These authors endorse a Practice Parameter from the American Academy of Pediatrics that concluded, "Based on the risks and benefits, neither continuous nor intermittent anti-convulsant therapy is recommended for children with one or more simple febrile seizures. The American Academy of Pediatrics recognizes that recurrent episodes of febrile seizures can create anxiety in some parents and their children and, as such, appropriate education and emotional support should be provided."[58] We would extend the conclusion to all febrile seizures, simple (typical) and complex (atypical).

There does not seem to be any compelling reason to treat children with drugs on a daily or intermittent basis after a first or second febrile seizure. The potential side effects of drugs outweigh their benefits. Exceptions might be made for a child living in an extremely remote area or with poor access to medical care or a marked tendency for prolonged or repetitive febrile seizure episodes.

Most children with multiple recurrent febrile seizures do not require drug treatment. If treatment is to be offered, the use of liquid rectal diazepam to be given at home at the time of an actual seizure is recommended. The benefit is prevention of a prolonged febrile seizure; the approach is appropriate for a well-organized family with only a few individuals caring for the child. Alternatively, intermittent oral diazepam or clobazam at the time of illness might be considered. For success, excellent compliance and a child with only a few caregivers are again essential.

There would appear to be very few indications for daily treatment with antiepileptic drugs. The child with many caregivers and multiple prolonged recurrences might be a candidate. If daily drug treatment is to be used, daily phenobarbital at 4 to 5 mg/kg/day is recommended provided there is careful monitoring for changes in the child's personality or behavior. A last resort would be daily oral valproic acid.

Chapter 125

Treatment of Provoked Seizures

Braxton B. Wannamaker

Harold E. Booker

Introduction

Provoked seizures are usually contrasted with "spontaneous" seizures. In reality, no seizures are truly spontaneous, as all result from the interaction of any number of intrinsic and external excitatory and inhibitory factors. The dynamic interaction of these factors determines when a seizure occurs. Yet in most cases, our knowledge of these factors is so limited that it is impossible to predict, with any reasonable degree of reliability, when a seizure will or will not occur. Thus, most seizures occur randomly but not spontaneously. In a tertiary care epilepsy center, 62% of patients identified at least one specific precipitant for their seizures.[14] In order of prevalence, those precipitants were stress, sleep deprivation, sleep, fever or illness, and fatigue. In some cases, however, one or (rarely) more consistent factors can be discerned preceding a seizure with a sufficiently short latency that a direct cause-and-effect relationship can be assumed. In certain cases, the seizure follows the provocative factor with such fixed latency and response rate that many have spoken of the "reflex epilepsies." In these cases, the provocative agent is a more or less specific sensory stimulus interacting with established epilepsy. These susceptible subjects almost always have "spontaneous" seizures as well. In other cases, the latency is longer and variable, and the provoking "stimulus" is not always followed by the "response" (seizure). Seizures in catamenial epilepsy and seizures after hyperventilation would be examples. Nevertheless, in either case, the relation is close enough that few would have difficulty in categorizing these seizures as being provoked. On occasion, provocative factors may be of sufficient intensity to bring on seizures in subjects who do not have epilepsy. Fever in young children and sleep deprivation in young adults are the two most frequent examples.

Provoked seizures are indistinguishable, once they have begun, from "spontaneously" occurring seizures. All major types of seizures can be provoked. The electro-clinical manifestations for each type of seizure are the same whether provoked or spontaneous. Thus, it is only the setting in which seizures occur that gives a clue to whether they are provoked or not. One should be suspicious of the presence of provoking factors in any patient who does not respond well to standard treatment or in whom the history suggests that seizures occur in characteristic circumstances, that is, at the same time of day, in the same phases of the diurnal cycle, or in specific psychosocial settings. Although this may also be true for pseudoepileptic seizures, the history usually fails to reveal any "secondary gain," as is so often seen in psychogenic pseudoepileptic seizures.

Provocative factors are both intrinsic and extrinsic. Common intrinsic factors include sleep deprivation,[6] sleep itself, the menstrual cycle, and any number of abnormal systemic toxic–metabolic states. Extrinsic factors include a large array of specific psychophysiologic stimuli (e.g., stroboscopic stimulation) and many less specific states, such as arousal, stress, and mood.

The significance of recognizing provoked seizures is that recognition offers another therapeutic option—that is, attempts to eliminate or avoid the provoking stimulus. Although simple in principle, this is often difficult in practice. Environmental stimuli are ubiquitous. A specific environmental stimulus may be difficult to recognize as the triggering factor. Emotional status is complex and often requires a multifaceted treatment regimen. Many patients require both short-term and long-term efforts to alter habits, behavior, and emotional status. Some patients report the ability to self-control their epilepsy by consciously avoiding high-risk situations and seeking low-risk situations. Further, some patients with aura or warnings can at times abort their habitual seizure.[42] Optimal medical and psychological therapy must be pursued aggressively in those who have coexistent epilepsy, as this is the primary treatment modality.

Isolated or single seizures occurring in nonepileptic subjects are found, on careful inquiry, to have been provoked in the majority of such cases. Identification of the provocative factor must be made with circumspection. Many of these seizures are related to commonly prescribed drugs. It becomes important to appreciate additional factors, such as severity of illness, neurologic status, renal clearance, hepatic elimination, drug dosing and administration route, polypharmacy, and physiochemical and toxicologic properties of the drugs. These factors modify pharmacotherapeutic and toxicologic responses, making their recognition and understanding vital for treatment.

Emotional Factors

Emotional stress is likely the most prevalent provocative circumstance to precipitate seizures in patients with epilepsy. The actual prevalence of this relationship is not known, yet clinical experience and the available clinical studies[28] support its ubiquity and impact. Patients have identified fear, worry, frustration, and anger as common stressors. An immediate temporal relationship is not usually evident—that is, the seizure usually does not occur at the instant the patient senses the anger or other emotion. Nevertheless, the patient is at maximal risk for one or more seizures in close temporal proximity to such states. Patients with complex partial seizures are more susceptible.

It is now appreciated that depression is the most common comorbidity in patients with epilepsy.[20] In patients with treatment-resistant epilepsy, depression reached 54%.[7] There is growing evidence that depressive disorders and epilepsy share an endogenous or biologic association.[20] The linkage of these two disorders and their basic mechanisms is inferred by epidemiologic studies and clinical observations, and supported by animal experimentation. It is apparent that depressive disorders in epilepsy patients may likely create a milieu for seizure provocation and must be appropriately treated.

Certain clinical neurophysiologic analyses are anecdotal yet elucidating.[10] Several different and indirect provocative

processes may occur as a consequence of emotional stress. Willful noncompliance with medication has been demonstrated. Hyperventilation can develop sufficiently to trigger electroencephalographic (EEG) changes and clinical seizures. Sleep deprivation can be a consequence of profound agitation and restlessness. These phenomena, which are associated with emotional stress, do modulate brain excitability. However, it is not clear from such clinical studies whether emotional stress modulates brain excitability through the kind of neuronal mechanisms implied by basic research studies or through other indirect mechanisms.

As emotional stress is ubiquitous and protean, evaluation for its presence should be a part of the initial assessment in every patient with epilepsy. Vigilance for changes in interpersonal relationships, in school or job performance, and in social circumstances should be a routine component of follow-up examinations. Clinical judgment is required to place the significance of this provocative factor in perspective for the individual patient. Failure to pursue this approach and to ameliorate problems often means an increased frequency of seizures regardless of the best attempts at medical therapy.

Treatment includes both medical and nonmedical therapy. Medical therapy may require not only antiepileptic drug treatment, but also use of tranquilizers, antidepressants, or neuroleptics. More specifically, long-term anxiolytics with antiepileptic properties can be helpful; these include clor-azepate and clonazepam. Antidepressants, mood stabilizers, or neuroleptics can be used concurrently with antiepileptic therapy if clinically indicated. However, there is minimal risk for exacerbation of seizures with some of these drugs. Further discussion follows in the section on drug-induced seizures.

More severely ill patients with paranoia, thought disorder, hallucinations, and extreme agitation require treatment with neuroleptics. As with antidepressants, therapeutic precautions apply. High doses of neuroleptics, rapid changes in their levels, and induction of drowsiness may worsen seizures in epileptic patients; some neuroleptics can provoke seizures by direct effect. However, the reduction in agitation, thought disorder, and hallucinations can exert a significant calming effect and restitution of normalcy, which in turn is associated with improved seizure control. Thus, the benefits warrant their use and treatment should not be delayed.

Nonmedical therapy is often the cornerstone in treating patients with emotionally induced seizures. Delineation of the areas of concern is often facilitated by an early consultation with the social worker. Creation of a treatment paradigm for problems in the family or interpersonal relationships or financial difficulties assists in targeting resources and efforts. Psychological methods include individual or group psychotherapy. Therapists who are knowledgeable about epilepsy can promote a more comfortable and effective therapeutic milieu. Other interesting strategies include reward management, self-control exercises,[42] relaxation, desensitization, and biofeedback.[10] Unfortunately, controlled trials that validate the benefits of these therapies are limited.

Fatigue and Sleep Deprivation

Typically, fatigue and sleep deprivation appear in students who study long hours and try to meet early classes, grueling examinations, or a combination of these along with many social exercises. Compulsive workers are also subject to a similar degree of sleep deprivation and fatigue. The addition of alcohol consumption further raises the potential for seizures. It is not uncommon to find this phenomenon of seizure induction by a combination of fatigue, sleep deprivation, and alcohol in nonepileptic patients.[13] Indeed, the revelation of such a circumstance in a particular patient should help dismiss the diagnosis of epilepsy in an otherwise healthy person. The frequency and extent of individual susceptibility to these factors is not known. Experience of the authors suggests that the occurrence of seizures associated with either fatigue or sleep deprivation is not unusual. Fatigue and sleep deprivation are often found to reflect emotional stress rather than isolated provocative stressors. Isolated fatigue may not influence seizures. At least in athletically conditioned epileptic patients, exercise may actually have a beneficial effect on seizure frequency.[9]

Treatment requires the determination of the cause of fatigue and sleep deprivation. Assessment of psychological problems can be revealing. Correction of those problems by counseling precludes the inappropriate addition or change of antiepileptic drugs. Appraisal of sleep deprivation or fatigue often reveals clinical depression or anxiety that warrants therapy with psy-chotropic medications or psychiatric intervention. Medical causes, such as sleep apnea,[6] caffeine abuse, or excessive alcohol use, require specifically directed treatment and counseling.

Alcohol

Alcohol is well recognized as a cause of seizures in nonepileptic patients (see Chapter 268). Basic and clinical concepts about this phenomenon have been considered in detail.[37] Importantly, the constant use of alcohol may represent a predisposition for the evolution of epilepsy in the nonepileptic patient through various mechanisms, including head injury.

Alcohol may be a trigger for seizures in patients with epilepsy. Some patients appear exquisitely sensitive to the effects of alcohol, and seizures occur even with small exposure. Alcohol may provoke seizures in several different ways. The frequent use of alcohol results in induction of liver enzymes, which in turn lowers antiepileptic drug levels. A soporific effect may immediately follow alcohol consumption. Additionally, normal sleep cycles may be disrupted by alcohol. These derangements in wakefulness and sleep have the potential for provoking seizures. Forgetfulness as a consequence of alcohol use may also cause medication noncompliance.

Generally, alcohol is to be avoided. An exact measurement of alcohol consumption by a patient is typically unreliable. Yet in the responsible and stable patient, permission to have an occasional glass of wine or beer is not associated with adverse effects on seizure control. For some patients, it is important to allay feelings of exclusion, which may preclude social integration.

Drug-induced Seizures

Seizures are not a common complication of drug therapy.[29,49] Most drug-induced seizures are self-limited and may be of limited consequence. On the other hand, even status epilepticus may occur as a consequence of drug induction. Failure to recognize that a specific drug is playing a role in causing seizures and continued administration of that drug will result in perpetuation of the seizure problem.

Drug-induced seizures cannot be predicted, but most are associated with excessively high brain concentrations of drugs or their metabolites. Awareness of general and specific circumstances for an individual patient will suggest predisposition. Those factors contributing to drug-induced seizures relate to the drug itself and have to do with the intrinsic epileptogenicity of a specific agent. The route of administration, dosing schedule, and plasma concentration are important. Factors that influence central nervous system levels include lipid solubility, molecular weight, ionization, and transport systems; however, practical knowledge of these drug properties is often missing at the bedside. Changes in protein binding can be inferred using

clinical information regarding serum albumin concentrations, use of multiple drugs that might compete for binding sites, or the presence of azotemia. Patients with impaired renal function (azotemia) and decreased clearance or hepatic dysfunction (decreased protein production) will be exposed to high central nervous system concentrations of drugs that are administered in doses appropriate for healthy patients. The total serum concentrations will be within therapeutic range, but the alterations in drug binding create higher free concentrations. If clinical information is utilized, inferences about brain concentrations can be made at the bedside.

Predisposing factors related to the patient include specific illnesses. Patients who are extremely ill with multiple metabolic problems or multiple organ impairment and those with central nervous system infection are more likely at risk for drug-induced seizures. Additionally, patients with underlying neurologic abnormalities, including tumor, stroke, or degenerative diseases as well as epilepsy, have greater risk. Many of these conditions have in common an impaired blood–brain barrier. Another important point to consider about drug-induced seizures is that whereas such seizures reflect drug toxicity of the brain, drug toxicity may be affecting other organ systems concurrently. If this is suspected, prompt attention to medical management for cardiac, hepatic, or renal effects of drugs is warranted.

Psychotropic and Neuroleptic Drugs

Psychotropic drugs and antidepressant medications[36] may trigger seizures. As discussed earlier, high doses and rapid changes in doses increase risk. Patients with epilepsy who require treatment with these drugs are at increased risk, but they generally do well when doses are moderate and antiepileptic drug serum concentrations are at appropriate therapeutic levels. Patients with epilepsy who require treatment for mood stabilization, as in bipolar affective disorder, can derive dual benefit with either valproate or carbamazepine. Treatment with lithium does not appear to provoke seizures at nontoxic serum concentrations in epileptic patients who are adequately treated with antiepileptic medications. An anticonvulsant effect in some patients with epilepsy is suggested.[40] Risk factors for lithium-induced seizures in patients with epilepsy have been reported as pre-existing EEG abnormality, clinical seizure disorder, acute psychotic symptoms, and decreased renal clearance.

Most antidepressant drugs are well tolerated and can be used safely. It is necessary that the patient have adequate antiepileptic drug levels, appropriate therapeutic drug monitoring, and modest but efficacious doses of the antidepressant. The treating physicians must be aware of drug–drug interactions. There appears to be a selective propensity for antidepressant drug-induced seizures. The drugs more likely to cause seizures include amitriptyline, imipramine, clomipramine, mianserin, maprotiline, and bupropion. Clinical evidence for toxicity otherwise may not be apparent. Serotonin reuptake inhibitors and monoamine oxidase inhibitors are less likely to induce seizures.

Antipsychotic neuroleptics such as clozapine, haloperidol, loxapine, promazine (no longer available), and chlorpromazine increase the risk for seizures in nontoxic doses. This is especially true for the aliphatic phenothiazines.[26] Indeed, intramuscular chlorpromazine administration was used at one time as a provocative test to elicit abnormal EEG activity in persons suspected of epilepsy. The butyrophenones may carry a lower risk for drug-induced seizures. In contrast, the new antipsychotic drug clozapine has been reported to cause seizures in about 2.8% of patients. Addition of an antiepileptic drug is recommended for that patient who has a seizure and requires continued treatment with clozapine. Some antipsychotic drugs may have pharmacokinetic interactions that reduce plasma concentrations of antiepileptic drugs and thus increase the predisposition to seizures of patients with epilepsy.

Antiepileptics Drugs

Antiepileptic drugs sometimes act as proconvulsant compounds. The proconvulsant effect is associated with exceptionally high drug concentrations, as has been described in phenytoin-activated seizures.[23] Further, those antiepileptic drugs that induce sedation may indirectly exacerbate seizures. Specific antagonism of certain seizure types by nontoxic doses of antiepileptic drugs can also be seen. The notion that phe-nytoin can exacerbate absence seizures[25] has been perpetuated in the literature, but supporting evidence is limited.[24] Trimethadione, which is no longer available, exacerbated generalized tonic–clonic seizures.[31] Carbamazepine has been observed to worsen seizure frequency in patients with atypical absence seizures and other generalized seizure types.[41] An EEG with generalized slow (2.5 to 3 Hz) spike-and-wave discharges can predict an increased risk for carbamazepine-induced seizures.

Essentially all antiepileptic drugs, including the most recently available ones, appear to share this propensity for inducing seizures. The literature contains reports on gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, valproate, and vigabatrin. Worsening of the treated seizure type or at times evolution of a new seizure type for that patient can be anticipated. The mechanisms for the worsening include intoxication and a relatively specific drug effect.[35]

Caution is urged when considering case reports, small series, or even clinical trial reports. Nonconvulsive status epilepticus was reported in epileptic[5] and interestingly in nonepileptic patients[50] during treatment with tiagabine and with levetiracetam.[1] Isolated reports of this type are problematic as other investigators[39] upon review of clinical trials have pointed out that there is a fairly high likelihood of spontaneous occurrence of status epilepticus (5% to 10%) in drug-resistant epilepsies over 3 years.

Drugs for Anesthesia

Certain anesthetics may induce seizures. Intravenous administration of lidocaine in elderly patients, who may have congestive heart failure, shock, renal or hepatic failure, and concomitant cimetidine therapy, increases risk for seizures.[15] Paradoxically, lidocaine has also been used to terminate seizures and has been used effectively to treat status epilepticus.[33]

General anesthetics can increase the possibility of seizures, including enflurane, etomidate, and ketamine.[38] Methohexital can induce epileptogenic activity on the EEG yet can have anticonvulsive properties as well.[30] Another short-acting intravenous anesthetic, propofol, has been used for outpatient surgery, anesthesia induction, and sedation in the intensive care unit. Seizures have occurred in epileptic and nonepileptic patients.[27] Like lidocaine, propofol also has been used successfully to treat status epilepticus.

Drugs for Medical Disorders

Certain drugs have been found to cause seizures during treatment for systemic illnesses.[15] These include antibiotics, cardiovascular drugs, chemotherapeutic agents, bronchodilators, antiviral drugs, analgesics, and contrast media. Patients who are treated with these drugs commonly have illnesses associated

with impaired organ function, which permits increased penetration of the drugs into the central nervous system. Most patients are quite ill. Specific drugs with increased epileptogenicity should be avoided or used cautiously in predisposed patients.

β-Lactam antibiotics increase central nervous system excitability. High doses of intravenous penicillin may cause seizures.[48] Imipenem is most often administered to patients who are critically ill, and these patients are particularly susceptible to seizures. Associated risk factors include high dose, renal impairment, pre-existing neurologic abnormalities, and, interestingly, *Pseudomonas aeruginosa* infection. Imipenem may induce an EEG picture of confusion and depressed sensorium, which precedes the evolution of myoclonic and generalized tonic–clonic seizures. Withdrawal of the drug results in cessation of seizures, albeit requiring a period of 24 to 72 hours.

Cephalosporins, earlier and recent products, produce seizures[47] if administered in high doses or to patients with renal failure. Laboratory studies in mice indicate that the mechanism of cephalosporin-induced seizures is mediated through the inhibition of $GABA_A$ receptors.[43]

The fluoroquinolone antibiotics can provoke seizures. Once again, the predisposing circumstances include high doses. Administration of these drugs with theophylline or nonsteroidal anti-inflammatory drugs increases risk. This group of antibiotics includes nalidixic acid, norfloxacin, ciprofloxacin, levofloxacin, and enoxacin.

Isoniazid can induce seizures, which are typically multiple. It is recommended that a specific therapy of pyridoxine in 1- to 5-g boluses be given repeatedly every 5 to 20 minutes until the seizures terminate.

Other agents thought to induce seizures include acyclovir, used to treat herpes simplex encephalitis, and zidovudine, foscarnet, and ganciclovir, used to treat HIV infection. Similarly, some vaccinations result in seizures, especially vaccination for pertussis. In each of these situations, the pre-existing central nervous system pathology makes correlation with induction of seizures less than clear.

The alkylating agents chlorambucil and disulfiram and the immunosuppressant agent cyclosporin may induce seizures.

Interferon-α therapy is in wide use for chronic viral hepatitis. Convulsions have been observed in 1% of adults and 4% of pediatric patients. The induced seizures are a latent (2 to 14 months) side effect of this immunologic therapy. While the pathogenic mechanism is unknown, disruption of the blood–brain barrier is an integral component of the epileptogenic process.[34]

Theophylline is well recognized for its ability to provoke seizures. The serum concentration of theophylline and its relationship to seizures is unpredictable.[2] Seizures may not respond well to antiepileptic drugs. Hemodialysis or hemoperfusion offers potential therapeutic modalities in severe overdose.

Reports of seizure induction by cardiovascular drugs are present in the literature. Clinical experience suggests that these drugs must be rare causes of seizures. There are reports of seizures being provoked by standard doses of mexiletine, tocainide, propranolol, alprenolol, metoprolol, oxprenolol, and sotalol, as well as digoxin and disopyramide.

Meperidine can be associated with induction of seizures.[46] After this medication is given repeatedly, its metabolite, normeperidine, accumulates and is responsible for the induction of seizures. Normeperidine concentration is enhanced in cases of impaired renal clearance. Other analgesics such as tramadol taken in large doses and regularly over an extended period (days or weeks) can provoke seizures.

Intravenous contrast media have been associated with seizures,[4,32] slightly, and this risk is increased in patients with metastatic brain cancer. Persons with epilepsy or other structural brain disease may be similarly predisposed.

Drugs of Abuse

Seizures frequently accompany illicit drug use.[8] Cocaine is probably associated with the highest incidence of seizures.[3,22] Phencyclidine, amphetamines, and heroin can also cause seizures. Seizures are not typically associated with the use of marijuana and LSD (lysergic acid diethylamide). Patients taking antiepileptic drugs are probably not protected from the direct toxic effects of these drugs.

Specific Stimuli

The term *reflex epilepsy* has been used in the literature to refer to the occurrence of seizures on a very consistent basis in response to an identifiable stimulus. Other investigators have preferred terms such as *sensory-precipitation epilepsy*, *stimulus-sensitive epilepsy*, and *epilepsy with reflex seizures*. The stimulus is specific for a given individual, and the seizures for that individual are likely to be stereotypical. However, seizures provoked by identifiable stimuli occur in patients with different types of epilepsy and promote different types of seizures. Stimulus-specific seizures have been described as complex partial, simple partial, tonic, absence, astatic, and myoclonic seizures. These provoked seizures are found in 5% to 6% of patients with epilepsy. Reflex epilepsy has been the subject of reviews.[11,51]

It is important to recognize that epilepsy is the primary problem of such patients. The provocation of seizures by specific stimuli is a unique epiphenomenon for these particular patients. Medical treatment of the epilepsy follows standard tenets according to seizure type, EEG and prognosis, and specificity and tolerance of the antiepileptic agent. When the specific stimuli are sought and recognized in an individual patient, efforts to alter patient response or remove the stimuli are undertaken. The efforts at treatment may then include avoidance, conditioning, and other behavioral approaches in addition to medical therapy. Most patients have random epileptic seizures in addition to those that are stimulus sensitive. Patients with stimulus-sensitive seizures also may have symptomatic epilepsy for which additional diagnostic concern and treatment should be given.

Provocation of partial seizures has been ascribed to startle, somatosensory stimulation, proprioception, music, sound or voice, hot-water immersion, eating, and various cognitive activities, such as reading, playing chess, and computation. Primary generalized seizures are related to specific stimuli of light and of thinking and decision making. Light-sensitive seizures may be provoked by different forms of light, including sunlight, sudden bright light, and flickering light. Alternating lines that oscillate out of phase on a television set have also been observed to bring on seizures. Some patients are especially sensitive to patterns and eye closure.

Treatment of light-sensitive seizures is most satisfactory with valproate. Benzodiazepines or ethosuximide has some utility. Avoidance and modification of light and pattern sources are also beneficial. Dark glasses can be helpful. Specifically, glasses that are blue and cross-polarized offer the best protection.[21] Moving back from a television set by a distance of <2.5 meters should be helpful. The proclivity for seizures persists into early adult life. However, there is a notable remission in the third decade,[19] and drugs may eventually be withdrawn.

Forster[12] demonstrated that humans with stimulus-sensitive epilepsy can respond to deconditioning in a Pavlovian paradigm. The primary problem with these techniques is that long-term and continuous conditioning, which is difficult to accomplish, is required.

The basic tenets for treatment of reflex or stimulus-sensitive epilepsies reflect the heterogeneous nature of this particular group of epilepsies. Medical therapy should be directed specifically at the type of epilepsy and epileptic seizures. Additional efforts to remove the provocative stimuli (stimulus avoidance) are sometimes quite successful. Alteration of the stimulus (stimulus modification) may be equally efficacious. Conditioning techniques, including behavioral and physical measures, can also be successful, but they require physician awareness and ingenuity as well as patient cooperation and long-term commitment.

The provocation of epileptic seizures by photic stimulation has taken on a public health posture. In our new society of intense audiovisual stimulation (television, video games, advertisements, special entertainment lighting), there has been a concurrent escalation of seizures triggered by now ubiquitous environmental stimuli that were once considered innocuous. The “pocket monster” (Pokemon) incident[45] in 1997 was associated with nearly 700 people being urgently treated for seizure symptoms after watching a television animated cartoon. The specific series of television frames of this cartoon containing long-wavelength (12-Hz) red frames alternated with blue frames was sufficient to induce seizures in healthy people and people with latent photosensitivity but who had never had seizures. Industry and government preventative guidelines for television broadcasting have focused on changes to ensure appropriate (a) flicker, (b) restriction of alternating high-contrast patterns, and (c) limitation of long-wavelength red.[16] These modifications have been successful in Japan[44] and are likely to be implemented internationally.[11]

Treatment of Provoked Seizures

Persons with Epilepsy

Epilepsy patients who have seizures provoked by photic stimuli are treated as discussed in the above section. The stimulus is removed or modified and AED treatment is administered. Most often valproate is successfully used.

With epilepsy patients whose control is incomplete, a thorough search for seizure-provoking stimuli always must be undertaken. Anxiolytics or selective serotonin reuptake inhibitors are indicated if anxiety or depression is clinically significant. Improvement of mood disorders by these medications can be more beneficial for control than addition of alternative antiepileptic drugs. Improved seizure control may also follow correction of other problems including sleep apnea, fatigue, sleep deprivation, alcohol excess, and use of medications with relative contraindications in epilepsy (e.g., bupropion, theophylline, meperidine, tramadol). For the epilepsy patient it is best to avoid or withdraw medications that have any potential for provoking seizures.

Routine surveillance of medication regimens given by the treating neurologist and also by the primary care physician and other specialists may prevent or discover reasons for seizure exacerbation.

Persons without Epilepsy

Persons without epilepsy who have a first seizure provoked by photic stimulation do not require treatment.[44] These individuals are usually young and 68% remain free from subsequent seizure.[18]

It is possible in many instances to identify agents or circumstances that are sufficient to provoke a seizure in an otherwise healthy individual. Nevertheless, it is impossible to be certain that a first seizure was not the first symptom of undeclared epilepsy. Counseling for avoidance is necessary but medical therapy is not indicated. It is prudent to recommend a period of observation just as one would do after a first unprovoked seizure. It is also prudent to recommend safety precautions for work and at home as well as no driving for at least 3 months. This period is based on the expected time for a majority of unprovoked seizures to recur.[17]

In a healthy person with a suspected provoked seizure, caution is urged when there are extenuating factors such as a nonspecifically abnormal EEG or focal features of the seizure. A 6-month period of observation and restriction after removal and avoidance of the provoking factor(s) is recommended. This is conservative yet indicated. A normal brain imaging study and other normal laboratory studies are favorable findings but do not influence this recommendation. Antiepileptic drug therapy is not warranted unless further seizures occur.

The critically ill patient who develops seizures will require acute antiepileptic drug therapy. All efforts are made to elucidate a cause for seizures. If a provoking substance is found, it should be withdrawn. The choice of antiepileptic drug is dependent on available access, organ viability/involvement, drug compatibility, and, to lesser degrees, seizure type and etiology of seizures. Benzodiazepines can be used acutely but should be converted for maintenance to a longer lived AED with an intravenous formulation. Maintenance therapy should be continued until all medical conditions are rectified. It is best to gradually withdraw this therapy after baseline medical and neurologic status is achieved and there are no further seizures.

Summary and Conclusions

Provoked seizures are those induced seizures for which a definite or putative cause can be identified. In reality, all seizures have provocative elements, although they are not always recognized. Identification and remediation of provocative factors can be therapeutic. Although the intrinsic changes leading to seizures are immensely difficult to determine, extrinsic provocative agents can include readily apparent factors, such as emotional stress, fatigue, alcohol, illicit drugs, television, computer-generated games, and widely utilized and effective drugs. In some patients, the aging process and changes in hepatic and renal function enhance the potential for provocation of seizures by drugs.

Thus, careful clinical assessment of multiple facets of the individual patient's situation provides the cornerstone for prevention and treatment of provoked seizures.

Chapter 126

Treatment of Status Epilepticus

Brian K. Alldredge

David M. Treiman

Thomas P. Bleck

Simon D. Shorvon

Introduction

Status epilepticus (SE) is a medical emergency that requires immediate and vigorous treatment directed at stopping all behavioral and electrical seizure activity. Physiologic changes occur during the course of SE that may result in severe systemic complications and also may damage or kill cerebral neurons. Physiologically, SE is defined as recurrent seizures without complete normalization of neurochemical and physiologic homeostasis in the brain between seizures. This physiologic definition makes clear the rationale for the operational definition of SE as recurrent seizures without full recovery of neurologic function between seizures. In this chapter, we consider goals and general principles in the management of SE and review general measures and specific pharmacotherapy for the successful management of SE.

