immunoreactivity of vasculature-associated astrocyte end-feet was lower compared with nonsclerotic human epileptic hippocampi.[45] This loss of perivascular AQP4 is probably secondary, following disruption of the dystrophin complex that is necessary for anchoring of AQP4.[3] In conclusion, in the sclerotic hippocampus of TLE patients dislocation of water channels in concert with reduced expression of Kir channels in astrocytes probably underlies the impaired K^+ buffering leading to increased seizure propensity.

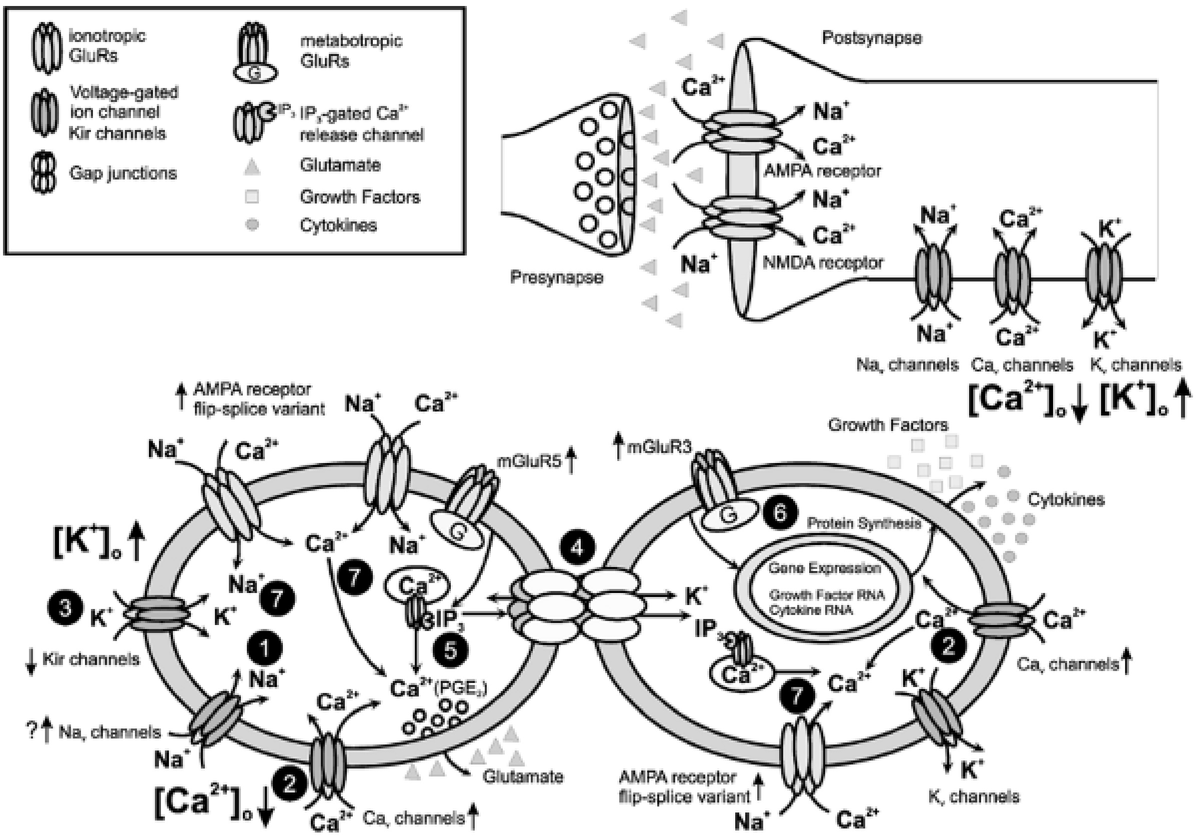

FIGURE 3. Temporal lobe epilepsyâ€“associated alterations of functional properties in glial cells. Neuronal hyperactivity produces enhanced release and spillover of glutamate, increase in $[K^+]_o$, and a reduction of $[Ca^{2+}]_o$. (1) Up-regulation of Na^+ channels in astrocytes of the sclerotic hippocampus might enhance $[Na^+]_i$ and modulate the activity of Na^+-dependent transporters in the glial membrane. (2) During seizure activity, $[Ca^{2+}]_o$ decreases at the focus site. Astroglial Ca^{2+} channels are up-regulated in experimental epilepsy, suggesting that part of the extracellular Ca^{2+} depletion is due to enhanced influx of Ca^{2+} into glial cells through Ca^{2+} channels. Enhanced $[Ca^{2+}]_i$ might promote the production and release of transmitters, cytokines, and growth factors from astrocytes. (3) Epileptiform activity is accompanied by an increase in $[K^+]_o$. Down-regulation of Kir channels was observed in astrocytes at the seizure site, leading to an impaired clearance of K^+ ions from the extracellular space and to stronger neuronal depolarization. (4) Glial gap junction coupling is involved in the propagation of intracellular Ca^{2+} waves, transmitter release, and neuronal activation, and thus might contribute to seizure spread. Clear evidence for a dysregulation of gap junctions in epileptic tissue is still missing. (5) Astroglial mGluR5 is up-regulated in animal models of epilepsy, which enhanced IP_3 hydrolysis, induced Ca^{2+} oscillations, and led to glutamate release through a prostaglandin E_2 (PGE_2)-dependent mechanism. This might strengthen the cascade described in (4). (6) Enhanced expression of mGluR3 was observed in astrocytes of epileptic tissue, suggesting the induction of gene expression and protein synthesis of growth factors and cytokines. Release of these factors from glial cells probably contributes to the reorganization of the neuronal circuitry. (7) Astrocytes in human Ammon horn sclerosis (AHS) primarily express the flip forms of AMPA receptors, leading to an enhanced influx of Ca^{2+} and Na^+. Coactivation of AMPA receptors and mGluRs linked to the IP_3â€“Ca^{2+} cascade stimulates Ca^{2+}-dependent glutamate release and generates Ca^{2+} waves in glial cells. The AMPA receptorâ€“mediated increase in $[Na^+]_i$ mediates an inhibition of Kir channels and reduces the K^+ buffer capacity of astrocytes. (From SteinhÃ¤user C, Seifert G. Glial membrane channels and receptors in epilepsy: impact for generation and spread of seizure activity. *Eur J Pharmacol.* 2002;447(2â€“3):227â€“237, with permission.)

Glutamate Transporters and Receptors

Several studies have suggested an involvement of glutamate transporters and receptors in seizure development and spread. Increased extracellular levels of glutamate have been found in epileptogenic foci.[51] Glutamate transporters are expressed by several CNS cell types, but astrocytes are primarily responsible for glutamate uptake. Important studies using mice with deletion[113] or antisense oligonucleotide-mediated inhibition of synthesis[102] of the astroglial transporter GLT-1 revealed that this subtype is responsible for the bulk of extracellular glutamate clearance in the CNS. GLT-1 knockout mice, but not antisense inhibition, developed spontaneous seizures and hippocampal pathology resembling alterations in TLE patients with AHS. Pharmacologic inhibition of GLT-1 reduced the threshold for evoking epileptiform activity.[26,36] Reduced GLAST and GLT-1 expression was also observed in a tuberous sclerosis epilepsy model,[130] but other animal studies were contradictory. Tessler et al.[115] investigated transporter expression on the mRNA and protein levels in human TLE specimens and found changes neither for GLT-1 nor GLAST. However, two other groups reported decreased GLT-1 protein as well as reduced[79] or increased[99] GLAST immunoreactivity in the sclerotic human hippocampus. The latter authors also noted an up-regulation of GLT-1 in the nonsclerotic epileptic hippocampus. These findings supported the hypothesis that reduced or dysfunctional glial glutamate transporters in the

hippocampus may trigger spontaneous seizures in AHS patients,[44] yet the underlying mechanisms are unclear. It has been proposed that the role of glutamate transporters in epilepsy may not be related directly to the control of excitation through synaptic glutamate concentration but rather to the glutamate-dependent metabolism.[76] In this context, the finding of a loss of glutamine synthetase in the sclerotic versus nonsclerotic hippocampus of TLE patients[46] deserves further consideration. After uptake of glutamate into astrocytes, this enzyme rapidly converts the transmitter into glutamine that is then transported to neurons, where it may be resynthesized to glutamate (see Astrocyte Metabolism section). Eid et al. did not observe epilepsy-related changes in the expression of GLT-1. They concluded that in the sclerotic tissue, down-regulation of glutamine synthetase caused a slowing of the glutamateâ€“glutamine cycling and accumulation of the transmitter in astrocytes and in the extracellular space.[46] This conclusion was compatible with findings in animal models of epilepsy and

earlier data, demonstrating slowed glutamateâ€“glutamine cycling in sclerotic human epileptic hippocampus with magnetic resonance spectroscopy.[97] Whether activation of glutamate transporters (e.g., through Î²-lactam antibiotics[103]) might be beneficial in the treatment of epilepsies remains a matter of further investigation.

A few studies addressed the potential involvement of ionotropic glutamate receptors in seizure generation. Mouse mutants with deficient GluR2 Q/R editing developed early-onset epilepsy with spontaneous and recurrent seizure activity, suggesting that enhanced Ca^{2+} influx through the Q form of the GluR2 subunit of AMPA receptors reduces seizure threshold.[22] Astrocytes also carry the GluR2 subunit, but altered glial GluR2 editing seems not to play a role in human TLE (but see Gliomas section). Rather, combined functional and single-cell transcript analyses put forward the idea that enhanced expression of GluR1 flip variants account for the prolonged receptor responses observed in hippocampal astrocytes of TLE patients with AHS.[106,107] This alteration in the splicing status of AMPA receptors predicts enhanced depolarization upon activation by endogenously released glutamate. Prolonged receptor opening will promote influx of Ca^{2+} and Na^{+} ions, and the latter plug astroglial Kir channels,[105] which will further strengthen depolarization and reduce the K^{+} buffer capacity of astrocytes (Fig. 3). It is yet unknown whether the changes in glial receptor function are causative of or result from the epileptic condition. Also, the question of how and to what extent alterations in glial GluR1 splicing contributes to seizure generation or spread requires further investigation. Astrocytes cultured from patients with Rasmussen encephalitis, a rare form of childhood epilepsy, showed spontaneous Ca^{2+} oscillations that were dependent on transmembrane influx of Ca^{2+}.[75] The authors speculated that these responses might add to neuronal hyperactivity, possibly due to autocrine ionotropic glutamate receptor stimulation by glutamate released from astrocytes. Another study suggested that the destruction of astrocytes by GluR3 antibodies plays a critical role in the progression of this autoimmune disorder.[129]

Ca^{2+} Signaling in Astrocytes: A Source of Glutamate

Under normal conditions, mGluR3 and mGluR5 are the predominant metabotropic glutamate receptor subtypes expressed by glial cells. Activation of these receptors affects cyclic adenosine monophosphate (cAMP) accumulation and leads to an increase in intracellular Ca^{2+}, respectively. The Ca^{2+} rise may oscillate and initiate Ca^{2+} wave propagation within the astrocyte network, activate Ca^{2+}-dependent ion channels, and induce glutamate release from astrocytes (see Membrane Physiology section). In experimental epilepsy, reactive astrocytes of the hippocampus persistently up-regulate mGluR3, mGluR5, and mGluR8 protein.[110] Electron microscopic inspection of hippocampal tissue from TLE patients revealed expression of mGluR2/3, mGluR4, and mGluR8 in reactive astrocytes, suggesting an involvement of these receptors in gliosis.[114] Up-regulation of astroglial mGluR2/3 and mGluR5 was also observed in epileptic specimens from patients with focal cortical dysplasia.[8] Because their activation modulates the expression of GLAST and GLT-1[7] and elevates $[Ca^{2+}]_i$, mGluRs in astrocytes might be involved in the generation of seizure foci (Fig. 3).

Over the past decade Ca^{2+} signaling mechanisms in astrocytes have received considerable attention. Of particular importance for this discussion is the novel observation that astrocytes exhibit Ca^{2+}-induced release of glutamate, which provides direct excitation to neighboring neurons (see Membrane Physiology section). Because of the observed changes in protein expression within astrocytes following injuries that lead to the development of epilepsy, it is tempting to speculate that alterations in this glial-derived excitatory pathway in coordination with reductions in glutamate uptake might provide an excitatory drive underlying seizure disorders. Recent work suggested that in chemically induced, acute epilepsy models, astrocytic Ca^{2+} oscillations and glutamate release contribute to the generation of synchronized epileptiform activity.[48,117] Future work has to elaborate whether astrocytes provide sufficient excitation to contribute to seizures and whether they indeed represent new targets for the development of antiepileptic treatments.

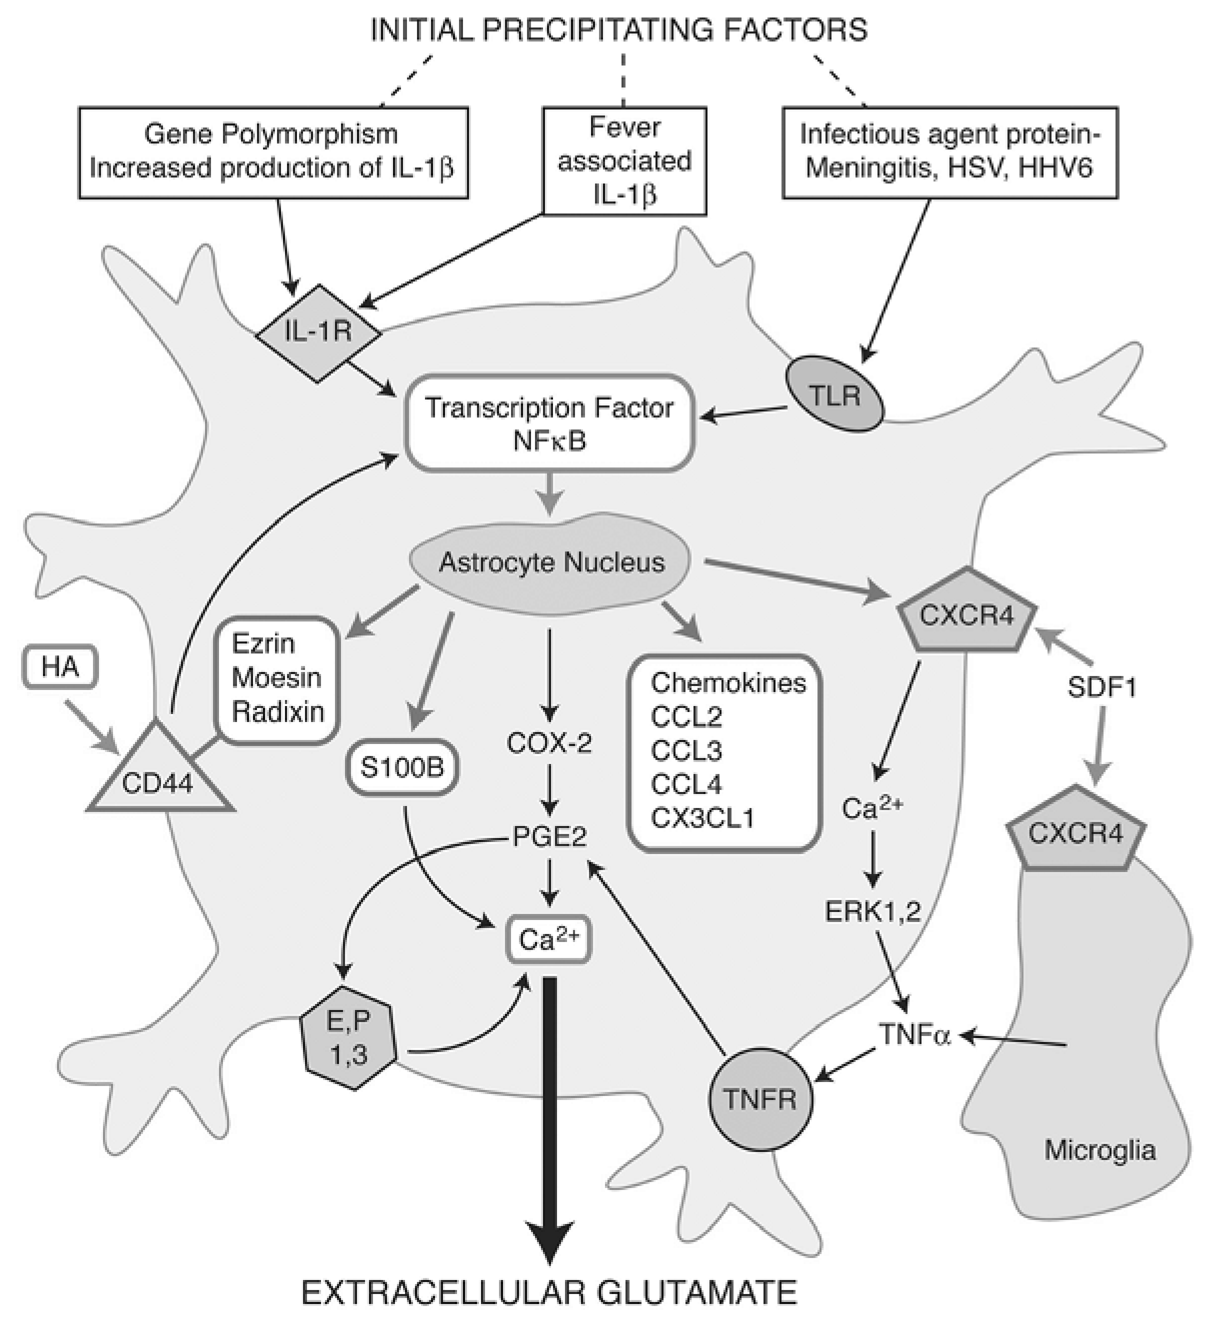

FIGURE 4. Probable molecular path-ways for glutamate release from astrocytes in the sclerotic hippocampus. This diagram is constructed on the basis of molecules produced by genes whose expression was found to increase in human temporal lobe epilepsy (TLE). The figure also shows that many of the pathways could be activated through known initial precipitating factors of TLE. CCL2, CCL3, and CCL4, CC family chemo-kines; CD44, CD44 antigen (homing function and Indian blood group system); CX3CL1, fractalkine; CXCR4, Î±-chemokine receptor; COX-2, cy-clooxygenase-2; EP1,3, calcium mobi-lizing receptors for PGE$_2$; ERK1,2, extracellular signalâ€“related kinases; HA, hyaluronan; IL-1Î², interleukin-1Î²; HSV, herpes simplex virus; HHV6, human herpes virus 6; IL-1R, interleukin 1 receptor; PGE$_2$, prostaglandin E$_2$; SDF1, stromal derived factor 1; TLR, Toll-like receptor; TNFR, tumor necrosis factor receptor; TNF-Î±, tumor necrosis factor-Î±. (Figure provided by courtesy of Dr. Tih-Shih Lee, PhD thesis, Yale University.)