Goals and General Principles

The goal in the management of SE is simple: To stop seizure activity as quickly as possible. By doing so, neurons are less likely to be damaged, physiologic consequences are less likely to cause organ failure, and patients are more likely to recover fully from the episode of SE. Ideally, SE should be stopped within 30 minutes from the start of the episode. Meldrum[32] and subsequently others[11,12,56] made a distinction between early SE (the first 30 minutes) and late SE (after 30 minutes). They found that physiologic changes occur in late SE that produce systemic complications and put neurons in jeopardy of permanent damage or death (Table 1). Furthermore, the longer SE persists, the more likely that neurons will be damaged by exposure of *N*-methyl-D-aspartate (NMDA) receptors to the excitatory amino acid neurotransmitter glutamate. Activation of NMDA receptors results in an opening of their cation channels to calcium. The marked increase in intercellular calcium that results sets up a cascade of intercellular biochemical events that damages or kills the cell.[17,31] Sustained seizure activity also results in a progressive reduction of γ-aminobutyric acid (GABA)–mediated inhibition.[20] These progressive physiologic and neurochemical changes may provide an explanation for the experimental and clinical observations that the longer the duration of the episode of SE, the more subtle will be the motor manifestations[50,57] and the more refractory the episode will be to pharmacotherapy.[26,50,57]

In most patients with SE, ongoing seizure activity is more likely to cause permanent neurologic damage than systemic factors.[33] Although systemic stress from hypoxia, hyperthermia, and hypotension can augment neuronal injury[33] and must be managed effectively, it is most imperative that early efforts focus on cessation of electrical and behavioral seizure activity. This can be accomplished by initiating treatment as soon as the diagnosis of SE is made and then monitoring the patient's electroencephalogram (EEG) during management. Treatment should never be delayed while awaiting the arrival of the EEG machine. EEG recording may be necessary, however, to confirm successful treatment of the episode. If behavioral seizures stop and the patient is observed progressively to recover consciousness, no EEG recording is needed. If behavioral seizure activity stops but the patient remains in a coma or in an impaired state of consciousness, however, EEG evaluation is essential to determine whether electrical seizure activity has ended. Treiman[49] reviewed the electroclinical aspects of various types of SE. He suggested that a variety of patterns can be considered ictal, including periodic epileptiform discharges, and proposed that all such epileptiform activity be stopped before the patient is considered successfully treated.[49] See Chapter 58 for a more detailed discussion of EEG changes during generalized convulsive SE and for EEG examples of ictal patterns.

General Measures

The management of SE can be divided into general measures and specific pharmacotherapy. General measures include the immediate evaluation and correction of physiologic abnormalities that may occur as a consequence of the episode of SE and concurrent evaluation for potential causes of the event.

Table 1 Physiologic changes in generalized convulsive status epilepticus

Transient or early (0–30 min)	Late (after 30 min)
Arterial hypertension	Arterial hypotension
Cerebral venous pressure (CVP) increased	CVP raised or normal
Arterial pO_2 low or normal	Arterial pO_2 low or normal
Arterial pO_2 high	Arterial pO_2 normal
CV pO_2 (low or high)	CV pO_2 (normal or low)
CV pCO_2 high	CV pCO_2 normal (or high)
Cerebral blood flow (CBF) increased	CBF increased, normal or decreased
Hyperglycemia	Normoglycemia, hypoglycemia
Hyperkalemia	Hyperkalemia
Hemoconcentration	
Lactic acidosis	Hyperpyrexia (secondary)

Source: Modified from Meldrum BS. Neuropathology and pathophysiology. In: Laidlaw J, Richens A, eds. *A Textbook of Epilepsy*. Edinburgh: Churchill-Livingstone; 1976:314–354.

The initial evaluation of any medical emergency, including SE, is focused on stabilization of airway, breathing, and circulation. Often, the most effective way to manage the airway is to terminate the seizures pharmacologically (see later discussion). If it is essential to establish a patent airway, insert an oral airway or an endotracheal tube. If neuromuscular junction blockade is required for intubation, a nondepolarizing agent should usually be chosen unless the patient lacks any risk factors for the development of hyperkalemia with a depolarizing agent. Respiratory effort also must be assessed and supported if insufficient. Arterial blood gas analysis and transcutaneous saturation monitoring are useful to guide airway management and determine whether supplemental oxygen is needed. Blood pressure must be evaluated and supported. Early in SE, blood pressure is usually elevated attendant to the rise in circulating catecholamines. With prolonged SE or administration of intravenous medications (particularly phenytoin, propofol, or barbiturates), however, hypotension may develop. If this occurs, vasopressor agents should be administered. Vasopressors and inotropes are almost invariably needed in prolonged status epilepticus. Once initial emergency evaluation is completed and the patient's airway, respiratory status, and circulatory status are stabilized, blood should be obtained for evaluation of hematologic and biochemical parameters, toxicology screen, and determination of antiseizure drug concentrations. An intravenous line should be placed, preferably in a large vein, and kept open with normal saline. Dextrose-containing solutions should not be used in institutions that use intravenous phenytoin because of the

potential for precipitation. This caveat need not be considered in institutions that have replaced parenteral phenytoin with fosphenytoin.

The patient's blood glucose concentration should be determined by finger stick. If hypoglycemia is detected, the patient should be given an intravenous bolus dose of glucose. The usual dose for hypoglycemia in adults is 50 mL of 50% glucose; the dose for children is 2 mL/kg of 25% glucose. Any adult who could be thiamine deficient (e.g., alcoholics or malnourished individuals) should be given 100 mg of thiamine intravenously before or simultaneously with the glucose in order to avoid Wernicke encephalopathy. Historically, it was common to administer a bolus of glucose to all patients with SE in case the episode had been precipitated by hypoglycemia. However, hyperglycemia may exacerbate neuronal damage caused by cerebral ischemia and SE.[8,18,48] Therefore, the blood glucose should be determined at the bedside and a dose of glucose only given if the concentration is ≤70 mg/dL (3.9 mmol/L).

The next step is to determine the cause of the event. SE may occur in persons with epilepsy (low antiseizure drug concentrations and alcohol are two common causes), as the initial manifestation of epilepsy, or as a consequence of a severe neurologic or systemic insult. The prognosis in the former situations is far better than in the latter.[43] In a patient with epilepsy in whom SE has been precipitated by withdrawal or reduction of maintenance antiseizure drug therapy, the rapid reintroduction of the relevant drug will usually terminate SE (the drug should be given intravenously if possible). In some instances, such as SE caused by metabolic derangements or medication overdose, specific treatments are available to address the underlying precipitant. For example, SE caused by hyponatremia may respond to gradual sodium replacement; SE caused by isoniazid overdose often responds to intravenous (IV) pyridoxine. In infants developing status epilepticus, IV pyridoxine is routinely given. In many cases, however, the immediate cause of SE is not apparent or etiology-specific treatment is not available. Even when there is no specific treatment for the cause of SE, the information is useful because neurologic outcome is largely dependent on the etiology. It is usually wise also to save 50 mL of serum in a patient in whom the cause is not obvious, for later analysis.

Medical complications should be identified and treated. The most common are cerebral complications (venous thrombosis, hemorrhage, infarction), cardiovascular complications (notably hypotension, cardiac arrhythmia, cardiorespiratory failure, pulmonary edema), and systemic complications (hepatic failure, renal failure, pancreatitis, electrolyte disturbance, disseminated intravascular coagulation, rhabdomyolysis, thrombophlebitis, and infections).[44]

Pharmacotherapy (discussed later) is indicated for patients who experience two or more seizures without full recovery of consciousness or who exhibit continuous seizure activity (either behaviorally or electrically) for 5 minutes or longer.[2,27,28,51] Simultaneously, other general measures should be considered. Hyperthermia is common during SE and may markedly exacerbate neuronal damage caused by ongoing electrical seizure activity.[32] Rectal temperature should be monitored during an episode of SE, and fever should be corrected quickly using passive cooling measures.[6] Acidosis from impaired ventilation and lactate release is common during SE and often does not need pharmacologic correction.[45] In the past, some advocated the use of bicarbonate to normalize the pH, but there is no evidence that transient SE-induced acidosis, even with serum pH ≤7.0, results in permanent injury. Generally, once SE is stopped, the serum pH normalizes rapidly. If large amounts of bicarbonate have been administered, however, this may result in iatrogenic metabolic alkalosis once SE is controlled.

The utility of steroids in reducing intracerebral edema during SE has not been proven, nor has the value of monitoring for increased intracranial pressure. Muscle paralysis is rarely indicated in the management of SE (except to facilitate intubation and in certain postoperative situations) and should never be used without ongoing EEG monitoring to detect ongoing seizures.

Table 2 Clinical pharmacologic properties of drugs used as initial therapy in status epilepticus (SE)

	Diazepam	Lorazepam	Phenytoin	Phenobarbital
Intravenous loading dose (mg/kg)				
Adult	0.15–0.25	0.1	20	20
Pediatric	0.1–1.0	0.05–0.5		
Maximum rate of administration (mg/min)	5	2	50	75
Effective serum concentration in SE	200–800 ng/mL	100–200 ng/mL	25–35 µg/mL	20 µg/mL
Time to stop SE (min)	1–3	6–10	10–30	20–30
Effective duration against SE	15–30 min	>24 hr	>24 hr	>24 hr
Elimination half-life (hr)	30	14	24	4–6
Protein binding (%)	97–99	85–93	87–93	45–50
Volume of distribution (L/kg)	1–2	0.7–1.0	0.5–0.8	0.7
Potential side effects				

Depression of consciousness	10–30 min	Several hours	None	Several days
Respiratory depression	1–5 min	Occasional	Occasional	Consider intubation before administration
Hypotension	Occasional	Occasional	Frequent	Occasional
Cardiac arrhythmias	No	No	In patients with heart disease	No

Principles of Drug Treatment

An ideal drug for the treatment of SE would be easy to administer, have immediate and long-lasting antiseizure effects, and would not cause adverse effects on respiratory drive, cardiovascular function, or level of consciousness. Intravenous therapy is always preferred because drugs administered by this route are completely bioavailable and have minimal delay in attaining a therapeutic effect. However, alternate routes of administration (e.g., rectal, buccal, and intranasal routes), have utility when intravenous access is not feasible, particularly in the out-of-hospital setting, and in selected situations for infants and children.[29,30,40] Thus, the choice of treatments for SE is based on efficacy, pharmacokinetic features, toxicity, and relative ease of use. Drugs useful for the termination of SE are most effective when given early in an episode. In one retrospective study, first-line therapy (usually a benzodiazepine followed by phenytoin) was effective in 80% of patients when administered within 30 minutes of the onset of SE. When treatment was delayed by 2 hours or more, however, ≤40% of patients responded.[26] Altered sensitivity of drug targets to antiseizure therapies may contribute to this reduction in pharmacoresponsiveness. In animals, $GABA_A$ receptors from dentate granule cells become progressively less sensitive to diazepam during 45 minutes of continuous pilocarpine-induced seizures. This plasticity in $GABA_A$-receptor function appears to be drug specific because sensitivity to pentobarbital was preserved over this same time interval.[22] These observations suggest a possible mechanism for reduced pharmacoresponse

during prolonged SE in humans, and suggest that future approaches to therapy may need to be tailored to the specific functional state of drug targets as opposed to the “one protocol fits all” approach to SE management that has been used historically.[25]

Pharmacotherapy

Unfortunately, few data directly compare the efficacy of drugs in the management of SE. A number of drugs have been used in the management of SE, including phenytoin; the benzodiazepines diazepam, lorazepam, midazolam, and clonazepam; the barbiturates phenobarbital, amobarbital, pentobarbital, and thiopental; valproate; propofol; paraldehyde; lidocaine; and, in Europe, chlormethiazole. Most evaluations of these drugs have been based on retrospective reviews of their potential efficacy and have reported success rates of 40% to 100% among the patients studied. Table 2 summarizes relevant clinical and pharmacokinetic information regarding the drugs commonly used in the initial treatment of SE.

Initial Therapy

The largest and most informative clinical trial to compare initial therapies for the in-hospital treatment of status epilepticus was the Veterans Administration (VA) Cooperative Trial performed by Treiman et al.[51] This is also the only randomized, double-blind clinical trial in SE to show a statistically significant difference in outcome between active treatments. These investigators compared four initial treatment regimens in 384 patients with overt (clinically evident) SE: (a) diazepam (0.15 mg/kg) followed by phenytoin (18 mg/kg); (b) lorazepam (0.1 mg/kg); (c) phenobarbital (15 mg/kg); and (d) phenytoin (18 mg/kg). Treatment success was defined by cessation of motor and electroencephalographic seizures for a 40-minute time interval beginning 20 minutes after the beginning of drug administration. Treatment was successful in 65% of patients who received lorazepam; 58% of those who received phenobarbital; 56% of those who received diazepam and phenytoin; and 44% of those who received phenytoin alone. Lorazepam was more effective than phenytoin by pairwise comparison (p = .002), but other differences were not statistically significant. There were no differences among the four treatments with regard to adverse effects or outcome at 30 days after the event. Patients with SE characterized by coma and ictal discharges on the EEG ("subtle SE") were much less likely to respond to the same treatments (success rates of 8%–24%), and there were no statistically significant differences in primary or secondary outcomes among treatments in this group. Some of the patients with subtle SE had myoclonus after severe anoxia. It seems likely that the prognosis in this group is worse, but the cases were not analyzed separately.

Diazepam has a much shorter duration of antiseizure effect than does lorazepam. Lorazepam is generally preferred as initial therapy of SE for this reason.[36] Diazepam is a highly lipophilic drug that enters the brain rapidly on first pass through the cerebral circulation. However, it also redistributes to other lipoid tissues quickly as well. As a result, brain concentrations of diazepam decline rapidly, and repeat doses are often needed at frequent intervals (e.g., every 15–30 minutes) to prevent seizures from recurring.[37] Lorazepam has a slightly less rapid onset of action but redistributes from brain tissue at a slower rate than does diazepam. This likely explains the longer antiseizure action of lorazepam, even though its plasma half-life (14 hours) is shorter than that of diazepam (30 hours). Midazolam and clonazepam also have been used successfully in the initial treatment of SE.[10,14,47,59] There is no reason, however, to prefer either over lorazepam as initial IV therapy. Buccal or intramuscular midazolam, however, has significant advantages over non-IV administration of other benzodiazepines in view of its unique solubility properties.

As illustrated by the results of the VA Cooperative Trial discussed previously, phenytoin should be administered in conjunction with a benzodiazepine when it is used for the initial treatment of SE. Peak brain concentrations of phenytoin are

P.1360

attained near the time of the end of drug infusion.[58] Phenyt-oin infusions should not exceed a rate of 50 mg/min due to an increased risk of hypotension and cardiac arrhythmias, and sometimes can be given no faster than 25 mg/min. Thus, completion of a phenytoin infusion often takes 20 to 30 minutes or longer, and the maximal clinical effect is correspondingly delayed.

The role of fosphenytoin in the treatment of SE is unclear.[26] Fosphenytoin is a water-soluble prodrug that is converted to phenytoin by phosphatases with a half-life of 15 minutes. Although fosphenytoin can be administered more quickly than phenytoin by the intravenous route (150 mg phenytoin-equivalents of fosphenytoin per minute), the time to attain a therapeutic concentration of unbound phenytoin mirrors that seen with phenytoin given at 50 mg/min.[27] Because fosphenytoin is water soluble, it lacks the propylene glycol diluent used in parenteral phenytoin solution and is administered at a slightly acid pH, in contrast to the highly alkaline pH required to keep phenytoin in solution. Cardiac toxicity has been reported with fosphenytoin,[1] and the relative safety of phenytoin and fosphenytoin given at maximal rates has not been directly compared. Fosphenytoin is much more expensive than parenteral phenytoin, and this is the primary reason for restricted use of the drug by some institutions and formularies.[21]

Because of the potential for phenytoin-induced hypotension and cardiac arrhythmias, blood pressure and electrocardiograms should be monitored in all patients during the administration of either phenytoin or fosphenytoin. Patients with preexisting cardiac disease and the elderly are at higher risk for phenytoin-related cardiovascular complications.[15] If hypotension develops, the rate of infusion can be slowed. If the QT interval on the electrocardiogram widens or if arrhythmias occur, phenytoin administration should be stopped. Extravasation of phenytoin produces severe necrosis of tissues in the vicinity. Intravenous administration has been reported to cause venous damage ("purple glove syndrome").[34]

Among the barbiturates, phenobarbital is the best studied for the initial treatment of SE, although remarkably little information is actually available.[41] Phenobarbital can be administered intravenously at the rate of 50 to 75 mg/min.[27] In many centers, in patients whose seizures continue despite benzodiazepine therapy, phenobarbital is preferred over phenytoin as initial therapy because of its rapidity of action, logistical advantages, and safety.[55] If the patient has already been given a benzodiazepine intravenously, however, the potential for respiratory distress is probably increased. Under such circumstances, respiratory support should be readily available. Phenobarbital may cause hypotension, as do most other anti-SE drugs, and the sedative effects of the drug are prolonged. Phenobarbital has been advocated as a second-line agent for SE, to be used in patients who fail to respond to lorazepam and phenytoin.[27] The likelihood, however, that a second or third agent would succeed after other initial therapies have failed is quite small. Data from the VA Cooperative Trial indicate that the likelihood of any second conventional antiseizure drug stopping SE when the first has failed is no greater than 7%.[7] This is likely to be a consequence of loss of efficacy of these drugs as the duration of SE increases. These data call into question any strategy involving sequences of conventional agents and argue for the earlier use of definitive therapy (e.g., general anesthetic doses of midazolam, propofol, or barbiturates). However, there are no prospective data indicating the outcome of such an approach.

The treatment protocols used vary among countries and centers. Whichever drug or drug sequence is used in the management of SE, however, it is now clear that SE is treated more effectively when a preestablished treatment protocol is used.[20] A number of algorithms have been recommended for the management of SE. FIGURE 1 outlines a protocol that is widely used, especially for the management of generalized convulsive SE.

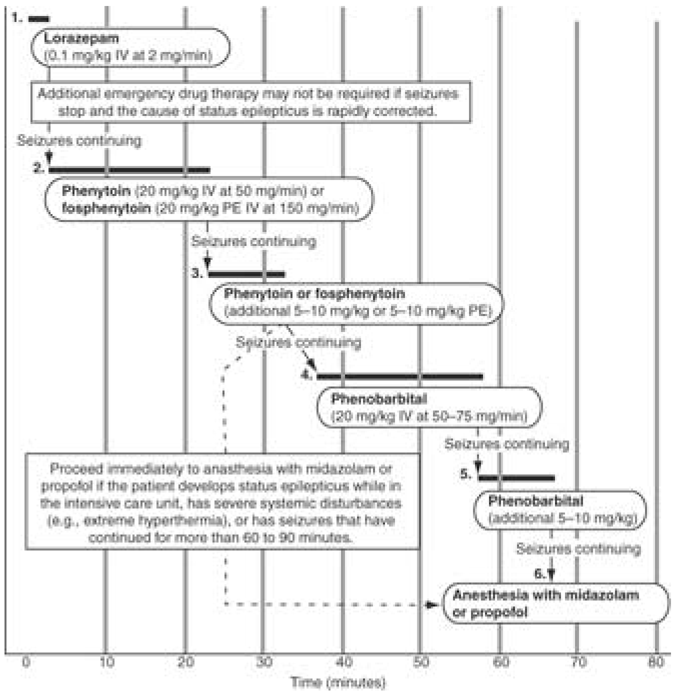

FIGURE 1. Drug treatment of status epilepticus. The horizontal bars indicate the approximate duration of drug infusions. IV, intravenous; PE, phenytoin equivalents. (From Lowenstein DH, Alldredge BK. Status epilepticus. *N Engl J Med*. 1998;338:970–976, with permission.)

Initial Therapy of Complex Partial, Simple Partial, and Absence Status Epilepticus

The previous discussion focused on generalized convulsive SE. The management of complex partial SE (Chapter 59), however, is more controversial. In the absence of cardiorespiratory or systemic compromise, most practitioners in Europe would not use an IV protocol for a straightforward case, but usually would rely on oral therapy or at most a single dose of IV lorazepam.[19,44] In the United States, though, more aggressive therapy is often used. Simple partial SE (Chapter 61) is usually treated orally with benzodiazepine or conventional antiseizure drugs. For patients with absence SE (spike-wave stupor), benzodiazepines and valproate (see subsequent discussion) are the drugs of choice (Chapter 60).[52] Drugs such as phenytoin and phenobarbital may exacerbate this form of SE and should not be used.

Valproate

Intravenous valproate sodium shows promise for the treatment of generalized convulsive, complex partial, simple partial, myoclonic, and absence SE.[24,35,42,46,60] No randomized trials of intravenous valproate in SE have been published. Most patients who have received this agent have been refractory to other SE therapies, been allergic to other SE therapies, or had myoclonic or absence seizures as a feature of their SE. Whether valproate should be considered as an initial therapy agent for generalized convulsive SE is not known, but it appeared to be effective in one study.[35] The drug has minimal effect on blood pressure, cardiac rhythm, and respiratory drive.[24] Therefore, valproate can be especially considered in patients with cardiovascular compromise for whom standard initial therapies might pose a

significant risk. The usual dose is 25 to 30 mg/kg, and the drug can be administered undiluted at rates of up to 500 mg/min in adults.[24,53] Although it appears reasonable to target serum valproate concentrations of 100 to 150 mg/L, a clear relationship between concentration and efficacy against SE has not been established. Valproate-related hyperammonemic encephalopathy has been reported after intravenous loading, and this complication should be evaluated (via serum ammonia concentration determination or EEG analysis) in patients who fail to regain consciousness following successful treatment.[38] Patients with urea-cycle disorders should not receive valproate.[9]

Special Considerations in Children

The principles of SE management and choice of drugs in children are similar to those in adults, except that drug doses are adjusted for body weight.[4] Children frequently tolerate higher rates of intravenous drug administration (on a mg/kg/min basis) than do adults. Under some circumstances, alternate routes of benzodiazepine administration (e.g., buccal, intranasal, or rectal) may be necessary either to initiate treatment outside of the hospital or because intravenous access is not feasible. Treatments that have been used successfully for repetitive seizures or premonitory SE in children include diazepam by rectal administration (using intravenous solution or gel formulations)[5,16] and midazolam by buccal or intranasal routes (using the intravenous solution).[23,29,30,40] Paraldehyde, if available, also can be given rectally. The usual dose of paraldehyde is 0.4 ml/kg diluted 1:1 in vegetable oil.[4]

Prehospital Treatment of Status Epilepticus

When SE occurs outside of the hospital, rapid transport to a medical facility is imperative. In past decades, as the emergent need to initiate drug treatment of SE as soon as possible became clear, many emergency medical services (EMS) systems implemented protocols that permitted paramedics to administer intravenous benzodiazepines to patients in SE prior to hospital arrival.[3] Although this approach has intuitive appeal, the safety of this practice had not been demonstrated until recently. Furthermore, the widespread practice in Europe now is to use buccal or intranasal midazolam or rectal diazepam in out-of-hospital situations.[29,30,40] Most paramedics receive little or no training on the recognition of SE, and treatment-related complications may present a significant management challenge in settings that lack the full range of medical equipment and consultants that are routinely available in modern emergency departments.[54] In addition, in dense urban areas, where the time required to transport a patient by ambulance to an emergency department is short, the risks of treatment complications or misapplied therapies could be outweighed by any incremental benefits from earlier drug treatment.

A recent prospective clinical trial in San Francisco addressed these concerns. Adult patients with out-of-hospital SE were randomly assigned to receive intravenous diazepam 5 mg, lorazepam 2 mg, or placebo.[2] Treatments were administered by paramedics, and an identical second injection was available if SE continued between administration of the first injection and arrival at a hospital. Patients were transported by ambulance to local emergency departments, where they received open-label treatment. The primary outcome was cessation of SE by the time of emergency department arrival. The rates of treatment success were higher for lorazepam (59.1%) and diazepam (42.6%) than for placebo (21.1%) (p = .001). After adjustment for covariates, the odds ratio for termination of SE by emergency department arrival in the lorazepam group compared with the placebo group was 4.8 (95% confidence interval, 1.9–13.0). The odds ratio was 1.9 (95% confidence interval, 0.8–4.4) in the lorazepam group compared with the diazepam group and 2.3 (95% confidence interval, 1.0–5.9) in the diazepam group as compared with the placebo group. With regard to secondary outcomes, the rates of posttreatment respiratory or cardiovascular complications were 10.6% for the lorazepam group, 10.3% for the diazepam group, and 22.5% for the placebo group (p = .08). These results highlight the safety and effectiveness of paramedic-administered benzodiazepines for prehospital SE therapy. Although historically there has been concern regarding the respiratory depressant effects of intravenous benzodiazepines, in fact lower rates of cardiorespiratory complications (primarily, respiratory compromise) were seen among patients who received active treatment as compared with placebo. This difference, however, was not statistically significant, but it suggests that respiratory compromise related to SE itself is at least as important a consideration as that caused by low doses of diazepam and lorazepam. In this study, no treatment-related differences in neurologic outcome at hospital discharge were found.

Although this study validated the practice of prehospital intravenous benzodiazepine therapy for SE in adults, several questions remain: What is the optimal dose of intravenous benzodiazepines for prehospital treatment of SE in adults? Is prehospital intravenous therapy of SE a safe and effective treatment approach for children? Are alternate routes of benzodiazepine administration (e.g., buccal, intranasal, intramuscular, or rectal) preferable to intravenous treatment in terms of rapid termination of SE and ease of use? Is there a role for other, nonbenzodiazepine antiseizure medications in the prehospital management of SE? These are important issues that require further study.

Refractory Status Epilepticus

The term refractory SE describes SE that fails to respond to two or three initial therapies. There have been no prospective studies of the treatment of refractory SE. Therapies in common use include midazolam, propofol, and pentobarbital. When used for refractory SE, these agents are administered in high doses by continuous infusion. Vigilant monitoring of respiratory, cerebral, and cardiovascular function is mandatory, and support measures to maintain blood pressure and adequate ventilation are often required. Thus, these therapies are best suited for application in the intensive care unit.

A review of published studies on midazolam, propofol, and pentobarbital for refractory SE yielded no clear consensus of preferred therapy.[13] Treatment failure was least likely with pentobarbital (3%), but a higher proportion of patients treated with this agent experienced hypotension requiring pressors (77%). Midazolam and propofol were similar with regard to treatment failure (20% and 27%, respectively) and hypotension (30% and 42%, respectively), but breakthrough seizures were more common with midazolam (51% vs. 15% with propofol). Mortality rates were high and not significantly different among the three treatments (midazolam 46%, propofol 52%, and pentobarbital 48%). This review, however, did not use meta-analysis methodology, and in the absence of large-scale trials, a meta-analysis of smaller studies would be valuable.

Topiramate and levetiracetam have been used in refractory SE with benefit in some patients, and the use of ketamine as an anesthetic agent with NMDA-blocking properties also shows promise. Some patients in refractory SE are also given a trial of

P.1362

high-dose corticosteroid therapy, although the efficacy of this treatment has not been systematically evaluated.

There is controversy regarding the EEG pattern that best represents treatment success in refractory SE. Some investigators titrated drug therapy to EEG background suppression, whereas others targeted seizure suppression regardless of background activity. Based on available evidence, Bleck advocated for seizure suppression on the EEG as the desired goal of treatment.[7] In clinical practice, more than one general anesthetic agent is often used to achieve the desired EEG outcome.[39] An evidence basis for this approach, however, is lacking. The treatment of refractory SE remains a major therapeutic challenge and one in which new approaches are urgently needed and multicenter studies would be helpful.

An important consideration in the management of refractory SE is how long to maintain drug-induced coma and how to reduce the dose of the coma-inducing agent. Here, too, no systemic data are available. Many neurologists maintain full suppression of the EEG for 48 to 72 hours and then begin to reduce the dose of pentobarbital, midazolam, or propofol. Before slowing of the rate of infusion, however, high concentrations of other antiseizure drugs should be ensured. One approach is to load to the patient to achieve a serum concentration of 30 µg/mL of phenytoin and 100 to 150 µg/mL of phenobarbital before reducing the rate of infusion of the intravenous anesthetic. If epileptiform activity returns, the dose of anesthetic agent is increased so that the EEG is fully suppressed again for another 48 to 72 hours or longer, and the process is repeated as many times as necessary. Some patients have recovered after 6 weeks or more of coma.

Summary and Conclusions

SE is a medical emergency that requires immediate and vigorous treatment. Goals of management of SE are to stop seizure activity as quickly as possible, protect neurons from SE-induced damage, and optimize the likelihood of a full recovery. Most neuronal damage is caused by the neurochemical events associated with continuous ictal discharges, but SE-induced neuronal damage can be exacerbated by systemic factors, especially by hyperpyrexia, which should be corrected if present. After establishing an adequate airway, respiratory drive, and circulation, one should obtain blood samples for chemistry, hematology, antiseizure drug levels, and toxicology. An intravenous line then should be established using normal saline, blood sugar should be checked by finger stick (and corrected if true hypoglycemia exists), and then specific pharmacotherapy should be initiated using a predetermined protocol such as the one outlined in this chapter. Children require different doses of antiseizure agents but otherwise should be treated in the same manner as adults in SE. Refractory SE may require high-dose therapy with barbiturates, benzodiazepines, or propofol as a continuous infusion to suppress all epileptiform discharges on the EEG. The patient can then be weaned intermittently to determine whether epileptiform activity on the EEG has ceased.

Chapter 127

Drug-resistant Epilepsy

Warren T. Blume

Introduction

This chapter discusses some factors that promote antiepileptic drug-resistant epilepsy in 20% to 30% of patients who have seizure disorders.

Accurate and prompt recognition of an epileptic condition that is likely to be intractable to medical and psychological therapy will guide management and the tendering of a prognosis to family and close associates. Unexpected intractability raises the possibility of a focal or diffuse progressive disease, discussed in Chapters 252 and 264.

After an initial section on definitions of intractability, principal aspects pertaining to focal and generalized epilepsies will follow. Interposed between focal and generalized sections, and applying to each, are brief discussions of propagation, genetics, and pharmacoresistance.

Defining Intractability

Paradoxically, defining "intractability" is probably more difficult than discerning which patients have or will have therapy-resistant seizures, as the following considerations illustrate.

Medical Treatment Failure

Persistent seizures despite about two or three appropriately selected and prescribed antiepileptic drugs constitutes medical failure, based upon the sharply declining probability that subsequent drugs will succeed.[2,7,26,31,57] Accurate classification of the seizure disorder through ictal semiology, electroencephalography (EEG) and presumed etiology is prerequisite for antiepileptic drug (AED) selection and sequencing.

Importantly, seizure freedom, only obtained by overt or covert AED toxicity, constitutes intractability. Covert toxicity occurs when polypharmacy is gradually attained or augmented (e.g., with two or more drugs in the "therapeutic range"). Patients, associates, and the treating physician may all be oblivious to this circumstance.

Seizure Occurrence

Minimum seizure frequency is one approach to this component of definition.[26,31] Does one count seizure number or number of seizure days per month or year? Seizure type and circumstance must be considered: A single tonic–clonic seizure in a truck driver will have more impact than rare, brief absences in a school child. The opposite approach is establishing the minimum duration of remission needed to *not* qualify as intractable.[2] With either or both criteria, patients could be classified as always, usually, seldom, or never intractable for each seizure type.

Time Dimension

To avoid hastily labeling as intractable certain patients having seizures with an acute illness or other circumstance, measures reflecting frequency with time have value: (a) minimum time that one is not free of seizures (e.g., 6 months or 12 months), (b) outcome at a specific point in time (e.g., failure to be in 6-month remission 2 years after diagnosis), and (c) minimum seizure frequency at any point in the disorder.[8]

Strict Versus Loose

A strict definition would have high specificity but may miss some patients who should be managed and followed as intractable. A loose definition would unfairly label, depress, and overinvestigate some patients. As the use of this definition will determine the stringency required, the concept of an intractability scale would be useful.[86] For example, a loose definition—or low point on a scale—would be appropriate for referral to an epileptologist, while a strict definition may be required for invasive investigations or surgery.

Children

Principles underlying any definition of intractability may closely resemble those generally applicable, except that age will play a relatively important role. An earlier age of onset correlates with a higher prevalence of intractability.[6,44] However, studies have shown an approximately similar prevalence of intractability in children as in adults, possibly as a higher proportion of benign syndromes that begin in childhood statistically counterbalances the several malignant syndromes of childhood onset (see further).

Intractability may be more difficult to predict in the pediatric age group. Berg et al.[7] found that outcome could not be predicted in almost 40% of children after 2 years of follow-up. Camfield and Camfield[20] found similar predictability in patients with dyscognitive seizures. Additionally, Berg et al.[7] reported ultimate remission in 14% of previously intractable patients. See Farrell et al.[32] for further discussion.

Extraneous Factors

Optimal application of any definition or set of criteria requires reliable data. Thus, an accurate diagnosis is essential, bearing in mind that many intermittent central nervous system events

represent nonepileptic disorders (e.g., syncope, migraine, pseudoseizures, and diurnal drowsy episodes when sleep deprived). This principle applies to both initial and follow-up information.

Additional causes of misleading data are AEDs inappropriate for a given seizure disorder, the wrong dose of a correct medication, or suboptimal compliance with the prescribed regimen. Premature abandonment of a useful drug may occur because of excessive haste to obtain seizure control or through overoptimistic therapeutic goals for disorders known to be intractable.

Table 1 Some Aspects Auguring Intractability

Focal epilepsies
Region
Temporal
Occipital
Primary motor cortex
Supplementary sensory motor area
Etiology
Mesial temporal sclerosis
Cortical dysplasia
Hemorrhagic lesions
Multifocal epileptogenesis
Progressive lesions
Generalized epilepsies
Onset in infancy or early childhood

High initial seizure frequency
Failure of initial appropriate AED
EEG
  Abundant multifocal or bisynchronous spikes
  Abnormal “background” activity
Progressive disorders

AED, antiepileptic drug; EEG, electroencephalography.

Stress increases seizure frequency.[37,67] Stress is often associated with depression, which disrupts sleep; this, in turn, lowers a seizure threshold.

Intractable Focal Epilepsies

Several interdependent factors may render a focus of epileptogenesis resistant to AEDs. This section discusses region of ictal onset, etiology, and multifocality of epileptogenesis (Table 1).

Brain Region

Temporal

The mesial temporal lobe is probably the most epileptogenic of brain regions. Hauser and Kurland,[46] in an epidemiologic study, found temporal lobe epilepsy (TLE) more prevalent (1.7 per 1,000) than all other focal epilepsies combined. Ninety percent of temporal lobe seizures begin in the mesial (i.e., limbic) components, as invasive EEG recordings have disclosed.[11,84] Such recordings have shown that temporal lobe seizures most commonly begin regionally within the mesial temporal lobe, involving several components simultaneously. The less common focal onsets arise more often in the hippocampus than in the amygdala.[29,77,83] Paradoxically, kindling, an important experimental model of epileptogenesis, is most easily elicited by stimulation of limbic structures,[38] especially the amygdala.[19]

Occipital

Ebersole and Chatt[28] found layer four of the striate cortex to be highly epileptogenic from effects of discrete penicillin applications to each layer. Similarly, Cain[18] readily produced kindling by electrical stimulation of the deep layers of the occipital cortex, whereas stimulation of superficial layers failed to evoke kindling.

Motor Cortex and Supplementary Sensory Motor Area

The face and hand area of the motor cortex is also a common site of seizure origin.[33,93] A fourth region often involved in intractable seizures is the supplementary sensory motor area.[72,74] Seizures from this region may be intractable because of its abundant efferents to several levels of the motor system.[10,64,92]

Etiology

Focal seizure etiology influences intractability at least as strongly as location. Mesial temporal sclerosis (MTS), cortical dysplasia, and hemorrhagic lesions are examples.

Mesial Temporal Sclerosis

Unfortunately, an unambiguous explanation of MTS epileptogenesis has not emerged from experimental and clinical data as causative, compensatory, and associative factors are intertwined. Although several basic and clinical studies have found data consistent with an increased or maintained γ-aminobutyric acid (GABA) inhibitory system,[17,30] such inhibition has been shown to be fragile[95] or even excitatory in certain circumstances.[3]

Spontaneous epileptic activity occurs in the entorhinal cortex in humans with epilepsy.[5] Collins et al.[23] found that the dentate gyrus only initially restricted propagation of penicillin-evoked seizures in rat entorhinal cortex; as this inhibition was overcome, seizure activity engulfed the hippocampus. Leung and Wu[59] described an increase in excitation of the rat entorhinal cortex–dentate gyrus pathway in kainic acid–treated rats and in CA1 of the hippocampus from CA3 stimulation. Vulnerability of CA3 stratum lucidum interneurons has also been found experimentally,[65] which may lead to an extensive remodeling of mossy fibers in CA3. This may shift the dentate granule–CA3 pathway from feed-forward inhibition to direct excitation, leading to excessive recruitment of CA3 pyramidal cells in epileptic activity.[58] Ratte and Lacaille[78] documented reduction of GABAergic cells in the stratum oriens and alveus in the kainic acid model, increasing the ratio of excitatory to inhibitory synapses in the stratum lacunosum moleculare. Thus, CA1 becomes hyperexcitable despite loss of a large proportion of Schaffer collateral afferents.

Several studies have disclosed enhanced excitation in the epileptogenic mesial temporal region. Leung and Wu[59] described opening of sodium channels with less depolarization producing larger sodium currents. Additionally, an increased pool of releasable glutamate and increased *N*-methyl-D-aspartate (NMDA) receptor activation in MTS has been found.[39,60]

From these physiologic data, it is not surprising that only 11%[81] to 25%[53] of patients with MTS are rendered seizure free by AEDs, whereas a far higher proportion (31%) of TLE patients without MTS are seizure free.[81]

P.1367

These and other epileptogenic physiologic aberrations are likely further accentuated in multifocal temporal epileptogenesis as Sadler[80] listed disseminated epileptogenesis (e.g., with dual pathology), as a factor leading to temporal lobectomy ineffectiveness.

Cortical Dysplasia

In our anecdotal experience, very frequent, cryptogenic focal seizures in an otherwise neurologically intact patient are often caused by cortical dysplasias (CDs). Studies have described up-regulated NMDA activity in both humans and rats with CD.[4,69,70] Several other investigations have disclosed impaired inhibition with CD.[9,41,79,85,97] This dual physiologic effect on the excitation:inhibition ratio in CD underlies its epileptogenicity: (a) cortical dysplasia is found in 25% of children with intractable focal epilepsy[55] and 15% to 20% of adults so afflicted,[56] and (b) 76% of Semah et al.[81] patients with dysplasia were medically intractable.

Hemorrhagic Lesions

Cavernous angiomas and other micro- or macro-hemorrhagic lesions also possess an epileptogenicity disproportionate to their size and growth and to the general health of the central nervous system. Experimental cortical injection of blood produces iron-filled neurons and macrophages, neuronal loss, and astrogliosis.[43,94] Three sequelae of hemorrhage-induced iron deposition in the brain produce epileptogenesis: (a) subsequent chronic increases in lipid peroxidation, which correlate with epileptiform discharges[82]; (b) impaired glial glutamate transport[27,89]; and (c) a decrease in nitric oxide synthesis from ferric chloride in the cortex, which augments hippocampal epileptogenicity.[40,51]

Multifocality

Multifocal epileptogenesis, as reflected in multifocal interictal EEG spikes, is often intractable: Studies of this EEG phenomenon found daily seizures in 33% to 60% and half had more than one seizure type.[14,71] Multifocal spikes also augment the incidence of secondary bilateral synchrony, a phenomenon also associated with multiple seizure types and with generalized seizures.[13]

Propagation and the Immature Brain

Discussion of some factors facilitating ictal propagation is interposed between the “focal” and “generalized” sections as they apply to each. Rapid propagation may complicate focal seizure semiology, while the distinction between primarily and secondarily generalized seizures may be blurred in some instances.

The "Hyperconnected" Cortex

Epilepsy onset in early childhood increases the likelihood of chronic intractability.[45] Aside from the inherent epileptogenicity of any causative lesion (e.g., tuberous sclerosis), components specific to the immature brain may persist to adulthood because of recurrent seizures. This augments the seizure tendency and its propagation and thus influences its clinical and EEG manifestations. Two examples follow.

The first is immature patterns of innervation. Brain-derived neurotrophin factor is increased in rat neurones whose action potential rate is augmented by seizure activity.[54] This may lead to development of an abnormal neuronal network enhancing epileptogenesis.[35,91] Seizures of the immature brain may lead to a failure of "pruning" or apoptosis, imprinting abnormal connectivity, a situation termed "the hyperconnected cortex."[15,48]

Gap Junctions

Secondly, neuronal gap junction communication (GJC) is particularly abundant in the immature brain, which harbors transient and extensive coupling between groups of neurones.[61,90] Experimental manipulation of GJC has supported its role in the genesis and maintenance of seizures.[75] Epileptic activity in early childhood may abnormally preserve the quantity of GJC, contributing to the network previously described. Such coupling may convert "spiking" neurones of CA1 to bursting cells. If this principle applies to neocortex, it may contribute to ictal propagation, for which intrinsic bursting cells are the principal conduit.[88]

The previously described mechanisms relating to early childhood seizure onset and later intractability are but two among possibly many—discovered and yet undiscovered—that not only enhance the epileptic tendency, but also confound clinical and laboratory analyses of these patients. However, despite the apparently irreducible complexity generated by such factors, most focal seizures of most patients propagate in a consistent manner, obeying the "beaten path" principle of Penfield,[73] confirmed experimentally by Petsche et al.,[76] and in subdurally recorded seizures by Blume et al.[12]

Thalamic Propagation

By circumscribing or undercutting penicillin-induced focal cortical epileptogenic lesions in newborn and pubescent (24 months) Macaca mulatta, Caveness et al.[21] found the direction of seizure propagation to shift from subcortical (presumably thalamic) to contiguous cortical with maturation. Any excessive preservation of subcortical pathways, in a manner similar to the "hyperconnected" cortex, could enhance generalization of a focally originated seizure.

Kindling, Genetics, and Pharmacoresistance

Increasingly appreciated aspects of intractability are genetics and mechanisms of pharmacoresistance.[68] Comprehensive reviews of the genetics of intractable epilepsy by Cossette and Rouleau[25] and of pharmacoresistance by Heinemann et al.[47] and Löscher et al.[63] are also available. These factors apply equally well to focal and generalized seizures and epilepsies.

Kindling has, thus far, been the principal animal model used to study drug resistance or pharmacoresistance. Both the amygdala and the hippocampus have lower afterdischarge (AD) thresholds and are the easiest to kindle. To illustrate the genetic influence in kindling, McIntyre's group succeeded in selectively breeding rats to be either seizure prone (fast kindlers) or seizure resistant (slow kindlers); this supported a concept that human epilepsy consisting of focal seizures with secondary generalization is somewhat influenced genetically. Significantly, although slow kindlers had higher AD thresholds than fast kindlers before kindling, their threshold dropped to equal that of fast kindlers after kindling. This suggests that seizures may convert a seizure-resistant mammal to a seizure-prone one. Thus, Löscher's group found kindling to convert some Wistar rats from phenytoin (and other AEDs) responders to nonresponders. Whether this relates to development of a "multiple

P.1368

drug-resistant gene" from the kindling process has not been determined.

Intractable Generalized Epilepsies

Most generalized epilepsies that resist medical management have the following characteristics: (a) usual onset in infancy or childhood, (b) high seizure frequency and initial failure of an appropriate antiepileptic drug, and (c) abundant multifocal and/or bisynchronous EEG spikes with abnormal "background" EEG activity (Table 1). Cognitive development slows, arrests, or regresses in many such cases.

Lennox-Gastaut syndrome (LGS) occupies a central nosologic position among generalized epilepsy syndromes and is defined as (a) a childhood epileptic encephalopathy with multiple types of seizures, particularly tonic attacks, but also atypical absences and atonic seizures; (b) interictal bilaterally synchronous slow spike-waves on EEG; and (c) runs of bilateral paroxysmal EEG fast activity.[1,36] The medical intractability and the EEG features suggest increased cortical excitability. For example, the slow repetition rate of slow spike-waves suggests an enhanced proportion of the longer $GABA_B$-mediated thalamic inhibitory postsynaptic potentials (IPSPs) that result from increased firing in corticothalamic pathways.[16,52] Bursts of fast rhythmic waves or polyspikes at 10 to 30 Hz, also known as the "epileptic recruiting rhythm," may be associated with tonic or absence seizures. The experimental correlate of this phenomenon appears to be "fast runs," during which most cortical neurons are depolarized.[87] Moreover, a phase of enhanced cortical excitability exists in early development of the mammalian central nervous system corresponding with the usual early onset of intractable epilepsies in humans.[42,66]

In addition to diffuse hemorrhage and multifocal dysplasias whose epileptogenic mechanisms are discussed in a previous section, anoxia and encephalitis may play ictogenic roles. Both non-NMDA and NMDA receptor mechanisms appear to be involved in postanoxia epilepsy.[49,50] A paucity of experimental data relates encephalitis to generalized seizure disorders. Putatively, micro-infarcts and hemorrhages may occur, inducing mechanisms discussed under anoxia and hemorrhage.[96] Astrocytic and microglia proliferation could impair glutamate uptake or alter gap junctions.[96]

Gene Defects

Identification of genetic abnormalities in association with cryptogenic generalized epilepsies may provide additional insights into pathophysiology. An increasing number of gene defects have been found associated with progressive myoclonic epilepsies.[62] Additionally, mutations of sodium channel α subunit type 1 (SCN1A) have been found in intractable childhood epilepsies, including severe myoclonic epilepsy in infancy (Dravet syndrome) and intractable generalized tonic–clonic seizures.[22,24,34]

Summary and Conclusions

This chapter reviews clinical and experimental data relating to medically intractable epilepsy. In the clinical setting, syndrome identification is a first and major step in early recognition or prediction of intractability. The principal syndrome components of seizure localization and etiology are reviewed.

This process allows the physician, the patient and the family to confront the magnitude of the disorder. An overoptimistic patient may prematurely lose faith in the physician and in the medications prescribed. Greater lifestyle modifications will be necessary to optimize medication effectiveness. Any surgical option will be recognized earlier; this allows its evaluation to be initiated while a logical sequence of medications is assessed.

Chapter 128

Prophylactic Treatment

L. James Willmore

Introduction

Because antiepileptic drugs (AEDs) target brain structures for their effect, they are being used to treat several neurologic conditions other than epilepsy. While control of seizures is the primary therapeutic use for such drugs, as specified in most submissions to governmental regulatory agencies, there is growing interest in AEDs for disease modification or for neuroprotection. *Prophylaxis* is defined as a process of guarding against the development of a specific disease by a treatment or action that affects pathogenesis. In contrast, to *prevent* means to render impossible by an advanced provision, or to keep from happening. A preventive intervention does not imply an effect other than alterations of symptoms, signs, or manifestations of a disease. Prevention may alter some component of a disease, but specificity is not implied, and effect on pathogenesis is not required.

Drugs that control epilepsy or change the intensity of seizures have been used to attempt disease modification. Within years of the introduction of phenytoin, investigators reported various open and uncontrolled trials purporting to show that drug's efficacy as an agent effective for antiepileptogenesis. However, randomized, controlled trials of both phenytoin and valproate failed to show that use of drugs with effects on seizures had any impact whatsoever on chronic epileptogenesis, a marker for brain injury.[68,69,70] In fact, animal studies of the effect of corticosteroids and phenytoin on brain lipid peroxidation initiated by a free radical generating mechanism showed phenytoin associated with unabated brain injury while seizures were controlled.[79] Of interest, high dose corticosteroids in this model caused abatement of both seizures and lipid peroxidation. There is continued interest in disease modification that might accrue should antiepileptic drugs control seizures and somehow protect neural tissue as well.[3] Mechanisms of action of AEDs that are critical to anticonvulsant activity have been considered as having a role in neuroprotection. If this were the case, the therapeutic value of AEDs would include not only control of seizure activity (anticonvulsant), but also the prevention of injury responses, resulting in *disease modification*.[76]

Neuroprotective agents have been sought among various molecular designs, including calcium channel blockers, anti-inflammatory drugs, and various sterol compounds. While animal trials have suggested robust efficacy, clinical studies have failed. Whether the end-point is inappropriate or the nature of the injury to neural tissue of such intensity that a pharmacologic intervention could not possibly succeed has yet to be determined.[50]

Better understanding of the mechanisms of brain injury has had impact on drug design, with introduction of several new antiepileptic drugs for clinical use that have unique actions. Mechanisms of injury in animals and in some human studies have included cerebral infarction, ischemia, status epilepticus, and traumatic brain injury.[66] Common cellular responses to injury include marked increase in the extracellular concentration of glutamate followed by increase in intracellular calcium and cell death.[6] Marked increase in glutamate occurs in humans having seizures as measured with microdialysis.[12] Similar changes occur in animals with status epilepticus.[75] In stroke and hypoxia, failure of high-energy substrates cause failure of transporters with loss of membrane potential and neurotransmitter release.[36] Glutamate binding to specific receptor molecules initiates signaling that is coupled to channels permeable to ions or to G-protein second messenger systems.[10] Inotropic glutamate receptors are categorized by selective responsiveness to *N*-methyl-D-aspartate (NMDA), kainate, or AMPA. Calcium entry into cells by the NMDA receptor complex in the various patterns of brain injury is critical to cell injury,[7] while antagonists are protective.[5,17]

Prevention

One example of preventive treatment is the administration of anticonvulsants to patients with head trauma of such severity that hypertension and hypoxia associated with a convulsive seizure would complicate management. Antiepileptic medications are administered to patients who are thought to be at risk to have tonic–clonic seizures with the intent to prevent the occurrence of convulsive seizures. Patients with absence seizures may be treated with a broad-spectrum antiepileptic drug prior to occurrence of a tonic–clonic seizure, rather than using a syndromic-specific agent such as ethosuximide. Preventive treatment in this narrow context may be successful. However, some patients are given anticonvulsants with an apparent attempt to interfere with the process of epileptogenesis. Examples of this prophylactic use include the routine administration of antiepileptic drugs to patients with head trauma,[54] or to patients undergoing neurosurgical procedures requiring incision of the neocortex.[77] Although prevention of seizures is a worthy goal and may be effective, prophylaxis of epilepsy in the strict sense may not be effective, since no data are available to suggest that antiepileptic drug administration has any impact on the process of epileptogenesis.[70]

Posttraumatic Epilepsy

Trauma dose as estimated by factors correlated with severity of head injury allow a crude prediction of the liability to develop posttraumatic epilepsy (PTE).[14] Classification of head injury based on clinical evidence of trauma dose reveals a correlation with epilepsy risk.[4] Patients with severe head trauma with cortical injury and neurologic sequelae, but with intact dura mater, have an incidence of epilepsy from 7% to 39%.[4] However, if dural penetration occurs in association with neurologic deficits, then the range of epilepsy incidence is 20% to 57%.[4] Application of weighted risk factors

allowing mathematical estimation of liability for development of PTE at the time of injury suggests correlation between severity of injury and subsequent epileptogenesis.[78] Brain volume loss also reflects trauma intensity and provides a correlation with PTE.[59]

Fifty-seven percent of head-injured patients developing PTE will have their first seizure within 1 year of injury.[59] Although specific mechanisms remain unknown, the latency between injury and occurrence of convulsive seizures must represent the process of epileptogenesis. Whether a seizure occurs immediately after injury, within the first week, or beyond the first week may have prognostic significance for development of epilepsy.[25] The occurrence of an immediate seizure, within hours after trauma, and posttraumatic status epilepticus may complicate management of an injured patient by adding hypoxia and hypertension to the primary processes initiated by trauma. Although an immediate seizure may be a nonspecific reaction, such a symptom may herald the presence of an intracranial hematoma.[23] However, if seizures occur within the first week after injury (an early seizure), then an increase in the incidence of late epilepsy has been observed.[26] Other predictors of risk of late epilepsy include 24 hours of posttraumatic amnesia, the presence of a depressed skull fracture, or an intracranial hematoma.[24]

Prophylaxis of Posttraumatic Epilepsy

Because uncontrolled studies suggested that antiepileptic drugs might have a prophylactic effect,[54,82,83] prospective, placebo-controlled assessments were undertaken. Penry et al.[48] administered phenytoin and phenobarbital to head-injured patients in a double-blind fashion, with placebo control. Their report, in abstract format, documented a seizure probability in the treated group of 21% and a probability of 13% in controls. The authors concluded that no significant difference was detected between the treatment and control groups, suggesting that anticonvulsant administration had no effect on the development of posttraumatic epilepsy in the treated patients.

Young et al.[83] reported experience with 179 head-injured patients treated with phenytoin or with placebo for 18 months in a prospective, double-blind fashion. Patients received loading doses of phenytoin or placebo; anticonvulsant blood levels were measured. Eighty-five patients were included in the treated group, while 74 patients were enrolled as placebo control. At the end of the study, seizures had occurred in 12.9% of the treated patients and in 10.8% of the control patients.

Temkin et al.[69] reported their experience with 404 patients treated in a prospective fashion. Patients with severe head trauma were assigned to receive an intravenous loading dose of either phenytoin or placebo. Serum levels were measured at regular intervals, blood levels of drug were maintained in the therapeutic range, and efforts were made to ensure that evaluations were blinded. At 1 year no difference in incidence of PTE was found between the treatment and control groups. However, they did observe that phenyt-oin was effective in prevention of seizures during the acute period immediately after injury. By 2 years PTE had occurred in 27.5% of phenytoin-treated patients and in 21.1% of controls. Valproate had some efficacy in changing the pattern of kindling in animals,[64] but failed as a prophylactic drug in a controlled clinical trial in humans with head trauma.[68,70]

Phenytoin controls seizures for up to 3 weeks after head injury, but no prophylactic effect was observed with regard to development of posttraumatic epilepsy. Although physicians tend to treat those patients with the most severe injuries with preventive intent, the agent that might serve as a prophylactic for a PTE agent remains to be identified.

Absence Epilepsy

Patients with absence epilepsy commonly develop generalized convulsive seizures as an additional manifestation of this epilepsy syndrome. Patients with the best prognosis for control of absence seizures have normal intelligence and a negative family history of epilepsy. These patients may have a 90% chance of remission. In contrast, the overall remission rate for all patients with absence ranges from 37% to 57%. Patients at high risk for the development of concurrent or subsequent generalized tonic–clonic seizures have late onset of absence epilepsy.[57]

Drugs used for treatment of absence epilepsy include ethosuximide, clonazepam, and valproic acid. Ethosuximide has specific efficacy for nonconvulsive seizures, while valproate is effective in controlling both absence and generalized convulsive seizures.[61] Ethosuximide used as initial therapy for this seizure syndrome may leave a patient vulnerable to the occurrence of convulsive seizures. Preventive treatment using a broad-spectrum anticonvulsant such as valproic acid would be appropriate for a patient with late childhood or early adolescent onset of absence seizures. There is no published report addressing the specific efficacy of this course of treatment as preventive for convulsive seizures, particularly with comparison of ethosuximide and valproate. Clinicians should be aware of the possibility of anticipation and prevention in this context by discussing such problems with parents of patients.

Cerebral Infarction

Six to nine percent of patients with stroke may develop the complication of epilepsy.[34] Precise prediction of development of postinfarction seizures may depend on etiology.[39] Not unlike head trauma, a differential liability to develop seizures may depend on acute versus late seizures relative to onset of the infarction.[63] The role of seizures as a so-called precursor to stroke remains controversial.[34] Patients with cerebral infarctions involving the cerebral cortex with persistent paresis have 20% liability to develop seizures.[9] Although the risk of epilepsy following stroke has been recognized, administration of anticonvulsant as a prophylaxis is not a common practice and has not been reported. If medications were to be administered to this group, then specific knowledge of the risks and benefits would be most important before such an action were recommended.

Febrile Seizures

Children from 3 months to 5 years of age may have convulsive seizures associated with fever or febrile illnesses (see Chapter 124). Nonfebrile seizures or epilepsy develop in 2% to 6% of patients with febrile seizures.[45] Risk factors predicting development of epilepsy include the presence of a neurologic abnormality; febrile seizures lasting longer than 15 minutes; a focality to the seizure; recurrent seizures in a single day; onset at <1 year of age, but especially during the first 6 months of life; and an immediate family member with epilepsy. However, identification of risk factors suggests that fever is a precipitant rather than a cause of epilepsy. Most preventive efforts are directed to the high-risk patients. Management of the acute illness may require pharmacologic interruption of a seizure or prevention of a recurrence during the same febrile illness. Rectal diazepam and valproate are effective, but problems with sedation must be anticipated. Although recurrence can be prevented by chronic use of phenobarbital, behavioral problems

and compliance difficulty make this approach impractical.[49] Until the issue of epileptogenesis is resolved, chronic prophylactic antiepileptic drug administration should not be used in patients without risk factors. Decisions regarding prophylactic drug administration in patients with risk factors for recurrence of febrile seizures or for development of epilepsy must be individualized, since data to guide treatment are not available.

The Single Seizure

Information is available regarding the critical factors involved in deciding when to treat a patient with a single seizure (see Chapter 122). The impact of antiepileptic drug therapy on the natural history of the process heralded by a single convulsive seizure is unknown. Sander,[60] in a thoughtful review, addresses issues with regard to prophylaxis within the context of prognosis of epilepsies. Remission of epilepsy, defined as being seizure free for 5 years, was achieved in 76% of patients by 15 years after onset.[1] The Tonbridge study provided similar data; 73% of patients had a period of being seizure free for 2 years.[18] Overall, between 70% and 80% of patients treated with AEDs will achieve remission. The remaining patients have chronic or intractable epilepsy. Data are unavailable to allow a conclusion that AED therapy had a prophylactic effect in preventing chronic epilepsy. However, some observations suggest that the pathologic substrate may be more important than seizure frequency in leading to chronic epilepsy.

Studies of epilepsy prevalence in developing countries provide some suggestions regarding the natural history of untreated epilepsy. A population-based study in Northern Ecuador[52] identified 45% of patients in a 2-year remission. Of the original sample identified, 28% achieved remission regardless of treatment with AEDs. Similar observations were reported for Nigeria,[46] Ethiopia,[67] China,[35] and India.[31] While suggestive, these data must be viewed with caution. Etiology of epilepsy and mortality[44] may influence prevalence rates. Taken together, these data suggest that pathogenesis rather than need for prophylactic drug effects are operant in those patients with chronic epilepsy.

Established Drugs: Neuroprotection

Some AEDs have shown neuroprotective effects in some animal models of injury.[50,51,55] Animal models for study of neuroprotection include induction of status epilepticus in rats by electrical stimulation that is maintained at a controlled rate even in the presence of an anticonvulsant.[19] This model allows measurement of the neuroprotective effect of a particular drug independent of any anticonvulsant activity. Variables can be biochemical, such as measuring the degree of fragmentation of DNA,[29,30] or morphologic, such as the extent of neuronal loss.[66] Phenytoin, phenobarbital, and carbamazepine have all been shown to be neuroprotective to some degree in an ischemic/hypoxic model of neuronal injury.