Responses to Immune and Inflammatory Factors

Astrocytes are known to contribute to the inflammatory environment of the CNS by producing a wide range of immunologically relevant molecules. They can express class II major histocompatibility complex antigens, and produce a variety of chemokines and cytokines.[39,63] Proinflammatory cytokines have only begun to be recognized for their role in seizure disorders. Kanemoto et al. observed a strong association of a polymorphism in the IL-1Î² gene in patients with sclerosis compared to nonsclerosis patients and nonepileptic controls.[12,65] The biallelic polymorphism favors high production of IL-1Î² in patients with AHS. Other etiologic factors in TLE, such as febrile seizures, are also associated with increased IL-1Î² levels.[42,55,123]). IL-1Î² can act on astrocytic IL receptors and, via the transcription factor NFÎºB, induce the expression of a variety of molecules (Fig. 4). Immunohistochemical analysis of hippocampi removed from patients with medically intractable TLE revealed increased production of the NFÎºB-p65 subunit in astrocytes of sclerotic tissue compared to control specimens.[30]

In a recent study of differential gene expression in sclerotic hippocampi of TLE patients, several genes that could be regulated through the NFÎºB pathway were found to be up-regulated, including S100Î², ezrin, radixin, and moesin; the chemokines CCL2, CCL3, CCL4, and CX3CL1; and the chemokine receptor CXCR4[35,70] (Fig. 4). IL-1Î² can also activate cells to induce CD44 to bind to hyaluronan,[100] and interleukins may also activate microglia to express CXCR4.[14] The presence of activated microglia that express CXCR4 in the sclerotic hippocampus has been demonstrated.[70] Such activated microglia may be an important source of tumor necrosis factor (TNF) and IL-1Î².[2,88] Glutamate release by astrocytes, via a Ca^{2+}-regulated exocytosislike process, has now been established. Molecules such as S100Î², CD44, and CXCR4 might directly or indirectly activate this glutamate release pathway[10,14] (Fig. 4). Hence, up-regulation of some of the relevant molecules in astrocytes in the sclerotic hippocampus may lead to increased release of glutamate. A closer study of immune mechanisms in the pathology of TLE may hold important new insights to this disease.

Furthermore, the immunologic responsiveness of astrocytes may provide the clue as to how a variety of initial precipitating factors[78] may be associated with the common pathologic substrate of hippocampal sclerosis. It is established that early childhood febrile seizures can be predisposing for TLE,[60,72] and such febrile seizures have been shown to be associated with increased IL-1Î² levels in CNS and blood plasma.[42,55,123] High IL-1Î² levels are also associated with a genetic polymorphism.[65,122] IL-1Î² can act on astrocytic interleukin receptors and, via the transcription factor NFÎºB, might induce molecular pathways leading to Ca^{2+}-dependent glutamate release (Fig. 4).

Infections of the brain such as meningitis,[90] human herpes virus 6, and herpes simplex virus[118] were also shown to be associated with TLE, and again astrocytes might be

important in this context. Human astrocytes express Toll-like receptors (TLRs),[24] which recognize pathogen-specific molecular patterns.[84] A wide range of TLRs is expressed by astrocytes, including those that respond to viruses and bacteria.[27] Both IL-R1 and TLRs induce signal transduction pathways, leading mainly to activation of the transcription factor NFÎºB[81] and possibly to enhanced release of astroglial glutamate in the sclerotic hippocampus (Fig. 4).

Astrocytes and Bloodâ€“Brain Barrier Modifications at Seizure Foci

It was reported as early as 1899[20] that there is proliferation of the microvasculature in the sclerotic Ammon horn. However, only recently has attention been paid to the role of the BBB in seizure disorders. The BBB is composed of endothelial cells characterized by extensive tight junctions, absence of fenestrations, and sparse pinocytic vesicular transport.[9] Astrocytic end-feet ensheathe blood vessels and release signals that support the formation and maintenance of the tight junctions between endothelial cells, as well as the expression of endothelial transport molecules. Astrocytes also play an active role in the short-term modulation of BBB permeability.[1]

The BBB participates in several important functions. Among them is the transport of glucose into the brain. GLUT1 is the principal glucose transporter in astrocytes. GLUT1 is found in at least two forms, a 55-kDa form in endothelial cells and a 45-kDa form primarily associated with astrocytes. There are little data on the role of GLUT1 in TLE, though in one study endothelial GLUT1 was reduced (interictally) in the temporal lobes of patients with complex partial seizures.[29]

Astrocytes play a significant role in buffering of extracellular K^+, and impaired K^+ clearance has been observed in the sclerotic human hippocampus (see K^+ Channels and Water Channels section). Kir4.1 and AQP4 water channels are predominantly located on astrocytic end-feet associated with the BBB. In astrocytes from sclerotic hippocampi, the polarity in the distribution of AQP4 is lost.[45,71] This may be associated with reduced clearance of extracellular K^+ and enhanced severity of seizures, as K^+ buffering through astrocytic Kir channels depends on a parallel flux of water.[45] In addition, there are several other molecules whose distribution along the end-foot membrane of the BBB are altered in epilepsy. These include increased expression of erythropoietin receptor,[21] increased plectin 1 (PLEC1),[73] and decreased dystrophin.[71]

Recent microarray studies,[70] while confirming the distribution of AQP4, PLEC1, and dystrophin, pointed to changes in the expression of several other molecules, including AHNAK, CD44, dystrobrevin A, CCL2, and CCL3. AHNAK is a molecule that is reported to be associated with a new type of vesicle, the â€œenlargosome,â€[19] which may contribute to enlarging the perivascular end-foot volume as reported in the brain of animal models of seizures.[4] It has been shown that human brain

microvessels carry chemokine receptors CCR1 and CCR2 on the parenchymal surface of the vessels.[5] The genes for the ligands of these receptors, CCL3 and CCL2, are up-regulated in mesial TLE (MTLE). These chemokines are thought to influence the permeability of the BBB.[1] In-depth analysis of the roles of these molecules at the endothelial/astrocyte interface may provide important advances in understanding the pathophysiology of TLE.

Astrocyte Dysfunction at Other Seizure Foci

Tubers in Tuberous Sclerosis

Several lines of evidence suggest that astrocytes in tuberous cortex seizure foci may play a major role in seizure initiation and maintenance. The strongest evidence comes from astrocyte-specific TSC1 conditional knockout mice. These mice have increased numbers of GFAP-positive astrocytes, in the absence of frank cortical tubers, and more interestingly, they exhibit electroencephalographically confirmed seizures.[119] These astrocytes display impaired glutamate transport and thus may cause seizures by extracellular accumulation of glutamate[130] as shown in human TLE hippocampus.[44] Further, in these mice, the hippocampus showed the most pronounced enlargement and significant architectural disorganization, whereas the cortex was grossly normal. These data strongly suggest that changes induced in astrocytes by TSC gene mutations may be even more important for seizures than neuronal disorganization of the cortex. These features associated with TSC1 dysfunction are surprisingly reminiscent of the sclerotic hippocampus in patients with MTLE, especially regarding astrocytic proliferation. Therefore, it is possible that a common pathology of astrocytes in MTLE and TSC may explain the occurrence of seizures in these disorders.

Gliomas

Intratumoral microdialysis studies have been carried out in patients with high-grade astrocytomas.[101] These studies show that glucose tended to be lower in the tumor than in the peritumoral region, whereas lactate was significantly higher in the tumor. Only necrotic tumors displayed significantly higher glutamate levels. Human gliomas of high-grade malignancy contained reduced adenosine compared to distant tissue.[85] In a more recent microdialysis study of grade III and IV gliomas, Bianchi et al.[15] reported significantly reduced glutamate levels in the tumor compared to peritumoral and distant cortex. Moreover, they observed significantly elevated levels of taurine, GABA, phenylalanine, isoleucine, tyrosine, valine, leucine, and lysine. Only in tumors associated with epilepsy, extracellular glutamate levels were significantly decreased and glutamate concentration strongly correlated with the degree of cell proliferation.

Two main hypotheses have been put forward as to how gliomas (glioblastomas) may contribute to epileptic seizures. One of the hypotheses is based on the discovery of the underediting of the glutamate receptor subunit GluR2 at the Q/R site in human malignant gliomas.[74] The GluR2 subunit is abundantly expressed by human astrocytes,[106] and transgenic mice with a reduced rate of Q/R-site editing developed early-onset epilepsy and premature death (see glutamate transporters and receptors section). Underediting at the Q/R site results in increased Ca^{2+} permeability of the AMPA receptor, which may modulate gene expression to activate pathways and result in increased glutamate release by the glioma cells, causing excitation of surrounding neurons and resulting in seizures and excitotoxic death, which permits the spread of the tumor. A second hypothesis is suggested by the work of H. Sontheimer's group.[133,134] Studying cultures of glioma cells isolated from glioblastomas surgically removed from patients and established human glioma cell lines, they found that these cells released larger than normal amounts of glutamate. They further showed that Na^{+}-dependent glutamate uptake by glioma cells was up to 100-fold lower than in astrocytes. Immunohistochemistry and subcellular fractionation studies showed very low expression of the astrocytic glutamate transporter GLT-1 but normal levels of GLAST, which, however, was mislocalized to the nucleus. Thus, these cells were deficient in glutamate clearance. The unusual release of glutamate from glioma cells was shown to be due to both the reduced Na^{+}-dependent glutamate transporters and an up-regulation of cystineâ€"glutamate exchange.[134] It is conceivable that excess release of glutamate by tumors may generate seizure activity in peritumoral neurons.

Summary and Conclusions

Astrocytes undergo morphologic alterations in epilepsy, and recent evidence suggests that the structural changes are accompanied by variations in cellular function. Since astroglial cells have been identified as direct communication partners of neurons, their dysfunction might be involved in the pathogenesis of the disease. In fact, surgical removal of sclerotic tissue often results in a significant improvement of the epileptic condition, suggesting that gliosis contributes to seizure generation. It remains an important issue to figure out what factors initiate the dysregulation of astrocytic signaling molecules, and whether these changes are causative for the development of the disease. Moreover, the specific role different astroglial subtypes play in epilepsy still has to be elaborated. If these cell types are differently affected in epilepsy, this will likely produce distinct consequences for the excitability of neural circuitry. In fact, cells with astroglial properties differ significantly in their morphologic and functional properties, but most studies describing glial alterations in epilepsy did not identify the cellular subtype affected. Thus, it is important to appreciate that some of the changes we have discussed may represent changes in the properties of one astroglial subtype, or changes could result in modified ratios of different subclasses of astrocytes. A further understanding of the diversity of â€œnormalâ€ astrocytes, by establishing critical parameter sets allowing unequivocal subclassification, will be an essential step to help us unravel the role of astrocytes in epilepsy and other neurologic disorders. Progress made in the field over the past years suggests that this should eventually open novel rational therapeutic approaches to seizure disorders, which, so far, can only be poorly controlled.

Chapter 27

Neuromodulation of Seizures, Epileptogenesis, and Epilepsy

Helen E. Scharfman

Robert Schwarcz

Introduction

Epilepsy is a complex disease that is influenced by a large number of diverse variables. Some of these factors, such as genes that influence seizure susceptibility, are internal. Others, which alter normal brain excitability, such as traumatic brain injury, are external.

These variables can have different and distinct effects. For example, genes may influence both the development of the disorder (epileptogenesis), or the frequency and severity of seizures after epilepsy is established. Furthermore, these same factors may also influence treatment, because they can alter the efficacy of antiepileptic drugs.

A broad range of endogenous factors include a subset that can be termed â€œneuromodulators.â€ These factors are essential components of the normal central nervous system (CNS) and play an important role in the balance of excitation and inhibition in the normal brain. Here, we review neuromodulatory compounds and principles that best exemplify those that affect seizure susceptibility, epileptogenesis, and epilepsy.

In this chapter, neuromodulators are categorized into proteins and small molecules that are (a) primarily expressed in, or released from, neurons; (b) present in the extracellular space as part of the milieu that is commonly referred to as the extracellular matrix (ECM); and (c) primarily associated with astrocytes.

This review emphasizes neuromodulators that influence excitability in the hippocampus and the adjacent parahippocampal region (including the entorhinal cortex), two brain regions known to be centrally involved in limbic seizure activity. This focus does not imply that neuromodulation is most robust in those areas, but rather reflects the fact that the majority of information in the field of epilepsy research derives from these limbic regions. This includes studies in humans, in which neuromodulation has been mostly examined using surgically resected hippocampal and parahippocampal tissue from patients with intractable temporal lobe epilepsy (TLE).

In view of the complexity of the subject matter, often involving multiple receptors as well as intricate modes of regulation of expression and release for any given neuromodulator, only specific examples will be discussed in detail in each category. Furthermore, a major message of this overview is that no single neuromodulator influences excitability in a simple manner, and that cross-talk between modulators is likely to be associated with seizure activity.

Tables 1,2,3,4 provide bulleted lists of the neuromodulator categories that have been associated with pathophysiologically or therapeutically relevant aspects of seizures or epilepsy. The selection included here should be viewed merely as a snapshot of current knowledge. There can be little doubt that additional members of these families will become relevant as well, and that novel, important neuromodulators will be identified in the future.

Neuron-derived neuromodulators

Neuropeptides

Neuropeptides comprise a variety of small proteins that were originally shown to be coexpressed with classical neurotransmitters in neurons; it was assumed that this coexpression indicated a role in synaptic transmission. Accordingly, many studies focused on the mechanism(s) by which peptides might exert their effects in concert with colocalized classical transmitters such as Î³-aminobutyric acid (GABA) or glutamate. It is widely recognized, however, that neuropeptides have effects independent of classical transmitters. These effects include an influence on ion channels, synaptic transmission, and hence excitability. Neuropeptides also affect growth, proliferation, vasculature, and neurogenesis, although these effects may only occur at a certain time during development or after an injurious insult.

A discussion of neuropeptides is particularly germane to epilepsy because many have robust effects on seizure threshold, seizure susceptibility, epileptogenesis, and epilepsy (i.e., the state of spontaneous, recurrent seizures). However, the concept that neuropeptides modulate seizuresâ€"and potentially epilepsyâ€"did not arise from studying their basic, fundamental properties as cotransmitters. Instead, it was initiated by reports that showed that seizures alter the expression of neuropeptides and their receptors. This was first demonstrated in laboratory animals,[80,138] although seizure-induced alterations in neuropeptides have also been found in surgically removed brain tissue from patients with intractable TLE.[50]

To date, it is still widely debated whether these changes in neuropeptide expression reflect a mechanism to repair the brain after seizure-induced neuronal damage or whether altered levels of neuropeptides indicate a compensatory, anticonvulsant response of the brain to prevent further seizure activity. An intriguing suggestion is that these changes are due to a pattern of genomic responses set into play to recapitulate developmental patterns.

Table 1 lists a large number of neuropeptides, organized according to the initial studies describing their expression and function throughout the body. Notably, these perspectives have evolved over time, because many of these peptides were identified in more than one brain area and found to have multiple functions.[204]

Figure 1 illustrates a focused view of these neuropeptides, using the dentate gyrus as an example. The dentate gyrus harbors a variety of GABAergic interneurons, which normally play an important role in preventing abnormal excitability. These neurons also contain one or more neuropeptides. In addition,

two principal cellsâ€"the abundant granule cells and the less numerous hilar â€œmossy cellsâ€â€"use glutamate as a neurotransmitter and also express various peptides, as well as other neuromodulators. This subregion of the hippocampus plays a central role in seizure generation and propagation in animals and humans, and has been studied extensively with regard to the neuromodulatory effects of peptides in epilepsy.

Table 1 Neuropeptides

Family Member	Amino Acid #	Receptors	Convulsant Pro (+) or Anti (â€“)	References
POMC-derived neuropeptides				
Adrenocorticotropin (ACTH)	39	MCR2	(-)	28

Melanocyte stimulating hormone (MSH)	13	MCR1	(-)	1
Î²-Lipotropin (Î²-LPH)	89			
Met-enkephalin	5	Âµ,Î´,Îº	Âµ: (+)	171,196
Leu-enkephalin	5	Âµ,Î´,Îº	Âµ: (+)	171,196
Î²-Endorphin	30	Âµ,Î´,Îº	(-)	229
Dynorphin	17	Âµ,Î´,Îº	(-)	196,229
Nociceptin (Orphanin FQ)	17	ORL-1	(-)	170
Tachykinins				
Substance P	11	NK1	(+)	229
Neurokinin-A	10	NK2		
Neurokinin-B	10	NK3	(+)	229
Bradykinin	9	B1, B2	(+/-)	2
Hypothalamic peptides				
Hormones				
Thyrotropin stimulating hormone (TSH)	201			
Oxytocin (OT)	9		(-)	1
Luteinizing hormone (LH)	204			
Follicle stimulating hormone (FSH)	204			

Vasopressin (AVP) or antidiuretic hormone (ADH)	9	V1A, V1b, V2	(+)	1, 37, 45
Growth hormone	191			
Releasing and inhibiting factors				
Corticotropin releasing hormone (CRH or CRF)	41	CRF1,2	(+)	
Thyrotropin releasing hormone (TRH)	3	TRH1,2	(-)	118
Growth hormone releasing hormone (GnRH)	44			
Luteinizing hormone releasing hormone (LHRH or GHRH)	10			
Somatostatin growth hormone release inhibiting hormone	14 or 28	SST (1-5)	(-)	20, 223
Gut peptides				
Motilin	22			
Cholecystokinin (CCK)	8	CCK1,2	(-)	244
Vasoactive intestinal polypeptide (VIP)-glucagon family				216
Secretin	27			
VIP	28	PACAPR type II	(+)?	39, 48
Pituitary adenylate cyclase activating peptide (PACAP)	27 or 38	PACAPR type I	(+)	37, 39

Glucagon-like peptide (GLP)-1	36	GLP-1R, rGLP-1R	(-)	58
Neuropeptide tyrosine			(-)	227
Neuropeptide tyrosine (NPY)	36	YR (1-5)		
Pancreatic polypeptide (PP)	36			
Peptide tyrosine-tyrosine (PYY)	36			
Bombesin peptides				
Bombesin (Gastrin-releasing peptide; GRP)	27	GRP R1,2	(-)	4
Gastrin	17			
Neuromedin B	10			
Galanin	29 or 30	GAL (1-3)	(-)	229
Neurotensin	13	NTSR1,2		
Calcitonin gene-related peptide (CGRP)				115
Vascular peptides				
Natriuretic hormone family				
Atrionatriuretic hormone (ANH) or atriopeptin	28	NPRA, B, C	(+)	136
Brain natriuretic hormone (BNP)	32		(+)	136

The major categories of neuropeptides are listed, with emphasis on those that have been associated with seizures or epilepsy. Peptide length refers to the number of amino acids. Receptor subtypes are shown for examples with multiple receptors. Peptides that have been shown to exert proconvulsant (+) or anticonvulsant (-) activity are indicated; mixed effects are denoted by +/-; a question mark indicates effects that are not clearly proconvulsant or anticonvulsant. References are primarily reviews, but specific citations are provided when reviews are unavailable.