Recently Available Antiepileptic Drugs

Lamotrigine

Pretreatment with lamotrigine attenuates the elevation of glutamate and aspartate that occurs during reperfusion following experimental ischemia. This attenuation of release of excitatory neurotransmitters by lamotrigine suggests a potential for neuroprotective effectiveness.[8] Some neuroprotective effect was observed during ischemia coupled with hypothermia.[2] Global brain ischemia was evaluated using indices of brain water content measured with magnetic resonance. Lamotrigine failed to prevent development of intracellular water accumulation.[28] However, some evidence for neuroprotective effect in cerebral ischemia was observed with combined administration of the calcium channel blocker flunarizine with lamotrigine.[33] While certain animal models of ischemia fail to demonstrate efficacy for lamotrigine, the drug does appear to have parallel protective efficacy to MK-801 in prevention of excitatory amino acid injury to neurons.[32,80]

Although clinical trials have yet to identify an antiepileptic drug that prevents epileptogenesis,[68,69] many agents are tried in the electrical kindling models to evaluate effect on various parameters. In one study, lamotrigine was found to be effective as an anticonvulsant, but the drug either failed to alter kindling or even facilitated the initial phase of kindling development.[53] Others found that lamotrigine did counteract kindling acquisition, suggesting potential as a neuroprotectant.[65]

Levetiracetam

Levetiracetam does inhibit the pace of kindling in a way similar to antagonists of NMDA receptors.[38] However, when used in focal ischemia, levetiracetam had a 33% protective effect as measured by infarct volume with doses in a range similar to those used in the kindling effect. MK-801 pretreatment, considered the standard in receptor blockage, reached 74% reduction in infarct volume, albeit with hypothermia as a confounding variable.[21,80]

Topiramate

Topiramate has been tested in several animal models of ischemia and limbic status epilepticus. In focal ischemia models, infarct volume was reported to be reduced by 50% to 80% when topiramate was given to rats at 40 mg/kg. This effect exceeded that of MK-801. In similar doses in animals undergoing global ischemia and treated 30 minutes after onset, cells were protected and behavioral skills preserved. Cellular injury was prevented in electrical limbic status epilepticus.[13,56] Protection in animals by topiramate against priming effects of hypoxic seizures and periventricular leukomalacia has been reported.[15,27]

Zonisamide

Zonisamide (ZNS) has been assessed in several models of ischemia, and has been found to have neuroprotective properties in all of them.[22,41,47] In one study, gerbils were subjected to ischemia both before and after administration of ZNS. Damage to the CA1 region of the hippocampus and associated extracellular glutamate accumulation were examined at 7 and 28 days postinjury. ZNS administered prior to the hypoxia resulted in less neuronal damage to the CA1 region and lower levels of glutamate accumulation at 7 days (p <0.05) and at 28 days (p <0.01).[47] In a similar study, rats subjected to 90 minutes of ischemia were treated pre- and postinjury with ZNS, sodium valproate, or carbamazepine at typical anticonvulsant doses. Only ZNS was found to reduce both neurologic deficit and neuronal loss, while carbamazepine demonstrated an effect only at a high dose (60 mg/kg/dose).[41] Neonatal rat pups subjected to ischemia were pretreated with ZNS or placebo by intraperitoneal injection. Mean plasma levels of ZNS were 47.9 µg/mL preischemia and 42.3 µg/mL postischemia. Reduction in the mean volume of both cortical and striatal infarcts was by roughly 90% in the ZNS-treated animals, despite seizure intensity showing no difference between ZNS- and vehicle-treated rats.[22]

While mechanisms for neuroprotection by AEDs in animal models remain unknown, some unique effects of ZNS may be

P.1374

operant. Zonisamide scavenges free radicals, including both hydroxyl and nitric oxide radicals.[43] This property was initially demonstrated in vitro but was subsequently confirmed in an animal study in which rats were given a cortical injection of ferric chloride, which is known to induce oxidative damage.[29] Rats that were pretreated with ZNS did not show the substantial increase in 8-hydroxy-2′deoxyguanosine (8-OHDG) that was found in the untreated animals, providing indirect evidence that the scavenging of these hydroxyl radicals was responsible for the protective, antioxidant activity of ZNS.[80]

Summary and Conclusions

Specific knowledge about the process of epileptogenesis as initiated by trauma, fever, or genetic factors may contain a specific clue about methods of prophylaxis. However, the principal impediment to pharmacologic interruption of the process of epileptogenesis is lack of knowledge of the mechanism that results in the formation or activation of a seizure focus. The clinical problem of a patient with trauma sufficient to initiate epileptogenesis, and with effects of injury that would be worsened by the occurrence of a convulsive seizure, requires practical intervention for protection during the acute illness. If an anticonvulsant is to be administered to prevent a seizure after a severe head injury, then that medication should be given intravenously, and pharmacologic principles should be followed.

Part of the problem is defining the clinical paradigm and selecting appropriate outcomes to even begin to detect a neuroprotective or prophylactic effect of a drug. Strategies involving antiepileptic drugs that appear to have unique and possibly important mechanisms of action may require multiple drug strategies. While neural injury most assuredly involves initiation at membrane surfaces and receptors, molecular manipulations could be useful. Families of receptors that are not thought of as involving antiepileptic drugs may be critical. Immunophilins regulate the transition pore of mitochondria, stabilize ion channels, act as molecular chaperones, and may well be excellent candidates a neuroprotectants.[20] Caspase inhibitors may have a role in various degenerative diseases.[37,62] Endocannaboids block presynaptic release of glutamate and activate intracellular signaling.[40] Finally, antioxidants have shown potential in various animal models.[16] To-copherol compounds are natural antioxidants that could be of use, particularly if issues of solubility and tissue penetration can be solved.[42,71,81] While amino acid transporter regulation is altered in epileptogenesis,[11,72,74] increasing the expression of glutamate transporters may have the potential to protect neural structures and alter epileptogenesis.[58,73]

Chapter 129

Ketogenic Diet

Carl E. Stafstrom

Eileen P. G. Vining

Jong M. Rho

Introduction

The ketogenic diet (KD) is a high-fat, low-carbohydrate, adequate-protein diet that has been used as an alternative therapy for intractable seizures since the early 1920s. At that time, only a few effective antiepileptic drugs (i.e., phenobarbital and bromides) were available to clinicians, and each of these carried significant side effects. In the 1940s and 1950s, when modern antiepileptic drugs such as phenytoin and ethosuximide became available, use of the KD declined rapidly. Nevertheless, there was an occasional resurgence of interest in the KD. In 1971, the medium-chain-triglyceride diet[34] was devised in an attempt to provide more flexibility with respect to carbohydrates, enhanced ketosis, and better palatability. Despite a flurry of new antiepileptic drugs in the 1990s, frustration with the medical intractability of childhood epilepsies has continued, and recently, public awareness of the KD has increased. The KD is now considered a safe and effective alternative therapy for children and adults with refractory epilepsy, with an efficacy that rivals (and perhaps exceeds) the newer antiepileptic drugs (AEDs).[83] More recently, alternative diets for epilepsy treatment, such as the Atkins diet and a low-glycemic-index diet, have been devised that represent modifications of the original KD.

History

Fasting for seizure control was reported as early as the 5th century BC by Hippocrates.[95] References to fasting for seizure control are also found in the Bible (Matthew 17:14-21 and Mark 9:14-29). Jesus, after curing a young boy with convulsions, advised his disciples that such "demons" cannot be purged except by prayer and fasting. Fasting is mentioned again in the medieval writings of John of Gaddesden.[50] There is no further mention of fasting in modern medical literature until 1911, when Guelpa and Marie[30] placed 20 patients on a 4-day fast, noted some improvement in seizure control, and referred to people with epilepsy as *trop alimentés* ("too well fed").

In 1921, Geyelin[28] reported that the beneficial effect of 3 weeks of fasting continued even after the fast was broken. The work of Geyelin and many others was probably prompted by reports of a young boy whose seizures were treated successfully with prolonged fasting by an osteopathic practitioner, Hugh Conklin. Conklin was a follower of the physical culturalist Bernard Macfadden.[95] Their regimen consisted of 3 to 4 weeks of fasting with only water allowed.[49]

Based on the observations by Geyelin, Wilder[96] theorized that the benefit achieved by fasting might depend on the resultant ketonemia. Utilizing earlier work showing that ketogenesis could be produced by diets very rich in fat and very low in carbohydrate, he proposed a formulation of the KD that is very similar to the one used currently. In 1922, Wilder and Winter[97] showed that ketosis occurred when the ratio of fatty acids to glucose in the diet was >2:1, and they recommended that to maintain ketosis, a ketogenic:antiketogenic (K:AK) ratio of at least 3:1 be used. Peterman,[67,68] working at the Mayo Clinic, revised the diet and determined minimal daily requirements for calories (75% of the Recommended Daily Allowance for a child's height and weight) and protein (1 g/kg body weight).

Studies of KD efficacy for seizure control were published in the 1920s by clinicians at the Mayo Clinic. Peterman reported seizure freedom in 50% of patients[67]; Helmholz and Keith found a third of patients to be seizure free and more than 50% showed "definite improvement" in seizure frequency.[32] These successes led several investigators to study the mechanism of action of fasting and the KD in patients using biochemical analyses.[8,27,48]

Mechanism of Action

Various hypotheses have been put forth over the years to explain KD efficacy, including acidosis, cellular and extracellular dehydration, a direct action of ketone bodies (acetoacetate, *β*-hydroxybutyrate, acetone) on neuronal firing or synaptic function, effects of lipids on neuronal excitability, changes in the source or utilization of energy within the brain, and alterations of mitochondrial metabolism. None of these is a sufficient explanation for the effectiveness of the KD. The challenge has been to understand how an anticonvulsant effect results from a metabolic shift from carbohydrate to fat as an energy source.[21a]

There are multiple sites within relevant biochemical pathways where seizure suppression could be facilitated, and the mechanism by which the KD exerts an anticonvulsant effect likely involves the combination of altered energy homeostasis and regulation of neuronal and synaptic excitability. It is also conceivable that the KD may work in different ways against different seizure types and epileptic syndromes. Both clinical studies and animal experiments have been used to decipher KD mechanisms.[79] Any explanation of mechanism of action must take into account clinical observations and known biochemical alterations resulting from ingestion of the KD (Table 1).

Overview of Brain Energy Metabolism

Since the original formulation of the KD, it has been assumed that fasting and the KD share a common mechanism in alleviating seizures. The first step in understanding how the KD may work as an antiepileptic treatment is to understand how ketosis occurs. Whether the antiepileptic effectiveness of fasting or the high-fat diet is related to the level of ketosis remains a lingering controversy.

Table 1 Animal Models of the Ketogenic Diet: Observations and Clinical Correlates

	Observation in animal models	Clinical correlate
Seizure type	KD is effective in models employing a wide variety of seizure paradigms	KD is effective in many seizure types and epilepsy syndromes
Age range	Younger animals respond better to KD	Children extract and utilize ketones from blood more efficiently than older individuals
Calorie restriction	Increases seizure threshold	Associated with seizure reduction
Diet type	Classic and MCT diets both increase seizure threshold	In patients, classic and MCT KDs are equally efficacious
Ketosis	A threshold level of ketosis is	Ketosis is necessary but not

	necessary but not sufficient to explain antiseizure effect	sufficient
Fat	Better effectiveness with higher ketogenic ratios; uncertain if type of fat is a critical variable	Practical concerns limit the ketogenic ratio; possible role of fat chain length and degree of saturation (e.g., PUFA)
Latency to KD effectiveness	Several days	Seizures may be seen during the pre-KD fast or after a latency of days to weeks
Reversal of protective effect when KD discontinued	Rapid (hours)	Rapid (hours)

KD, ketogenic diet; MCT, medium-chain triglyceride; PUFA, polyunsaturated fatty acid.
From Stafstrom CE. Dietary approaches to epilepsy treatment: old and new options on the menu. *Epilepsy Curr*. 2004;4:215-222.

Ordinarily, the brain is an obligate user of glucose as its energy source. However, when carbohydrates are restricted, as in fasting or the KD, the brain can no longer use glucose exclusively. Metabolism shifts such that the brain preferentially oxidizes ketone bodies derived from fats, instead of carbohydrates, as the primary fuel source.[17,63,77] Dietary fats are ordinarily

broken down by *β*-oxidation in the liver into two-carbon acetyl CoA molecules (Fig. 1A), which then enter the tricarboxylic acid (TCA) cycle, producing energy via generation of adenosine triphosphate (ATP). However, under conditions of fasting, starvation, or the high-fat KD, acetyl CoA entry into the TCA cycle is reduced because of low availability of the TCA rate-limiting substrate oxaloacetate and the rate-limiting enzyme *α*-ketoglutarate dehydrogenase (which have been diverted to gluconeogenesis). Instead, acetyl CoA is used to synthesize the four-carbon ketone bodies, *β*-hydroxybutyrate (BHB) and acetoacetate (AcAc), as well as the volatile ketone acetone, which is exhaled with fasting, and the KD produces ketosis (i.e., elevated blood levels of BHB and AcAc). The liver lacks the enzymes necessary to break down ketone bodies, so BHB and AcAc are exported in the circulation to tissues such as muscle and brain.

Therefore, during fasting or high-fat/low-carbohydrate intake, the brain can utilize ketones as the main oxidizable substrate for cerebral metabolism (Fig. 1B).[18,77] Ketones are transported across the blood–brain barrier by facilitated diffusion, using a monocarboxylate transporter[66] induced by fasting. Brain monocarboxylate transporter levels are upregulated by KD treatment.[14,47]

Neurons and glia possess the requisite enzymes to break down BHB and AcAc into acetyl CoA fragments (BHB dehydrogenase and 3-oxoacid-CoA transferase, respectively). Acetyl CoA molecules can in turn enter the TCA cycle and produce energy (Fig. 1B). These enzymes are regulated developmentally, with maximal expression early in life, consistent with the better utilization of ketones at young ages.[14] Although the brain can metabolize ketones if deprived of its usual carbohydrate fuels, cerebral activity may be optimal only if *some* glucose is present. A recent study showed that cortex, brainstem, and primary cultures of cortical astrocytes can express ketogenic enzymes, especially early in development.[13]

Ketones

A reasonable hypothesis is that ketone bodies exert anticonvulsant activity, much like antiepileptic drugs.

Serum ketone concentrations rise markedly in subjects on the diet and urinary ketones are used clinically to indicate ketosis. However, several clinical and experimental studies have shown that the relationship between serum or urinary ketones and seizure control is imprecise.[7,29,33,53] Direct effects of ketones on excitatory and/or inhibitory neurotransmission and on ictal activity in vitro have been disappointingly negative.[78,87] However, in vivo, rats on the KD or a calorie-restricted normal diet exhibited increased paired-pulse inhibition in the hippocampal dentate gyrus and increased resistance to maximal dentate activation (a form of seizure activity).[6] Acetone could also exert an anticonvulsant effect.[51,52,54,59,60,72] In summary, there appears to be a "threshold level" of ketosis that must be achieved and maintained for the KD to be maximally effective.

Alterations in Energy Metabolism and Mitochondrial Function

The alteration in cerebral energetics induced by the KD favors an increase in "energy charge" (i.e., a relative increase in the ATP:ADP ratio resulting from metabolic alterations of the enzymes involved in glycolysis and the TCA cycle[17]). The greater availability of brain energy may reduce cellular excitability by enhancing energy available for cellular processes such as membrane pumps and transporters, which enhance hyperpolarization. The "energy charge" hypothesis is supported by recent studies in fasting humans using ^{31}P spectroscopic imaging, in which ketones are transported from the blood to the brain and are utilized by neurons.[64,65]

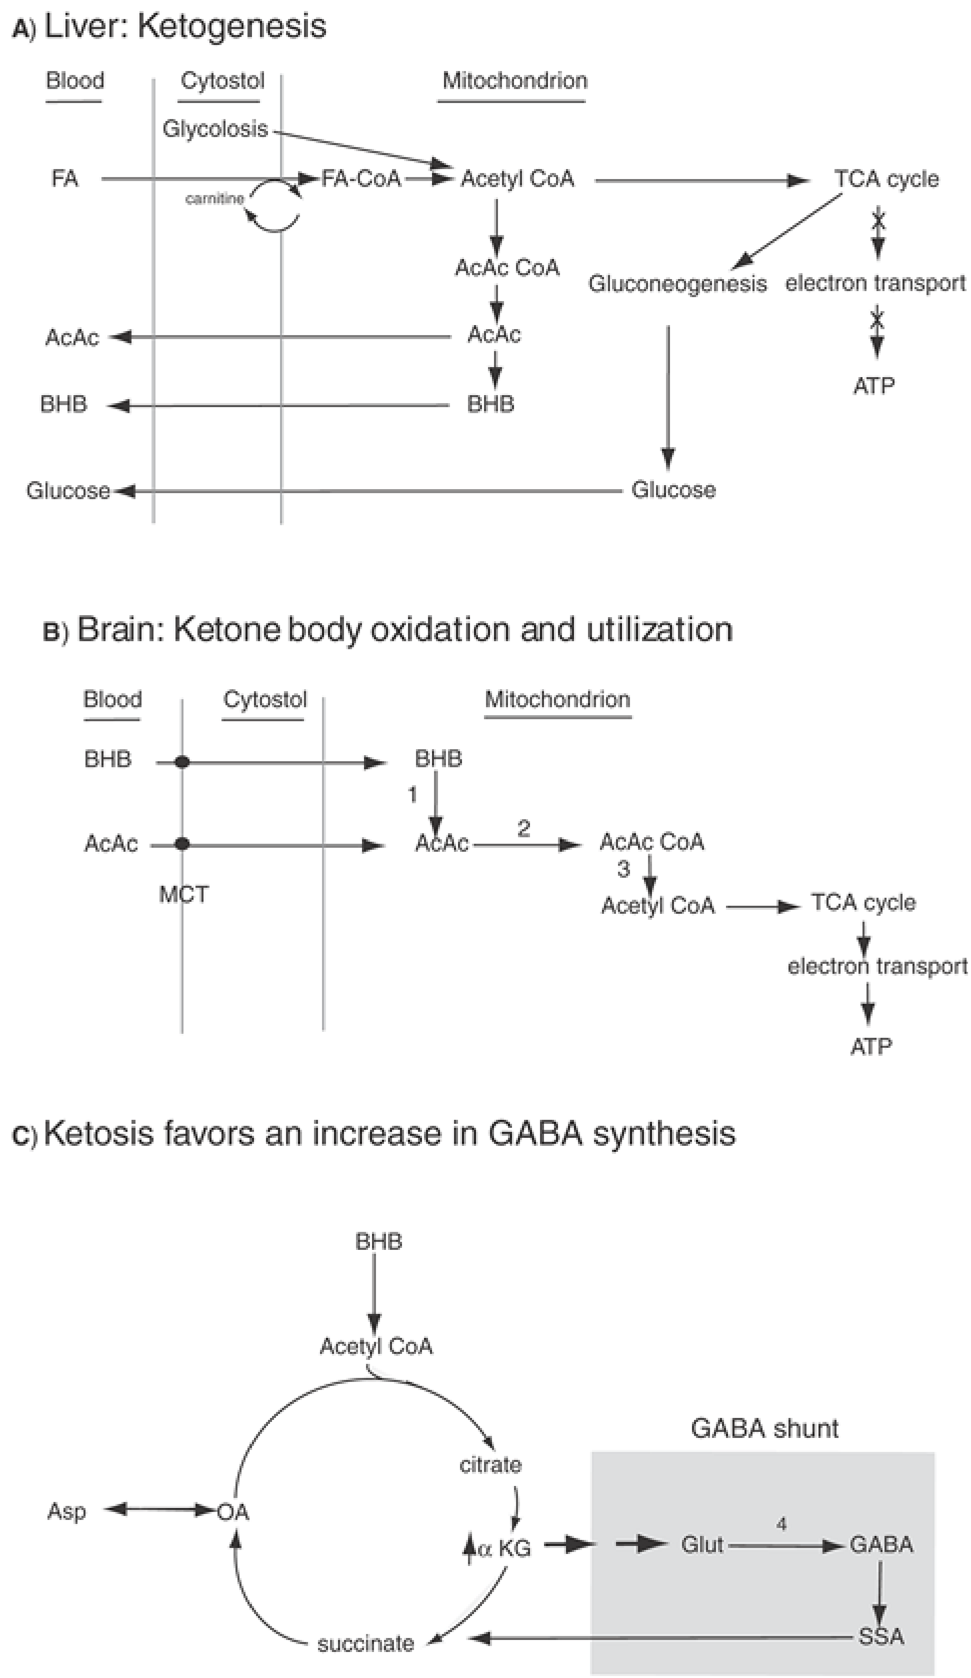

FIGURE 1. Ketogenesis and ketone body utilization by the liver and brain. **A:** Ketogenesis in the liver. Fatty acids (FAs) from the circulation enter hepatocytes, and then cross the inner mitochondrial membrane by either diffusion (short- and medium-chain FA) or via carnitine transport (long-chain FA). Under conditions of fasting or the ketogenic diet, carbohydrate substrate is lacking, so FAs are metabolized. Since oxaloacetate (a tricarboxylic acid [TCA] cycle intermediate) is diverted to

gluconeogenesis, the TCA is not actively involved in energy generation (*X'd arrows*). Acetyl coenzyme A (CoA) is therefore not funneled into the TCA, but instead is used for ketone body synthesis (acetoacetate [AcAc], *β*-hydroxybutyrate [BHB]). Ketones are exported into the circulation, since the liver lacks the enzymes required to catabolize AcAc and BHB. **B:** In the brain, BHB and AcAc enter neurons via monocarboxylic acid transporters (MCTs). In mitochondria, BHB and AcAc are broken down (by enzymes 1, 2, and 3) into acetyl CoA molecules that can then enter the TCA cycle for energy production. **C:** TCA cycle and γ-aminobutyric acid (GABA) shunt. In ketosis, α-ketoglutarate is increased and GABA synthesis from glutamate (via enzyme 4) is favored.[101] In addition, the GABA shunt, bypassing normal oxidative metabolism, facilitates GABA synthesis. ATP, adenosine triphosphate; AcCoA, acetyl CoA; citr, citrate; succ, succinic acid; OA, oxaloacetate; asp, aspartate; α-KG, α-ketoglutarate; glut, glutamate; SSA, succinic semialdehyde; 1, BHB dehydrogenase; 2, succinyl-CoA transferase; 3, acetoacetyl-CoA thiolase; 4, glutamic acid decarboxylase.

The mechanism by which seizures induce neuronal damage includes mitochondrial dysfunction with the formation of injurious reactive oxygen species (ROS). The KD has recently been shown to increase the expression of brain mitochondrial uncoupling proteins,[84] which act to reduce ROS formation. It was recently demonstrated that BHB and AcAc (in millimolar concentrations) prevented neuronal hyperexcitability induced by exogenous hydrogen peroxide administration in vitro, and that ketones were capable of significantly reducing ROS formation in isolated mitochondria.[38] Additional support for the

P.1379

involvement of the KD in enhancing brain metabolism comes from microarray studies of gene transcription. Of 42 gene transcripts upregulated by the KD, 39 encode mitochondrial proteins.[6a] Taken together, these observations suggest that the KD may protect against seizure activity (and may also be neuroprotective) through antioxidant mechanisms activated by fatty acids and ketones.

Alterations in Neurotransmitters and Synaptic Transmission

The ketogenic diet may enhance the function of γ-aminobutyric acid (GABA), the main inhibitory neurotransmitter of the mammalian brain. GABA is synthesized from glutamate via the

P.1380

action of glutamate decarboxylase (Fig. 1C). In pathways of ketone body metabolism (GABA shunt), glial conversion of glutamate to glutamine (a GABA precursor) is increased by ketosis.[19,100] Enhanced GABA accumulation or function at the receptor level could lead to reduced cortical excitability. At the same time, the rate of glutamate conversion to aspartate, which has an excitatory role, is reduced.[101] In ketosis, α-ketoglutarate, the precursor of glutamate, is increased, thereby enhancing the synthesis of GABA via the "GABA shunt" (Fig. 1C).[19]

Ketones mimic GABA structurally, so they could play a direct inhibitory role on cellular excitability by stimulating GABA receptors or enhancing their action. Ketogenic diet treatment (and calorie restriction) increases the expression of glutamic acid decarboxylase (GAD65 and GAD67) isoforms, providing a mechanism by which GABA synthesis might be increased on the KD.[11] In a study utilizing a variety of seizure induction methods, the most consistent protection with the KD was found when seizures were induced by blocking GABA receptors (i.e., picrotoxin, bicuculline).[4]

Effects of Lipids and Polyunsaturated Fatty Acids

Fatty acids may be important in mediating an anticonvulsant effect. Typically, a KD includes mostly saturated fats of various chain lengths. No attempt is made to specify fat type or chain length in the KD formulation, except for the medium-chain-triglyceride diet, described above.[34] In early clinical studies, there was a correlation between plasma lipids and seizure control in children with epilepsy treated with the diet.[15] Plasma lipid levels peaked as KD-induced seizure control became maximal. In experimental studies, young rats fed a variety of different fat types developed seizure resistance independent of the level of ketosis but dependent upon qualitative differences (i.e., different sources of fats).[16,53] In general, increasing the ketogenic ratio leads to improved KD efficacy.[7,23]

The essential fatty acids, especially the long-chain polyunsaturated fatty acids (PUFAs) of the ω-3 class (as found in certain fish oils), are necessary for the development of neuronal membranes and for subsequent normal behavior and cognition.[43] Fatty acids exert modulatory effects on cellular excitability and receptor-mediated signaling pathways.[82,92,93,99] It is tempting to speculate that PUFAs might be utilized clinically. In human volunteers, a KD enriched with PUFAs resulted in higher levels of circulating BHB than a standard KD.[25] In a case series of nine children on the classic KD, increased serum levels of PUFAs were found and the level of at least one PUFA (i.e., arachidonic acid) correlated with improved seizure control.[21] These findings are of interest because arachidonic acid is known to reduce neuronal excitation.[20] In rats, seizure control correlates with a higher ketogenic ratio, with maximal protection against pentylenetetrazole (PTZ)-induced seizures at a fat–to–carbohydrate plus protein ratio of 6:1.[7] Humans would not tolerate such a high fat content.

Clinical dietary trials of PUFAs were effective in disorders of cardiac excitability.[45] To date, a single human study (not blinded, no control group) has evaluated the efficacy of a PUFA-enriched diet in patients with epilepsy.[74] A supplement consisting of 65% ω-3 PUFAs was given to five institutionalized patients with epilepsy daily for 6 months. Seizure frequency decreased from 1 to 14 seizures per week to 0 to 1 per month with PUFA supplementation. Although intriguing, these findings must be verified in a much larger, well-controlled prospective study.

Calorie Restriction

The original idea for a KD derived from the beneficial effect of fasting on seizures, and this observation has been verified in the modern setting.[24] The health benefits of modest calorie restriction include an increased lifespan, reduced risk of cancer and cardiovascular disease, amelioration of the degenerative effects of aging, and neuroprotection.[12,70] In rats receiving the convulsant kainic acid, there were fewer learning deficits and less histologic damage in rats on a calorie-restricted diet,[9] possibly due to reduced oxidative stress.

Reliable data on calorie restriction in humans with epilepsy are lacking. Children on the KD are typically restricted to 75% of the Recommended Daily Allowance for their ideal weight and height, allowing linear growth but not significant weight gain.[91] In individuals on the KD, blood glucose levels are usually in the lower end of normal, but patients are rarely hypoglycemic.[75] Therefore, a metabolic adaptation occurs in response to the KD to maintain relative euglycemia. The main clinical question, as yet unanswered, is whether calorie restriction reduces seizure burden independent of ketosis.

Recent animal studies have provided evidence that calorie restriction alone can reduce seizures. In epileptic EL mice on a diet restricted to 85% of normal calories, seizure onset is delayed several weeks compared to control EL mice, an effect that is dependent on plasma glucose level.[57,88] In another model, in response to intravenous PTZ, seizure threshold was elevated in calorie-restricted rats.[5] These data suggest that calorie restriction is sufficient to increase seizure threshold and calorie restriction may augment the effects of the KD.

Other Possible Mechanisms and Antiepileptogenesis

Numerous other possibilities are being explored in the search for KD mechanisms, including the roles of fatty acid oxidation,[31] neurotransmitters,[86] neuropeptides,[94] and glia.[35] Of particular interest is whether the KD can exert an antiepileptogenic effect in addition to an anticonvulsant action. There is clinical evidence that the KD results in long-term efficacy, with continued seizure control even after the diet is withdrawn.[23] Experimentally, the KD reduces the occurrence of spontaneous seizures and abnormal sprouting of dentate granule mossy fibers in the kainic acid model.[58] In mice with deletion of the Kv1.1 potassium channel gene, spontaneous seizures and mossy fiber sprouting were also diminished.[73] The KD was also neuroprotective against the damaging effects of kainic acid seizures by inhibition of caspase-3–mediated apoptosis.[61]

The Ketogenic Diet in Practice

There have been multiple variations on the KD since its initial description by Wilder in 1921. These include the classic ketogenic diet, the medium-chain-triglyceride diet, a modified medium-chain-triglyceride diet, and more recently, modified Atkins and low-glycemic-index diets. All of these diets involve some degree of ketosis and restriction of carbohydrates. Ketogenic diets can be adapted for use in diverse cultures and cuisines, including those of Asia and South America.[41]

Selection of appropriate patients is guided by the age of the patient, type of seizure, seizure severity, and response to previous therapies. Initially, the KD was thought to be useful in children with absence seizures, as the alkalosis of hyperventilation and resulting exacerbation of seizures might be compensated with ongoing acidosis. Livingston[55] extended use of

P.1381

the KD to patients with drop (atonic) seizures, and through the years the diet has frequently been prescribed for children with Lennox-Gastaut syndrome. Experience also suggests that it may be useful in infantile spasms[42] and in severe myoclonic epilepsy of infancy (Dravet syndrome).[10]

No randomized clinical studies clearly differentiate which seizure type is more responsive, but there is some evidence that generalized epilepsies may be more responsive than partial epilepsies. Clinicians generally agree that the KD is indicated for intractable childhood epilepsy, glucose transporter type 1 (GLUT1) deficiency, and pyruvate dehydrogenase complex deficiency. The KD can be used effectively over a wide age range (infancy to adulthood).[56,62,76] Absolute contraindications to the use of the KD include pyruvate carboxylase deficiency and porphyria. Relative contraindications include certain mitochondrial cytopathies. Use of the ketogenic diet should be considered when a child's seizures have not been controlled after a trial of two appropriate anticonvulsants, except when specifically contraindicated as noted above. The KD is not a benign therapy, and requires considerable commitment from both the family and the medical community. However, when the burden of seizures and side effects of medication outweigh the potential problems associated with the KD, children should clearly have an opportunityto try it.

The stringency of the KD is explained to the family and/or the patient. Families and patients are encouraged to talk with other patients to learn more about living with the KD. The importance of a multidisciplinary team to manage the KD cannot be emphasized strongly enough.[85]

A decade ago, children were admitted to the hospital for fasting and given only limited water until they became strongly ketotic and lost 10% of their body weight. Seizures are often observed to decrease markedly during the fasting phase.[24] Nevertheless, because of concerns about the stress of this regimen and the pressures of ever-increasing demands for shorter hospital stays, these stringent requirements have eased. Many centers do not use any fasting or hospitalization at diet initiation.[3,37,89,98]

When fasting is used, the child begins fasting after dinner the night before admission. Families are advised to decrease carbohydrates markedly for 2 days before admission. Fasting is then maintained in the hospital, with blood sugar monitoring (Dextrostix) performed every 4 to 6 hours. Unless the patient becomes symptomatic, blood glucose levels as low as 20 to 40 mg/dL are not treated. Fasting is continued until the child becomes strongly ketotic (urine Ketostix large: 4+; 160 mg/mL) or for 48 hours. The KD is then introduced gradually, beginning with a third of the eventual caloric goal on the first day, two thirds of the calories on the second day, and the full number of calories on the third day. Large quantities of fat in ketotic children may lead to vomiting and refusal to eat. Generally, a child who is tolerating the diet on the fourth or fifth day is discharged. The parents are instructed to monitor urinary ketones with Ketostix for the first month. During the brief hospitalization (3 to 7 days), parents and children receive extensive instruction in how to calculate and prepare the KD, including potential sources of glucose and other errors.[23]

Table 2 Basic Diet Calculations

1. Calculate calories needed per day.
   Example: 15 kg (weight of child) × 68 cal/kg/d = 1,000 cal/d
2. Calculate number of dietary units needed per day.
   On the 4:1 diet, each unit is 40 cal (4 g fat = 36 cal; 1 g protein or carbohydrate = 4 cal).
   (1,000 cal/d)/(40 cal/U) = 25 U/d

3. On a 4:1 diet, calculate the number of grams of fat required per day.
   Fat: 25 U/d × 4 g/U = 100 g/d
4. Calculate the remainder of units/calories, allotted to protein and carbohydrate.
   Protein and carbohydrate: 25 U/d × 1 g/U = 25 g/d (combined)
5. Calculate protein requirement.
   Protein: 1 g/kg/d × 15 kg = 15 g/d
6. Calculate remainder, allotted to carbohydrate.
   Carbohydrate: 25 g/d - 15 g/d = 10 g/d
7. Divide these allotments into three meals.