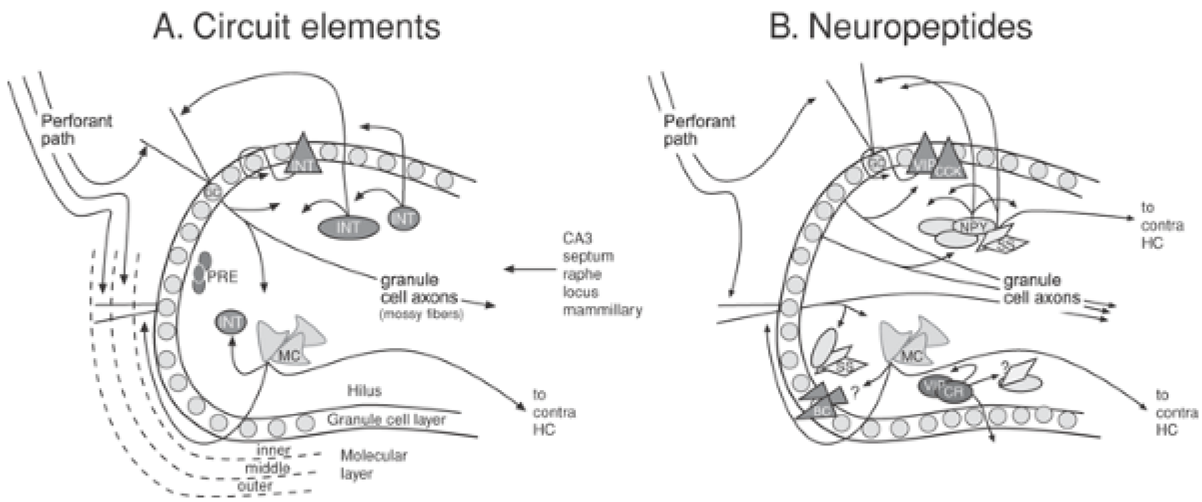

FIGURE 1. Circuit elements and neuropeptides in the rat dentate gyrus under normal conditions. **A:** Major components of dentate gyrus circuitry. These include the dense layer of granule cells (*GC*); diverse GABAergic â€œinterneuronsâ€ (*INT*), hilar mossy cells (*MC*), as well as precursors to granule cells (*PRE*) that are located in the subgranular zone. The major afferent input to the dentate gyrus is the perforant pathway, which contains the axons of neurons in the entorhinal cortex. Lateral entorhinal neurons innervate the outer molecular layer (*outer*) and medial entorhinal neurons innervate the medial molecular layer (*medial*). Mossy cells and other fibers innervate the inner molecular layer (*inner*). In addition, inputs to the dentate gyrus also arise from area CA3 pyramidal cells, the septum, dorsal raphe, locus coeruleus, mammillary bodies, and other areas. The main projections from the dentate gyrus are from the granule cell axons (the mossy fibers), which terminate locally on hilar processes and the layer containing the proximal dendrites of CA3 pyramidal

cells (stratum lucidum; not shown). In addition, mossy cells project both ipsilaterally and contralaterally to the dentate gyrus. Some GABAergic neurons also project contralaterally. Reproduced with permission from Freund TF, Buzsaki G. Interneurons of the hippocampus. *Hippocampus*. 1996;6:347â€"470; and Scharfman HE. The role of nonprincipal cells in dentate gyrus excitability and its relevance to animal models of epilepsy and TLE. In: Delgado-Esqueta AV, Wilson W, Olsen RW, Porter RJ, editors. *Basic mechanisms of the epilepsies: molecular and cellular approaches*, 3rd ed. New York: Lippincott-Raven; 1999:805-820.[77,179] **B:** Many neuropeptides are expressed in the normal dentate gyrus, and some of the most well-studied examples are shown.[77] Opiates are mainly expressed in granule cells. In contrast, other neuropeptides are primarily present in interneurons. Basket cells contain both vasoactive intestinal polypeptide and cholecystokinin; hilar neurons that innervate the outer molecular layer (as well as other targets) express neuropeptide Y and/or somatostatin; vasoactive intestinal polypeptide and calretinin that define a population that innervates the inner molecular layer, as well as other interneurons; in addition, other vasoactive intestinal polypeptide-containing cells exist and may be coupled by gap junctions.[90] Recent studies have indicated that substance P has widespread expression in interneurons.[197] (See color insert.)

Neuropeptide Y

Neuropeptide Y is the first example. This peptide is normally expressed in a subset of GABAergic neurons in the dentate gyrus. The axons of these cells project to numerous areas of the region and thus exert multiple effects (Fig. 2A). A primary effect of neuropeptide Y is to reduce excitatory transmission from granule cells to their targets, thereby decreasing the excitatory output of the dentate gyrus to hippocampal pyramidal cells. Thus, when synthetic neuropeptide Y is applied to slices of rodent dentate gyrus, it inhibits the excitatory output of granule cells by acting on neuropeptide Y receptors on the terminals of granule cell axons. This function is likely to be important in the control of seizure activity in the hippocampus since overexpression of neuropeptide Y is anticonvulsant[227] and because decreased neuropeptide Y expression leads to increased seizure susceptibility.[13]

Neuropeptide Y also has other actions in the dentate gyrus. For example, it modulates calcium entry into granule cells,[139] and also affects a specific potassium ion (K^+) channel on GABAergic neurons in the dentate gyrus.[156] The latter could influence neuronal firing and GABA release and therefore modulate the targets of GABAergic neurons.

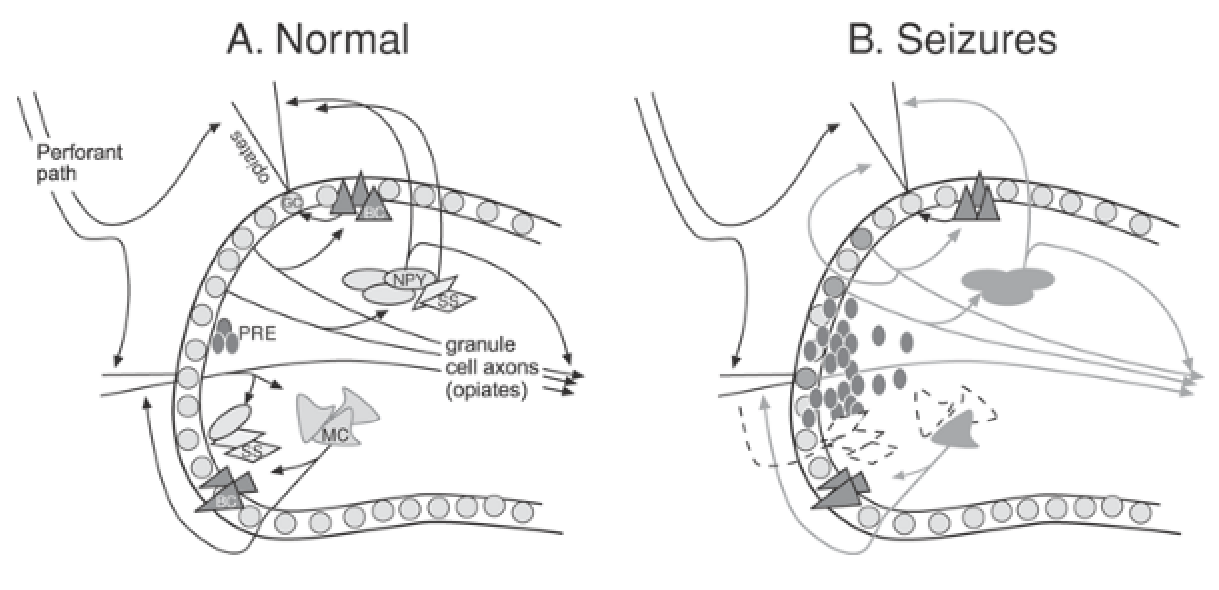

FIGURE 2. Changes in neuropeptide Y and somatostatin in the dentate gyrus after seizures. **A:** Normal circuitry and expression of neuropeptide Y and somatostatin in the rodent dentate gyrus. **B:** Alterations in neuropeptide Y and somatostatin in animal models of epilepsy are illustrated schematically. For the neuropeptide Y system, these changes include: (a) new expression in granule cells and their axons, the mossy fibers; (b) increased expression in interneurons that normally express neuropeptide Yâ€"this effect appears to develop mostly after acute rather than chronic seizures; (c) novel expression of neuropeptide Y in some mossy cells;[88] and (d) expression in newly formed granule cells, although the extent that this occurs is unclear. In addition, changes in receptors occur (not shown). For the somatostatin system, the best documented alteration is seizure-induced cell death of those interneurons that normally express this peptide. (See color insert.)

Neuropeptide Y also facilitates the proliferation of new granule cells in the adult brain, and thus influences adult neurogenesis.[88] These actions appear to be mediated by the Y1 subtype of neuropeptide Y receptors, which are situated on the proliferating cells. The source of neuropeptide Y may be the GABA/neuropeptide Y coexpressing interneurons, which have axon terminals in the subgranular zone, where the proliferating cells are located.[52]

Neuropeptide Y function may change after seizures, as initially suggested by studies showing that seizures affect the expression of neuropeptide Y in granule cells. Particularly after chronic seizures, the axons of the granule cells strongly express neuropeptide Y (Fig. 2B).[11,129]

P.292

This phenomenon may be functionally significant for two reasons: first, neuropeptide Y may exert more robust effects on the normal targets of granule cell axons; second, neuropeptide Y may have additional effects at new locations, because the axons of granule cells (mossy fibers) make new connections after chronic seizures (â€œmossy fiber sproutingâ€). Indeed, neuropeptide Y inhibits the effects of glutamate released from the sprouted axons of granule cells in epileptic rodents.[218] These data support the concept that neuropeptide Y is â€œanticonvulsantâ€ and its upregulation after seizures is â€œcompensatoryâ€ in nature. Interestingly, acute seizures, as opposed to chronic seizures, appear to have different effects on neuropeptide Y expression. Thus, a brief seizure results in a preferential, transient increase in neuropeptide Y expression in GABAergic neurons,[200] but does not cause robust changes in neuropeptide Y expression in granule cells. The functional role of the increase in neuropeptide Y within GABAergic neurons is still not clear, but it could be a way to inhibit glutamate release, which could prevent another seizure. It is important to add that this transient increase of neuropeptide Y in GABAergic neurons may be underestimated, because seizures may injure neuropeptide Yâ€"containing neurons.[29,49,212]

Additional complications arise from the fact that some, but not all, neuropeptide Y receptors change as a consequence of seizures. It appears that the predominant change is an increase in Y2 receptors. This would be likely to enhance the ability of neuropeptide Y to inhibit glutamatergic transmission, because Y2 receptors are normally responsible for this effect.[65,226]

However, other receptors do not necessarily show robust changes, or the studies to date are not in complete agreement.[12] An increase in receptors may not lead to a change in effect if neuropeptide Y is not released in sufficient concentration to activate the new receptors.

To add to the complex picture, granule cells formed after seizures, although likely to express neuropeptide Y, have distinct physiological properties and may therefore release neuropeptide Y differently. On the other hand, neurons in the epileptic brain likely release more neuropeptide Y. This may be the case for newly-formed granule cells, which typically exhibit burst discharges[181] and therefore may release neuropeptide Y.

In summary, a series of experimental studies have documented the robust influence of neuropeptide Y in the normal dentate gyrus and suggested that this peptide be considered an endogenous anticonvulsant. Moreover, neuropeptide Y expression is highly plastic and altered by seizures. These changes appear to indicate anticonvulsant properties and a compensatory inhibitory role for neuropeptide Y in epilepsy. However, the complexities of neuropeptide Y changes after seizures, and the lack of a detailed understanding of several of these changes, suggest that firm conclusions are still premature.

Somatostatin

Somatostatin is another example of a neuropeptide with robust actions in the dentate gyrus, making it another candidate to serve an endogenous anticonvulsant role.[20,223] Normally, somatostatin is preferentially expressed in a subset of GABAergic neurons in the dentate gyrus, which innervate the outer molecular layer and have collaterals in the hilus (Fig. 2A). The axonal projection to the outer molecular layer has received greatest attention because it is most dense, and because of the potential for selective modulation of the lateral perforant path, a major cortical input to the dentate gyrus, which terminates in the outer molecular layer.

In most but not all cases, somatostatin appears to depress this input when single afferent stimuli are tested.[14,178] More robust effects are observed after tetanization, which would

normally lead to long-term potentiation (LTP); somatostatin blunts this effect.[14] These data suggest that somatostatin depresses the glutamatergic activation of granule cells by an action at the site of synaptic input, and it does so preferentially after high-frequency input. In addition, somatostatin depresses calcium-mediated action potentials (calcium â€œspikesâ€) in granule cells by inhibiting N-type calcium channels. The net effect could contribute to the depression of LTP in the lateral perforant path.[14] In light of these results, it is no surprise that somatostatin inhibits seizures in animal models of epilepsy.[20] Likewise, in somatostatin knockout mice, seizures elicited by chemoconvulsants are more severe, and after discharges are longer in animals that are kindled by stimulation of the perforant path.[29]

Somatostatin may also have other actions, however. Thus, in other areas of the hippocampus, exposure to somatostatin leads to additional effects, such as modulation of the M-current.[188] This action may have numerous consequences, because M channels are located in diverse areas of the dentate gyrusâ€"not only on neuronal somata, but also on their axons.

As is the case of neuropeptide Y, somatostatin expression is dramatically changed after seizures. The decrease in somatostatin is due to the fact that somatostatin-containing neurons are extremely vulnerable to seizure-induced neuronal death (Fig. 2B). The loss of somatostatin may contribute to the change in hippocampal excitability following seizures.

However, somatostatin cell loss appears to be selective for animal models of epilepsy in which seizures are severe (i.e., models that use an initial period of status epilepticus to induce chronic seizures). Somatostatin cell loss is also evident in hippocampal tissue resected from patients with intractable TLE.[167] In contrast, animal models in which seizures are milder, such as electroconvulsive shock or kindling, do not necessarily result in the loss of somatostatinergic neurons, but lead to an *increase* in somatostatin expression within those neurons that normally express this neuropeptide.[153,186]

It is also necessary to consider that somatostatin receptors may be altered in epilepsy. In tissue resected from patients with pharmacoresistant TLE, only type 2 (i.e., the receptor known to mediate anticonvulsant effects) is altered in the dentate gyrus.[47] It appears that both the mRNA for the type 2 receptor and receptor binding increase in the granule cell layer, remain unaltered in the inner molecular layer, and decrease in the outer molecular layer. The latter changes may reflect a compensation for the loss of afferents, which degenerate due to the vulnerability of hilar somatostatin neurons. Other somatostatin receptors (types 1â€"4) in the dentate gyrus remain remarkably normal after kainic acid (KA)-induced status epilepticus, although changes occur elsewhere in the hippocampus.[162]

Taken together, the source of somatostatin and its receptor-mediated actions differ substantially between the normal and the epileptic brain. These differences are likely to alter the peptide's effects in a pathologic situation. This implies, for example, that synthetic somatostatin analogs may not be able to depress perforant path transmission in the epileptic brain because of the lack of appropriate receptor targets (see earlier discussion), and that it may be possible to design somatostatin-related therapeutic interventions that are geared specifically to the epileptic condition.

The changes in neuropeptide Y and somatostatin in the rat dentate gyrus after chronic seizures are illustrated schematically in FIGURE 2. As noted earlier, neuropeptide Y and somatostatin are just two of a long list of neuropeptides that have been studied intensively in the dentate gyrus in the context of seizures (Table 1). Thus, many neuropeptides appear to modulate excitability normally and specifically influence seizures/epilepsy in animal models of epilepsy. Most of them also have the same dual relationship with seizures as neuropeptide Y and somatostatin (i.e., they are both regulated by seizures and capable of modulating seizures). Finally, it should also be noted that there appear to be significant species differences in neuropeptide expression in the dentate gyrus. However, despite the fact that some of the peptides present in humans are not identical to those in rats or mice, the relationship of peptidergic neurons to epilepsy appears to be essentially similar in rodents and humans.

Calcium-Binding Proteins

Calcium-binding proteins have also received considerable attention with respect to their influence on the function of neurons in the dentate gyrus. Strictly speaking, this group has many members (Table 2), but those in the dentate gyrus that have received most attention are those that have the highest levels of expression. One example is calbindin D28K, which is primarily expressed in granule cells, although studies have also shown immunoreactivity in selected GABAergic neurons.[193] Other examples of calcium-binding proteins include parvalbumin and calretinin, which have been selectively localized to GABAergic neurons.[198]

The distinct distribution of these proteins naturally raises questions about their specific functions in various cell types. Interest grew after it was shown that those neurons in the dentate gyrus that appear most prone to seizure-induced damage (i.e., somatostatin-containing neurons and the glutamatergic mossy cells) lacked either calbindin or parvalbumin. However, later studies suggested a more complex relationship between calcium-binding proteins and vulnerability, because calcium-binding proteins such as calretinin were also found in susceptible neurons.[78]

Functional studies revealed that calbindin and parvalbumin have important roles in the regulation of calcium within the cell. In the granule cell, calbindin modulates calcium levels and therefore has several potential functions, including an influence on transmitter release. Indeed, overexpression of calbindin leads to alteration in granule cell transmission to pyramidal cells of CA3 due to a presynaptic mechanism at granule cell boutons. These changes are clearly important because of the dramatic alteration in hippocampal function in vivo after overexpression of the protein only in granule cells.[57] Parvalbumin also appears to have important functional roles in the regulation of calcium entry, primarily presynaptically.[40] These are likely to be substantial in their net effect in vivo, given that parvalbumin knockout mice have altered seizure susceptibility.[185] It is not clear, however, whether this is a specific defect in normal parvalbumin function or a compensatory effect.

In human tissue derived from patients with intractable TLE, calbindin expression in granule cells is reduced,[131] and the expression of parvalbumin immunoreactivity undergoes complex changes depending on hippocampal subregion and clinical features.[198,233] Some argue that these changes may be neuroprotective if intracellular calcium levels were effectively lowered by calcium-binding proteins, but others would suggest that this might not necessarily be the case.[219] In summary, the functional significance of neuromodulation by calbindin, parvalbumin, and many other calcium-binding proteins in epilepsy is still controversial and requires careful additional investigation and analysis.[35]

Endogenous Trace Metals

Trace metals exert a number of biologic effects throughout the body that are caused, among other mechanisms, by the metals' ability to serve as cofactors to a large number of enzymes. They also interact directly with cell membrane and intracellular receptors, and regulate oxidation/reduction processes within

cells. Several of these properties play a role in the metals' effects on cellular excitability in the CNS. It is therefore not surprising that metals such as iron, manganese, and selenium, acting in a neuromodulatory role, may influence the development or termination of seizure activity.[85,189,208]

The endogenous trace metal zinc has been most frequently associated with seizures. This is primarily due to the observation that zinc is localized in, and can be released from, many glutamatergic neurons throughout the limbic system. Granule cells in the dentate gyrus, and especially their axon terminals, contain a particularly high concentration of zinc. Within the cell, zinc is bound to specific proteins, such as metallothioneins, or exists in presynaptic vesicles and can be released into the extracellular compartment. Extracellularly, zinc can have quite diverse effects, making it difficult to predict its net function. Thus, zinc can depress (e.g., by reducing NMDA receptor function) or enhance (e.g., by interfering with $GABA_A$ receptor-mediated inhibition) excitability.[76]

The inhibition of $GABA_A$ receptor function by zinc is particularly interesting in the context of epilepsy. The metal normally has little effect on $GABA_A$ receptors on granule cells, because the receptor subunits are not assembled in a combination that optimizes zinc sensitivity. However, these subunits change their expression patterns under epileptic conditions, resulting in reductions in the Î±1- and Î³2-subunits and an increase in the Î´-subunit; these changes greatly enhance zinc sensitivity of the receptor.[3,42,174]

Zinc may also show increased effects on $GABA_A$ receptors in the epileptic brain, because zinc-rich mossy fibers develop collaterals that innervate the proximal dendritic region of granule cells (mossy fiber sprouting). These new collaterals constitute an increased source of zinc, which may be of functional significance, because enhanced zinc release from sprouted mossy fibers may further decrease the inhibition of granule cells. In addition, the release of zinc may be greater under conditions of chronic epilepsy, given the predisposition for burst discharges.[30] Such a dampening of the normal inhibitory â€œgateâ€ function of the dentate gyrus might facilitate seizure activity in limbic circuits. Thus, zinc appears to play a critical role in the mechanisms that link changes in $GABA_A$ receptor subunits and mossy fiber reorganization in the epileptic brain to the epileptic state.

Cytoskeletal Proteins

Cytoskeletal elements are a fundamental component of nerve cells, and recent studies suggest relevance to epilepsy, particularly for the filamentous proteins. This group includes actin filaments, intermediate filaments (e.g., neurofilaments), and microtubules (such as Î±- and Î²- tubulin). In addition to this group, proteins such as clathrin and stathmin are important to consider, because they are critical to endocytosis.

Recent evidence suggests that several of these proteins may also be involved in epileptogenesis, in the response of the nervous system to seizures and, in the developing brain, in the resistance to seizure-induced neuronal damage.[126] Notably, some of the seizure-related changes in the expression pattern of cytoskeletal proteins, which may in part be due to cell swelling, have been revealed using gene profiling techniques.[127]

The involvement of cytoskeletal elements in epilepsy is probably related to their role in the intracellular movement of proteins into different cellular compartments, which, in turn, can modify neuronal excitability. Thus, cytoskeletal proteins are involved in the trafficking of neurotransmitter receptors. Proteins such as clathrin may alter excitability by changing the concentration of molecules available to the extracellular milieu. In addition, the cytoskeleton may be causally involved

in the dendritic deformation that has been described in animals with chronic seizures and in humans with TLE. For example, electron microscopic analysis indicates that cytoskeletal changes may be responsible for the unique beading of dendrites in epileptic tissue,[222] although other hypotheses that are independent of the cytoskeleton have also been suggested.[207]

Growth Factors

The term â€œgrowth factorâ€ is defined loosely here to refer to several protein families, expressed either in neurons or glia, that were originally identified for their roles in CNS growth and development (Table 3). Subsequent studies revealed that these same proteins influence neurons after maturity, and, interestingly, have striking effects in the context of epilepsy.

Growth factors influence excitability in the adult CNS both directly and indirectly.[180] Many of the effects are due to modulation by transcription factors, which in turn affect the expression of proteins that can alter excitability. Their importance to epilepsy is supported by studies showing that the expression of growth factors and their receptors is dramatically altered by seizures, both in animal models of epilepsy and in TLE.[180] Similar to the neuropeptide changes observed after seizures (see previous section), these effects may be compensatory in nature and may recapitulate developmental programsâ€"a plausible interpretation in light of the prominent role of growth factors in brain development.

Experimental interference with growth factor function can result in the withering or retraction of axonal pathways, suggesting that these proteins regulate axonal growth and maintain neuronal integrity.[206] Furthermore, growth factors influence the morphology and density of dendritic spines,[67,111] and also cause additional structural alterations of synapses.[228] All these effects may be critical in epilepsy, in which dramatic spine changes occur as a consequence of seizures,[213,235] and the axons of injured neurons degenerate. In addition, growth factors may contribute to circuit rearrangements after seizures, including axonal sprouting, formation of new synapses, and other structural alterations.[100]

Several families of growth factors can be categorized in many ways. In Table 3, the classic growth factor families are organized according to their receptors, which are primarily receptor tyrosine kinases or serine threonine kinases. These include the tyrosine kinase receptor superfamily (ephrins, epidermal growth factor [EGF] family, fibroblast growth factor [FGF] family, insulin growth factor [IGF] family, neurotrophins, and vascular endothelial growth factor [VEGF] family), and the serine threonine kinase receptor superfamily (including transforming growth factor [TGF]-Î² family). In addition, Table 3 includes two other categories critical to normal growth and development. These include axon guidance molecules (netrins, the reticulon family, semaphorins, and slit proteins) and morphogens (bone-morphogenic proteins, hedgehog family, wnt family). Inflammatory cytokines (interleukins [IL] and tumor necrosis factor [TNF] family) are discussed in Chapter 25. Chemotactic cytokines (chemokines) are also relevant, particularly in relation to the mechanisms that control axon guidance, but to date limited evidence points to their role in seizures, excitability, and epilepsy.

Neurotrophins

The neurotrophins are a family of growth factors that show robust expression in the adult CNS and are known to influence a wide variety of normal functions. They also provide some of the best examples of growth factors that have been shown to influence seizures. The dentate gyrus is useful as an example of a site in which neurotrophins are likely to affect seizure activity, because of the evidence that this region shows robust neurotrophin expression and action. Most of these studies are focused on brain-derived neurotrophic factor (BDNF) or NT-3, and much less is known about the other neurotrophins, (e.g., the prototypic member of the neurotrophin family, NGF, and the fourth major member, NT-4/5).

Figure 3 depicts the normal expression pattern of BDNF in the rodent dentate gyrus. The same pattern appears to be present in humans.[148] Thus, BDNF is mainly localized in granule cells, although a small proportion may also be contained in nongranule cells and in afferents from the entorhinal cortex (i.e., the perforant path).[41,231,242] Notably, BDNF enhances the expression of neuropeptides such as neuropeptide Y in GABAergic neurons, indicating potentially significant interactions between hippocampal neuromodulators.[134] Simply viewed, neuropeptide Y induction may limit excessive excitation by BDNF and thus prevent the development of seizures.

BDNF not only supports dendritic structure and plasticity in the dentate gyrus, but also stimulates the proliferation of cells in the subgranular zone, a major source of newly-generated dentate granule cells in the adult brain.[175] Moreover, BDNF has robust effects on the physiology of granule cells and their targets, influencing glutamatergic and GABAergic circuits.[24,116,151] These effects often involve changes in transmitter release and depend on protein synthesis.[24] In addition, BDNF depolarizes granule cells by an effect on the Nav 1.9 sodium channel.[116] Finally, BDNF may also signal via glial cells.[168]

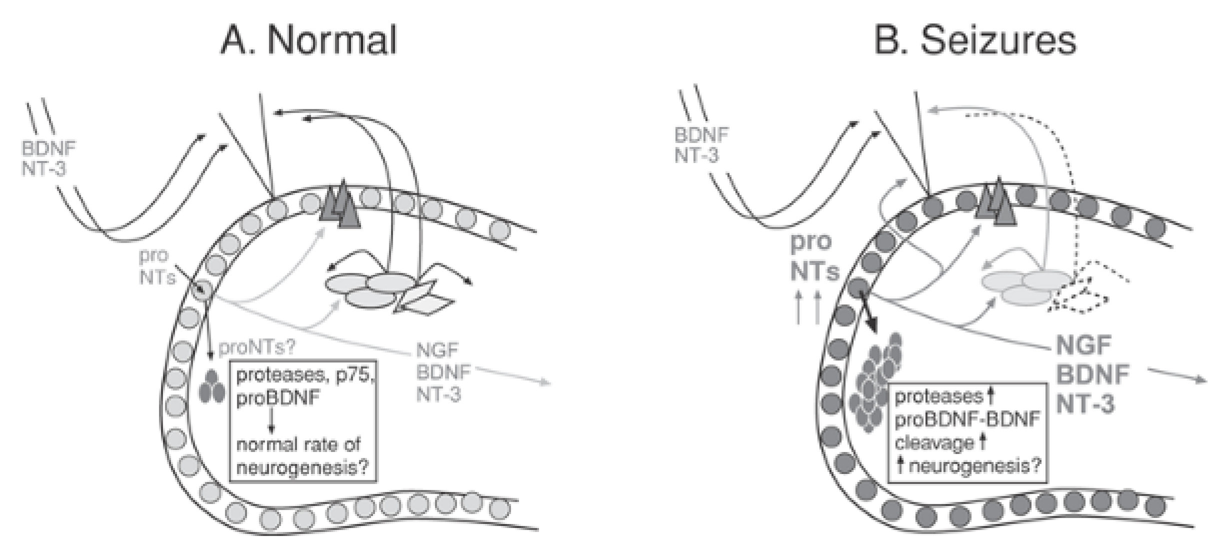

FIGURE 3. Changes in neurotrophins in the dentate gyrus after seizures. **A:** Normal pattern of expression of the neurotrophins NGF, BDNF, and NT-3. The predominant cell type expressing neurotrophins normally is the granule cell. In addition, lower levels of BDNF and NT-3 are present in perforant path axons. Proneurotrophins are present in the soma and are thought to be released in the vicinity of the soma. Proneurotrophins are typically cleaved by extracellular proteases, but can also act directly on p75 receptors to modulate survival. **B:** Changes in neurotrophins associated with chronic seizures are schematically illustrated. NGF and BDNF expression is increased in granule cells, and NT-3 levels decline; BDNF and NT-3 decline in the perforant path when seizure-induced entorhinal cell loss occurs. The altered levels of neurotrophins are likely to have diverse effects on granule cell structure and function. In addition, indirect effects may occur, such as induction of neuropeptide Y by BDNF, either in granule cells or adjacent interneurons (cf. FIGURE 2). Upregulation of proneurotrophins are also likely and, in the case of proBDNF, increased synthesis may influence seizure-induced cell death by increased activation of the p75 neurotrophin receptor, or seizure-induced neurogenesis by the increase in BDNF that would result from proBDNF cleavage. These changes, as well as alterations in receptors for neurotrophins, are likely to have a complex net effect on the excitability of the dentate gyrus. (See color insert.)

After seizures, BDNF levels rapidly increase in granule cells.[81] Judged from studies in both experimental animals and patients with intractable TLE, this effect appears to persist for weeks if the initial seizures are severe (e.g., status epilepticus).[180,182] This, and the fact that BDNF protein is also expressed in sprouted axons,[182] supports the pathophysiological relevance of BDNF in chronic epilepsy.

The neuromodulatory effects of BDNF are probably also influenced by its precursor, proBDNF. proBDNF exerts its own physiological functionâ€"for example, the regulation of cell deathâ€"through the p75 receptor.[94] This function is increased after seizures. These increases, together with elevations in mature BDNF, might contribute to seizure-induced neuronal loss. To add to the complexity, however, seizures also increase the activity of matrix metalloproteases (MMPs),[132] which are able to cleave proBDNF into BDNF.[119] This could generate BDNF at extrasynaptic locations where proBDNF, but not BDNF, is likely to be released. Extrasynaptic release of this newly formed BDNF may then influence epileptic phenomena by targeting novel receptor sites (Fig. 3).

Because of the multiple proexcitatory roles of BDNF in the dentate gyrus in physiology and pathology, it is not surprising that BDNF infusion can cause seizures, that BDNF overexpression increases seizure susceptibility, and that deficits in trkB receptors can block kindling epileptogenesis.[21] Furthermore, BDNF polymorphisms have been linked to febrile seizures,[21,176] and BDNF or trkB are frequently identified in microarray studies of genes linked to epilepsy.[128] However, analogous to the caution suggested for neuropeptide Y as an â€œanticonvulsantâ€ (see the earlier discussion), more information is needed before considering BDNF an endogenous â€œconvulsant.â€ This caveat is supported by studies that demonstrate complex and unexpected effects of trkB transgenic and conditional BDNF knockout mice.[176] In vivo infusions of BDNF, too, yield somewhat conflicting results,[176] possibly due to the fact that chronic BDNF treatment downregulates its own receptor.[240] These and related issues must be resolved before BDNF manipulation can

P.296

P.297

P.298

be viewed as a bona fide approach to ameliorate seizure disorders clinically.

Vascular Endothelial Growth Factor

VEGF was initially discovered as a protein that has robust effects on the vasculature, altering permeability and also enhancing angiogenesis.[32] Although it was not originally anticipated to have an influence in the CNS, recent studies have demonstrated that VEGF expression occurs throughout the brain, and that neurons are influenced by exposure to VEGF.

VEGF exists in more than one isoform (VEGFA-E) and has numerous receptors (VEGFR1, VEGFR2, neuropilins), leading to the potential for a variety of distinct effects. Normally, VEGF is primarily associated with glia and endothelial cells, so that many of its effects are likely to be directed at glia or blood vessels under physiologic conditions. However, in animal models of injury, VEGF expression appears to increase in various areas of the brain.[46] Interestingly, after seizures, VEGF expression also increases in neurons, and some of these changes occur in brain areas that are highly susceptible to seizures, such as the hippocampus. These findings have led to the suggestion that VEGF may have a role in epilepsy.

More evidence of a link between VEGF and epilepsy has come from functional studies. Thus, VEGF alters potassium channel function and synaptic transmission, although it is not clear whether these effects are direct or indirect.[137,241] Perhaps the most relevant of these functional studies as it pertains to epilepsy is that VEGF depresses synaptic transmission and reduces epileptiform activity in vitro.[137] The reduction in activity appears to be greater if epileptiform discharges are examined in slices from an animal with recurrent spontaneous seizures (i.e., epilepsy), as compared to slices from a normal animal that are acutely exposed to a disinhibitory agent. The results suggest potent effects in the epileptic brain relative to normal brain, possibly due to altered expression of VEGF and its receptors after recurrent seizures.

Intercellular Modulators

Components of the extracellular matrix (ECM), a scaffolding system in the interstitial space made up of glycoproteins, proteoglycans, and other molecules such as hyaluronic acid (Table 4), have begun to attract attention as modulators of neuronal function with possible links to epileptogenesis. This is in part based on the fact that the expression of several matrix molecules, such as neural cell adhesion molecule (NCAM),[149] tenascins,[25,150] and chondroitin sulfate proteoglycans such as phosphocan and neurocan, is altered in animal models of TLE. These changes are chronologically and topographically associated with the development of granule cell dispersion and mossy fiber sprouting in epileptic animals.[25,92] Gene microarray studies have confirmed and expanded the correlation between extracellular matrix components and seizures, adding cell adhesion molecules to the list of neuromodulatory proteins.[128] Notably, elevations of glycosaminoglycans and tenascins are also seen in surgical brain tissue obtained from patients with pharmacoresistant TLE. Jointly, these studies therefore raise the possibility that changes in the extracellular matrix may be *causally* involved in the cellular and synaptic reorganization seen in TLE.[7,38,92,96]

Another important aspect of the ECM that is relevant to axonal and cellular reorganization in epilepsy are changes in MMPs after seizures. These enzymes are notable because they normally degrade the ECM and appear to be altered in their expression after seizures.[83] Again the question of whether neuromodulators interact is raised, because the MMPs also cleave proBDNF to BDNF. Thus, degradation of the ECM and elevated BDNF may work in concert to facilitate changes in neural circuits, including mossy fiber sprouting. Finally, the ECM may also modulate excitability through intercellular and transmembrane proteins, like the integrins.

These proteins bind both to the ECM and to neuronal plasma membranes and can therefore activate signaling cascades that regulate neural activity.[163] Taken together, these studies suggest that the ECM, both directly and indirectly, could modulate excitability in the context of epilepsy.

Neuromodulation by Astrocytes

The abnormal appearance of non-neuronal cells in the epileptic brain has long been appreciated.[163] Until relatively recently, however, gliosis was viewed simply as a reaction to seizure-related neuronal injury or degeneration, without major functional consequences for the disease process. With a few exceptions, the conceptual and experimental approach to the primary goal of epilepsy researchâ€"that is, the elucidation of the cellular mechanisms underlying human epilepsiesâ€"was decidedly neurocentric. In functional terms, glial cells (including â€œreactiveâ€ glia) were at best regarded as sinks to buffer the abnormal, proconvulsant rises in extracellular K^+ concentrations that were known to accompany seizure activity.[98,199]

It was not until the late 1970s (first articulated comprehensively in an influential monograph of Brotchi),[27] that glial cells began to be considered as significant pathogenic factors in chronic epilepsy. The contributions of these cells to *epileptogenesis* were recognized even later. Noninvasive imaging methods, modern electrophysiologic approaches in animals and humans, the revolution in molecular biology and genetics, and the

recent enthusiastic embrace of glial biology by the neuroscience community, have jointly focused the attention of epilepsy research on the pathophysiological role of glia. It is clear that glial cells participate actively in the development and maintenance of chronic epilepsy, although the involvement differs between the three major types of glial cells (microglia, oligodendrocytes, and astrocytes). Moreover, accumulating evidence suggests that abnormal glial function may also be a determining factor in the very early stages of epileptic disorders.

The role of resident and, in particular, activated microglial cells in epilepsy appears to be closely linked to the cells' function as the resident immune cells of the brain. As a major source of paracrine signals releasing pro- and anticonvulsive cytokines, growth factors and other neuroactive peptides, and proteins, the agile microglia are increasingly thought to influence not only neuronal communication in the normal brain, but also to facilitate the excessive electrical discharges characteristic of epileptic conditions.