Food	Grams per day	Calories per day	Grams per meal
Fat	100	900	33.3
Protein	15	60	5.0
Carbohydrate	10	40	3.3
TOTAL		1,000	

There is little documented experience in using the diet in adults. Sirven et al.[76] did demonstrate its efficacy in 11 adults. The diet was initiated after 24 hours of fasting at home and another 48 hours of fasting until 4+ ketonuria in the hospital. A 4:1 diet was then initiated beginning with one third of the planned calories and increasing by thirds every two meals until the full diet was achieved.

Calculating the Classic Ketogenic Diet

The KD is calculated for each individual, with each child's food preferences taken into consideration.[102] The calorie count is based on an assessment of the patient's intake according to a dietary history and how close the patient is to ideal body weight. This typically ranges from 60 to 80 cal/kg. Most children are started on the diet with a ratio of ketogenic to antiketogenic foods of 4:1 (a “4:1 diet”). The 4 g of fat plus 1 g of protein and carbohydrate, considered together as a dietary unit, yield 40 calories (36 calories of fat and 4 calories of protein/carbohydrate). The diet allows 1 g of protein per kilogram of body weight daily. Fluid is restricted to 60 to 65 mL/kg/day, generally never more than 1,200 to 1,500 mL/d. A 15-kg child would require about 1,000 calories (68 cal/kg) or 25 dietary units per day. The dietary calculations would be made as in Table 2.

Table 3 Allocating Nutrients for a Basic Meal

1. Follow the calculations in Table 2 .

Food	Calories per meal	Grams per meal
Fat	300	33.3

Protein		20	5.0
Carbohydrate		13	3.3
TOTAL	333		

2. Calculate the amount of heavy cream first. Half of planned carbohydrate in meal is from cream.

0.5 × 3.3 g = 1.7 g carbohydrate as cream

3. Check nutritional tables regarding cream being used. In

100 g of 36% cream are the following:

3.0 g carbohydrate

36 g fat

2 g protein

To provide 1.7 g carbohydrate, give 57 g 36% cream. (100 × 1.7)/3.0 = 57

The 57 g cream also contains 1.1 g protein. (57 × 2)/100 = 1.1

4. Calculate the additional carbohydrate.

Allot 1.7 g carbohydrate as cream, then additional 1.6 g carbohydrate as vegetable B. Using tables, this becomes 23 g vegetable B, which also contains 0.5 g protein.

5. Calculate protein.

Allotment: 5.0 g

As cream: 1.1 g

As vegetable: 0.5 g

Remainder as meat: 3.4 g (5.0 – 1.1 – 0.5)

Using tables again, this allows 15 g of meat. This amount of meat also contains 2.5 g fat.

6. Calculate the remaining amount of fat to be added.

Allotment: 33.3 g

As cream: 57 g of 36% cream = 20.5 g fat (0.36 × 57)

As meat: 2.5 g

Remainder as butter: 10.3 g (33.3 – 20.5 – 2.5)

Once the number of calories per meal has been determined and the number of grams of the various constituents is known, a meal plan can be constructed. There is a hierarchy in this calculation, with fats calculated first, as the fat content is the most important constituent. For example, in a 15-kg child, if 3.3 g of carbohydrate is allowed per meal, then 1.7 g (half of the planned carbohydrate) might be allocated to whipped cream, which often serves as an important fat component. Nutritional tables (or a computer program) are consulted, and as 100 g of 36% cream contains 3.0 g of carbohydrate, 57 g of cream is included in the meal to yield 1.7 g of carbohydrate. The other 1.7 g of carbohydrate is allocated to fruits or vegetables. The remaining protein (meat/fish/poultry, cheese, or egg) that is required is then calculated by subtracting the protein in the cream and vegetable from the total protein allowance. The amount of remaining fat to be eaten is then calculated by subtracting the fat in the cream and protein from the total fat allowance. The cream provides 20.5 g of fat (57 × 0.36), leaving about 12 to 13 g of fat to be added, in the form of mayonnaise, butter, or other high-fat foods (Table 3).

P.1382

Traditionally, there have been six basic meal plans. Each includes fats, protein, and carbohydrate. They are arranged as follows: (a) meat/fish/poultry, fruit, fat, cream; (b) cheese, fruit, fat, cream; (c) egg, fruit, fat, cream; (d) meat/fish/poultry, vegetables, fat, cream; (e) cheese, vegetables, fat, cream; and (f) egg, vegetables, fat, cream. As is evident from this list, meat, fish, and poultry are considered interchangeable. Other protein sources are cheese and egg. There are two lists of vegetables (A and B). Group B vegetables are higher in carbohydrate, so twice the amount of group A vegetables can be used. Two levels of carbohydrate content are also recognized within the fruit category (10% or 15% fruit). Families are instructed that the entire meal must be eaten in order to maintain the ratio. A sample meal plan for a child is given in Table 4.

Table 4 Outline of Meal

	Food group		
Food	**Fat, g**	**Protein, g**	**Carbohydrate, g**
57 g 36% cream	20.5	1.1	1.7
15 g meat	2.5	3.5	
23 g group B	0.5	1.6	
Vegetable			
10.3 g butter	10.3		
TOTAL	33.3	5.1	3.3

Sample lunch:
Chocolate milk shake (using the 20.5 g cream and allotted liquid as sugar-free chocolate soda)
Steamed broccoli with spicy butter
Julienned chicken sauteed in butter and herbs

The KD can also be calculated as a portable eggnog or a formula for tube feedings. The availability of computerized programs has allowed considerably greater flexibility and accuracy in substituting a wider variety of foods. A nutritionally complete powdered formula (KetoCal, Scientific Hospital Supplies) has also added to the potential convenience of the diet. The KD is deficient in water-soluble vitamins (B and C) and calcium; therefore, a sugarless multivitamin with iron and 600 to 650 mg of oral calcium are prescribed.

Problems during the first month may include hunger, thirst, and toxicity from antiepileptic drugs. The child should neither lose nor gain weight. If either occurs, the calorie content may need to be adjusted. Ice chips, a "free" lettuce leaf once or twice a day as a snack, or vegetables in group A or 10% fruit may be given to increase the quantity of food that can be consumed until the child becomes accustomed to the smaller portions. Thirst can usually be managed by encouraging the child to drink small quantities more frequently. Spices make the meals more palatable, and cutting foods in attractive ways and presenting them in a pleasing manner may make the meals more appetizing. Sometimes using a decorative, smaller plate is helpful. The child should also be involved in choosing food, and if old enough should be involved in meal preparation. The diet can be managed at school with cooperative teachers and students, and the family can travel and dine out by planning carefully in advance.

Drugs need to be monitored as toxicity may occur, especially during fasting. The eventual goal is to decrease or eliminate drugs if seizure control is obtained with the diet. Acetazolamide, which can exacerbate metabolic acidosis, should be discontinued before instituting the KD. Although there has been some concern about the use of various anticonvulsants, including valproic acid, topiramate, and zonisamide, with the ketogenic diet, multiple studies have not demonstrated a significant problem.[1,13a,41a,55a] Sedation may be increased, especially during fasting, in children taking phenobarbital or benzodiazepines.

Clinical Efficacy and Side Effects

The clinical efficacy of the KD has been well documented through the decades. Blinded studies are difficult to perform because of the nature of the therapy, and no blinded studies of efficacy have been done. Even prior to the resurgence of interest in the KD a decade ago, a large number of mostly retrospective studies demonstrated its efficacy. In multiple studies performed over many decades, and despite the availability of many new AEDs, the KD appears to provide excellent seizure control (>90% seizure reduction) in 20% to 30% of patients and improved seizure control (>50% seizure reduction) in 60% to

80% of patients when evaluated at 6 months. The KD does not appear to work in 20% to 40% of patients. Efficacy ultimately depends on a number of factors, including types of seizures, seizure etiology, patient age, compliance with the diet, length of follow-up, and methods used to determine efficacy.

A prospective multicenter study of the classical ketogenic diet, using an intention-to-treat design, showed that 29% of the 51 children who had started the diet had >90% im-provement at 6 months and 53% had >50% improvement.[90] In a larger, similarly designed single-center study, 32% of the 150 children who had started the diet had >90% improvement at 6 months and 51% had >50% improvement.[22] Using these data and nine other studies, a technical review performed for the Blue Cross Blue Shield insurance group in the United States concluded that the KD demonstrated a “significant reduction in seizure frequency” and that “it is unlikely that this degree of benefit can result from a placebo response and/or spontaneous remission.”[46] Furthermore, cognitive improvement is often seen when children are placed on the KD, either as a result of the diet itself or because sedating AEDs can be reduced.[71]

It is difficult to determine the frequency of side effects in children treated with the KD, as few long-term prospective studies have been undertaken. Many of the problems are mild and can be managed with conservative measures. The most common side effects are gastrointestinal in nature, including poor appetite, nausea, vomiting, and especially constipation. Sometimes these problems are associated with excessive ketosis and require alterations in the diet. Constipation is usually managed by increasing fluid intake, maximizing fiber, and using a laxative such as MiraLax (polyethylene glycol). Occasionally an enema is necessary. Renal stones are relatively common and occur in 5% to 7% of children on the diet.[26] These children are typically managed with increased fluids, but sometimes require either lithotripsy or surgical removal. Children with a family history of renal stones should be carefully watched, and occasional screening for hematuria appears appropriate in all patients. There is the possibility that stones can be avoided by monitoring the urine calcium:creatinine ratio. If this ratio is elevated, urine can be alkalinized with Polycitra. A wide variety of other problems have been reported in association with KD use, including sepsis, pancreatitis, hepatitis, cardiomyopathy, prolonged Q-T interval, optic neuropathy, anemia, mineral and vitamin deficiencies, hypocarnitinemia, and osteopenia.[1,2,36,39] Although these adverse effects are rare, they must not be ignored. Parents need to be aware that a wide variety of problems can occur, as when any new medication is started. Typically, if a child becomes ill or his or her function and behavior changes in an adverse manner, these problems must be considered. If an intercurrent infectious illness occurs, the child should be seen by a pediatrician for appropriate laboratory testing.

Long-term concerns regarding growth and bone health are of concern, especially as the diet is being used in younger patients and for longer periods of time.[91] In addition, dyslipidemia has been documented in a prospective study, although its clinical impact in the setting of an otherwise altered metabolic condition is unknown.[44]

Other Forms of Dietary Therapy for Epilepsy

An alternative diet, the medium-chain-triglyceride (MCT) diet, was designed in an effort to increase the palatability of the KD.[34] Huttenlocher et al. noted that the triglycerides of octanoic and decanoic acids are more ketogenic than dietary fats and suggested that 60% of calculated caloric maintenance be given as MCT oil. The oil was mixed with at least twice its volume of skimmed milk and consumed as the beverage for the meal. Instead of 87% of calories as fat, as would be used in the 3:1 classic KD, only 71% of the calories in the 3:1 MCT diet are given as fats, freeing considerably more calories for protein and carbohydrate (10% of calories as protein and 19% as carbohydrates).

A modified MCT diet (the Radcliffe Infirmary diet) was created to eliminate some of the perceived difficulties with the conventional MCT diet (i.e., gastrointestinal distress) while allowing increased flexibility.[75] It allows the recommended daily intake of calories, but gives only 30% of calories as MCT oil and 41% of calories as long-chain saturated fats. It still allows 10% of calories as protein and 19% as carbohydrate.

While the ketogenic and MCT diets are the most widely recognized dietary therapies for epilepsy, other dietary approaches are being developed.[80] A modified Atkins diet recently has been reported to be effective in controlling seizures in a small, uncontrolled case series.[40] This diet does not restrict calories and allows liberal amounts of fats and proteins. However, carbohydrate is restricted to 10 to 20 g/day, which can result in ketosis. In this series of six patients with intractable epilepsy from 7 to 52 years of age, three patients (all below 18 years of age) achieved a seizure reduction of >90% for as along as 20 months, without side effects and with a reduction of their other AEDs. Although the relative roles of calorie restriction versus ketosis in the seizure-protective effect of the Atkins diet have not been elucidated,[81] the Atkins diet represents an easier-to-use and more palatable form of the KD.

Finally, a low-glycemic-index (LGI) diet has recently shown promising efficacy in treating patients with medically refractory epilepsy.[69] Clinical observations suggest that even small amounts of carbohydrate given to patients on the KD will terminate its protective effect and cause seizures.[33] Foods with a low glycemic index cause only modest increases in blood glucose, so such a diet could afford seizure protection yet allow a wider range and amount of carbohydrates than the KD. Of 20 patients initiated on an LGI diet for at least 3 weeks, 10 patients achieved a seizure reduction of >90%, and few side effects were reported. This efficacy rate compares favorably with the KD, and seizure control was reached with less ketonemia than usually seen with the KD.

Summary and Conclusions

The KD has a long history of efficacy in controlling intractable seizures in childhood epilepsy. It appears beneficial in a wide variety of seizure types, although controlled studies evaluating efficacy are lacking. It remains unclear how the KD suppresses seizures. Experimental approaches, including those that allow in vivo evaluation of brain metabolism, are necessary to elucidate the mechanisms involved. It might be possible to design a therapy that is less rigorous and intrusive than the current KD, and promising alternative dietary approaches such as the Atkins diet and LGI diet are emerging. Insights into mechanisms might also lead to a better understanding of seizure pathogenesis, as had been hoped by early investigators such as Lennox.

Chapter 130

Sex-Hormone Treatment

Andrew G. Herzog

Introduction

There is considerable scientific evidence at molecular biologic, neuronal, experimental animal, and clinical levels to indicate that reproductive steroids have neuroactive properties that play a substantive role in the pathophysiology of epilepsy and the pattern of seizure occurrence. Steroids act in the brain by receptor-mediated genomic (long latency), receptor-mediated posttranscriptional (intermediate latency), and direct membrane-mediated (short latency) effects.[40,57,60] Steroid effects may also be valuable in therapeutic interventions using naturally occurring hormones and in the development of hormonally based neuroactive synthetic analogs with potent antiepileptic properties.

Reproductive Hormonal Effects on Epilepsy

Estradiol

Estradiol exerts direct excitatory effects at the neuronal membrane, where it augments *N*-methyl-D-aspartate (NMDA)-mediated glutamate receptor activity.[68,76] This enhances the resting discharge rates of neurons in a number of brain areas, including the hippocampus,[39,68,76] where estradiol increases excitability of the hippocampal CA1 pyramidal neurons and induces repetitive firing in response to Schaffer collateral stimulation.[76]

Estradiol potentiates neuronal excitability by regulating neuronal plasticity. It increases the density of spines and excitatory, NMDA receptor-containing synapses on the apical dendrites of hippocampal CA1 pyramidal neurons via a posttranscriptional mechanism.[78,79] The dendritic spine density on these neurons correlates positively with the levels of circulating estradiol during the estrous cycle of the rat and is decreased by oophorectomy.[78] Estradiol may thus further increase excitatory input to the CA1 neurons.

Estradiol may affect neuronal excitability by cytosolic neuronal estrogen receptor-mediated, genomically dependent mechanisms. Receptors are particularly abundant in the temporolimbic system, especially in the medial and cortical amygdaloid nuclei, and occur in much fewer numbers in the hippocampal pyramidal cell layer and the subiculum.[61,66] Estrogen receptor-containing neurons colocalize with other neurotransmitters, including γ-aminobutyric acid (GABA).[12,56] By regulating the expression of genes affecting the activity, release, and postsynaptic action of different neurotransmitters and neuromodulators, estrogens may act to increase the excitability of neurons, which concentrate estradiol. For instance, estradiol lessens inhibitory neurotransmission by decreasing GABA synthesis in the corticomedial amygdala by reducing the activity of glutamic acid decarboxylase,[75] and enhances brain epileptogenic muscarinic neurotransmission by increasing choline acetyl transferase and acetylcholine.[50]

In adult experimental animals, the thresholds of limbic seizures in female rats fluctuate during the estrus cycle inversely to estradiol levels.[72] Physiologic doses of estradiol activate spike discharges[49,53] and lower the thresholds of seizures induced by electroshock, kindling, pentylenetetrazol, kainic acid, ethyl chloride, and other agents and procedures.[36,49,59,70,77] In fact, topical brain application, as well as intravenous systemic administration, of estradiol in rabbits produces a significant increase in spontaneous electrically recorded paroxysmal spike discharges.[49,53] The increase is seen within a few seconds of application to suggest a direct membrane rather than a genomic effect and is more dramatic in animals with pre-existent cortical lesions.[53] The role of estrogen, however, may be more complex since there is also evidence in some models that estradiol can raise seizure thresholds in the hippocampal region and provide neuroprotection against seizure-induced injury.[73]

Clinically, Logothetis et al.[48] showed that intravenously administered conjugated estrogen clearly activated epileptiform in 11 of 16 women and was associated with clinical seizures in four.

Progesterone

Progesterone and particularly some of its neuroactive metabolites, most notably allopregnanolone, exert direct membrane-mediated inhibitory effects by potentiating $GABA_A$-mediated chloride conductance.[16,57,60] It also potentiates the action of the powerful endogenous inhibitory substance adenosine.[62] Progesterone itself also substantially diminishes nicotinic acetylcholine receptor-mediated conductance, which may be relevant to autosomal dominant nocturnal frontal lobe epilepsy.[6]

Progesterone may act via genomic mechanisms to influence the enzymatic activity controlling the synthesis and release of various neurotransmitters and neuromodulators produced by progesterone receptor-containing neurons.[56] Progesterone binds specific cytosolic receptors not only to produce its own characteristic effects, but also to lower estrogen receptor numbers and thereby antagonize estrogen actions.[37]

Chronic progesterone decreases the number of hippocampal CA1 dendritic spines and excitatory synapses faster than the simple withdrawal of estrogen, counteracting the stimulatory effects of estradiol.[78] Progesterone and allopregnanolone have also been shown to have neuroprotective effects on hippocampal neurons in kainic acid-induced seizure models.[14]

In most adult female animal models, progesterone depresses neuronal firing[67] and lessens spontaneous and induced epileptiform discharges.[46,59,70] It retards kindling and decreases seizure occurrence.

Backstrom et al.[3] found that intravenous infusion of progesterone, sufficient to produce luteal phase serum levels, was

P.1388

associated with a significant decrease in interictal spike frequency in four of seven women with partial epilepsy.

Neurosteroids

Most of the membrane effect of progesterone is due to the action of its 3α-hydroxylated (i.e., A-ring-reduced) metabolite, 3α-hydroxy-5α-pregnane-20-one or allopregnanolone (AP).[16,60] AP and the 3,5-hydroxylated natural metabolite of the mineralocorticoid deoxycorticosterone, allotetrahydro-deoxycorticosterone (allo-THDOC), are among the most potent of a number of endogenous neuroactive steroids with a direct membrane effect on neuronal excitability.[16,52,60] AP, but not allo-THDOC, is devoid of hormonal effects and may, together with other related neuroactive steroids, be thought of as an endogenous regulator of brain excitability with anxiolytic, sedative-hypnotic, and anticonvulsant properties.[16,52,60] AP and allo-THDOC hyperpolarize hippocampal and other neurons by potentiating $GABA_A$-mediated inhibition.[16,60] At physiologic (nanogram) concentrations, they act as positive allosteric modulators of the $GABA_A$ receptor, interacting with an extrasynaptic steroid-specific site near the synaptic receptor to facilitate chloride channel opening and prolong the inhibitory action of GABA on neurons.[16,51,52,60,80] At higher pharmacologic (micromolar) concentrations, AP also has a direct effect at the synaptic $GABA_A$ receptor to induce chloride currents.[16,60] AP is one of the most potent ligands of $GABA_A$ receptors in the central nervous system, with affinities similar to those of the potent benzodiazepine flunitrazepam, and approximately a thousand times higher than pentobarbital.[16,60] The parent steroid, progesterone, enhances GABA-induced chloride currents only weakly and only in high concentrations.[60,80] Plasma and brain levels of AP parallel those of progesterone in rats. In women, plasma levels of AP correlate with progesterone levels during the menstrual cycle and pregnancy.[60] However, brain activity of progesterone and AP is not dependent solely on ovarian and adrenal production, as they are both synthesized de novo in the brain.[9] Their synthesis is region specific and includes the cortex and the hippocampus.[9] By contrast, allo-THDOC is only synthesized by the adrenal gland and not in the brain.[60]

AP, allo-THDOC, and a number of other endogenous and synthetic pregnane steroids have a potent anticonvulsant effect in bicuculline-, metrazol-, picrotoxin-, pentylenetetrazol-, pilocarpine-, and kainic acid–induced seizures and against status epilepticus, but are ineffective against electroshock and strychnine-induced seizures.[5,16,41,42] The anticonvulsant properties of allopregnanolone resemble those of the benzodiazepine clonazepam.[12,16,42] AP is less potent than clonazepam but may have lower relative toxicity.[41,42] The anticonvulsant effect of AP is greater in female rats in the diestrus-1 part of the ovulatory cycle (equivalent to human midluteal phase when progesterone levels are high) than in estrus (equivalent to ovulation when estrogen levels are high) or in the male.[12,13] Enhanced midluteal efficacy at the $GABA_A$receptor may be related to a progesterone-induced enhanced formation of the δ $GABA_A$ receptor subtype. Rapid withdrawal of progesterone in late diestrus makes the $GABA_A$ receptor insensitive to benzodiazepine, but not AP, perhaps as the result of a decrease in the benzodiazepine-sensitive synaptic $GABA_A$ receptors. This effect can be blocked by inhibiting the formation of the α4 subunit of the $GABA_A$ receptor.[51,69]

By contrast, some of the sulfated neuroactive steroids have excitatory neuronal effects. They include pregnenolone sulfate and dehydroepiandrosterone sulfate (DHEAS), the naturally occurring sulfated esters of the progesterone precursor pregnenolone, and progesterone metabolite DHEA.[60] They increase neuronal firing when directly applied to neurons by negatively modulating the $GABA_A$ receptor[60] and by facilitating glutamate-induced excitation at the NMDA receptor.[38] In animal seizure models, pregnenolone sulfate and DHEAS have a proconvulsant effect.[35] Of note, serum DHEAS levels are substantially reduced by enzyme-inducing antiepileptic drugs such as phenytoin and carbamazepine.[33,45]

Testosterone

The effect of testosterone on experimental seizures appears to be mixed.[40] Testosterone acts on specific neural receptors to promote aggression, competition, potency, and libido. Aromatization to estradiol, a major testosterone metabolite, potentiates glutamate transmission and seizures.[68,76] Reduction to dihydrotestosterone blocks glutamate, specifically NMDA, transmission.[63] Another reduced androgen metabolite, androstanediol, has potent GABAergic, neuroprotective, and antiseizure properties.[15] The net effect of testosterone on neuronal excitability, therefore, may depend on the balance of its conversion to excitatory and inhibitory metabolites, which, in turn, is tissue dependent and varies with the relative local activities of reductase and aromatase enzymes.[68,76] Tissue specificity may be even more complicated. For example, sex- and age-dependent differences in proconvulsant and anticonvulsant actions of sex steroids have been demonstrated between the anterior and posterior regions of the substantia nigra in the rat.[74]

Catamenial Epilepsy

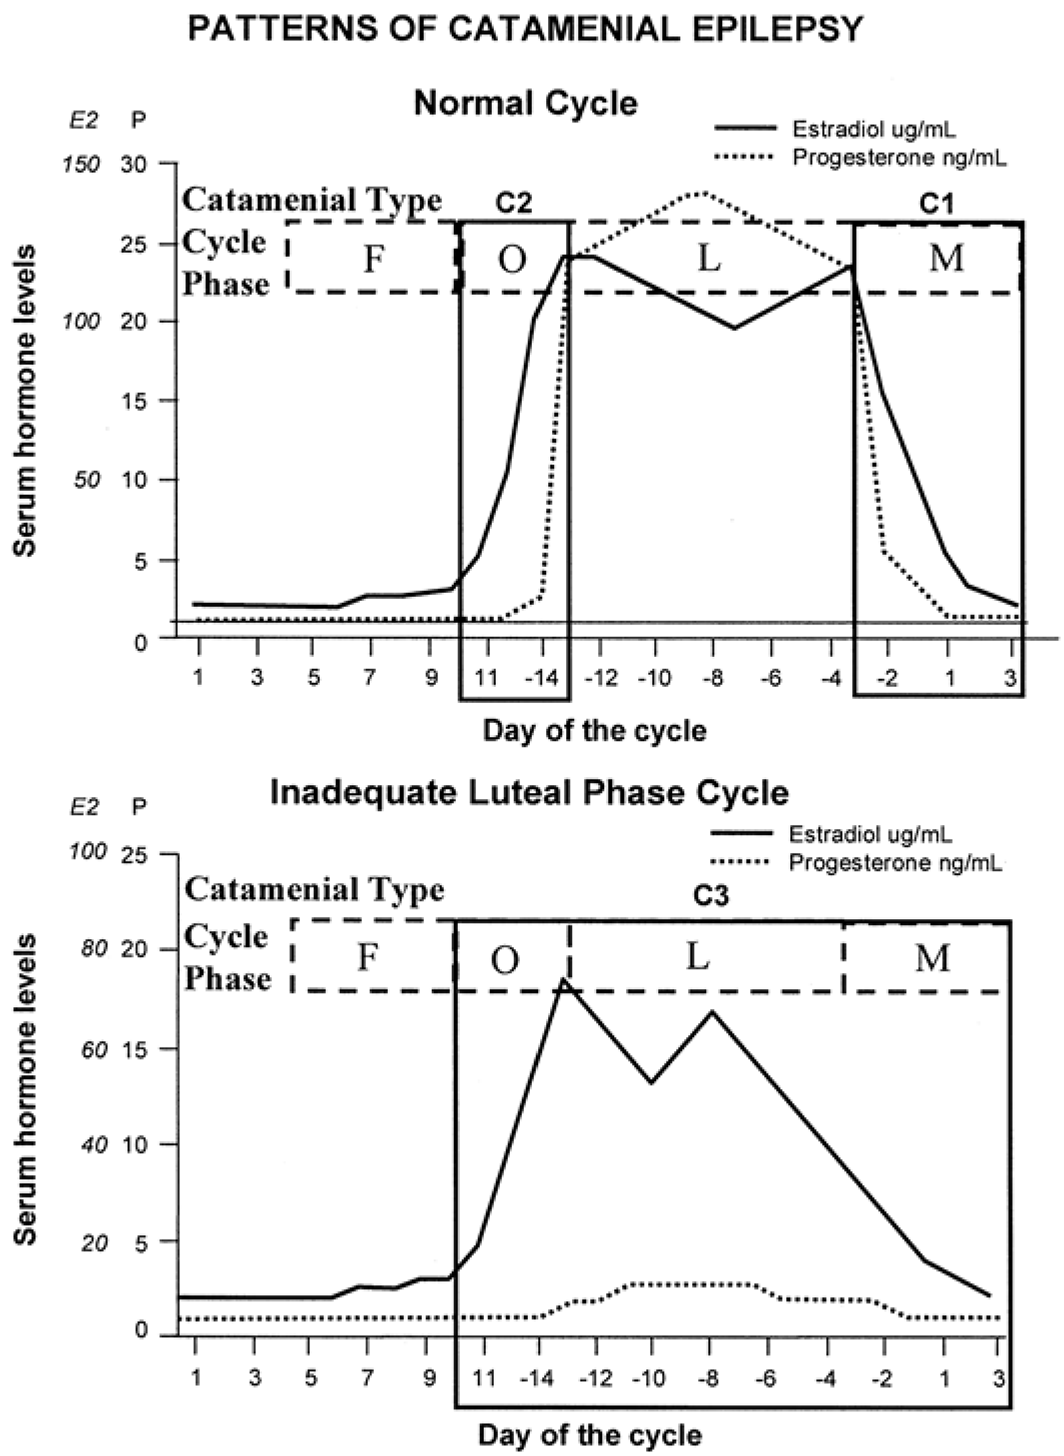

FIGURE 1. Three patterns of catamenial epilepsy: Perimenstrual (C1) and periovulatory (C2) exacerbations during normal ovulatory cycles, and entire second half of the cycle (C3) exacerbation during inadequate luteal-phase cycles where day 1 is the first day of menstrual flow and day 14 is the day of ovulation.

Seizures do not occur randomly in the majority of men and women with epilepsy.[71] They tend to cluster in over 50% of cases.[71] Seizure clusters, in turn, may occur with temporal rhythmicity in a significant proportion of men (29%) and women (35%) with epilepsy.[1] In women, seizures may cluster in relation to the menstrual cycle, commonly known as catamenial epilepsy.[44] This may be attributable to (a) the neuroactive properties of steroid hormones and (b) the cyclic variation in their serum levels.

Physiologic endocrine secretion during the menstrual cycle influences the occurrence of seizures (Fig. 1). In ovulatory cycles, seizure frequency shows a statistically significant positive correlation with the serum estradiol:progesterone ratio.[2] This ratio is highest during the days prior to ovulation and menstruation and is lowest during the early and midluteal phases.[2] The premenstrual exacerbation of seizures has been attributed to the rapid withdrawal of the antiseizure effects of progesterone.[2,52] Midcycle exacerbations may be due to the preovulatory surge of estrogen, unaccompanied by any rise in progesterone until ovulation occurs.[2,44] Seizures are least common during the midluteal phase when progesterone levels are highest,[2,52] except in anovulatory cycles, in which the midcycle surge in estrogen still occurs, albeit not as high as in ovulatory cycles, but unaccompanied by any substantial increase in progesterone levels.[25]

Herzog et al.[25] presented statistical evidence to support the concept of catamenial epilepsy and the existence of at least three distinct patterns of seizure exacerbation in relation to the menstrual cycle (Fig. 1): (a) perimenstrual (C1: days –3 to 3) and (b) periovulatory (C2: days 10 to –13) in normal cycles, and (c) luteal (C3: days 10 to 3) in inadequate luteal phase cycles. In these cycles, day 1 is the first day of menstrual flow and ovulation is presumed to occur 14 days before the subsequent onset of menses (day –14). These three patterns can be demonstrated simply by (a) charting menses and seizures and

(b) obtaining a midluteal phase serum progesterone level to distinguish between normal and inadequate luteal-phase cycles (<5 ng/mL).

While the precise definition of catamenial epilepsy remains arbitrary, one may maximize the efficiency of distinguishing between women whose seizure occurrence shows a high versus low degree of hormonal sensitivity by using the points of inflection of the S-shaped distribution curves that define the relationship between the severity of seizure exacerbation and the number of women who have exacerbation.[25] These points are calculated to be in the vicinity of a twofold increase in average daily seizure frequency during the phases of exacerbation relative to the baseline phases for all three types of catamenial exacerbation. We propose the use of these points of inflection values in seizure frequency for the designation of catamenial epilepsy. By this criterion, approximately one third of women with intractable partial epilepsy would qualify for the designation of having catamenial epilepsy.[25,32] Adoption of a standard albeit arbitrary nomenclature may provide greater uniformity to study designs for the investigation of the pathogenesis and treatment of catamenial seizure exacerbation.

Table 1 Investigational Sex Hormone Treatments of Women with Epilepsy

Investigational treatments	Dosage	Potential adverse effects
Progesterone lozenges	Days 14–25: ½–1 lozenge tid Days 26–27: ¼ - ½ lozenge tid Day 28: 1/4 lozenge tid	Sedation, depression, breast tenderness, vaginal bleeding, constipation, exacerbation of asthma, weight gain
Depomedroxyprogesterone	150–250 mg IM q1–3mo	As above plus delay of months to 2 years in recovery of ovulatory cycles during which time seizure numbers may increase sometimes beyond baseline
GnRH analog	Leuprolide:	Menopausal symptoms unless concomitant

	3.75 mg IM q4wk 11.25 mg IM q12wk	estradiol and progesterone supplement is administered
Clomiphene	Days 5–9: 25-50 mg daily	Ovarian overstimulation syndrome (distention of ovaries can be very painful)

GnRH, gonadotrophin-releasing hormone.

Table 2 Adjunctive Cyclic Progestogen Therapy

	Medroxy progesterone (Herzog 1983)	Progesterone suppositories (Herzog 1986)	Progesterone lozenges (Herzog 1995)	Progesterone lozenges (Herzog 3-year follow-up)
Regimen	5-10 mg qd days 15–28 of cycle	100–200 mg tid days 15–28 of cycle	100–200 mg tid days 15–28 of cycle	100–200 mg tid days 15–28 of cycle
Assessment	@ 3 months	@ 3 months	@ 3 months	@ 3 years
Subjects	24	8	25	15 of original 25
Number improved	10 (42%)	6 (75%)	18 (72%)	15 (100%/60% overall)
Seizure frequency	-10%	-68%[a]	-54%[b] CPS -58%[a] SGMS	-62%[b] CPS -74%[a] SGMS

[a] $p < 0.05$.
[b] $p < 0.01$.
CPS, complex partial seizures; SGHS, secondary generalized motor seizures.

Sex-Hormone Treatment of Seizures in Women

Progestogen Therapy

The term *progestogen* refers to the broad class of progestational agents. These include progesterone (i.e., naturally occurring progesterone) and progestins (i.e., synthetic progestational agents). Progestogen treatment (Tables 1 and 2) has taken two forms: (a) cyclic progesterone therapy that supplements progesterone during the luteal phase and withdraws it gradually premenstrually and (b) suppressive therapy in which the goal is to suppress the menstrual cycle, which is generally accomplished using injectable progestins or gonadotropin-releasing hormone analogs.

Cyclic Progesterone Therapy

In contrast to published cyclic oral progestin investigations that did not result in significant reduction of seizure frequency,[10,54] two open-label trials of adjunctive progesterone therapy did result in clinically important and statistically significant reductions in seizure occurrence (Table 2).[18,24] Progesterone therapy benefits some women with catamenial epilepsy.[18,23,24] In one investigation of women who had inadequate luteal-phase cycles with catamenial exacerbation of intractable complex partial seizures, six of eight women experienced improved seizure control with a 68% decline in average monthly seizure frequency over 3 months for the whole group.[18] In a subsequent open trial of adjunctive cyclic progesterone versus the optimal antiseizure medication alone in 25 women (14 with inadequate luteal-phase or anovulatory cycles and 11 with normal cycles and perimenstrual seizure exacerbation), 19 (72%) experienced fewer seizures with an overall average monthly decline of 54% for complex partial and 58% for secondary generalized seizures over 3 months.[24] Progesterone was more efficacious when administered during the entire second half of the cycle, rather than just premenstrually, and then tapered and discontinued gradually over 3 or 4 days at the end of the cycle.[24] Failure to taper gradually premenstrually can result in rebound seizure exacerbation. At 3 years, the average daily seizure frequency per patient showed that the 15 women who remained on cyclic progesterone therapy and their original antiepileptic drugs continued to show improved seizure control in comparison to their own baseline (Table 2: 3-year follow-up).[26] Three women were entirely seizure free. Four had total seizure reductions of 75% to 99%. Eight had reductions of 50% to 74%. Complex

partial seizures in these 15 were lower by a statistically significant 62% (baseline: 0.328, 3-year follow-up: 0.125; p <0.01); secondary generalized motor seizures, by 74% (baseline: 0.148, 3-year follow-up: 0.038; p <0.01). Antiepileptic drug serum levels continued to show no significant change. The three remaining women who continued on progesterone therapy had 10% to 50% improvement at the end of the original investigation at 3 months and were not considered further because they changed antiepileptic drugs.

By way of critique, the weakness of these preliminary progesterone investigations is that they were not placebo controlled or blinded. The favorable 3-year follow-up results are biased by analysis of only 15 of the original 25 subjects. These 15 who remained on the original treatment regimen are more likely to represent those who had the most favorable response. There are reasons, however, to consider that the results of this investigation may represent more than placebo effects: (a) few placebo studies, including our own progestin trial that used a similar methodology and could be used, therefore, as a retrospective control, show favorable response in more than 50% of subjects; (b) few placebo treatments have resulted in >50% seizure reduction; and (c) while placebo effects generally wear off over a few months, substantial and statistically significant improvements in the present investigation persisted after 3 years in the majority of subjects.[28] Another argument against the placebo explanation is that the beneficial effect of progesterone can be eliminated by the concomitant use of a reductase inhibitor[31] that presumably blocks the reduction of progesterone to its potent GABAergic metabolite allopregnanolone. Finally, there is transcranial magnetic stimulation evidence that progesterone may increase inhibition in the brain premenstrually.[29] A prospective multicenter, randomized, double-blind, placebo-controlled investigation of cyclic, adjunctive progesterone therapy in the management of women with catamenially exacerbated, intractable localization-related epilepsy is now under way.[32]

Natural progesterone is available as an extract of yams or soy in lozenge form in variable dosages ranging from 25 to 200 mg and should be administered three times daily because of its brief half-life of about 4 to 6 hours.[18,22,24] The daily regimen to achieve physiologic luteal-range serum levels measured 4 hours after administration ranges from 50 to 200 mg., taken three times daily, with the usual optimal daily dose ranging from 300 to 600 mg.[18,22,24] The maintenance dosage and regimen should be individualized and based on a combination of clinical response and serum progesterone levels between 20 and 40 ng/mL. Progesterone is also available in micronized form in an oral capsule preparation that may also exert similar antiseizure effects, although formal investigations to this effect are lacking. Theoretically, it is possible that first pass through the liver using the oral micronized form may result in the delivery of different concentrations of progesterone and its neuroactive metabolite to the brain.

Adverse effects occur with overdosage and include sedation, emotional depression, and asthenia.[18,22,24] Progesterone use may also occasionally be associated with breast tenderness, weight gain, irregular vaginal bleeding, and sometimes constipation. The vehicle used to dissolve progesterone for suppository use may rarely be responsible for the development of an allergic rash. Discontinuation of the hormone or lowering of the dosage resolves these side effects.[18,22,24]

Drug interactions are an important consideration. Higher progesterone dosages may be required to achieve luteal-range levels in women who take antiseizure medications because carbamazepine, phenytoin, and barbiturates are known to enhance the hepatic metabolism of gonadal and adrenal steroid hormones as well as to increase hormonal binding to serum proteins.[55] Progesterone use has been associated with changes in antiseizure medication levels in some cases, but this effect has been sporadic and not in a predictable direction. Therefore, total and possibly free serum antiseizure medication levels should be checked regularly during concomitant hormonal therapy.

Progestin Therapy

Parenteral depomedroxyprogesterone may lower seizure frequency when it is given in sufficient dosage to induce amenorrhea.[54,81] In one open-label study of 14 women with refractory partial seizures and normal ovulatory cycles, parenteral depomedroxyprogesterone administration in doses large enough to induce amenorrhea (i.e., 120 to 150 mg every 6 to 12 weeks) resulted in a 39% seizure reduction.[54] It was unclear whether the effect was due to direct anticonvulsant activity of medroxyprogesterone or to the hormonal consequences of the induced amenorrhea. One patient who had absence rather than partial seizures did not improve. Side effects included those encountered with natural progesterone. Depot administration, however, is also commonly associated with hot flashes, irregular breakthrough vaginal bleeding, and a lengthy delay of 6 to 12 months in the return of regular ovulatory cycles.[54] Long-term hypoestrogenic effects on cardiovascular and emotional status need to be considered with chronic use. Bone density is generally maintained.

Oral synthetic progestins administered cyclically or continuously have not proven to be an effective therapy for seizures in clinical investigations,[10,54] although individual successes with continuous daily oral use of norethisterone and combination pills have been reported.[18]

Clomiphene Therapy

Clomiphene acts as an estrogen antagonist to increase gonadotropin secretion and induce ovulatory cycles in estrogen-secreting anovulatory women who do not have primary pituitary or ovarian failure.[7] Normalization of reproductive endocrine functions and menstrual cycles among women who have both partial seizures and menstrual disorders with documented inadequate luteal phase has been demonstrated to significantly and sometimes dramatically lessen seizure frequency.[20,47] In one investigation of 12 women, 10 improved and seizure frequency declined by 87%.[20] Clomiphene, however, is a drug with considerable pharmacologic potency and potentially disturbing side effects. Therefore, it should be used only after potential risks and benefits are weighed carefully and treatment with antiseizure medications and progesterone prove inadequate to control seizures. Clomiphene should not be administered in cases of suspected pregnancy or in the absence of adequate birth control measures unless it is used in conjunction with a gynecologist as part of a fertility program. Endometrial carcinoma should be ruled out prior to institution of therapy if abnormal uterine bleeding is present and normal liver function should be assured since clomiphene is excreted in the feces via the enterohepatic circulation.

Clomiphene is available in 50-mg tablets and can be administered in dosages ranging from 25 to 100 mg daily on days 5 to 9 of each cycle. Treatment should be initiated with the lowest dose, and the daily dose may be raised by increments of 25 to 50 mg monthly as required to induce an ovulatory cycle with normal luteal phase. Improved seizure control has been related to normalization of the reproductive endocrine cycle but, as yet, has not been recognized as an approved indication for continued clomiphene use.

In the one published investigation of clomiphene use in a series of 12 women with complex partial seizures, six experienced some side effects ranging from minor breast tenderness and pelvic cramps in three to severe lower abdominal

pain with ultrasound-documented ovarian cysts due to overstimulation of follicular development in two, and one unwanted pregnancy.[20] Women with polycystic ovarian syndrome, which constituted the majority of the epileptic women in this investigation, appeared to be particularly sensitive to the development of overstimulation of follicular development and painful cyst formation.[20] Discontinuation of clomiphene was associated with a return of ovarian size to normal in both cases encountered in this series.[20]

Clomiphene therapy has not significantly altered total or free serum antiseizure medication levels in the few cases that have been studied, but a well-controlled investigation of possible drug interactions remains to be carried out.[20]

Gonadotrophin-releasing Hormone Analog Therapy

Bauer et al.[4] used triptorelin, a synthetic gonadotrophin-releasing hormone (GnRH) analog (3.75 mg) in a controlled release depot form intramuscularly every 4 weeks for an average of 11.8 months in 10 women (aged 20 to 50) with catamenial seizures intractable to high therapeutic doses of carbamazepine, diphenylhydantoin, phenobarbital, and valproic acid in monotherapy or combined. They remained on a stable dose of the anticonvulsant throughout the period of treatment with triptorelin. They reported that three patients became seizure free; four showed a decrease in seizure frequency of up to 50%. In one, the duration of seizures was shortened; two had no therapeutic effect. These results were attained within the first 2 months of starting triptorelin. The study was not a controlled study and longer-term follow-up was not available for some of the patients. Serum luteinizing hormone (LH) and estrogen were measured in one patient before and during the second month of triptorelin treatment, and as expected showed marked inhibition of LH and estrogen production. All the women became amenorrheic. Eight of the ten patients experienced hot flashes, headache, or weight gain.

Haider and Barnett[17] reported on their use of goserelin 3.6 mg subcutaneously every 4 weeks in a 41-year-old woman who had had frequent catamenial status epilepticus despite therapeutic anticonvulsant drug levels, which also did not respond to levonorgestrel/ethinyl estradiol. They reported a decrease in frequency from ten admissions for status epilepticus to three over a similar period.

GnRH analogs basically create a medical oophorectomy. Common side effects are flushing, vaginal dryness, and dyspareunia. Serious long-term risks include osteoporosis and cardiovascular disease. Reid and Gangar[64] suggested the addition of medroxyprogesterone acetate and conjugated estrogens to goserelin to prevent this while still abolishing most of the cyclical fluctuations of ovarian hormones. Finkelstein et al.[11] recently discussed the use of parathyroid hormone to prevent bone loss in women treated with GnRH analogs. Although neither Bauer et al.[4] nor Haider and Barrett[17] reported exacerbation of seizures with GnRH analogs, Herzog[23] found that during the first 3 weeks, when there is an initial stimulation of estrogen before its production is inhibited, some women experienced such a marked exacerbation of their seizures and auras that they could not tolerate further use of GnRH analog.

Sex-Hormone Treatment of Seizures in Men

Sex-hormone treatment trials in men with epilepsy originated in attempts to treat sexual dysfunction rather than seizures. Sexual interest and potency, as assessed by questionnaires in men with localization-related epilepsy and normal controls, suggest that sexual dysfunction occurs in 20% to 25% of men with epilepsy.[19,29,30] It occurs substantially and statistically significantly more often in the setting of hypogonadism.[19,29,30] Hypogonadism in men with epilepsy is unusually common and has been attributed to a number of possible causes. These include (a) psychosocial stress,[30] (b) antiepileptic drugs,[34,43] and (c) epilepsy itself.[19,29,39,58] Each of these is recognized to alter reproductive endocrine secretion. Of note, enzyme-inducing antiepileptic drugs, specifically carbamazepine and phenytoin, have been associated with significantly more sexual dysfunction and lower bioavailable testosterone levels than lamotrigine.[34]

Testosterone Therapy

Testosterone replacement is the most common form of therapy for hypogonadism. In 12 men with localization-related epilepsy who had sexual dysfunction and hypogonadism, intramuscular injections of testosterone enanthate in doses of 200 to 400 mg every 3 or 4 weeks have been associated with normalization of serum-free testosterone levels and moderate improvement in sexual interest and potency scores in all 12 men. Seizure frequency showed no significant change.[26] An ongoing study using biweekly rather than monthly administrations of similar doses of testosterone, however, is showing notably favorable effects not only on sexual function, but also on mood and seizure frequency (Herzog, unpublished). Therefore, the role of testosterone supplement in the management of seizures remains as yet unresolved.

Therapy with Testosterone and Aromatase Inhibitor

Since enzyme-inducing antiepileptic drug use is associated with the rapid conversion of testosterone to estradiol[22,30] that might negatively impact seizure control and androgen production, the use of aromatase inhibitors has been tried.[26] The administration of 300 to 500 mg of testolactone, an aromatase inhibitor, daily and of 400 mg of Depo-Testosterone biweekly to a 52-year-old man with intractable seizures and hypogonadism on carbamazepine improved sexual questionnaire scores and decreased seizure frequency more than the addition of testosterone alone.[26] One study did a retrospective comparison that showed a superior outcome for combined treatment with testosterone and an aromatase inhibitor as compared to testosterone alone not only on sexual function, but also on seizure frequency.

Clomiphene Therapy

Clomiphene dramatically improved sexual interest, potency, and seizure control in a case report of a man with complex partial seizures and hypogonadotropic hypogonadism.[21] Seizures were eliminated during clomiphene use in another case with epilepsy and oligospermia.[8] Clomiphene offered no benefit, however, for a man who had complex partial seizures and hypergonadotropic hypogonadism, that is, gonadal failure.[21] Total and free antiepileptic drug levels were not affected. The mechanism of clomiphene action on seizure activity is conjectural, but may involve the normalization of serum testosterone levels along with increased inhibitory neuroactive steroid concentrations or direct antiestrogenic effects on epileptogenic limbic structures, which have a high density of estradiol receptors.

P.1393

Summary and Conclusions

Many natural and synthetic reproductive hormones can increase or decrease neuronal excitability. Physiologic, pathologic, and pharmacologic endocrine changes, therefore, can be responsible for the exacerbation of seizures. Hormones, however, may also provide improved seizure control when used in conjunction with antiepileptic drugs or, perhaps rarely, alone. Early investigations suggest that hormonal therapy may be a useful adjunct in the comprehensive management of epilepsy, specifically in the treatment of seizures, reproductive dysfunction, and emotional disorders.[52]

Chapter 131

Vagus Nerve Stimulation

Steven C. Schachter

Paul Boon

Introduction

For patients with medically refractory seizures, the major nonpharmacologic options are limited to epilepsy surgery, the ketogenic diet, and vagus nerve stimulation (VNS). In 1997, the VNS Therapy System (Cyberonics, Inc.) was approved by the Food and Drug Administration (FDA) as adjunctive therapy for adults and adolescents over 12 years of age whose partial-onset seizures were refractory to antiepileptic drugs (AEDs), thereby becoming the first (and only) FDA-approved nonpharmacologic treatment for epilepsy. This chapter reviews the relevant anatomy, possible mechanisms of action, and clinical results in patients with epilepsy.

Relevant Anatomy

The cell bodies of the nodose ganglion relay afferent sensory information that is carried by the vagus nerve to the nucleus of the solitary tract (NTS). From there, one pathway ascends to the forebrain via the parabrachial nucleus, lateral to the locus coeruleus.[98] The parabrachial nucleus transmits sensations of visceral origin to the ventroposterior parvocellular nucleus of the thalamus, which then projects to the insular cortex.[18] The parabrachial nucleus and NTS also project to the amygdala and basal forebrain. c-Fos mapping studies show activation of these nuclei and pathways by VNS,[84] and one intriguing animal study underlines the possible involvement of the locus coeruleus.[52]

Because the right vagus innervates the cardiac atria more than the left vagus nerve and the left vagus nerve provides the predominant innervation of the ventricles,[97] electrical stimulation of the left vagus nerve has generally been used in clinical practice, though right-sided VNS has been reported safe in one case series[73] and is equally effective against seizures as left-sided stimulation in rat models of epilepsy.[53]

Mechanism of Action

Neurophysiologic Studies

Early work showed that repetitive VNS either synchronizes or desynchronizes cortical activity in anesthetized animals, depending on stimulus frequency and current strength, which determines whether myelinated fibers are activated.[20,21,22] Desynchronization of cortical rhythms implied a possible anticonvulsant effect of VNS and prompted further animal experiments in a variety of models,[61,74,104,114,115,116] including a recent report in genetic absence epilepsy rats from Strasbourg that showed no effect of VNS.[23]

Low-intensity trains of VNS (100 µA, 30 Hz, 500 µs, 20 seconds on time) have been found to hyperpolarize pyramidal neurons of rat parietal association cortex.[117] Interestingly, low-intensity stimulation, which predominantly activates myelinated fibers, was more effective in this model in inducing long-lasting inhibitory effects than higher stimulus intensities, which also entrain nonmyelinated vagus fibers. Consistent with these findings, a study of transcranial magnetic stimulation in five patients treated with VNS for epilepsy showed significantly increased cortical inhibition associated with stimulation without any evidence of an effect on cortical excitability.[27] Further, in a limited series of patients whose seizures responded to VNS, Marrosu et al.

found normalization of impaired neuronal inhibition.[71] The same group has more recently shown decreased synchronization of theta frequencies and an increased gamma power spectrum and synchronization in 11 patients treated with VNS.[70] By contrast, Ebus et al. were unable to find a relationship between clinical response to VNS and a reduction of electroencephalographic (EEG) spike discharges after implantation compared to preimplantation.[28]

Neuroimaging Studies

The intracranial effects of VNS have been evaluated with positron emission tomography (PET), single photon emission computed tomography (SPECT), and functional magnetic resonance imaging (fMRI) scanning. The findings on PET studies have variably demonstrated increased blood flow in the ipsilateral anterior thalamus and cingulate cortex[35] or the contralateral thalamus and temporal cortex, and ipsilateral putamen and cerebellum.[50] The group at Emory correlated the extent of bilateral thalamic changes in blood flow and reductions in seizure frequency.[41]

SPECT studies have generally shown decreased regional cerebral blood flow in the medial thalamic regions bilaterally,[93,109] without a relationship between the extent of these changes and clinical outcomes with VNS.[111] An exception is the study of Van Laere et al., which showed a correlation between long-term clinical efficacy and (a) initial stimulation changes in the right amygdala and (b) right hippocampal perfusion changes.[109]

In a series of nonepileptic patients enrolled in a trial of VNS for depression, Bohning et al. assessed VNS-synchronized functional MRI (fMRI) and found changes in bilateral orbitofrontal and parieto-occipital cortices, the left temporal cortex, the hypothalamus, and the left amygdala.[12] The same group has shown that the pulse width of VNS determines the pattern of regional activation, and that a pulse width of 130 microseconds is insufficient for activation of some regions.[78] An fMRI study in four patients treated for epilepsy found that VNS activated the left superior temporal gyrus, inferior frontal gyrus (bilateral), medial portions of the superior frontal gyrus in the region of the supplementary motor cortex (bilateral), and posterior aspect of the middle frontal gyrus (bilateral).[103]

Other fMRI studies reported activations in the thalami (left greater than right) and insular cortices[83] and positive correlations between thalamic activation and clinical response to VNS.[60]

Short-term Efficacy Studies

The first patient with epilepsy was treated with VNS in 1988,[90] followed by two pivotal trials of patients with partial epilepsy, the E03 study[8,37,92,107] and the E05 study.[38] Prior to approval, a compassionate-use trial evaluated VNS in 124 patients with intractable seizures (the E04 study).[56]

The E03 and E05 studies were multicenter, blind, randomized trials that compared two different VNS stimulation protocols for partial-onset seizures: High stimulation (30 Hz, 30 seconds on, 5 minutes off, 500 microseconds pulse width) and low stimulation (1 Hz, 30 seconds on, 90 to 180 minutes off, 130 microseconds pulse width). Enrolled patients were at least 12 years of age, with at least six seizures per month treated with a mean of 2.1 AEDs at study entry.

In both studies, the primary measure of efficacy was the percentage change in seizure frequency during VNS treatment compared to the preimplantation baseline. Changes in seizure frequencies in the high- and low-stimulation groups were then compared in each study. The hypothesis was that the low-stimulation treatment was less effective than the high-stimulation treatment. In the E03 study, the high-stimulation group had a mean reduction in seizure frequency of 24.5%, versus 6.1% for the low-stimulation group ($p = 0.01$). Furthermore, 31% of patients receiving high stimulation had at least 50% reduction in seizures compared to 13% of patients in the low-stimulation group ($p = 0.02$). In the E05 study, the corresponding decreases were 28% and 15% for the high- and low-stimulation groups, respectively ($p = 0.039$), and 11% of patients in the high-stimulation group had at least a >75% reduction of seizures compared to baseline, versus 2% of patients in the low-stimulation group ($p = 0.01$). Thus, both studies showed that high stimulation was more effective than low stimulation.

Long-term Efficacy

Seizure control is maintained in long-term studies of VNS,[26,37,41,42,43,44,45,46,47,48,76,95,108,113] including in catastrophic childhood epilepsy,[67] but these results should be interpreted cautiously since long-term studies are not blinded, and stimulation parameters and AED dosages could be adjusted as clinically indicated. One retrospective study of 269 patients whose AEDs were kept constant for 1 year after VNS implantation found a 45% seizure reduction at 3 months postimplantation compared to preimplantation baseline, and 58% reduction at 12 months postimplantation.[57] On-demand stimulation with the supplied magnet can be an effective adjunct to chronic stimulation for attenuating or interrupting seizures in some patients.[15]

Efficacy in Other Seizure Types and in Children

A number of open case reports and uncontrolled studies of VNS have been published, suggesting possible benefits for patients with medically refractory generalized seizures; in children with intractable seizures, including Lennox-Gastaut syndrome[4,16,32,40,44,65,79,80,82,86,89]; and in developmentally disabled or mentally retarded patients with epilepsy.[36,45] In one adult described in a case report, VNS apparently terminated status epilepticus.[88] Given the limitations of all these studies, randomized, controlled trials are needed to further evaluate VNS in these populations.

Effects on Other Comorbid Conditions

Two studies showed improvement of mood in patients with medically refractory partial-onset seizures[29,39] independent of changes in seizure control. Other studies have also found improvements in mood, as well as reduced tenseness and dysphoria.[1,43,81]

Other studies suggest that VNS may improve daytime alertness and vigilance,[33,94] as well as sleep quality in some patients with reduced daytime sleepiness,[69] though the opposite effect has been described in another study.[42]

Safety and Tolerability of Vagal Nerve Stimulation in Patients with Epilepsy

In the E03 study, side effects that occurred in at least 5% of patients receiving high stimulation were hoarseness (37%), throat pain (11%), coughing (7%), shortness of breath (6%), tingling (6%), and muscle pain (6%), although hoarseness was the only side effect that occurred significantly more often with high stimulation than with low stimulation. In the E05 study, shortness of breath and voice alteration were the only two side effects that occurred significantly more often in the high-stimulation group than in the low-stimulation group. No significant changes in heart rhythm (as measured by Holter monitoring) or pulmonary function were found. No deaths occurred during either study.

Long-term safety and tolerability studies of VNS generally show improved tolerability over time. Among 444 patients who continued VNS after participating in a clinical study, the most commonly reported side effects at the end of the first year postimplantation were voice alteration (29%) and tingling (12%); at the end of 2 years, voice alteration (19%) and cough (6%); and at 3 years, shortness of breath (3%).[77]

Though physiologic studies have generally found no clinically relevant effects of chronic VNS on cardiorespiratory function,[10,31,34] transient asystole lasting up to 20 seconds has been reported in association with the lead test, which is performed during implantation, in approximately 0.1% of cases.[3,5,106] Complete heart block due to atrioventricular nodal block has been documented in one series.[2] There have been no reported serious consequences in any of these reported patients.

A variety of other side effects have been described in case reports or small series.[11,17,48,49,58,63,68,91,96] Children with severe mental and motor retardation on assisted feeding may aspirate if fed during VNS.[66,99] Infections of the subcutaneous pocket that holds the VNS generator, while infrequent, usually require explantation.[87,101]

Patients have been cautioned by Cyberonics not to undergo short-wave diathermy, microwave diathermy, or therapeutic ultrasound diathermy. This warning is based on the theoretic possibility that the generator or lead could heat up and then cause thermal tissue damage, although there are no documented cases of this complication in VNS-treated patients.

After the VNS generator battery is expended, seizure frequency may increase in some patients,[105,112] and others may note decreased or irregular perception of stimulation.[112] Fortunately, the end of battery service can be predicted with the current VNS model, allowing for elective generator replacement before the battery is fully depleted.

The presence of an implanted pacemaker is widely regarded as an absolute contraindication to MRI. In MRI of the heart, considerable heating at the lead tip occurred in animal experiments. Changes of pacing parameters due to MRI could be seen in chronic experiments. Potential risk of tissue damage could not be excluded, even though no reproducible alterations at the histologic level could be found.[64] Dramatic increases in both MRI usage and device-based therapy have resulted in an estimated 50% to 75% probability of a patient being indicated for an MRI over the lifetime of his or her device.

Some recent studies, all of which addressed cardiac pacemakers and defibrillators, have demonstrated “safe procedures” and “no adverse events” in the limited populations, clinical situations, and specific devices and lead orientations tested. While these investigations are useful to help ascertain the hazards for patients with cardiac devices, they do not demonstrate clear freedom from risk.[47]

Since 1996, changes in pacemaker electronics including decreased ferromagnetic content, increased sophistication of the circuitry, and on-board computer capabilities suggest that the absolute contraindication of MRI for pacemaker patients should be reconsidered.[62] An fMRI study at 1.5T showed that enhanced product ion (EPI) scanning could be performed safely in epilepsy patients with an implanted vagal nerve stimulator.[103] From what is currently known, it can be concluded that safety during MRI procedures, especially with 3T, is not established. The future challenge for manufacturers is that all components of active implantable systems should be engineered during the design stage to provide safety in current and evolving MRI environments. Subsequently, device manufacturers need to secure regulatory approval to confirm safety of their devices under multiple clinical and technical variables.

Clinical Use

In clinical use, VNS requires a team of health care providers to implant the device, teach the patient and his or her family about its use, titrate the stimulation parameters to optimum clinical response, and monitor the patient's side effects and the device's battery life. The physician can program the output current (typically 1 mA), signal frequency (typically 30 Hz), signal pulse width (typically 500 microseconds), signal on time (typically 30 seconds), and signal off time (typically 5 minutes). In addition, magnet-activated stimulus parameters—pulse width, output current, and on time—are also programmable.

Besides intermittent stimulation, on-demand stimulation may be brought on by the patient or a companion by placing the supplied magnet on the patient's chest over the generator for several seconds. The stimulator settings employed for on-demand stimulation usually utilize a higher current and pulse width than those used for intermittent stimulation. Some patients have reported that on-demand stimulation interrupts a seizure or reduces its severity if administered at the onset of the seizure, and can be used by patients to attempt to abort an ongoing seizure.

The generator delivers intermittent stimulation until the battery wears out, which is predicted to take 6 to 11 years with the Model 102, depending on stimulation parameters used for an individual patient.