Very few studies indicate an involvement of oligodendrocytes, the second major classes of glial cells in the brain, in seizure activity.[146,234] Normal or seizure-induced changes in oligodendrocyte function are therefore not likely to be a major, consistent feature of epileptogenesis or epilepsy. However, this conclusion is still tentative and may have to be revisited in view of recent evidence linking oligodendrocyte function to neurogenesis, a likely factor in the pathophysiology of TLE.[157,177]

Astrocytes are intimately related to neurons in terms of lineage, anatomic arrangements, and function. As indicated by the recently coined term â€œtripartite synapse,â€[5] astrocytes are now in fact considered integral players in neurotransmission. This notion, in turn, prompted a closer look into the function of these glial cells in epilepsy. It is now clear that astrocytes, and astrocyte-derived factors, play a critical role in the modulation of acute and chronic seizure activity.

Astrocyte Changes in Epilepsy

Although the â€œreactive gliosisâ€ seen in the brain of epileptic patients was long suspected to signify disease-related morphological changes in astrocytes, definitive proof for the identity of the abnormal glial cells was unavailable until relatively recently. This changed with the discovery of glial fibrillary acidic protein (GFAP), a 55-kDa member of the intermediate filament protein family, which is the major fibrous protein of astrocytes.[19] Using anti-GFAP antibodies, hypertrophied astrocytes were soon visualized immunohistochemically in excised tissue specimens obtained during epilepsy surgery[103] and in several animal models of chronic epilepsy. GFAP immuno-staining labels pathological astrocytes primarily in limbic brain areas such as the hippocampus and the parahippocampal region, which are also preferentially sensitive to seizure-induced neurodegeneration.[87,165] GFAP-positive astrocytes were therefore originally believed to be a highly selective tool to identify epileptic lesions. It turns out, however, that abnormal, GFAP-immunoreactive astrocytes are also seen in anatomic sites distant from the seizure focus.[33] Further analyses of the effects of the nature, frequency, and duration of the epileptogenic stimulus on GFAP-positive cells, the use of additional structural astrocyte markers such as vimentin and laminin, and the use of various distinct animal models, also revealed a more complex picture of astrocytic involvement in epilepsy.

Astrocytes react rapidly (within 1 hour) to strong convulsive stimuli through upregulation of glial protein synthesis,[203] but change more slowly in response to moderate seizure activity.[117,205] Although the duration of these and other seizure-related changes (see later discussion) has so far not been studied methodically, they are likely to persist in chronically epileptic animals.[84] Surprisingly, prominent brain regionâ€“specific astrocytic hypertrophy can sometimes be detected in the absence of substantive neurodegeneration. This includes kindled animals, in which the glial changes are accompanied by a reorganization of the cytoskeleton and persist for weeks after the last seizure,[108,109] and the EL mouse, in which astrocytes proliferate in the hippocampus.[55] These and a considerable number of other supportive examples indicate that a variety of seizures, ranging from single, intense convulsive insults to repetitive, mild episodes, cause regionally distinct structural astrocytic changes that are not necessarily associated with overt neuronal loss or injury. However, these microscopic data do not consider the molecular events(s) linking seizure activity to the glial reaction. They also do not address the presumed functional significance of astrocytic hypertrophy and/or proliferation, including the possible role of these reactive processes in the development and maintenance of chronic epilepsy.[7,144,166]

Astrocytes as Modulators of Extracellular Glutamate

The fact that astrocytes undergo physical changes in response to seizure activity led many investigators to examine the fate of astrocytic neurochemistry in epilepsy. The most obvious molecule of interest in this regard was glutamate, which had been speculatively associated with the pathophysiology of epilepsy as early as 1954.[91] The realization, two decades later, that glutamate is the major excitatory neurotransmitter in the brain initially suggested that enhanced *neuronal* glutamate release might be critically involved in the precipitation of epileptic discharges.[54] Although neuron-derived glutamate is still believed to play a major role in seizure activity, attention has increasingly shifted to astrocytes as the major determinants and sources of extracellular glutamate levels in both the normal and epileptic brain. Thus, the physiological concentration of glutamate in the extracellular milieu, which is in the low micromolar range, is controlled mainly by two highly efficient astrocytic glutamate transporters (GLT-1 and GLAST). These uptake sites also prevent the accumulation of convulsant, excitotoxic concentrations of the amino acid, as demonstrated in animals with a genetic deletion in either one of these proteins.[169,209,230] These studies, as well as a report showing substantial reductions in GLT-1 and GLAST expression in epilepsy-prone rats prior to seizure onset,[60] are particularly important because they provide evidence that malfunctioning astrocytes can *cause* seizure activity by elevating extracellular glutamate to pathologic levels. Interestingly, GLT-1 is also reduced as a sequela of epilepsy, thus potentially exacerbating the clinical condition.[173]

Selective transporters are not the only determinants of extracellular glutamate linked to astrocyte function. As shown originally by Haydon et al., neuronal stimulation induces a frequency-dependent calcium response in closely apposed astrocytes, which then causes these cells to release glutamate. This astrocyte-derived glutamate, in turn, modulates glutamatergic neuronal transmission.[5] It follows that any breakdown of this finely tuned interplay between neurons and astrocytes may result in enhanced glutamate release and seizure activity.[70] This hypothesis, which again indicates that astrocytes can be *causally* involved in epileptogenesis, has recently been supported by experimental manipulation of intracellular astrocytic calcium (Ca^{2+}).[214]

Within astrocytes, glutamate serves as a substrate of glutamine synthetase, an essential component of the glutamineâ€“glutamate shuttle between astrocytes and neurons.[95] This enzyme can be viewed as a precursor of potentially neurotoxic neuronal glutamate.[8] Alternatively, glutamine synthetase may function as a guardian against the accumulation of convulsive

P.300

and neurotoxic concentrations of glutamate in large astrocytic vesicles, which release their content via SNARE-dependent exocytosis to cause excitation in neighboring neurons.[105] It is therefore unclear whether inhibition of glutamine synthetase, which normally causes a *decline* in extracellular glutamate levels in the brain,[23] has pro- or anticonvulsant consequences under epileptic conditions. Measurements of glutamine formation in animal models of epilepsy[59,215] and in the brain of patients with TLE[63,201] have produced equivocal results and have so far failed to clearly define its role in seizures. Similarly inconclusive data have been obtained in nuclear magnetic resonance (NMR) spectroscopic studies in epileptic tissue, which examined the astrocyte-specific incorporation of ^{13}C-acetate into ^{13}C-glutamate and ^{13}C-glutamine.[114,141,147,155]

The external mechanisms controlling astrocytic glutamate disposition are currently only poorly understood, but are of obvious relevance for epilepsy, because unchecked glutamate release is likely to intensify both acute and chronic seizure activity. It is therefore noteworthy that hemichannels and multidrug resistance proteins[68] (i.e., proteins that regulate glutamate exocytosis from astrocytes) are upregulated in astrocytes in chronic epilepsy.[120,133,221] Notably, several subtypes of metabotropic[6,210,220] or ionotropic[192] glutamate receptors are also overexpressed in astrocytes in the epileptic brain, although the functional significance of these receptors has not been clarified so far.

Taken together, these studies leave little doubt that astrocytes, rather than neurons or other brain cells, hold the key to the role of glutamate in epileptic phenomena. Conceptually, glutamate may therefore be assigned the somewhat unorthodox function of an astrocyte-derived or astrocyte-controlled *neuromodulator*. However, because of the large number of functional proteins serving as its intra- and extracellular targets, and due to its multiple roles in cytosolic and mitochondrial energy flux and intermediary metabolism, the participation of astrocytic glutamate in epileptogenesis and chronic epilepsy is highly complex and requires considerable additional scrutiny.

Neuromodulation by Other Astrocytic Factors and Mechanisms

The role of astrocytes in seizure generation and maintenance is not only defined by the complex fate of glutamate itself but also involves several other glial products, which indirectly affect glutamate metabolism and function. This growing list of endogenous factors includes nitric oxide (NO), which is produced by nitric oxide synthase (NOS). At least two isoforms of this enzyme (neural NOS [nNOS] and inducible NOS [iNOS]) are upregulated in reactive astrocytes in response to seizures,[34,102] leading to increased NO formation, which in turn stimulates glutamatergic neurotransmission and may thus affect hyperexcitability.[71] The neuroexcitatory glutamate homolog aspartate, too, is formed in astrocytes, although it is still unclear whether glial release of this amino acid can augment or substitute for the neuronal effects of glutamate under physiological and pathological conditions. Resolution of this issue seems important in view of the fact that extracellular aspartate levels are significantly enhanced in TLE[110,195] and in animal models of epilepsy.[66,142,161] The activity of its degradative enzyme, aspartate aminotransferase, is also increased in actively spiking human epileptic cortex[110]; however, the de novo synthesis of ^{13}C-aspartate from ^{13}C-acetate is unchanged in chronically epileptic rats.[141] Notably, astrocytes also play a major role in the generation and disposition of other endogenous amino acids such as glycine and D-serine, or dipeptides like N-acetylaspartylglutamate, all of which profoundly influence glutamate function in the normal brain. These agents, sometimes cumulatively termed â€œgliotransmitters,â€ are therefore increasingly studied for their possible role in the pathophysiology of various brain diseases, including epilepsy.[43,101]

Another astrocytic product with links to glutamatergic neurotransmission is kynurenic acid (KYNA), a neuroinhibitory metabolite of the kynurenine pathway of tryptophan degradation. KYNA's preferential blockade of *N*-methyl-D-aspartic acid (NMDA) receptor function[158] probably accounts for its potent anticonvulsant and anti-excitotoxic properties.[74] Interestingly, the extracellular levels of endogenous KYNA are acutely elevated following the administration of convulsive agents.[237] Moreover, KYNA-forming astrocytes are hypertrophic, and KYNA synthesis is enhanced in the limbic brain areas of chronically epileptic animals.[56,236] Interpreted teleologically, enhanced KYNA production and release can therefore be viewed as an endogenous attempt to mobilize astrocytes for anti-epileptogenic, anticonvulsant, and neuroprotective purposes. Related to this role of KYNA, attention must also be paid to the lysine metabolite Î±-aminoadipate, which is present in the mammalian brain in micromolar concentrations and is avidly accumulated by astrocytes.[89,164] Within astrocytes, Î±-aminoadipate inhibits the biosynthesis of KYNA and may thus indirectly facilitate seizure activity.[191,238]

The active participation of astrocytes in seizure activity is not necessarily limited to molecules and mechanisms that affect glutamatergic neurotransmission directly. Thus, astrocytes express a large number of proteins that cause structural changes in the cell, alter extracellular ion concentrations, or control intra- and intercellular signalling through an array of messenger molecules. Seizure-related changes in several of these proteins have been reported in TLE and in both acute and chronic animal models of epilepsy, and may contribute toâ€"or protect againstâ€"pathology. Examples include the embryonic intermediate filament component nestin, which may remodel the glial cytoskeleton in the epileptic brain;[190] S100Î², which may be involved in structural reorganization in association with chronic seizure activity;[17] and the small heat-shock protein 27, which may actively participate in seizure-induced neurodegeneration.[18] Seizures also cause abnormal expression patterns and changes in the biophysical properties of astrocytic K^+ and Na^+ channels,[22,86,202] increase astrocytic communication by upregulating the connexin 43 gap junction protein,[73] and reduce the density of the water channel aquaporin 4, which regulates the clearance of extracellular K^+along the perivascular membrane domain of astrocytes.[62] These changes are accompanied by dysfunctional astrocytic enzymes, receptors, and transporters, which influence seizure activity through altering the metabolic fate and biologic effects of important chemical messengers such as GABA,[121,183,187] adenosine,[69] and prostaglandins.[53] Future research will need to dissect the respective contributions of these diverse impairments to disease manifestation. In addition, we must consider that the pathogenic role of microglia-derived cytokines in epileptogenesis and epilepsy, too, is at least in part dependent on the presence of astrocytes.[125,225]

Astrocyte Dysfunction: Implications for Pathogenesis and Therapy

Despite the large number of studies demonstrating astrocytic abnormalities, most of the information accumulated so far is correlative in nature and does not clarify if astrocyte impairment can in fact *cause*, rather than play an adjuvant role in, the epileptic condition.[26,93] Causality is especially difficult to establish in the chronically epileptic brain, in which astrocytes have already undergone structural and functional changes as a consequence of seizure activity. This distinction between a

primary and secondary role of astrocytes in epileptic disorders is of more than theoretical interest because it has implications for the design of therapeutic strategies. Experimentally, the question can be most unequivocally addressed by selectively manipulating astrocyte function in the normal brain and assessing the effects of the intervention on various seizure parameters. Approaches include direct or indirect interference with astrocytic glutamate function (see the earlier discussion) and the specific elimination of astrocytic proteins such as S100Î²[61] or GFAP.[154]

Other studies have successfully used fluorocitrate, an aconitase inhibitor that selectively incapacitates astrocytes by reversibly blocking tricarboxylic acid cycle activity. These experiments, which are especially instructive in view of the established dysfunction of cellular energy metabolism in epilepsy,[106] showed that transient astrocyte poisoning causes epileptiform discharges and even convulsive seizures[232] and also lowers the seizure threshold to systemically administered chemoconvulsants.[122] Taken together, all these studies provide convincing evidence that astrocyte dysfunction can singularly trigger epileptogenic events in the normal brain.

Each of the many changes in astrocytic biochemistry seen in epileptic animals and humans may play an active role in pathophysiology. As described earlier for some of the most prominent examples elaborated to date, these changes can be simplistically categorized into being either facilitatory or inhibitory of the clinical condition. It follows that it may be possible to develop novel therapeutic agents by targeting astrocytes to specifically interfere with proconvulsive mechanisms or to boost endogenous anticonvulsive principles. Exploitation of this conceptâ€"the pharmacological targeting of glial neuromodulators for the treatment of epilepsyâ€"is still in its infancy,[236] although the use of astrocytes for therapeutic purposes has received considerable attention, for example, in the area of Alzheimer disease and Parkinson disease.[36,184] Notably, this approach is not limited to those glial mechanisms known to be chronically impaired in the disease, but could also be advantageously used to influence physiological signalling processes that normally link astrocytes to neuronal and cerebrovascular function.[112,159] Any of these manipulations of astrocyte function may, in fact, play a role in the clinical efficacy of a number of currently used anticonvulsant drugs and therapies.[31,75,160,243]

Summary and Conclusions

Although often considered relatively minor role players, neuromodulators are increasingly recognized as critical factors in brain physiology. As reviewed here, their ability to modulate neuronal excitability provides a logical link to seizure activity. Indeed, studies in animals have demonstrated that virtually all neuromodulators examined so far are capable of enhancing or reducing seizure susceptibility in the normal brain either directly or indirectly. Alone or in concert, they may therefore play a significant role in seizure initiation under otherwise physiological conditions.

Perhaps more intriguing, neuromodulators appear to be critically involved in processes that are relevant to the development of epilepsy, such as neurogenesis, axonal sprouting, and, more generally, the altered expression of genes that are causally related to epileptogenesis. In turn, neuromodulatorsâ€"and neuromodulationâ€"are themselves altered once the state of chronic epilepsy is established. This and concomitant persistent alterations in receptors for neuropeptides and growth factors, as well as changes in neural circuitry, glia, and extracellular milieu, explain why the same neuromodulator may have quantitatively and qualitatively different effects in the normal and epileptic brain. In addition to being relevant for pathophysiological considerations, these differences also highlight the importance of studying animal models that approximate the epileptic condition in humans.

Despite their complexity, the neuromodulatory mechanisms summarized here provide a vast, varied, and rich resource for new potential therapeutic targets. Indeed, one could argue that a focus on modulators would constitute a superior strategy for anticonvulsant drug development, because it may minimize the side effects associated with conventional targets such as classic neurotransmitters systems (glutamate, GABA) or ion channels (sodium channels, potassium channels). Given the rapid progress in our understanding of the role of neuromodulation in the pathophysiology of epilepsy, this concept could be evaluated clinically in the not too distant future.

Chapter 28

Gene Expression Underlying Changes in Network Excitability

Katarzyna Lukasiuk

Raymond Dingledine

Daniel H. Lowenstein

Asla PitkÃ¤nen

Introduction

Remarkable progress in the fields of molecular biology and molecular genetics has added a new dimension to epilepsy research. Just few years ago, studies on the basic mechanisms of epilepsy were limited primarily to anatomic, electrophysiologic, and pharmacologic analyses. However, molecular approaches have provided a more direct and specific means for studying biochemical events in the brain, leading to the recognition that seizures and other forms of injury can induce complex changes in gene expression. These changes are likely to regulate the molecular architecture of neuronal cells and circuits that contribute to longer-term process of epileptogenesis as well as seizure initiation, spread, and cessation. The application of molecular biology to investigate epilepsy can be divided into two broad categories: (a) studies on the genetic or inherited basis of epilepsies (which will not be discussed here) and (b) studies on the role of alterations in expression levels of specific genes or ensembles of genes during epileptogenesis and in epilepsy. This chapter focuses mainly on recent results of global analyses of gene expression in humans and in experimental models of epileptogenesis and epilepsy that provide new understanding of cellular and metabolic processes occurring in the brain affected by the disease.

Basic Principles of Gene Expression

This section provides a brief review of the main steps involved in the conversion of genetic information encoded by DNA into proteins (for a detailed review, see Drlica[44]).

DNA Replication

The genetic code for all cellular proteins is contained in DNA. In its native state, DNA exists as a double helix of deoxyribonucleic acids bound together by phosphate and hydrogen bonds. The hydrogen bonding between DNA strands ensures that the base adenosine (A) will pair with thymidine (T), whereas guanine (G) pairs with cytosine (C). Replication (or duplication) of DNA requires unraveling and separation of the complementary strands of DNA, attachment of DNA-binding proteins, annealing of small primer fragments, and creation of new complementary strands via DNA polymerase enzymes. Because each strand is replicated once, the process is termed *semiconservative*. DNA replication occurs prior to cell division or mitosis, but not in nondividing cells. The combination of highly specialized enzymes and the ability to â€œproofreadâ€ during the synthesis of a new strand of DNA makes this a remarkably reliable process. Even nondividing cells must constantly maintain the integrity of the DNA by using a host of scanning, editing, and repair enzymes. The double-stranded nature of DNA helps to ensure that a mutation in one strand will be rapidly detected and repaired by the cell.