Summary and Conclusions

VNS is effective, safe, and well tolerated in patients with long-standing, refractory partial-onset seizures.[25] There has been no indication of reduction of effectiveness in long-term, open studies. Side effects occur during stimulation in the minority of patients, are usually mild to moderate in severity, and diminish with time or reduction in stimulation intensity. Caution should be exercised when considering VNS for patients with pre-existing sleep apnea,[72] cardiac conduction disorders, and asthma.[63] Surgical complications are infrequent, especially with enhancements in surgical techniques and postoperative care.[19,59,85,110]

Since VNS was approved for epilepsy, clinicians have actively debated its role.[6,9,14,75] Today VNS is generally considered an option for patients with well-documented medically refractory partial-onset seizures, who are either opposed to intracranial surgery, who are not candidates,[54] or whose medically refractory seizures were not substantially improved by prior intracranial epilepsy surgery.[51] Two studies have evaluated the costs of VNS treatment. One study showed an average of $3,000 annual savings in hospital costs per VNS-treated patient, comparing the 18 months preceding implantation with the 18 months after implantation.[7] A prospective study showed that among patients with refractory epilepsy who were nonsurgical candidates, epilepsy-related direct medical costs over 2 years were lower in those who underwent VNS compared to medically treated patients.[13]

While identification of factors that accurately predict the outcome of VNS has been elusive, one retrospective study found that an absence of bilateral interictal epileptiform discharges correlated with seizure freedom during the first year postimplantation,[46] a finding that requires confirmation in a larger, prospective study.

Further controlled studies are also needed to more fully understand the safety, tolerability, and efficacy profile of VNS in children and in patients with generalized seizures, to determine whether any stimulation settings provide more benefit than standard initial settings,[24,55] and to identify patients preoperatively whose seizures are likely to improve with VNS, thereby avoiding the potential surgical complications and costs of implantation in patients who have no clinical response to VNS.[30]

Behavioral Therapies

Peter Wolf

> To abolish this disease, one must apply the element which is opposed to it, and not what is favourable and habituated.
>
> *On the Sacred Disease*—Hippocrates

Introduction

Epilepsy is traditionally treated with drugs, and, for pharmacoresistant cases, there may be a possibility of epilepsy surgery. But, although little noticed in textbooks, there is a third line of therapy that can be useful if applied to the appropriate patients: Behavior modification. Behavior modification can be defined as any type of nonpharmacologic intervention aimed at the prevention or abortion of seizures. Like all other epilepsy therapies, the ultimate goal of behavior modification is complete seizure control. To achieve this goal, behavior modification can be used alone or in conjunction with other therapies. It can be used to arrest seizure activity after onset or to prevent seizures altogether.

Arrest of Seizures

History

Treating seizures by some countermeasure that interrupts their development is the oldest of all existing therapies. Probably discovered by patients, arresting seizures was mentioned as an established procedure by Hellenistic physicians such as Aretaeus the Cappadocian and Galen, in the first and second centuries. It was well known to physicians that seizures beginning distally in a limb and spreading to the brain could be interrupted by manipulations such as the application of ligatures. This may have contributed to the concept of sympathetic epilepsy, which was thought to originate in the periphery where a pneumatic substance would spread through the body and to the brain like poison from the bite of a scorpion.[30] The ligature was applied in view of arresting the spread of this substance.

The arrest of seizures through application of ligatures remained in use throughout the history of medicine. Tissot[31] mentions numerous examples and regarded the effectiveness of such procedures as supporting the concept of sympathetic epilepsy. One of the discoveries that seriously shattered this concept was the finding of Odier in 1811[11] that ligature arrested fits due to a cerebral tumor as effectually and more frequently than with any other cause.

Under the influence of Brown-Séquard's experiments, where external stimuli produced convulsions, Jackson[15] suggested in 1870 that a similar relation existed between a peripheral aura sensation preceding the seizure and the internal discharge, the beginning of which was reflected in the outward spasm. However, such a relation could explain only the action of a ligature applied between a first aura sensation and the onset of spasm—not after the onset of the spasm.

Gowers[11] conceived a totally new theory:

> “The arrest must be effected, not in the limb convulsed, but in the centre in which the

discharge is occurring, of which the local convulsion is the outward manifestation. The strong peripheral impression on the limb above the part convulsed probably raises the resistance in the nerve-cells of the corresponding parts of the brain, and thus arrests the spread of the discharge. The effect of the ligature must first be exerted on the sensory centre, and through this on the motor centre. The two are connected intimately, and their mutual interaction must be constant, so that the condition of the motor centre is no doubt readily influenced through the sensory centre. Hence, a fit may be arrested by the ligature, whether it begins by a sensation or by a motion, i.e., whether the sensory or motor centre leads in the discharge. Additional observation is necessary to determine whether the ligature is more effective in one class of fits than in the other."

The knowledge and discussion of these phenomena were common to the British neurologists of the late 19th century. The Jacksonian seizures of the first patient operated on for epilepsy without evidence of a lesion[13] began with flexor twitching of the thumb, and were arrested by stretching the thumb or applying a ligature. For Horsley, this suggested "the possibility of the so-called muscular sense being represented in the excitomotor area."[13] Ligature and passive stretching of a muscle in spasm are simple countermeasures that have often been reported. In other instances, much more intricate procedures were applied.[15]

Gowers[11] reported a variety of countermeasures (Table 1). Ligature proximal to convulsion, forcible prevention of spasm, and other cutaneous stimulations were often successful in seizures commencing in a limb. Muscular exertion, strong olfactory impression, and strong gustatory sensation were sporadically effective in "attacks which begin by a general or bilateral aura, or by the epigastric sensation" and which can rarely be arrested. However, Gowers pointed out that nitrate of amyl, which had been given in view of vasal dilation, was most successful in cases with a deliberate olfactory aura, perhaps acting through the olfactory nerve.

At the turn of the 19th century, when bromides were the only effective pharmacotherapy available whereas epilepsy surgery mostly dealt with focal motor seizures and carried a rather high mortality risk, treatment by behavioral seizure arrest was an important and sophisticated part of the therapeutics of epilepsy. The advent of new, more potent, and better tolerated antiepileptic drugs starting in 1912 with phenobarbital changed this. Epilepsy came to be considered as a disease for the most part curable with drugs that make the seizures disappear.

In more recent years we have become aware that not all patients respond sufficiently to the available drugs, nor do all patients tolerate all drugs well. New drugs have new side effects and are not effective in all pharmacoresistant patients. Epilepsy surgery for these patients is by no means always possible. Stimulation methods are still experimental or have the drawback of being invasive but only palliative.

Table 1 Arrest of Seizures

Ligature proximal to convulsion
Forcible prevention of spasm
Other cutaneous stimulations (pinch, prick, rub)
Muscular (e.g., quickly walking around the room)
Strong olfactory impression (ammonia, nitrite of amyl)
Strong gustatory sensation (chewing a piece of ginger, swallowing a handful of common salt)

From Gowers WR. *Epilepsy and Other Chronic Convulsive Diseases*. London: Wood; 1881.

P.1402

Therefore, additional therapeutic options are sometimes most welcome. In addition, quite some patients today hesitate to take drugs, especially on a long-term basis, and ask for treatment alternatives. Often, such patients are prepared to accept responsibility for and contribute to a therapeutic strategy. Ketogenic and other diets are one type of nonpharmacologic conservative intervention and are dealt with in Section V, Part E, Alternative Approaches. Behavioral modification is another.

Modern Accounts

The modern literature about treatment with seizure arrest starts in 1956 with the important case report of Efron[7,8] about a patient whose epilepsy became cured by using an olfactory stimulus to arrest her habitual olfactory aura. No drug treatment was involved. The olfactory stimulus had been the patient's idea, and it took some time to find the most effective smell and the correct timing of the stimulus. The second and even more interesting step in this case report was the conditioning of the olfactory stimulus to a visual stimulus following a request by the patient who, being a professional singer, wanted to avoid the visible procedure of using a sniff bottle in public. She learned to evoke the smell by looking at and, later, thinking of a bracelet that was used as the conditioned stimulus. After some time, the patient began to experience the conditioned smell instead of her habitual aura; eventually this also stopped.

For a long period, no replications of Efron's work were reported, but two authors[22,23] found independently that about 60% of patients with localization-related seizures had personal experiences with countermeasures to arrest ongoing seizure activity. Richard and Reiter[24] estimated that practically all patients had this kind of experience, but this statement is not based on specific investigations.

The applied countermeasures belong to a variety of categories. Specific sensory stimuli, such as a peripheral ligature for focal seizures commencing in a limb or an olfactory stimulus in a seizure with a habitual olfactory hallucination, relate directly to the cortical area involved in the seizure generation and spread. Many patients apply nonspecific arousal and concentration techniques,[24] the action of which can be understood by the well-known antiepileptic effect of exercise[17]; others rely on relaxation procedures. The antiepileptic actions of yoga[41] and of aromatherapy[1] have recently been reviewed.

Anecdotal Observations

Chance observations of patients who are not in medical treatment have led us to assume that successful self-therapy by seizure arrest may not be uncommon among patients who are not undergoing medical treatment. Many of these patients may not even be aware that they are dealing with epileptic phenomena.[36] This possibility should be considered in future epidemiologic field studies of epilepsy because there is no other way of quantifying it.

Table 2 Curative Effect of Aura Interruption: A Hypothesis

1. Detection of an effective countermeasure
2. Systematic well-timed application of countermeasure
3. Successful arrest of all seizures
4. Conditioned reflex interruption
5. Unlearning of seizures by negative feedback

In this five-step process, steps 2 and 3 represent the therapeutic intervention of behavior modification. The therapy becomes potentially curative only if step 4 can be observed, in which seizure arrest becomes an involuntary conditioned response. Step 5 is hypothetic.

Our own experiences with seizure arrest in drug-resistant patients in a specialized epilepsy center by methods building on spontaneous patient experiences and cortical direct-current (DC) biofeedback[6] indicate that, in resistant patients, treatment by systematic seizure arrest is neither less nor more effective than is treatment by a new drug.[36] However, successful behavioral therapy is only possible with well-motivated patients because it requires an unusual amount of effort and compliance. Sometimes, the intervention must be supported by comprehensive psychotherapy.[2] When patients are successful, increased self-esteem and improved self-control are welcome side effects.

We do not propose that patients use trained seizure arrest as a treatment alternative but, rather, as part of a comprehensive therapeutic program that includes pharmacotherapy. In some patients, a tripartite approach combining pharmacotherapy, surgery, and behavioral seizure arrest may be most appropriate.

Theoretical Concepts

Seizure interruption is an intervention suitable only for focal seizures. This is because seizure discharge starts locally from a small neuron population that is continuously producing paroxysmal depolarizations.[18] When these depolarizations spread to partially affected neurons in the vicinity of the focus, a shift may occur from a normal to a paroxysmal mode of discharge. Even normal neuron populations may become involved in the seizure discharge, which then may become generalized.

On the neuronal level, an intermediate state of activation is a prerequisite to the generation of paroxysmal depolarization shifts.[27] Hyperpolarized neurons are inactive and cannot easily be recruited to fire, whereas strongly depolarized neurons already producing action potentials are not available for further activation. A seizure is arrested if all or most neurons that habitually participate in the secondary seizure spread either cannot be recruited or are unavailable.

Curative Effect

If seizures can be successfully treated by arrest, complete relief may result.[8,36] This is surprising because epilepsy therapy usually aims at complete control, including isolated auras, whereas seizure arrest allows isolated auras (i.e., simple

P.1403

partial seizures) to occur. At best, one would expect this therapeutic achievement to stabilize in the long term. The observation of further improvement seems to indicate that the action is part of the processes of remission that are still little understood.[40] We have suggested a tentative stepwise process (Table 2) that comprises the behavioral therapeutic intervention, observable conditioned responses, and a hypothetic negative feedback mechanism.[36]

Prevention of Seizures

Theoretically, seizure prevention is possible whenever stimuli that precipitate seizures can be defined or conditions that favor the manifestation of seizures can be prevented.

Specific Precipitating Factors

Preventing seizures became possible when specific precipitating factors had been described, that is, with the discovery of what is commonly called *reflex epilepsy*. These factors are discussed in Chapter 257. Forster[10] has devoted extensive investigations to the possibility of treating patients with such disorders by desensitization or extinction of the precipitating stimuli. However, his investigations were little replicated and remained largely isolated. We have reported a partially successful desensitization procedure in a patient with seizures precipitated by touch.[38] In photosensitive epilepsy, the use of protective glasses[3,12,32] and instructions concerning television watching[12,34] have become part of a comprehensive treatment that includes behavioral aspects. In the small group of patients with photosensitive epilepsy, in whom seizures occur exclusively in response to intermittent light stimuli, optic protection may be used as the only line of therapy.[39]

Case 1. Heide W., seen at age 31 years, had, from age 12, a total of six generalized tonic–clonic seizures, all during television watching. She had been treated with carbamazepine for a short time but had discontinued it when she continued to have seizures. The last seizure had occurred when, passing by, she perceived at short distance and from an oblique angle a small-screen television set. The patient was otherwise healthy and active. Her seizures, however, resulted in extreme anxiety in the presence of all electronic displays, and a phobiclike behavior developed. To avoid possible exposure to screens, she rarely left her house. She had never had a spontaneous seizure. Investigation by electroencephalography (EEG) showed that this patient was highly photosensitive. In addition, when she viewed a 38 × 29-cm television screen from a distance of 2.5 meters for 2 minutes, no spike-and-wave activity was noticed. However, viewing the same screen from a distance of 2 meters provoked spike-and-wave activity after a few seconds. Duplex linear polarizing glasses[32] in an angle providing 75% light absorption suppressed the photoparoxysmal response and enabled her to view the screen from a distance of 1.5 meters. The patient adapted to wearing these glasses in all environments that previously caused anxiety. No more problems occurred with television or other intermittent light stimuli, and after a few months the patient felt that she had control of her condition and no longer restricted her activities. She has been followed until the age of 41 and never had another seizure.

In complex reflex epilepsies, such as reading epilepsy[35] and seizures precipitated by praxis[14] or by eating,[42] patients may learn to prevent seizures by finding nonprovocative or less provocative ways of performing the respective activities. For most patients with reading epilepsy, orofacial reflex myocloni (ORM) will precede a convulsive seizure. These can serve as a warning to the patient to stop reading, thereby preventing the seizure.[35]

Nonspecific Precipitating Factors

Preventing seizures by interventions directed toward factors that cause or facilitate seizures is a time-honored therapeutic approach. Those interventions include rigorous early antipyretic treatment in febrile illnesses of children who are prone to febrile convulsions and regulation of the sleep–waking cycle in patients with juvenile myoclonic epilepsy, grand mal on awakening,[16] or other epilepsies sensitive to irregularities of sleep.

The history of this approach is inseparable from that of patients' attempts at psychologically coping with a disease that can strike at any moment. The ability to predict and prevent seizures enables patients to gain a certain amount of control over their lives.[20] Changing an irregular lifestyle or reducing alcohol intake is certainly more helpful than attributing seizures to uncontrollable influences such as menstruation, phases of the moon, or the weather, as some patients are inclined to do.

The provocation of seizures by exogenous stimuli is probably more common in the early phases of epilepsy.[16] Preventing seizures by avoiding precipitating factors is certainly most effective at these times.

Case 2. Bettina K., now aged 30 years, had three generalized tonic–clonic seizures at 19, 20, and 21 years of age. Phenytoin was prescribed. She developed a skin rash after 10 days, stopped the medication, and started homeopathic treatment. She presented at our clinic when, during the following 17 months, she had suffered another three seizures. Initially, no focal signs had been observed, but during the commencement of the last three seizures, a conscious version of eyes and head to the right had occurred. At the onset of one of these, the patient described a right visual hallucination; afterward, she had no recollection of this. One EEG showed generalized spike-and-wave discharges. The magnetic resonance imaging (MRI) was normal except for a moderate widening of the left lateral ventricle, which may account for the focal traits in what otherwise suggested an incipient idiopathic generalized epilepsy. With most seizures occurring shortly after awakening and one seizure occurring during evening leisure, the patient presented the classic biorhythmicity of epilepsy with grand mal on awakening. Typical of this syndrome, almost all seizures had been preceded by irregularities in her sleep–waking rhythm. Because the patient was strictly opposed to drug treatment, a strategy was developed to avoid provocative factors (see Chapter 254). She was fully compliant with this regimen and, in the 7 years of follow-up, has remained completely seizure free.

Psychogenic Precipitants

Perhaps the most common public belief about the causality of epilepsy, as it is broadly reflected in literary accounts of the condition,[37] is that seizures are caused by emotional irritation. Although difficult to assess, this is certainly a possibility, and drug-resistant epilepsies may become treatable when underlying effects such as shame, embarrassment, anxiety, and learned helplessness are therapeutically addressed.[26]

Upsetting events cannot always be avoided, but the therapeutic approach, rather than attempting to avoid the unavoidable, would be to try to define how the arising emotions can be noticed and dealt with in ways that bypass the imminent seizure.

In a behavior analysis preceding treatment of 18 patients, Dahl et al.[5] categorized patients according to whether they were able to predict seizures (by aura sensations, situation association, or both), had at some time been able to counteract seizures, could elicit seizures on demand, could identify situations at low risk for seizure occurrence, reported mainly

positive consequences associated with seizures, and had established healthy social behavior.

These factors occurred with equal frequency in three groups of six patients, each of whom were treated with behavior modification or served as attention controls (a kind of placebo group receiving a psychologist's attention equal to that of the treatment group) or simple controls. Patients in the group receiving behavioral modification were the only ones to experience a decrease in seizure frequency. This program comprised reinforcement of seizure control techniques and healthy behavior as well as relaxation techniques. It also included education of parents and teachers, role-playing, and homework assignments for all persons involved. Fenwick[9] has looked at similar indicators of psychogenesis of epileptic seizures and found them to be unexpectedly common, and inviting behavioral intervention.

In a more psychophysical approach, some authors selected a variety of EEG parameters[28] or the sensorimotor rhythm[19] for EEG biofeedback because they were supposed to exert or be correlated with anticonvulsant action. The results were only partially convincing, but more sophisticated approaches have been developed that aim at individually defining sets of rhythms that require some increase and some down-training. A tailored training program based on these appeared to be a quite successful.[33]

The behavioral and psychophysical views are reconcilable, as shown by Rockstroh et al.[25] in their work on cortical self-regulation by biofeedback of the DC EEG. Our group[6] has used the same method in a more specific way—for seizure arrest in response to an aura. This approach is founded on the observations of negative DC shifts at the onset of seizures.[4] Patients are advised to produce a learned positive DC shift in response to an aura, a strategy comparable to relaxation techniques and opposite to the depolarizing action of seizure arrest by sensory stimuli or arousal. The group has recently tried to develop predictors of success of this treatment based on the initial cortical excitability, the epileptic focus, and personality variables.[29]

Another approach targets biofeedback at the galvanic skin response, and this method was proved effective in a randomized controlled design using sham biofeedback as a control.[21] The proposed mechanism of action is sympathetic arousal.

Behavior Modification Today

At present, there are four main indications for behavioral therapy in epilepsy:

1. Nonsymptomatic first seizures and incipient epilepsies if precipitating factors can be identified. Behavior modification may, in these cases, be applied alone or together with medication. In the latter case, it seems to be the more important agent.
2. Reflex epilepsies, especially the pure forms where no spontaneous seizures occur.
3. Patients who are opposed to taking drugs but seek medical treatment with a request for conservative treatment alternatives. If there is a realistic chance that they will respond to behavioral treatment, they should receive it. Even if the chance of success seems low, patients should not be left to charlatans. Rather, they should be given the best possible medical advice, and some behavioral intervention should be tried. In our experience, several patients after failure of serious attempts at behavioral treatment could accept pharmacotherapy, which they had previously declined, with good compliance. Some patients may decline a dosage increase of their antiepileptic drug and choose behavioral therapy as an adjuvant approach.
4. Patients with drug-refractory epilepsies and poor indications for surgery or patients who refuse further attempts to find successful therapy. In these cases, behavioral modification will typically be part of a complex therapeutic setting.

To provide patients with a full therapeutic program, behavioral therapy should become a more common part of the armamentarium of specialized epilepsy centers. These centers can also best be expected to apply such therapies critically and to evaluate their usefulness and quality. Much more critical research concerning these therapies must be done. Randomization and placebo control of the type used in pharmacotherapy is not possible, and even similar procedures are extremely difficult to design for behavioral interventions. In some of the existing studies,[5,25,29] the introduction of treatment control mechanisms has been attempted with some success. Other studies have combined retrospective and prospective phases and have used patients as their own controls, but the methods of evaluating these therapies should be further developed.

Summary and Conclusions

Before the advent of potent drugs, behavioral modification was an important therapeutic approach to epilepsy. It is receiving renewed interest in response to medical intractability due to inefficacy or intolerance to drugs. The available interventions comprise:

1. Seizure arrest by specific stimuli (simple or complex), nonspecific arousal, relaxation, or DC EEG biofeedback. The probable action of these countermeasures is that they reduce the availability or recruitability of groups of neurons for further seizure spread.
2. Seizure prevention by avoidance, modification, counteraction, or desensitization of nonspecific facilitating factors such as irregular sleep, psychogenic factors, and specific precipitating factors (as in *reflex epilepsies*).

These interventions are often part of a complex therapeutic setting but may occasionally be applied alone. Their main indications are incipient epilepsies, reflex epilepsies, and pharmacoresistant focal seizures. Many patients who are unwilling to take antiepileptic drugs prefer behavioral modification. Behavioral treatment should be part of the therapeutic armamentarium and should become the subject of research in specialized epilepsy centers.

Chapter 133

Complementary and Alternative Medical Therapies

Steven C. Schachter

Carlos Acevedo

Keryma A. Acevedo

Chi-Wan Lai

Amadou G. Diop

Introduction

Despite the introduction of new antiepileptic drugs (AEDs), increasing use of brain surgery, and aggressive worldwide campaigns to improve the diagnosis, treatment, and access to care of patients with epilepsy, nearly one in three patients continues to have seizures despite therapy and others endure side effects from treatment,[9] while the large majority of people with epilepsy around the world have no access to modern treatments.

Whereas AEDs and epilepsy surgery are relatively new in the history of epilepsy treatment (e.g., bromides were introduced in 1857, phenobarbital in 1912, and epilepsy surgery in the 1940s), people with epilepsy have used a variety of therapies for thousands of years. Some of these therapies persist today, especially in regions of the world where access to medical care is poor, and are generally called complementary and alternative medical (CAM) therapies.

The National Center of Complementary and Alternative Medicine (http://nccam.nih.gov/), a National Institutes of Health (NIH) Center, defines CAM therapies as those health care and medical practices that are not currently an integral part of conventional medicine. In this context, “conventional medicine” is generally understood to represent the “Western” system of medical knowledge and practices, as taught in Western medical schools.

CAM therapies emphasize a focused and individualized approach to patients, with respect for the connection between mind and body, the responsibility of patients for their health, the spiritual nature of people, and the need to stimulate the strength and vital energy necessary for the recovery and sustenance of health.[66]

Patients with chronic illnesses, including epilepsy, use CAM therapies for several reasons. They may prefer “natural” treatments to “artificial” or “synthetic” drugs, assuming that “natural” treatments are better and safer. They may believe that alternative health care providers give them more control over their health care decisions. Lastly, they may have ready access to CAM therapies but not Western-style treatments due to geographic, economic, cultural, social, or religious conditions and factors, which is particularly the case in developing countries.

CAM therapies include traditional Chinese medicine, Ayurveda, homeopathy, naturism and acupuncture; mind–body therapies, such as yoga, hypnosis, music therapy, prayer, and therapeutic touch; botanicals and other “natural” substances, including herbs, herbal medicines, and herbal formulas, which in the United States are classified as dietary supplements; special diets; movement and massage therapies, including reflexology, massage, osteopathy, Reiki, and Qigong; and electromagnetic forces.

This chapter reviews several of the more commonly used CAM therapies for epilepsy, regulatory aspects of herbal medicines, safety issues, and opportunities for further research. A discussion of other CAM therapies for patients with epilepsy, such as acupuncture,[94,155] dietary approaches,[92,115] and neurofeedback,[69,90,132,146] is beyond the scope of this chapter. Interested readers are also referred to a book on CAM therapies and epilepsy[29] in which these topics are discussed at length, as well as several other excellent reviews on herbal medicines and epilepsy.[35,101,130,142]

Scope of Use

Developed Countries

In developed countries, CAM therapies are often used for general health maintenance or by patients with chronic conditions that respond poorly or incompletely to conventional treatments, such as back pain, anxiety, depression, headaches, and fibromyalgia.[32,116,145] Despite a lack of evidence for efficacy and safety, surveys suggest that up to one third of patients with epilepsy in the United States and the United Kingdom take herbal medicines and/or dietary supplements, and that the majority of these patients do not discuss this intake with their physicians.[31,107,128] One survey of patients attending an American epilepsy clinic found that ginseng, St. John's wort, melatonin, gingko biloba, garlic, and black cohosh were the most frequently taken herbal medicines and dietary supplements[107]; another found that garlic, gingko, soy, melatonin, and kava were most often taken.[128]

Some of these herbal medicines may be taken for non-seizure-related symptoms (e.g., valerian for difficulty sleeping, St. John's wort for depression, and ginkgo biloba for memory disturbance). Therefore, the herbal medicines and dietary supplements taken by patients with epilepsy may be clues to possible side effects from AEDs or symptoms of possible comorbid disorders.

Developing Countries

Throughout history, CAM practices and therapies have reflected cultural beliefs about epilepsy.[34] In developing countries, people turn to CAM practitioners, often under the influence of their families, either before seeing a Western-style doctor or after the perceived failure of Western medicine.[3,33,36,139] According to a survey conducted in China in 1988, nearly 40% of the respondents would suggest that a friend with epilepsy ask for an herbal medicine doctor or seek acupuncture.[71] It should be understood that traditional local treatments are alternative, or “CAM,” from the Western perspective, not from the local perspective.

Lack of education may favor magical beliefs in the power of CAM therapies.[13,23] For example, in sections of the world

where epilepsy is still believed to have supernatural causes, spiritual healing and CAM therapies are used under the direction of traditional healers and include forehead scarifications, shaving of the entire body using glass, herbal concoctions, roots, baths, infusions, or banishment.[7,12,45,86,91,120]

The situation in Africa is particularly illustrative. Epilepsy is known in African societies by a variety of names, including *ngbitie* (Ivory Coast; meaning the brutal, sudden, or surprising disease); *ibi-foukougni* (Burundi; the snoring disease); *adigbe* (Benin; the falling disease); *tibu sugo* (Mali; the “falling like a rock” disease); *say* (Senegal; convulsion or trance or rabies); and *haoua* (Nigeria; the [strong] black bull). In much of Africa, epilepsy is conceived as a manifestation of supernatural forces, caused by ancestral spirits or attributed to possession by evil spirits, demonic possession, or divine punishment for the commission of sins. It is also thought to be due to witchcraft and “poisoning,” and is often taken to be contagious, especially via breath, blood, sperm, and genital secretions. Consequently, affected persons may seek out traditional healers in addition to practitioners of modern (“Western”) medicine, particularly when it is clear the disorder is chronic.

African traditional healers utilize a variety of techniques for diagnosis, including “complementary exploration” via search with cowries, sand, stones, animal sacrifices, interpretation of dreams, and contact and dialogue with supernatural personages and forces. Recommended treatments usually utilize different elements derived from animals, vegetables, minerals, and liquids, according to the potential benefits as assessed by the practitioner, and may be recommended as amulets or to be inhaled, eaten, drunk, or bathed in. Supernatural forces will be “invited” during special mystical celebrations to either visit the patient if they are protective or to be withdrawn from the patient's body and soul if they are negative. These rituals are often witnessed by the public and accompanied by religious songs and dances. The themes of these evocations generally focus on the patient's family and ancestors. Blood from sacrificed animals may be used to satisfy evil forces or to calm devils.

In many other developing countries around the world, CAM therapies are administered in conjunction with AEDs,[25,74] and authors have stressed the relevance of CAM therapies in the management of epilepsy in those settings.[25,28]

Complementary and Alternative Medicine Therapies Used for Epilepsy

Herbal Medicines and Other Dietary Supplements

Herbal medicines have been used to treat seizures for centuries. Arguably the earliest use of herbal medicines for epilepsy dates back to 6000 BC in India. According to old Chinese medical texts, herbal epilepsy treatments started in China about 3000 BC. In Peru, iconographies on stones dating back to about 3000 BC describe the medicinal use of Saint Peter herb (*Trichocereus peruvianis*). Persian medieval medical texts document the clinical manifestations and herbal treatments of epilepsy.[44] Numerous substances were used to treat seizures over the past 500 years in Europe and in pre-Columbian America.[34] In 1763, Pedro de Horta in Mexico wrote an extensive monograph on epilepsy, including the use of herbal medicines, earning his title as the first American epileptologist.[39] Today, many herbal medicines around the world are anecdotally believed to have anticonvulsant properties in humans, generally with inadequate scientific support.[21,80]

Traditional Chinese Medicine

The use of herbal medicines in China has a long and sophisticated tradition based on a well-developed system of medical principles.[147] Lai and Lai noted that the first known document on epilepsy in China is in The Yellow Emperor's Classic of Internal Medicine, Huang Di Nei Ching, dating from about 770 to 221 BC.[72] Today, traditional Chinese herbal medicine is widely practiced. Similarly, in Japan, over 100 herbal (Kampo) medicines are reimbursed by the national health system and widely prescribed; for example, over 70% of the members of the Kyoto Medical Association who responded to a survey questionnaire on CAM practices routinely prescribe Kampo medicines.[149,150]

Herbal medicines traditionally used to treat convulsive diseases in Asia include *Chai-Hu-Long-Ku-Mu-Li-Tan*, a mixture of extracts from 13 herbal medicines[153]; *Gastrodia elata*[64]; *Uncaria rhynchophylla*[73]; *Menispermum dauricum*[79]; *Shitei-To*, a mixture of extracts from three medicinal herbs, *Shitei* (Kaki Calyx; calyx of Diospyros kaki L. f.), *Shokyo* (Zingiberis Rhizoma; rhizome of Zingiber officinale Roscoe), and *Choji* (Caryophylli flos; flowerbud of Syzygium aromaticum [L.])[87]; a mixture of radish and pepper (which contains the alkaloid piperine)[30]; *Qingyangshen*[46]; *Kanbaku-taiso-to*, a mixture of three herbal drugs, *Glycyrrhizae Radix, Tritici Semen,* and *Zizyphi Fructus*[141]; *Paeoniae Radix*[18]; and *Zheng Tai Instant Powder* (a complex prescription of traditional Chinese medicine used for tonic–clonic seizures).[54]

Published reports suggest that several of these herbs have neuroprotective properties,[51,53,64,65,73] efficacy in animal models of epilepsy[19,30,51,52,53,54,65,87,88,141] and hippocampal slice models,[5] and effects on gene expression.[135,136] Interpretation of these studies is limited, however, by inconsistent descriptions of herbal production and extraction methods as well as the lack of characterization of active ingredients.