Transcription

During transcription, the enzyme RNA polymerase recognizes and attaches to a specific region at the starting point of a gene. RNA polymerase synthesizes a single-stranded RNA molecule that is complementary to the DNA template, with the exception that ribonucleic acids are substituted for deoxyribonucleic acids and the base uracil (U) is substituted for thymidine in the coding scheme. Transcription continues until the enzyme reaches a termination sequence in the gene. Once the full-length gene is transcribed, segments that do not code for a specific portion of a protein (termed *introns*) are excised, and only the *exons*, which contain specific information for the coding of proteins, remain. In addition, a long tail of adenosine bases is attached to the RNA, thereby identifying it as â€œmessengerâ€ RNA (mRNA). Messenger RNA is then used to translate the genetic code from ribonucleic acids into amino acids and proteins.

The mechanisms controlling the recognition and attachment of RNA polymerase to the starting point of a gene are critical determinants of the pattern of gene expression in a cell. Specific DNA-binding proteins known as *transcription factors* can attach to a regulatory element upstream from the starting point of the gene. Depending on the type of transcription factor, this may either promote or inhibit binding of the RNA polymerase and subsequent transcription. Similarly, other upstream and downstream regions known as *enhancer* or *repressor sites* can also influence transcriptional activity. These transcription factors are critical links in the process of stimulus-induced regulation of gene expression.

Translation

Transcribed mRNA is translated into protein by an interpretive process involving ribosomes, transfer RNA (tRNA), and a variety of other proteins that facilitate the process, such as initiation factors and elongation factors. Protein synthesis begins with the attachment of the mRNA to a ribosome near the â€œstart codon.â€ A *codon* is a triplet of RNA bases that codes for either a specific amino acid or a start or stop to the translation procedure. A tRNA, which carries a particular amino acid, then joins the complex based on the complementary nucleotide sequence of the mRNA (codon) and tRNA (anticodon). The polypeptide chain is created by sequentially bringing pairs of

tRNAs together on the ribosome using the mRNA as a template. A peptidyl transferase reaction forms a new peptide bond between the two amino acids on the tRNAs. This process continues until the end of the mRNA encoding sequence is reached, and the newly formed polypeptide is released in the cell with the aid of specific release factors.

Aspects of Gene Expression Unique to the Central Nervous System

When the techniques of modern molecular biology are applied to the study of epilepsy and neural injury, certain special aspects of the central nervous system (CNS) must be taken into consideration. Although these unique characteristics do not necessarily limit the use of molecular methods in neurobiology, they do provide insight into the complexities of gene regulation that are unique to the signal processing and cellular repair mechanisms of the CNS. This section discusses several of these aspects.

One of the most notable aspects of neurons is that they are postmitotic.[92] Most mature neurons, therefore, are required to maintain their functional integrity for, ideally, the lifetime of the organism. To do this, neurons use many â€œhousekeepingâ€ functions. These functions include replacing and repairing cytoskeletal structures, replenishing membrane and membrane-associated proteins, synthesizing and packaging neurotransmitters, and maintaining integrity of synaptic contacts. If cell injury occurs, genes are activated in an attempt to restore function and to protect from further injury.[17,27,54,109,111,124,145] If cell death occurs, in certain systems new synaptic contacts are made by the surviving presynaptic neurons, presumably in response to the lost functional connectivity of the dead neuron.[110]

In addition to being postmitotic, neurons have a considerable amount of phenotypic diversity and plasticity. *Phenotypic diversity* refers to the unique characteristics of various types of neurons, such as differences in neuron size and shape, classes of neurotransmitters and peptides released, firing conditions and frequencies, and responses to stress and injury.[108,174] *Phenotypic plasticity* refers to the ability of an individual neuron to alter its function. There are numerous levels of control of phenotypic plasticity. Neurons can transiently modify the quantity of neurotransmitters they release in response to both external stimuli and intracellular signaling mechanisms, as has been suggested in certain forms of long-term potentiation.[11,116] Phenotypic plasticity is a dynamic process that is highly dependent on the molecular aspects of cellular physiology. Neurons can modulate the relative amounts and properties of proteins they express through changes in gene expression, editing of mRNA transcripts, and a variety of posttranslational modifications. For example, in response to repeated stimulation, neurons can synthesize new ion channels and membrane receptors that may contribute to long-lasting changes in membrane excitability.[42,57,98,118,126] Similarly, following stimulation or seizures, neurons may modify the response characteristics of specific voltage-dependent ion channels and membrane receptors and alter expression of mRNAs coding for various synapse-modifying proteins.[41,119] Phenotypic plasticity is an ongoing and constant component of neuronal and glial behavior and is an essential ingredient in the ability of the CNS to interact with the environment.

An especially interesting example of phenotypic diversity in neurons comes from the observation that protein synthesis may be highly localized in specific regions of the cell that are distant from the nucleus and regulated independently from translation occurring in the cell body. In most cells, translation of mRNA into protein occurs within the cell body, and newly synthesized proteins are then transported to their appropriate site based on intracellular signaling mechanisms. Most neurons are polarized cells with three fairly distinct compartments: (a) the dendritic processes, (b) a central regulatory soma, and (c) axonal projections ending with presynaptic terminals. Each of these regions has specific functions and interactions with its microenvironment.[33] mRNA can be differentially distributed and translated in dendritic processes.[13,33] Furthermore, ribosomes necessary for carrying out protein translation have also been located in dendrites. This localized distribution of mRNA and ribosomes suggests that dendrites have the capacity to support highly localized and site-specific protein synthesis. This additional level of phenotypic plasticity may prove to be an important element in the synaptic modifications implicated in activity-dependent learning. It is interesting that there is no evidence that a similar phenomenon of localized protein synthesis occurs in axons.[33] This implies that the neuron may rely on intracellular transport mechanisms, such as axoplasmic flow and microtubule systems, to deliver newly synthesized protein to the axon terminal.

Epilepsy and Alterations in Gene Expression

An â€œIntelligent Guessâ€ = Candidate Gene Approach

Changes in gene expression leading to network reorganization and neuronal hyperexcitability are crucial to understanding epilepsy and have been studied with traditional methods. Several candidate genes encoding proteins having a role in brain excitability have been tested. Obviously, much attention has been given to genes coding for proteins directly influencing electrical properties of neurons, such as receptors and channels. The other group of genes has been those coding for proteins involved in remodeling of neuronal networks, such as growth factors and their receptors, synaptic proteins, or other structural proteins. However, such studies have concentrated mostly on seizure-induced alteration and only within hours after seizures. These data were reviewed recently[49,175] and are only briefly mentioned here. Less information is available on alteration in expression of selected genes during late epileptogenesis and in epileptic tissue. In this chapter, we briefly review only data on changes in the expression of genes that are hypothesized to influence brain excitability directly or indirectly. Data from both human tissue and experimental models of epileptogenesis and epilepsy are included, but data on immediate effect of seizures or status epilepticus, reflecting influence of increased neuronal activity on gene expression, are omitted.

Traditional Methods Most Commonly Used for Studies of Gene Expression Levels

The reverse transcription polymerase chain reaction (RT-PCR) is a powerful technique for making many copies of DNA from minute quantities of RNA targets used as starting material. For gene expression analysis, the first step is synthesis of complementary DNA (cDNA) on the basis of mRNA extracted from the studied tissue using the enzyme reverse transcriptase. The PCR is then used to amplify cDNA representing the gene of interest. PCR uses an enzymatic reaction to repeatedly copy the original DNA fragment present in the reaction.

The PCR reaction mixture includes four basic components: (a) the target DNA, (b) oligonucleotide â€œprimers,â€ which are designed to hybridize the sequence of DNA to be amplified, (c) an excess of individual nucleotides (deoxyadenosine 5â€²-triphosphate [dATP], deoxycytidine 5â€²-triphosphate

[dCTP], thymidine 5â€²-triphosphate [dTTP], deoxyguanosine 5â€²-triphosphate [dGTP]), and (d) a DNA polymerase that is extremely stable at a high temperatures. With the use of an automated heating block, this mixture is cycled through a series of temperature changes that are designed to allow the polymerase to repeatedly duplicate the target DNA. Each cycle begins with a high temperature (e.g., 94Â°C) to separate the strands of target DNA (â€œstrand separation phaseâ€). The temperature is then dropped (i.e., 42Â°Câ€“60Â°C, depending on reaction conditions) to allow the oligonucleotides to anneal (â€œprimer annealing phaseâ€). Then the temperature is increased to 72Â°C, which is the optimal temperature for Taq polymerase activity, so that the DNA replication occurs using the oligonucleotides as the primers (â€œprimer extension phaseâ€). Repeated cycling through these steps results in amplification of the DNA in a highly efficient fashion.

A *Northern blot* is a method for detecting the presence of a particular mRNA transcript in a sample. RNA is isolated from tissue or cells using standard extraction procedures and separated by size via gel electrophoresis. The size-separated RNA is transferred to a membrane, and the membrane is then exposed to a radiolabeled probe. If the mRNA of interest is in the sample, the probe will specifically *hybridize* to the mRNA and produce a signal at the predicted size on the autoradiogram.

In situ hybridization provides a means of determining the pattern of mRNA expression at the cellular level. Whereas Northern analysis uses mRNA derived from homogenized tissue, in situ hybridization uses fixed tissue sections so that the cellular anatomy is preserved. Otherwise, the technique uses the same concepts described for Northern analysis. The tissue sections are mounted on slides and prepared in a way that allows the labeled probe to have access to the cellular compartments and to hybridize with the mRNA. Radioactively labeled probe is then detected with X-ray film. To obtain cellular detail, the slides are coated with photographic emulsion, such that the radiolabeled probe will expose the emulsion directly overlying the cells. The slides are then â€œdevelopedâ€ in the same manner as film, and silver grains in the emulsion seen as black specks reflect the presence of this signal, signifying the presence of the specific mRNA transcript. In case of fluorescently labeled probe, the results of hybridization are analyzed using standard fluorescent microscopy techniques.

Immediate-Early Genes

In recent decades, a class of genes termed *immediate-early genes* (IEGs) has been identified that appears to function as a vital link between acute activity-dependent events and long-term changes in gene expression.[15,31,63,88,89,102,150,154,175] By definition, induction of expression of IEG mRNAs is rapid and does not depend on protein synthesis. Protein products of IEGs often serve as transcription factors regulating the transcription of other genes (e.g., c-fos, c-jun, c-myc, jun-B, krox-20, krox-24, fra-1, zif/268, etc.).

Expression of IEGs in neurons has been shown to be induced by a wide range of stimuli, including membrane depolarization due to both physiologic[14,15,55,67,70,83,84,85,86] and nonphysiologic stimulation,[37,41,42,82,88,105,113,127,133,147,152,161] mechanical trauma,[43] and ischemia.[140] Studies using seizures induced by kindling, electroconvulsive seizures, electrolytic lesions, and chemoconvulsants have also shown that IEGs are markedly induced in specific CNS regions such as the hippocampus and cerebral cortex. Much effort has been invested in understanding molecular pathways leading to induction of IEGs expression following seizures, and the results of these studies are reviewed in detail elsewhere.[139,175]

For the purposes of this review, an important question is, what are the target genes for transcription factors (IEGs and other) participating in the development of epilepsy? Several target genes that can influence neuronal excitability and their relation to transcription factors governing their expression have been described. For example, expression of the metabotropic Î³-aminobutyric acid receptor GABA$_B$R1a and GABA$_B$R1b isoforms in hippocampal neurons is mediated by the cAMP response elementâ€“binding protein (CREB), which binds to unique cAMP response elements in the alternative promoter regions. CREB is then critical for transcriptional mechanisms that control GABA$_B$R1 subunit levels in vivo.[153] In addition, the activating transcription factor-4 (ATF4) differentially regulates GABA$_B$R1a and GABA$_B$R1b promoter activity.[153]

The DREAM transcription factor that is expressed widely in the nervous system can be induced by seizures.[29,123] Its target genes include genes related to neuronal plasticity such as c-fos and preprodynorphin.[28,29]

The AP-1 transcription factor (which is composed of proteins belonging to the Fos and Jun families) has been shown to regulate expression of nerve growth factor (NGF) after hilus lesionâ€“induced seizures[48] and proenkephalin and prodynorphin after kainic acidâ€“induced seizures.[96,143]

There are also IEGs upregulated during epileptogenesis that lack transcription factor functions and can have lasting effect on neuronal excitability. One of these proteins is homer-1, which codes for a scaffold protein anchoring metabotropic glutamate receptors to the cytoskeleton and regulates pyramidal neuron excitability.[24,141,148]

Neurotransmitter Receptors and Ion Channels

Alterations in the expression of mRNAs encoding neurotransmitter receptors and ion channels are likely candidates for affecting network excitability. Table 1 gives a summary of such changes in experimental and human epilepsy.

In the mature nervous system, GABA$_A$ receptors function as ligand-gated chloride channels that confer fast inhibitory synaptic transmission. Several studies have demonstrated abnormal GABA$_A$ receptor function in epileptic tissue.[22,64,80] Because receptor properties depend on subunit composition,[113,169] altered expression of GABA$_A$-receptor subunits can explain functional abnormalities. In fact, changes in mRNA expression for selected GABA$_A$-receptor subunits have been reported in epilepsy models induced by kainic acid[162] and pilocarpine[23,146] and electrically induced status epilepticus (SE),[103,134] as well as following hippocampal kindling.[134]

Metabotropic GABA$_B$-receptor expression has been studied in epileptic animals. Changes in the expression of mRNA encoding GABA$_B$

receptors occur in the hippocampus of patients with temporal lobe epilepsy (TLE)[60] as well as in kainic acidâ€"induced epilepsy,[59] hippocampal kindling,[134] and epilepsy following electrically-induced SE.[134]

Glutamate, the major excitatory neurotransmitter in the brain, acts on ionotropic and metabotropic receptors. Sixteen genes encoding for ionotropic receptors that belong to three functional families (Î±-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA], kainate, and *N*-methyl-D-aspartic acid [NMDA] receptors) have been identified.[38] Alterations in the expression of AMPA receptor subunits have been demonstrated in human epilepsy[61,121] as well as in electrically-[90,173] and pentylenetetrazole-induced kindling.[46] Changes in kainate receptor subunits occur in human epileptic tissue[68] and the kainate model of epilepsy[163] as well as in amygdala and hippocampal kindling.[75,91] Changes in the expression of NMDA subunits were observed in patients with TLE,[7,121,122,130] in rats kindled with amygdala[94] or hippocampal stimulation,[100,101] and following intra-amygdala injection of kainic acid.[144]

CA1, CA1 subfield of the hippocampus proper; ECS, electroconvulsive seizures; KA, kainic acid; MPSS, massively parallel signature sequencing; SAGE, serial analysis of gene expression; SE, status epilepticus; TLE, temporal lobe epilepsy.

There is little information about the long-term changes in mRNA expression of metabotropic glutamate receptors in

epilepsy. Kindling induced a transient decrease in metabotropic glutamate receptor mGluR5 and an increase in mGluR1.[1] Increase in mGluR1 was also observed following intraperitoneal kainate injections.[19]

Sodium channels are of particular importance for epilepsy because many epilepsies are associated with mutation in these channels, and several antiepileptic drugs (AEDs) have their site of action on sodium channels.[97] Data on the mRNA expression of sodium channels in epileptogenesis and epilepsy are sparse. Changes in mRNA levels for sodium channels were found in WAG/Rij absence epileptic rats,[95] after induction of SE with pilocarpine[47] or electrical stimulation of the hippocampus,[4] and in the human epileptic hippocampus.[172]

Various types of calcium channels contribute to increased excitability in epilepsy.[53,81,136,155] Accordingly, protein levels of subunits have been demonstrated to be altered in both experimental and human epilepsy.[39,164] The little that is known about the expression of mRNA indicates changes in Q, R, and L-type voltage-sensitive Ca^{2+} channels in kindling[18,72] and in Q-type channels in the kainic acid model.[168] It has been suggested that the epileptic phenotype in adult genetic absence epilepsy rats from Strasbourg (GAERS) may relate to elevation in the levels of mRNA encoding T-type calcium channels.[158]

Hyperpolarization-activated cyclic nucleotide-gated cation channels (HCNs) mediate the hyperpolarization-activated (I_H) currents in the brain.[135] Long-lasting changes in function of HCNs have been implicated in epileptogenesis.[25,30] It has been suggested that the normal or modified HCN channels might be involved in epileptogenic or protective mechanisms in the epileptic hippocampus.[171] Increase in HCN1 expression was observed in hippocampi of patients with TLE and in the pilocarpine model of chronic TLE in rats.[12] Alterations in HCN mRNA expression was also found in the rat model of febrile seizures.[25]

Other Genes Involved in Regulation of Neuronal Excitability

Apart from ion channels and receptors, there are also other known mechanisms that can influence neuronal excitability, including the effects of transporters, peptide neurotransmitters, growth factors, and other neuromodulators.[5,65,99,160,166] Some of these have been studied in epilepsy, but data on long-term regulation of expression of genes coding for members of these pathways are sparse.

Extracellular glutamate levels are controlled by glutamate transporters that remove glutamate from synaptic cleft. Upregulation of glial glutamate transporter GLT-1 and neuronal excitatory amino acid transporter EAAC1 has been reported in patients with TLE.[142] As summarized in Table 1, altered expression of mRNA encoding glutamate transporters also has been reported in several models of experimental epilepsy, including genetically epileptic-prone rat,[2] EL mice,[79] GAERS rats,[78] Fe^{3+}-induced epilepsy,[40] and pilocarpine-induced epilepsy.[35]

Neuropeptide Y (NPY) has a significant role in regulating seizure activity. Its presynaptic Y2 receptors are capable of suppressing seizure activity by inhibiting glutamate release from mossy fibers.[167] On the other hand, Y1 receptor antagonists have anticonvulsive potential.[62] Marked increases of NPY mRNA in hippocampal granule cells and interneurons were found in Ihara's epileptic rats and spontaneously epileptic rats.[157] In epileptic human hippocampus, NPY mRNA was increased in hilar interneurons of sclerotic and nonsclerotic specimens. Thus, together with upregulation of Y2 receptors, downregulation of Y1 receptors in the hippocampus of patients with Ammon's horn sclerosis may be an endogenous anticonvulsant mechanism.[58]

Neurotrophins can influence neuronal network excitability, and their expression following seizures has been extensively studied. Little information about their mRNA expression is available in other epilepsy-related situations. Increased expression of brain-derived growth factor (BDNF) mRNA has been observed in the neocortex of animals in which spontaneous seizures were induced following injection of tetanus toxin. At later times there was an upregulation of BDNF mRNA at the injection site and downregulation in a surrounding cortical zone. This could contribute to plastic changes in epileptic neuronal circuits and may be associated with the inhibitory surround that hampers seizure spread but facilitates the persistence of a chronic epileptic focus.[107] Epileptic patients with hippocampal sclerosis show increased granule cell mRNA levels for BDNF, nerve growth factor (NGF), and neurotrophin 3 (NT-3).[120,128]

Global Analysis of Gene Expression

Studies of gene expression in epilepsy using traditional molecular biology methods have focused on a limited number of preselected genes at a time. Recent technological developments allow the analysis of gene expression at the level of nearly the whole transcriptome, which provides an unbiased insight into molecular events that occur in the brain during epileptogenesis and epilepsy. The data derived from these studies can be expected to highlight the most prominent metabolic pathways or other phenomena that underlie reorganization of the epileptogenic circuitry and, eventually, guide our efforts at identifying candidate targets for antiepileptogenic treatments.

As described earlier, numerous studies have demonstrated up- or downregulation of a variety of neuropeptides, transporters, ion channels, and receptors in the epileptic state, as well as a host of immediate early genes and other potential effector genes. These studies demonstrate that seizures trigger transcriptional programs that can be long lasting. Unfortunately, they have not guided us to a satisfactory understanding of the molecular events underlying epileptogenesis, partly because the only genes that have been examined so far are those for which prior physiologic or anatomic study suggested their involvement. It is expected that a large array of genes may be involved in epileptogenesis, including genes involved in cell growth control, cell adhesion and migration, intracellular signal transduction, apoptosis, protein turnover, cytoskeleton, and others. Lack of information on the molecular basis of epileptogenesis directly limits the development of treatments that might prevent epilepsy from developing after, for example, traumatic brain injury.

Experiments in which global analysis of gene expression was used to study epileptogenesis and epilepsy have, to a large extent, confirmed data previously gathered with conventional methods.[34,114,116] However, large-scale studies of gene expression have provided insight into other, often unexpected metabolic pathways that may be of great importance for epileptogenesis and epilepsy. Data described in this chapter are summarized in Table 2.

Methods Used for Global Analysis of Gene Expression

Several methods have been developed for the analysis of the whole transcriptome. Here we focus on those that have been successfully used in epilepsy research.

Differential display is an RT-PCRâ€“based method used to identify differentially expressed genes. First, mRNAs from brain tissue specimen are reverse transcribed, and then they are amplified using nonspecific primers. The array of bands obtained from a series of such amplifications is separated on a sequencing gel and compared with analogous arrays from different samples. Any bands unique to a particular sample are differentially expressed. The bands can be purified from the gel and sequenced.

Serial analysis of gene expression (SAGE) is a method for comprehensive analysis of gene expression patterns.[165] It allows the quantitative and simultaneous analysis of a large number of transcripts without the need for creating a probe for each transcript. The principle of SAGE relies on the production of small cDNA tags on the basis of studied mRNA and their subsequent sequencing, counting, and assignment to corresponding genes using bioinformatic tools. The frequency of a specific tag is related to the abundance of the corresponding mRNA in the cell and allows for a comparison of mRNA expression of both known and novel genes in different samples.

Massively parallel signature sequencing (MPSS) is similar to SAGE and is capable of analyzing gene expression without *a priori* knowledge of the transcript sequence and mRNA abundance. MPSS also relies on the production of short tags. However, due to the combination of in vitro cloning of cDNA molecules on the surface of microbeads with nonâ€“gel-based high-throughput signature sequencing, a single MPSS experiment can generate >10^7 tags (100 times more than that in a SAGE experiment).[26]

DNA microarrays are increasingly popular in studies of gene expression. They enable evaluation of the expression levels of thousands of genes at the same time and thereby provide global insight into transcriptional events taking place in a studied phenomenon. The principle of DNA microarray technology is based on the hybridization of labeled cDNA synthesized on the basis of mRNA derived from the tissue of interest, applied to a microarray consisting of a large number of gene probes placed with high density on a solid surface. The strength of the hybridization signal to the particular gene probe reflects the abundance of the respective mRNA in the sample. There are two main types of microarrays: (a) spotted microarrays and (b) Affymetrix Gene Chips. For spotted microarrays, the probe (oligonucleotides or cDNA) is usually spotted on a glass surface. The sample cDNA for hybridization is typically fluorescently labeled. These microarrays offer the possibility of using cDNA from two different conditions (e.g., control vs. treated) labeled with different fluorochromes for simultaneous hybridization to the same chip. Differences in expression are detected by comparing the signal from the two fluorochromes used for labeling the examined samples. Most commercial and academic microarrays belong to this category. In the case of GeneChips produced by Affymetrix (Affymetrix, Inc., Santa Clara, CA), the oligonucleotide probes are synthesized directly onto the surface. The use of perfect and mismatch probe pairs and several probes for each gene increases the specificity and reproducibility of the quantitative results. Some methodologic issues concerning the use of microarrays in the brain have recently been extensively reviewed.[6,114,151]

The recent development of high-density cDNA or oligonucleotide microarrays has brought a new level of sensitivity and specificity to large-scale monitoring of gene expression. This technology has been most productively used in yeast, for which the sequence of every gene is known and available for analysis on microarrays. Rapid progress has occurred in the

P.313

P.314

identification of human and mouse genes; a substantial proportion of all human and mouse genes are already available for study.

Changes in Pattern of Gene Expression in Response to Brief Seizures

One of the first studies using cDNA arrays to evaluate se-izure-induced gene expression was performed by Sandberg and colleagues.[149] The study examined whether neurobehavioral differences in mice from different strains are linked to differences in gene expression. In addition to defining the basal gene expression in different brain areas, it also examined gene expression in response to seizures in two mouse strains that display differences in susceptibility to seizure-induced damage: 129vEv (susceptible) and C57BL/6 (resistant). The seizures were evoked by subcutaneous application of pentylenetetrazole, and animals were sacrificed 1 hour after seizure. Two Affymetrix GeneChips, Mu11KsubA and Mu11KsubB, were used for gene profiling. The two mouse strains differed in their transcriptome response to seizures. Twenty-four genes were differentially expressed between the two mouse strains in all brain areas examined, and >50 genes were differentially expressed in specific brain areas.

French et al.[56] sought to identify the genes involved in plasticity in the hippocampus by using electroshock-evoked seizures as a model. Animals were sacrificed 1 hour after application of current via corneal electrodes. Control animals were exposed to the electrodes without stimulation. Samples from area CA1 of the hippocampus were profiled using the Mouse GEM1 microarray (Genome Systems). Of 9,000 genes that were present on the microarray, only 14 genes were found to have significant changes in expression following seizures. Nine were downregulated and five were upregulated. Subsequent validation of the expression changes with in situ hybridization, however, failed to detect any mRNA expression of six of the candidate genes. Upregulation in area CA1 was confirmed for only one gene (nerve growth factorâ€“induced clone B [NGFI-B]), and the authors were unable to confirm differential expression of any other candidate genes. Three genes were upregulated in the dentate gyrus. These findings suggest that, in contrast to the dentate gyrus, seizures do not appear to be accompanied by large modulation of gene expression in area CA1 of the hippocampus in the model used.

The influence of electroconvulsive seizures (ECS) on the profiles of gene expression has also been extensively studied in relation to effect of ECS on mood. Newton et al.[132] studied the expression of neurotrophic growth factors and related signaling molecules in the rat hippocampus in response to electroconvulsive seizures using a custom microarray containing 645 gene probes. They reported regulation of several genes involved in growth factor signaling and angiogenesis, which could have an important role in the molecular action of ECS.

Changes in Patterns of Gene Expression as an Immediate Consequence of Status Epilepticus

One of the first attempts to describe global changes in gene expression following SE was done by Nedivi and coworkers.[131] They used differential cloning to search for plasticity-related genes. Gene expression was studied in the dentate gyrus 6 hours after SE induced by intraperitoneal injection of kainic acid. Granule cells of the dentate gyrus are resistant to kainic acidâ€"induced neurotoxicity and display plastic changes such as axonal sprouting, growth of basal dendrites, and changes in the number and morphology of dendritic spines. About 5% of the screened genes had a change in level of expression following the seizures (candidate plasticity genes [CPG]). Fifty-two clones derived from genes showing altered expression were partially sequenced. Seventeen of those genes were previously known, with some having a link to neuronal plasticity. Five transcription factors with known role in neuronal plasticity were identified (*c-jun*, zif/268, *c-fos*, *fosB*, and cAMP responsive element modulator [CREM]). The product of another gene, TIMP (tissue inhibitor of metalloproteinase), is a component of the TIMP/matrix metalloproteinase [MMP] system, which influences neuronal plasticity by controlling enzymatic activities of metalloproteinases and regulating local proteolysis of extracellular matrix.[45] An interesting group of genes are involved in the functioning of vesicles (such as clathrin heavy chain, dynorphin, secretogranin) or in encoding the components of synapse (catechol-*O*-methyltransferase [COMT], syndecan).

Further work by Nedivi et al. identified a total of 362 candidate plasticity genes.[74] The sequencing and characterization of unknown CPGs revealed a role in the neuronal plasticity for some of them. For example, CPG15 (also known as neuritin) is an activity-induced molecule that promotes dendritic growth of projection neurons and neurite outgrowth and arborization in culture.[129] Its involvement in experience-induced neuronal plasticity has been shown in well-established models of barrel cortex plasticity and visual cortex plasticity.[71,104] The other gene, CPG2, influences synaptic properties by regulation of endocytosis of glutamate receptors.[32]

Tang et al.[159] used Affymetrix microarrays to study the genomic response in the rat striatum and cortex to a variety of brain-damaging insults including kainate-induced SE. Subcutaneous injection of kainic acid resulted in upregulation of 187 genes and downregulation of 89 genes in the parietal cortex 24 hours later. Expression of many of these genes was also changed by ischemic stroke, intracerebral hemorrhage, and hypoglycemia or hypoxia. The protein products of the regulated genes belong to a variety of functional classes, including stress-related proteins, proteases, cytoskeletal proteins, and receptors. The function of a number of genes responding to kainate treatment implicates their involvement in remodeling of neuronal networks (see earlier discussion). For example, c-jun, fos, tissue inhibitor of metalloproteinases 1 (TIMP-1), and syndecan participate in regulation of dendritic spine morphology and hippocampal long-term potentiation (LTP).[51,87]

Recently, response to kainic acidâ€"induced SE has been studied also by Hunsberger et al.[77] In this study, gene expression profiles of the rat hippocampi were characterized at 24 hours after intraperitoneal application of kainate using custom cDNA array. Kainic acidâ€"induced genes were classified into multiple functional classes such as angiogenesis, cell cycle and proliferation, cell death, extracellular matrix signaling, kinases and phosphatases, neuroprotection, neurotransmitter signaling, and transcription factors.[77] Thirty-six novel kainic acidâ€"regulated genes were found in addition to those that were discovered in previous studies, including transcription factors (CCAAT/enhancer binding protein Î´ [C/CEBPÎ´], glycoprotein 38 [gp38], and ankyrin repeat and SOCS box protein 13 [ASB13]) and those involved in neurotransmitter signaling (fibroblast growth factor receptor 4 [Fgfr4], G proteinâ€"coupled receptor 18, and L-myc-1 proto-oncogene protein [Lmyc1] transcription factor).

Lukasiuk and colleagues examined gene expression profiles during epileptogenesis at 1 day after SE induced by electrical stimulation of the amygdala using Research Genetics Rat Array (Research Genetics, Huntsville, AL) containing approximately 5,000 genes and expressed sequence tags (ESTs). One day after the induction of SE, changes were observed in the expression of 37 genes in the hippocampus (8 downregulated and 29 upregulated) and 29 genes in the temporal lobe (13 downregulated and 16 upregulated). Products of some of those genes are involved in normal metabolism, including cytochrome function, protein synthesis, and carbohydrate and amino acid metabolism. Some of these changes might reflect rescue efforts from metabolic

P.315

disturbances. Others, such as downregulation of predominantly neuronal synaptophysin or 14â€"3-3 gamma, might reflect ongoing neurodegeneration.[114,115]

Changes in Pattern of Gene Expression During Late Epileptogenesis

Hendriksen et al.[73] investigated the pattern of gene expression in the hippocampus of rats undergoing epileptogenesis that was induced by SE evoked by electrical stimulation of the angular bundle. Four hours after the stimulation, SE was stopped with pentobarbital. The hippocampus contralateral to the stimulation site was isolated 8 days after stimulation and used for gene profiling with SAGE methodology. During the latency period, rats were under continuous electroencephalographic (EEG) monitoring, and only the animals that did not express any seizure activity during monitoring were included in the study. Sequencing >10,000 tags for each group revealed 92 differentially regulated tags. Genes with altered expression were associated with expression of ribosomal proteins, protein processing, axonal growth, and glial proliferation. The authors classified 6 genes as related to axonal growth and regeneration and therefore as likely involved in the remodeling of neuronal network, including cyclophilin, glycoprotein 65, Î±-tubulin, Thy-1 antigen, thymosin Î±-10, and an expressed sequence tag highly similar to tubulin Î² chain.

Elliot et al.[50] characterized the pattern of gene expression in the pilocarpine model of rat epilepsy. SE was induced by an intraperitoneal injection of pilocarpine hydrochloride and terminated after 2 hours of convulsive SE with diazepam. Animals were sacrificed 14 days later. In this study, the authors focused on the analysis of gene expression in the dentate gyrus of the hippocampus. Expression levels were analyzed using the Affymetrix chips, and changes in level of expression were found for 129 genes. Genes altered during epileptogenesis represented a wide range of functions, with a high number of genes involved in response to injury and cell survival. The authors hypothesized that epileptogenesis shares some features with normal development of the nervous system. Therefore, they compared gene expression in the dentate gyrus of the hippocampus during development and epileptogenesis. A total of 37 genes had an altered level of expression during both epileptogenesis and development. According to functional annotations performed by authors, genes altered during epileptogenesis have functions related mainly to injury and survival, morphology, signaling, metabolism, and cell cycle. Our bioinformatic analysis of this data set that was undertaken to detect overrepresentation of functional gene groups revealed statistically significant overrepresentation of genes involved in RNA metabolism, neurogenesis, cytoskeleton organization and biogenesis, development and cell differentiation, and nerve maturation.[116] Some of these genes may be of particular interest in the context of remodeling of neuronal network. For example, internexin neuronal intermediate filament protein Î± (Inexa) may play a role in neuronal regeneration in response to injury. Bhlhb3 (basic helix-loop-helix domainâ€“containing protein class B3) has been implicated in the regulation of neuronal differentiation during development and adaptive neuronal plasticity and neurite outgrowth in the adult. Finally, protein phosphatase 1 regulatory subunit 9B (Ppp1r9b) and Ras homolog enriched in brain (Rheb) play a role in synaptic plasticity. Another gene, Synthenin, is abundant during the period of development characterized by intense growth and synapse formation and stabilization and may play a role in determining the formation and maturation of synapses.[76] Vascular growth factor (VGF) plays a key role in neuronal differentiation and survival and regulates synaptic function in hippocampal neurons, neurotrophic tyrosine kinase receptor type 2 (Ntrk2) is a receptor for brain-derived neurotrophic factor, and CD24 antigen (Cd24) may be involved in neuronal migration during development.

Becker et al.[9] also studied gene expression in the dentate gyrus and the CA1 region of the hippocampus at 3 and 14 days after pilocarpine-induced SE with Affymetrix microarrays. Increased expression of >400 genes in the dentate gyrus and 700 genes in the CA1 was observed 3 days after SE, whereas a lower number of genes was regulated at 14 days after SE: >50 genes in the dentate gyrus and 400 genes in the CA1. The authors suggested that several genes from their data set might be involved in stress reaction and structural reorganization of the hippocampus. Regulated immediate early genes include transcription factors (JE-immediate early gene, c-fos), tissue plasminogen activator (tPA; a component of the plasminogen system), as well as mitogen-activated protein kinase 1 (MEKK1) and cell division control protein 2a (cdc2a) kinases. Some genes may be linked to structural plasticity such as microtubule-associated protein 2 (map2), pentraxin, TIMP-2, glial fibrillary acidic protein (GFAP), or Thy-1 cell surface antigen. Others, like Ras-related protein Rab-3 (rab3), regulating synaptic membrane exocytosis (Rim) IÎ±, neurexin III-Î±, and neurexin I-Î², are associated with the synapse and can influence synaptic plasticity.

Lukasiuk et al. analyzed changes in gene expression in rats undergoing epileptogenesis after SE induced by electrical stimulation of the amygdala.[115] Tissue was sampled in the hippocampus and temporal lobe at 4 and 14 days after induction of SE. Four days after stimulation, 10 genes were upregulated and 2 were downregulated in the hippocampus. In the temporal lobe, 57 genes were upregulated and 98 were downregulated. Fourteen days after stimulation, there were 3 genes upregulated and 11 downregulated in the hippocampus and 17 genes upregulated and 15 downregulated in the temporal lobe. Many genes regulated during epileptogenesis are involved in basic metabolism, including energy metabolism, protein synthesis and degradation, and signal transduction. Further analysis revealed statistically significant overrepresentation of functional gene classes. At 4 days after SE there was an upregulation of genes involved in cytoskeleton organization and biogenesis (Ywhag [tyrosine 3-monooxygenase/tryp-tophan 5-monooxygenase activation protein, Î³ polypeptide], Lasp1 [LIM and SH3 protein 1], Dlc1 [deleted in liver cancer 1], and stathmin 1) and in cell differentiation (vav 1 oncogene, selenoprotein 15, Ywhag, interferon-related developmental regulator 1 [Ifrd1], bone morphogenetic protein 4, dual-specificity phosphatase 6).[116] At 14 days after SE, genes involved in electron transport and secretion were overrepresented. One of the genes that may be of particular importance for plastic changes was munc13â€“4, which encodes a protein mediating synaptic vesicle exocytosis from glutamatergic synapses.

Changes in Pattern of Gene Expression in Epileptic Tissue

Global analysis of gene expression has been used for characterization of epileptic tissue both in animal models and in surgically resected human tissue.

Several studies have dealt with global alterations in gene expression in human temporal lobe epilepsy. Becker et al.[8] studied patterns of gene expression in the resected human epileptic hippocampus with Ammon's horn sclerosis and compared them to unlesioned nonepileptic hippocampal tissue using the Atlas Human Neurobiology array. Nine genes were upregulated and 12 were downregulated in the sclerotic hippocampi. Subsequent real-time quantitative RT-PCR analysis of gene expression in laser-microdissected cells enabled identification of the genes that were differentially regulated in the neuronal and glial cell populations. For example, ataxin-3 was upregulated in neurons and GFAP (glial fibrillary acidic protein) in

P.316

astrocytes. On the other hand, calmodulin expression did not differ in individual neurons sampled from sclerotic or unlesioned hippocampus, suggesting that a decrease in its expression in tissue extracts is due to the loss of calmodulin-expressing neurons.

In their further work, Becker et al. characterized and compared gene expression profiles in rat and human epileptic tissue using Affymetrix microarrays.[9] In rats, epilepsy was induced by pilocarpine-evoked SE. Gene expression was studied and compared in the CA1 and DG regions of the rats exhibiting either low or high seizure frequency. In animals with high seizure frequency, 96 genes were altered in the CA1 and 74 in the dentate gyrus. In the group with low seizure frequency, 89 genes were altered in the CA1 and 57 in the dentate gyrus. In general, fewer alterations in gene expression were detected in epileptic animals than in rats that were sacrificed for analysis at 3 or 14 days after pilocarpine application (epileptogenesis phase). Genes induced in chronically epileptic animals included neurotransmitter receptor genes (D1A dopamine receptor), channels (Kv3.2 potassium channel), and genes important for synaptic transmission such as pentraxin, Rim, and neurexins. Our analysis of this data set revealed overrepresentation of genes belonging to several functional groups, including synapse organization, response to stress, and the wounding or immune response.[116] In addition, the authors compared gene expression profiles in hippocampi of epileptic rats and hippocampi of human epileptic patients. Eighteen genes were similarly regulated in epileptic animals and in humans, demonstrating remarkable interspecies similarity in gene expression profiles. Coregulated genes are involved in cellâ€“matrix interactions, cell growth and differentiation, cellular metabolism, neuronal signaling, and regulation of transcription.

Lukasiuk and colleagues studied patterns of gene expression of the hippocampi and temporal lobes of rats that developed spontaneous seizures following SE induced by electrical stimulation of the amygdala.[115] In the hippocampus, 12 genes were upregulated and 30 genes were downregulated. In the temporal lobe, 58 genes were upregulated and 4 genes were down-regulated. It is interesting that there was little overlap between the genes regulated in epileptic animals in comparison to animals that did not have spontaneous seizures at the same time after stimulation. The regulated genes have a variety of functions, including those related to basic metabolism, cell cycle, and signal transduction.

Gene expression profiling also has been used to study genetically epileptic rats. Bo et al.[20] searched for differentially expressed genes in the cerebral cortex of genetically epilepsy-prone P77MC rats using Atlas Expression Array. They found 13 genes elevated and 2 genes downregulated in P77MC rats compared to normal Wistar rats. These genes were involved in protein synthesis, metabolism, membrane transport, cytoskeleton, and ion channels.

Arai et al.[3] studied genetically epileptic Ihara rats that have genetically programmed micodysgenesis in the hippocampus. They used SAGE to compare the expression pattern of IERs with that of control Wistar rats at 2 months of age, that is, prior to the expected manifestation of spontaneous seizure activity. They identified 21 differentially regulated genes. The genes upregulated in IER rats were involved in protein synthesis, metabolism, membrane transport, the cytoskeleton, and ion channels. Genes coding for intracellular components and neurotransmission-related proteins were downregulated. Most of these genes had not been previously implicated in epileptogenesis or epilepsy.[3]

Kim et al.[94] studied cortical dysplasia and compared gene expression in dysplastic with nondysplastic cortex. Three genes were upregulated and four genes were downregulated in dysplastic cortex. It is interesting that the majority of the genes showing altered expression were associated with apoptosis.

An earlier study of cortical dysplasia by Crino at al.[34] using targeted cDNA array revealed that GluR4, NR2B, and NR2C subunit mRNAs were increased and NR2A and GABA$_A$RÎ²1 subunit mRNAs were decreased in dysplastic neurons, whereas GABA$_A$RÎ±1, -RÎ±2, and -RÎ²2 as well as GluR mRNA levels were reduced in both dysplastic and heterotopic neurons.

Changes in Pattern of Gene Expression During Kindling

Apart from SE-induced epileptogenesis, kindling has also been used as a model to study plasticity-associated changes in trans-criptome. During kindling, repetitive application of an initially subconvulsive electrical stimulus results in development of epileptiform activity and finally generalized seizures in response to the same stimulus.[66] One advantage of this model is the absence of severe brain damage that is present in SE models. Therefore, genes that change expression level during kindling are presumably related to changes in excitability, and the data set is less likely to be contaminated by alterations related to neurodegeneration.

Liang and Seyfried[106] used RT-PCR differential display (DD) to study hippocampal tissue at 0.5 hour, 1 day, 1 week, and 1 month after rapid kindling. Out of 30,000 bands analyzed, 50 were differentially displayed. Northern blot analysis confirmed changes in 26 of these genes. Fourteen of them were known genes and 12 were novel. Only 5 genes had changed expression level for at least 1 day. Kinase Î±CaMK II, phosphatase PP2A, and GTPase-like protein Cyr 61 were downregulated, whereas King12 was upregulated for up to 1 day after kindling. Only RGS4, a GTPase-activating protein, was persistently downregulated up to 1 month after rapid kindling.

MPSS was used to study gene expression in the rat amygdala kindling model by Potschka et al.[141] Kindling by repeated electrical stimulation of the amygdala resulted in the differential expression of 264 genes in the hippocampus compared to sham controls. The most strongly induced gene was Homer 1A, an immediate-early gene involved in the modulation of glutamate receptor function. Because kindling induces overexpression of Homer 1A in the hippocampus and mice overexpressing Homer 1A exhibited retardation in kindling, this may represent an intrinsic antiepileptogenic mechanism in counteracting progression of the disease.[141]

Gu et al.[69] studied the effect of amygdala kindling on gene expression in the temporal lobe with Affymetrix microarrays. A number of genes were regulated during kindling, and the authors clustered >200 of them into 15 protein pathways or functional classes. These functional classes could reflect ongoing changes leading to increased excitability and included G-protein signaling, synaptic transmission, CA^{2+}-dependent kinases, ion channels, transcription factors, neurofilaments, microtubules, surface-linked signal transduction, and others.

Influence of Antiepileptic Drugs on Pattern of Gene Expression

Large-scale molecular profiling studies have provided opportunities to discover new mechanisms of action of AEDs that extend beyond their antiepileptic effects and can mediate their effects on neuronal recovery after epileptogenic insult. Such analyses have been performed with tissues exposed to valproic acid, lamotrigine, or phenytoin. Bosetti et al.[21] administered 200 mg/kg of valproic acid to rats for 30 days and reported that 87 of 8,799 genes on a U34A Affymetrix oligonucleotide microarray were downregulated and 35 were upregulated. The regulated genes affect a variety of molecular pathways, including synaptic transmission; ion channels and transport; G-protein signaling; lipid, glucose, and amino acid metabolism; transcriptional and translational regulation; phosphoinositol

P.317

cycle; protein kinases and phosphatases; and apoptosis. The actions on these pathways might explain some of the effects of valproic acid on psychiatric conditions as well as on the recovery process after epileptogenic brain insults. One of the effects might be on angiogenesis and cell proliferation. It is interesting that valproic acid (0.25â€“1 mM) was recently reported to inhibit endothelial cell proliferation and migration as well as reduce angiogenesis in vitro and in vivo, effects that are probably mediated by the inhibition of histone deacetylase and decreased expression of endothelial nitric oxide synthase.[125] Suppressed expression of the angiogenic factors vascular endothelial growth factor and fibroblast growth factor is also proposed to contribute to the antiangiogenic actions of valproate.[176] The effect on cellular proliferation has sparked interest in valproate as an antineoplastic agent.[16] Whether trauma- or seizure-induced proliferation of neuronal and glial cells is affected by valproic acid is unknown.

Wang and colleagues[171] exposed hippocampal primary cell cultures to 0.1 mM lamotrigine for 1 week. Of 1,200 genes on the Atlas Rat 1.2 array, 8 genes were upregulated and 6 were downregulated. Regulated genes included subunits of ion channel receptors, kinases, phosphatases, and proteins involved in cell survival. The functional significance of the data has not yet been explored.

The effects of phenytoin on gene expression in human dermal fibroblasts were studied by Swamy et al.[156] Of the 18,000 elements on the cDNA microarrays, 1,500 genes were differentially expressed after exposure of cultures to 20 Âµg/mL phenytoin for up to 48 hours. The major growth factors and their receptors involved in wound healing were upregulated, as were the genes encoding proteins involved in extracellular matrix degradation (e.g., matrix metalloproteinase-1). These findings suggest a molecular basis for some peripheral effects of phenytoin, including its beneficial effects on wound healing. They are also consistent with earlier studies demonstrating that in an experimental model of wound healing, as well as in stroke patients with peripheral ulcers, phenytoin facilitates fibroblast infiltration and neovascularization.[36,137] Further investigation of the effects of phenytoin on genes encoding proteins that contribute to the reorganization of the extracellular matrix and blood vessels in neuronal tissue after brain trauma seems very worthwhile.

Gu et al.[69] studied the effect of levetiracetam on gene expression during amygdala kindling. Levetiracetam had no effect on gene expression in control rats. However, application of levetiracetam during kindling not only suppressed kindling, but also influenced gene expression patterns in the temporal lobe. Expression of some epilepsy-related genes such as neuropeptide Y, thyrotropin-releasing hormone, and DFAP was partially normalized by levetiracetam treatment. Nevertheless, a significant number of genes remained altered by kindling even on levetiracetam treatment.

Caveats in Large-Scale Profiling of Epileptic Tissue

Despite the rising number of reports of global analysis of gene expression in epileptogenesis and epilepsy, the most essential molecular players in these processes are still unspecified. The first analysis of various data sets available a few years ago led to the conclusion that there are very few common features among different studies.[114] Differences may relate to technical issues associated with large-scale gene expression analysis. Methods of global analysis of gene expression have limited sensitivity, especially when brain tissue is studied. It has been suggested, for example, that GeneChips reliably detect no more than 30% of the hippocampal transcriptome.[52] In addition, in the case of SAGE or other methods using large-scale sequencing, rare transcripts may not be detected. Furthermore, the brain is obviously not a homogeneous tissue and consists of multiple cell types. Therefore, if a particular transcript is regulated in only one cell type, this alteration may be â€œdilutedâ€ in extracts from the tissue and remain below the level of detection. In addition, techniques of global analysis of gene expression do not provide information regarding cellular localization of the detected changes in gene expression. In case of neurodegenerative diseases, some changes can be related to the disappearance of selected neuronal populations, as demonstrated by Becker et al.[8] Finally, investigators have used different animal models or human tissues as well as analyzed the pattern of gene expression at different stages of disease development and in different brain areas. As Lukasiuk et al. showed, the changes in gene expression induced by SE are dynamic and change with time.[115] Furthermore, changes in the expression of the majority of genes are often specific to the a brain area, and there is limited overlap between genes regulated, for example, in the hippocampus and the temporal lobe.[9,115] Thus, there is a great variability in genes considered to be regulated depending on the experimental model, time point, and experimental procedure used in the study. Finally, the microarray approach will not identify posttranslational events that may be critical to the process of epileptogenesis.

Global Analysis of Gene Expression in Epileptogenesis and Epilepsyâ€”Attempt at a Synthesis

To reassess the information in data sets available from epileptogenic or epileptic tissue, Lukasiuk et al. used emerging bioinformatics methods that were designed for the global analysis of gene expression to search (a) highly represented functional gene classes (gene ontology [GO] terms) within data sets and (b) individual genes that appear in several data sets and, therefore, might be of particular importance for the development of epilepsy due to different etiologies.[116] The investigators focused on two well-described models of brain insult that induce the development of spontaneous seizures in experimental animals: (a) SE and (b) traumatic brain injury (TBI). A few papers describing gene expression in rat and human epileptic tissue were included for comparison.

The analysis revealed that various epileptogenic insults induce statistically significant changes in gene expression in functionally linked genes that were predefined as GO terms (Fig. 1). The representation of statistically significant GO terms describing biologic process was time dependent. Within hours after epileptogenic brain insult, the GO term â€œregulation of transcriptionâ€ was overrepresented. It is interesting that this GO term did not become significant at any later time point. Many of the transcription factors detected by the analysis can contribute to ongoing neurodegeneration or, more generally, to cell stress. On the other hand, changes in the expression of some transcription factors might induce succeeding events that are presumably crucial for epileptogenesis, such as neuronal plasticity. Genes under the GO term â€œneurogenesisâ€ become apparent at 1 day after injury. In epileptic tissue collected from humans or animals with spontaneous recurrent seizures (i.e., the end result of epileptogenic process), the presence of the GO terms related to â€œsynaptic organizationâ€ (BDNF), â€œplasticityâ€ (BDNF), and â€œtransmissionâ€ (apolipoprotein E [APOE], synaptosomal-associated protein 25 kDa [SNAP25]) emerged. This supports the idea that neuronal plasticity occurs for a longer period of time after an insult, and can progress even after epilepsy is diagnosed.[138] It is interesting that several GO terms, including â€œimmune response,â€ â€œcell motility,â€ â€œresponse to stress,â€ â€œresponse to wounding,â€ and â€œion homeostasis,â€ are represented across different time points after an insult. Numerous individual genes change their expression in more than two models of epileptogenesis (Fig. 2). Alterations in their expression are time specific. A closer look at altered individual genes as well as GO terms indicated an involvement of many

P.318

P.319

processes previously linked with epileptogenesis such as cell death and survival, neuronal plasticity, and immune response. It is interesting, however, that only a few genes are involved in defining the electrical properties of neurons and glia. Perhaps the most striking finding was that the predominant function of genes with altered expression is related to the immune response. Although inflammation and immune response in brain trauma and epilepsy are receiving more attention, they have not been considered to have a key role in epileptogenesis and epilepsy.

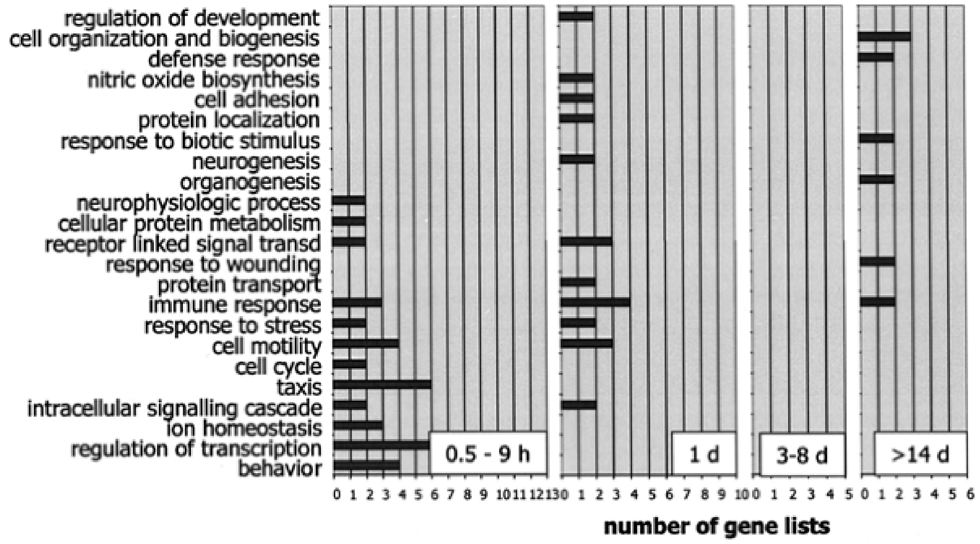

FIGURE 1. Summary of biological process gene ontology (GO) terms that are overrepresented after epileptogenic brain insults (status epilepticus or traumatic brain injury). Overrepresented functional gene classes were detected by meta-analysis of GO terms in gene lists that were generated from the data provided in selected papers using GOstat software (available at http://gostat.wehi.edu.au).[10] Only GO terms overrepresented in at least two lists within a time window are presented. For details of the analysis see Lukasiuk et al.[116] For an extended version of the results see http://www.uku.fi/aivi/neuro/research_epilepsy.shtml or http://www.nencki.gov.pl/labs/epg.htm.[116]

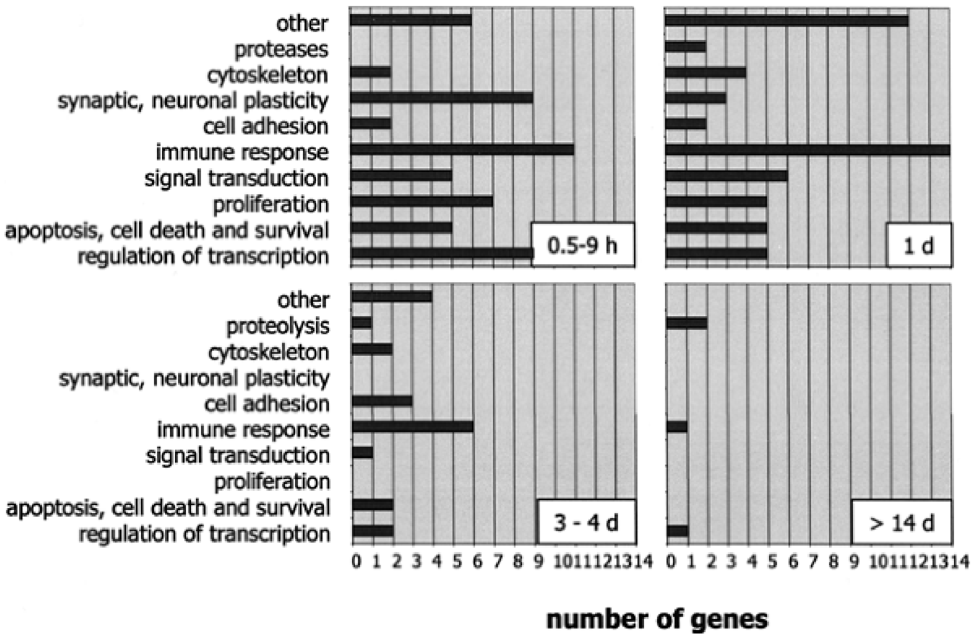

FIGURE 2. Functional classification of individual genes that appear in several data sets describing global analysis of gene expression following epileptogenic insult (status epilepticus or traumatic brain injury). transd, transduction. To find a particular gene with altered expression, data provided in selected manuscripts were reannotated and analyzed using a purpose-build relational database on a MySQL server platform. For an extended version of the results see http://www.uku.fi/aivi/neuro/research_epilepsy.shtml or http://www.nencki.gov.pl/labs/epg.htm.[116]

Summary and Conclusions

Alterations in gene expression that underlie cellular modifications leading to epileptogenesis and epilepsy have been extensively studied by using conventional molecular biology methods as well as by global analysis of gene expression. Most studies have focused on the immediate effects of seizures or SE on gene expression and therefore describe the effects of increased neuronal activity or neuronal injury on gene expression. An overall review of the studies indicates that gene lists obtained by global analysis include very few of the genes studied previously with traditional methods, such as those having a role in regulation of neuronal excitability such as receptors or channels. These observations suggest that receptor or voltage-gated channelopathies may just be some of the phenomena that occur in serial and parallel manner (possibly interacting) with other cellular changes (e.g., inflammation) that underlie the development of epilepsy and change in excitability, and these should be investigated to greater extent.