Based on the traditional Chinese medicine (TCM) principles of holism and differentiation,[75,81] practitioners recommend individualized prescriptions (formulas/combinations) of herbal medicines and acupuncture to their patients with epilepsy[147] (Fig. 1). Differentiation is the process in TCM whereby different treatable syndromes are diagnosed according to various theories and principles based on symptoms, physical signs, disease history, and other information gathered from other diagnostic methods. As a result, herbal formulas with varying components and acupuncture using different points are commonly recommended to different patients who may have the same seizure type, leading to methodologic issues in conducting clinical research. Accordingly, a comprehensive literature search carried out in March 2005 of published studies using herbal medicines for the treatment of epilepsy in the Far East identified only three randomized controlled trials and five nonrandomized controlled trials, whereas there were six case control studies and 57 observational studies including case reports.[105] Over 135 individual herbal medicines were used singly or in various combinations (formulas) in these investigations (Park, personal communication; Table 1). Rarely was the same herbal formula used in more than one study. Consequently, evidence from controlled trials to support the use of specific Asian herbal medicines either alone or in combination for patients with epilepsy is lacking, and further research is needed.

11	*Citrus reticulate*	Chen Pi
11	*Uncaria rhynchophylla*	Gou Teng
10	*Glycyrrhiza glaba*	Gan Cao
10	*Salivae miltiorrhizae*	Dan Shen
7	*Scolopendra subspinipes*	Wu Gong
7	*Bupleurum falcatum*	Chai hu
7	*Succinum*	Hu Po
7	*Paeonia albiflora*	Bai Shao
6	*Panax ginseng*	Ren Shen
6	*Perichaeta communissma*	Di Long
6	*Curcuma longa*	Yu Jin

From Park, personal communication.

Ayurveda

"Ayurveda" means the knowledge of life and is derived from two Sanskrit words: *Ayu*, which means life, and *Veda*, which means to know. Ayurveda is both a medical system and a science of life that is believed to have originated in India 6000 years BC.[59] Ayurveda guides the selection of food and lifestyle so that healthy people stay healthy and those who are sick

improve their health. Specific recommendations are individualized based on ancient texts and are validated by observation, inquiry, and direct examination. Encyclopedic texts written about 1000 BC by Caraka and Susruta are considered the most authentic representatives of the original Ayurveda.[59]

The Ayurvedic literature contains references about several aspects of epilepsylike symptoms, etiology, diagnosis, and treatment. Epilepsy is called "Apasmara." *Apa* means loss or negation and *smara* means memory, cognition, recollection, or consciousness.[82] Epilepsy is classified into four types, all of which are caused by disturbances of the three humors (*doshas*) that are believed to govern the body's physiologic properties: *vayu* or *vata* (air), *pitta* (bile), and *kapha* (phlegm).[59,82] The causes of seizures are thought to be directly related to practices involving diet, lifestyle, emotions, and ingestion of toxins. If toxins in the body are believed to be abundant, they must be eliminated by drastic emesis, enemas, and purgatives.[59]

According to Ayurveda, seizures can be reduced by avoiding looking at shining, fast-moving, or rotating objects; climbing hills or trees; eating candies or oily food; drinking alcoholic beverages; being exposed to coldness or hot temperatures; eating red meat, and masturbating. Further, seizures may be aborted by applying drops of white onion juice into the nose, applying a preparation of water and bitter gourd powder to the nose, inhaling black pepper smoke, or ingesting either fresh or dried tulsi leaves. In addition to these recommendations, Ayurveda includes nutritional guidelines to reduce excessive *dosha*, complemented by herbal supplements once the patient has been cleansed and consoled.[59] Herbal supplements are available for external application, internal use, and topical use in the eyes and nose. The most common ones are Brahmirasayan, Brahmighritham, Ashwagandha, old pure desi ghee, daily fresh juice of brahmi with honey, garlic juice in oil, and powdered root of wild asparagus with milk. Others include *Acacia arabica, Acorus calamus, Bacoppa monnieri, Clitorea turuatea, Celastrus panniculata, Convulvulus pluricaulis, Emblica officinalis, Mukta pishti, Whitania somnifera,* and *Vaca brahmi yoga* (see also reference 17). A growing literature provides an experimental basis to support controlled studies of some of these therapies in patients with epilepsy.[63,70,124,127]

Marijuana

Marijuana, the herbal preparation of *Cannabis sativa*, has been used for thousands of years in Ayurvedic treatments as well as in Unani medicine in the Arabic tradition. There is also evidence of its medical use in Europe dating to the 13th century.

Cannabis contains more than 60 lipophilic cannabinoids. Cannabidiol is the main nonpsychoactive component and Δ^9-tetrahydrocannabinol (THC), identified in 1949 and synthesized in the 1960s, is the primary psychoactive component. Two cannabinoid receptors in the central nervous system are known.[50,152] GABAergic (γ-aminobutyric acid) interneurons in the hippocampus, amygdala, and cerebral cortex express high levels of CB_1 receptors.[57]

Some animal studies suggest that THC may suppress kindling, but others have found a proconvulsant effect.[62,83,144] There are no controlled data to support the use of marijuana in epilepsy.[42]

Melatonin

The dietary supplement melatonin has been reported to be useful for the treatment of sleep disorders (including in children with epilepsy), jet lag, and even glioblastoma.[16,47,49,78,129] Abnormal nocturnal salivary melatonin levels have been found in pediatric patients with epilepsy,[111] though the significance of this finding is uncertain.

Melatonin enhances hippocampal excitability, and nocturnal activation of hippocampal melatonin receptors in rats enhances seizure susceptibility, suggesting a proconvulsant effect.[133] Other animal studies support a possibly beneficial effect of melatonin on seizures.[26,37] Results in humans with epilepsy and neurologic disorders are similarly mixed.[108,126] Given that melatonin is commonly taken by persons with

P.1410

epilepsy who use CAM therapies,[31,107] additional studies of its efficacy and safety when taken long term by patients with epilepsy are clearly needed.

Psychological Therapies and Mind–Body Techniques

Psychological therapies and mind–body techniques,[41] discussed in detail in Chapter 132, are designed to reduce seizure frequency, avoid AED side effects, and improve quality of life. Examples include behavioral inhibition of symptoms at seizure onset,[6,38] massages[93] (note that certain oils used in aromatherapy have been anecdotally reported to cause seizures[130]), relaxation techniques,[27] creative therapies,[121,140] cognitive-behavior therapy,[38] and systematic desensitization.[11,24,138] Further controlled studies are needed to identify which therapies or techniques are effective and to determine how to select specific therapies for individual patients.[112]

Yoga

Health in the traditional Indian view is the result of perfect harmony between body, mind, and spirit. *Yoga* derives from the Sanskrit word *Yug*, which means “mind control.” There are several forms of yoga: Sahaja yoga, hatha yoga, and transcendental meditation. Yoga practices include exercises with different postures (asanas), special respiratory techniques (pranayama), and mental relaxation and meditation (dhyana).

The aim of yoga is to reach a state of pure consciousness, joy, and relaxation. Yoga and yogic mindfulness meditation have been used for stress reduction[85,96] and therefore have a theoretic role in epilepsy, particularly for patients with stress-induced seizures. However, the last Cochrane review on yoga and epilepsy found no conclusive benefit of yoga as a treatment for epilepsy.[112] Nonetheless, given its favorable safety profile, yoga and other relaxation techniques can potentially be useful in the management of stress in patients whose seizures appear to be associated with stress,[104] and further well-designed studies should be conducted.

Homeopathy

The term *homeopathy* comes from the Greek word *homoios*, which means "similar," and *pathos*, relating to suffering or disease. The basic principles of homeopathy were advanced by Hippocrates and rediscovered by Samuel Hahnemann (1755–1843). Its main tenet is "like should be cured with like"; that is, a homeopathic preparation to treat symptoms in a patient incorporates a drug, often derived from plants or animal products, that causes similar symptoms when given to a healthy volunteer.[143] As proposed by Hahnemann, the active ingredient is serially diluted and then vigorously shaken.[137] Specific preparations are then recommended to a patient based on his or her symptoms or what are believed to be the underlying causes of the symptoms rather than on a specific diagnosis.

Significant doubt has been expressed about the efficacy of homeopathic medicines.[143] Recently, Shang et al. compared placebo-controlled trials of homoeopathy and allopathy and concluded that the clinical effects of homeopathy seen in placebo-controlled trials are compatible with placebo effects.[123] Nevertheless, homeopathic medicines are not infrequently taken by patients with epilepsy,[139] and while the risks appear to be relatively low given the extreme dilution of these preparations, further research to determine their efficacy and safety is needed.

Regulatory Aspects of Herbal Medicines

Reviewing regulations concerning herbal medicines in each country is an insurmountable task, and would quickly become out of date. The situation in the United States is therefore presented as an example and to stimulate discussion in other regions of the world.

Herbal medicines in the United States are regulated by the 1994 Dietary Supplement and Health Education Act (DSHEA), whereas the clinical development, manufacturing, and marketing of prescription drugs must meet the more rigorous requirements of the Federal Food, Drug, and Cosmetic Act. The Food and Drug Administration's (FDA) Office of Nutritional Products, Labeling, and Dietary Supplements is responsible for developing policies and regulations for dietary supplements (http://www.cfsan.fda.gov/~dms/onplds.html; accessed 9/4/2006).

Under the DSHEA, a dietary supplement is defined as a product taken by mouth that contains a dietary ingredient intended to supplement the diet. The dietary ingredients in these products may include vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, and metabolites (http://www.cfsan.fda.gov/~dms/ds-oview.html; accessed 9/4/2006). Manufacturers of herbal products are responsible for the truthfulness of the claims they make on product labels and for controlling the quality of their products and verifying their safety. They cannot claim that their herbal product is effective against a specific disease or medical condition, such as epilepsy, but they may claim it has some effect on a part of the body or its function as long as the claim is accompanied by the following words: "This statement has not been evaluated by the FDA. This product is not intended to diagnose, treat, cure, or prevent any disease."

No U.S. government agency, including the FDA, is required by law to independently review and verify the labeling claims and supporting evidence of herbal products or to independently verify the quality of herbal products and their safety. That is, the FDA is not legally required or authorized to "approve" dietary supplements based on evidence of safety and efficacy. Similarly, no U.S. government agency is required by law to verify that the production of herbal products is consistent with "Good Manufacturing Process" (GMP) standards, as is the case for pharmaceutical products. Therefore, herbal products could potentially be contaminated with microorganisms, pesticides, or toxic metals, as has been documented with some Ayurvedic herbal medicine products sold commercially.[118] Further, they could be adulterated with other herbs or drugs, and the potency and amount per pill/capsule may vary significantly within the same bottle or from batch to batch, or from one branded product to another because of variable manufacturing processes. This situation could occur anywhere in the world. For example, a study conducted in Taiwan found that herbal products from China, Taiwan, and other countries were adulterated with phenobarbital.[55]

In light of the frequent use of herbal medicines and dietary supplements by patients with epilepsy, clinicians should inform patients about the differences in how their particular country's government oversees the production, testing, and labeling of pharmaceuticals as compared to dietary supplements.

Safety Issues

Despite being “natural,” herbal therapies are not necessarily safe, intoxication may be fatal, and the long-term safety of most herbal therapies is not known.[56,106] Likewise, the

pharmacokinetic interactions between herbal medicines and AEDs, with few exceptions, are not well studied. As reviewed by Conry and Pearl,[21] certain herbal medicines, including St. John's wort,[103] garlic, echinacea, pycnogel, milk thistle, American hellebore, mugwort, and pipsissewa, affect cytochrome P450 enzyme activities and therefore have the potential to alter the serum concentrations of hepatically metabolized AEDs. In addition, a number of herbal products and dietary supplements have been anecdotally reported to precipitate seizures, including in patients with epilepsy.[80,131,142] Examples are anisatin (which is used in Spain and other countries to treat infant colic and is also known as Japanese star anise),[40,60] gingko nuts,[89] essential oils,[131] evening primrose and borage,[130] and the stimulant ephedra (ma huang).[48,67] The extract of star fruit (*Averrhoa carambola*) has been reported to cause seizures in uremic patients[15,97] and its extract is used experimentally to elicit seizures.[14] Similarly, an extract of a Chinese herb used to treat schizophrenia induces a kindling model of pharmacoresistant temporal lobe epilepsy in rats.[148] Therefore, clinicians should take a thorough history regarding herbs and dietary supplements from their patients and ask to see the actual bottles to verify the ingredients. Further, physicians should consult reliable databases for information on herbal medicine safety, as well as possible adverse effects on seizure frequency and AED serum concentrations.

Opportunities for Further Research

Given the need for new AEDs, herbal medicines with a tradition of use for epilepsy and compounds isolated from them, as well as herbal medicines and their constituents that are known experimentally or clinically to have mechanisms of action relevant to epilepsy,[5,8,19,77,84,95,102,151] are particularly attractive targets for research, especially if the herbal medicines are readily available and have low apparent toxicity.[101] Accordingly, a growing number of groups around the world, in addition to the work already cited from Asia, are studying their local or regional herbal medicines as potential anticonvulsants in animal models,[1,4,10,20,100,109,110,157] in vitro assays,[61,113,131] and patients with epilepsy.[2,58,76,125,154] It is anticipated that promising findings from these inquiries will be translated to clinical research when possible.

As an example of the strategies used by workers in this field, the authors and collaborators in Asia are currently engaged in an effort to:

- develop a list of high-priority herbal medicines to be considered for evaluation, based on a number of considerations such as clinical recommendations of senior herbal experts, electronic database searches, review of original text references, existing well-characterized herbal extracts/compounds, and promising results from published clinical studies;
- test crude extracts and selected fractions of these herbal medicines, as well as pure compounds isolated from those fractions, in well-validated animal models of epilepsy; and
- evaluate those fractions and compounds with activity in the animal models using in vitro assays to evaluate mechanisms of action.

The goal of these evaluations is to identify herbal medicines and pure compounds derived from those herbal medicines that are candidates for further preclinical and clinical testing. For example, Huperzine A, a sesquiterpene lycopodium alkaloid isolated from Chinese club moss (*Huperzia serrata*), also known as the Chinese folk medicine *Qian Ceng Ta*, has been traditionally used in China for the treatment of swelling, fever and inflammation, blood disorders, and schizophrenia,[156] and is approved and used in China for the treatment of Alzheimer disease. Huperzine A is a potent, orally active, noncompetitive antagonist of the *N*-methyl-D-aspartate receptor, likely acting at or near the PCP and MK-801 ligand sites, but without psychotomimetic side effects.[43] Huperzine A is active in several animal models of epilepsy; its effects in the 6-Hz model are particularly interesting and appear to offer potential advantages over several classical anticonvulsants as well as the newer agent levetiracetam.[119,151] A phase II clinical study in patients with medically refractory epilepsy is planned.

In addition to potentially identifying new therapies for epilepsy, this approach and others under way around the world may also yield agents that are neuroprotective.[134] Finally, some of the herbal medicines and their derived compounds that are active in the animal models of epilepsy may be found to have novel mechanisms of action that could lead to the development of additional pharmacologic interventions for epilepsy.[79] Natural products have already significantly impacted drug discovery in other fields[22,68]; for example, they have led to the identification of new cell cycle pathway targets for novel chemotherapeutic agents.[98,99]

Summary and Conclusions

CAM therapies are a very heterogeneous system of concepts and therapies with origins in different cultures, religions, and philosophical and healing systems. A significant proportion of people with epilepsy around the world have used one or more types of CAM therapies, often because of lack of access to AEDs and usually without the knowledge of their treating physician, if they see a physician.

Despite the popularity of CAM therapies, there is a paucity of sound evidence at the present time to support their use by patients with epilepsy; further, some herbal medicines may pose a safety risk. As a matter of routine, physicians should ask their patients whether they use these therapies and discuss the risk-to-benefit ratio of CAM therapies with their patients who use or plan to use these treatments.[114,139] In addition, physicians should be familiar enough with these treatments to advise their patients about the use of these treatments, not only in the treatment of epilepsy, but also in the context of their overall health care.

Further research is needed to understand the full scope of use of CAM therapies among people with epilepsy around the world, and particularly with regard to herbal medicines, to explore their mechanisms of action, efficacy, safety, and tolerability.[117,122]

Introduction

People with epilepsy, their families, and the clinicians who care for them await the advances that will cure or prevent epilepsy, but all want to know what can be done now (or in the near future) when medications fail or are unrelentingly toxic? This chapter collects a miscellaneous group of therapies that may partially address this question. By selection criteria to be in this chapter, none of the therapies yet is proven as safe and effective. Most, but not all, are available in experimental protocols, none as part of standard therapy.

A general theme of the experimental therapies in this chapter is an attempt to be relatively noninvasive. Surgical procedures should not have to remove more than the minimal amount of brain necessary to stop seizures, or perhaps they should remove no brain at all. Electrical brain stimulation therapies have attempted seizure control without resection. Several targets and strategies have been employed, but most active now are deep brain stimulation in the anterior or centromedian thalamus, subthalamus, or hippocampus, or direct stimulation of a cortical seizure focus. Stimulation can run on a cycle, as with vagus nerve stimulation for epilepsy. Alternatively, stimulation can be made contingent upon recording an electroencephalographic (EEG) pattern indicative of an ongoing (seizure recognition) or impending (seizure prediction) seizure. Noninvasive trans-cranial magnetic stimulation has been tested for seizure control, since transcranial electrical stimulation tends to be painful. Transcranial magnetic stimulation used for diagnostic purposes is discussed elsewhere in this volume.

Focal brain radiation may or may not be less invasive than surgery, but some investigators argue that it is. More important than the avoidance of a craniotomy with Gamma Knife or CyberKnife radiation therapy is the possibility that radiation can spare cells with a sublethal dose but still inhibit seizures.

Why distribute an antiepileptic drug to every region of brain and body when it might only be needed within a restricted region of the central nervous system (CNS)? Why should a kidney stone or severe leukopenia be a risk of therapy for treating the brain? Techniques to distribute medication focally in the brain include intracerebroventricular perfusion, catheter-mediated perfusion in the cortex, drug-eluting polymer wafers, targeted liposomes, seizure-activated prodrugs, and cell transplants that release drugs. The genetic machinery of the neurons and glia in a seizure focus can be altered by gene transplants via viral vectors. Altered genes can produce renewable local neurotransmitters or neuromodulators that serve to inhibit local excitability.

Not every exciting potential new therapy can be covered in one chapter. For example, rapid cooling of a seizure focus[113] has been shown to be effective in blocking seizures in animal systems and in small uncontrolled series of patients. In the following section, investigators working with some of the new technologies will provide a very brief overview of the methods, promise so far, and potential limitations. The hope is that some of these therapies will prove successful, and migrate to the standard care sections of the future editions of this compendium.

Deep Brain Stimulation

Electrical brain stimulation to control intractable epilepsy has been attempted intermittently for several decades, using a variety of neural targets: Cerebellar cortex, deep cerebellar nuclei, caudate nucleus, locus ceruleus, hippocampus, centromedian nucleus of thalamus, anterior nucleus of thalamus, subthalamic nucleus, neocortex, and vagus. Space limitations do not permit review of each stimulation site, but reference may be made to several published recent reviews.[36,40,45,55,65,67,79,82,134] Stimulation of brain tissue to control or partially control medically intractable seizures has several potential advantages over resective surgery. Firstly, stimulation may influence a seizure focus or multiple foci in regions of brain, for which it would not be safe to remove tissue. Secondly, electrical stimulation is an adjustable therapy, with many parameters available for individualization on an empirical basis for each patient. Thirdly, stimulation can be discontinued, as opposed to an irreversible surgery. Nevertheless, clinical experience and at least one randomized study[148] overwhelmingly support resective surgery in circumstances for which a seizure focus safely can be removed. Neural stimulation, therefore, is a candidate for a palliative role, in circumstances for which seizure control is not possible with medications or removal of the seizure focus.

Stimulation of the thalamus for epilepsy originally was proposed by the pioneering neurosurgeon Irving Cooper.[17,18,19,143,144] Only a few studies so far have investigated basic mechanisms of electrical stimulation for seizures. The results of stimulating neural tissue are not predictable from basic physics and electrical field principles. Complications include a complex geometry of nuclei and tracts in the brain; "sign-changing" circuitry, by which inhibitory pathways may be activated or deactivated; exquisite dependence of outcome on parameters of electrical stimulation, such as frequency, intensity, bipolar versus referential application, and intermittent or continuous stimulation; and many other parameters, including some that undoubtedly are not yet recognized. Studies with in vitro slice tissue indicate that both alternating currents[73] and direct-current electrical fields[108] can in some circumstances inhibit epileptiform activity in the model systems. One likely mechanism may be the polarization of neurons with release of extracellular potassium, leading to an induced spreading depression.[8] Inactivation of sodium channels from excess depolarization, thereby blocking action potential formation, may play a role. Direct effects on inhibitory or excitatory systems by stimulation also could reduce excitability in the brain.

P.1416

Stimulation of the anterior region of the thalamus in rats can raise the threshold for seizures provoked by the acute application of the convulsant drugs pentylenetetrazol[90] and pilocarpine.[44] However, a recent study[69] failed to find benefit, and in fact observed increased seizure frequency, with anterior thalamic stimulation in rats with chronic epilepsy induced by previous doses of kainic acid.

In the 1990s, electrical stimulation to treat epilepsy rarely was the object of serious study, until two events refocused interest on this potential new modality: Success of vagus nerve stimulation for epilepsy[7] and success of deep brain subthalamic stimulation for movement disorders.[4] Two types of brain stimulation currently are in multicenter pivotal clinical trials for treatment of epilepsy: Open-loop stimulation and closed-loop stimulation, which also is referred to as responsive or contingent stimulation. Open-loop stimulation delivers stimuli on a scheduled basis, either intermittently or continuously, but not dependent upon detection of epileptiform activity. Responsive neural stimulation (see elsewhere in this chapter) uses EEG sensors to detect epileptic stimulation and deliver stimuli to the region of the suspected seizure focus or foci. Open-loop electrical stimulation of human diencephalon has been performed in the centromedian thalamus, subthalamus, and anterior thalamic nuclear group.

Centromedian Stimulation

Velasco et al.[146] identified the centromedian nucleus of thalamus as a promising target for electrical stimulation. To date, this target represents the most stimulated site in the brain for epilepsy, but no large, controlled trial has yet been completed of centromedian stimulation to document efficacy. The largest group of patients with centromedian stimulation was published by Velasco et al.[145] A total of 49 patients with a variety of intractable seizures were subjected to bilateral centromedian stimulation at intensities of 2.5 to 5 V, with stimulation frequencies ranging from 60 to 130 Hz. In the study population, centromedian stimulation was effective against generalized tonic–clonic seizures, tonic seizures, and atypical absence seizures, but not against complex partial seizures. A small cross-over trial of centromedian stimulation in seven patients with mixed seizure types[29] showed a trend toward benefit, but not of statistical significance.

Subthalamic Nucleus Stimulation

The subthalamic nucleus is a primary target for electrical stimulation to ameliorate tremor and Parkinson symptoms.[4] Laboratory studies suggest that subthalamic stimulation also can benefit seizures in animal models of epilepsy produced by kindling,[70] genetic absence,[147] fluorothyl,[70] and kainic acid.[79] Nine patients treated with subthalamic stimulation for epilepsy have so far been reported.[5,13,21,79] Six of the nine were said to show more than a 75% improvement in seizure frequency, although each of these reports was uncontrolled.

Anterior Thalamic Stimulation

The anterior thalamic nucleus provides efferents to superior medial frontal and cingulate cortex. In turn, the cingulum white matter projects to the entorhinal cortex, and thereby to the hippocampus. Stimulation of the anterior thalamic nucleus therefore is well placed to influence certain frontal and temporal seizures. Initial work on thalamic stimulation for epilepsy was performed by Cooper, with published results on several dozen patients.[19,143] These studies reported beneficial outcome in several patients, but details and long-term follow-up results were not provided in the publications. Sussman et al.[128] reported in abstract form the benefit of anterior thalamic stimulation at 100 Hz and approximately 5 V in three of five patients tested. Subsequently, pilot studies of anterior nucleus thalamic stimulation were performed on 14 patients from four different study sites.[40,48,58]

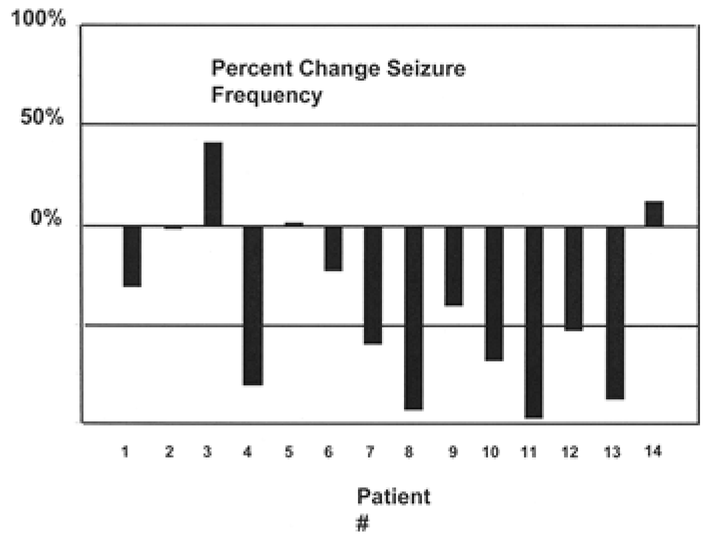

FIGURE 1. Percent change in seizure frequency, measured at a time 7 to 12 months after onset of bilateral anterior thalamic stimulation for 14 patients in the pilot trial of anterior thalamic stimulation. (From Graves NM, Fisher RS. Neurostimulation for epilepsy, including a pilot study of anterior nucleus stimulation. *Clin Neurosurg.* 2005;52:1–8.)

Table 1 Responsive Stimulation after Induced Seizures

	Duration of afterdischarges		
	<2 seconds	2–5 seconds	>5 seconds
With responsive stimulation	115	22	89
Without responsive stimulation	21	114	340

p <.001.
From: Lesser RP, Kim SH, Beyderman L, et al. Brief bursts of pulse stimulation terminate afterdischarges caused by cortical stimulation. *Neurology.* 1999;53(9):2073–2081.

Figure 1 shows the changes in seizure frequency for the patient group before and after stimulation. The mean seizure frequency at 12 months of stimulation was 55% ± 39% of baseline, and 57% of patients exhibited at least a 50% improvement in seizure frequency (responders). Among those believed to have frontal or temporal seizure foci, the responder rate was 67%.[40] Five patients had seizures capable of producing falls; four of these had a marked reduction in such seizures.[58] None of the 14 patients in the pilot trial experienced a serious complication. However, placement of deep brain stimulation electrodes is known to comprise a measurable risk for hemorrhage[9] and infection.[132] One patient implanted at a fifth institution using a similar thalamic stimulation pilot protocol had a hemorrhage leading to contralateral hemiparesis. Hodaie et al. in Toronto[48] have suggested that implantation itself might account for much of the perceived benefit, either by a microlesion effect or placebo effect.

Based on anecdotal and uncontrolled evidence of possible efficacy for anterior thalamic stimulation, a pivotal, multicenter, randomized, and blinded trial has been launched, called SANTE, for Stimulation of the Anterior Nucleus of Thalamus for Epilepsy (see www.epilepsycontrol.com). Eligible patients are those with medically uncontrolled partial or secondarily generalized seizures, not believed amenable to surgical resection. Seizures must be severe enough to interfere seriously with quality of life and must occur at a frequency of at least six per month. The SANTE trial utilizes bilateral implantation of deep brain-stimulating electrodes in the principal portion of the anterior nuclei, connected to a dual-channel Intercept (Medtronic) stimulation module. Stimulation parameters are 145 pulses per second with 90-μsec (approximately 0.1 msec) duration pulses, charge-balanced negative and positive on for 1 minute and off for 5 minutes. Voltage is set to 5 V in the treated group and 0 V in the placebo group. Since the patients, caregivers, or treating medical team cannot perceive the stimulation, this is a true double-blind study. After a 3-month baseline phase, patients receive either 5 V or 0 V stimulation for 3 months, then open-label therapy via a limited number of

P.1417

parameter sets for 10 additional months. At time of this writing, the study had passed the midstudy "futility analysis" by the unblinded data-monitoring safety board, and the investigators have been given the go-ahead to complete the trial. Final outcome of the trial is not yet known.

Responsive Neurostimulation

Some patients with intractable epilepsy either are not candidates for surgery or do not want to undergo resective or disconnective surgery. For these patients, one option that is currently under investigation is responsive stimulation. Responsive stimulation, as currently available, differs from deep brain stimulation in two major ways: (a) deep brain stimulation involves continuous open-loop therapy delivered into a target region of interest. It is delivered all the time without detection of brain activity in the target or feedback from the target tissue. In contrast, responsive stimulation is closed loop. It is delivered intermittently in response to detected EEG abnormalities. (b) The pulse generator for available deep brain stimulation (DBS) systems is implanted in the chest wall below the clavicle, while the currently available responsive stimulator is implanted entirely within the skull.

The goal of responsive stimulation is to provide brief target stimulation only in response to an EEG-detected "preictal state" or ictal onset. For this approach to work successfully, it requires a precise methodology to detect ictal or preictal EEG activity on the afferent side of the loop and effective stimulation delivery on the efferent side of the closed loop.

The Afferent Loop: Seizure Detection

In order to terminate clinical seizures by responsive stimulation, the seizure must be detected and treated before it spreads to a degree that it cannot be controlled with focal stimulation. This suggests that this therapy will be most effective if stimulation is delivered as early and precisely in the epileptic discharge as possible, usually before the onset of clinical symptoms. Responsive stimulation thus requires sufficiently accurate seizure prediction algorithms (SPAs) for EEGs recorded from intracranial electrodes.

All recent SPAs utilize a "sliding window analysis" in which a window of recorded EEG activity is mathematically analyzed using either linear or nonlinear algorithms. Linear algorithms calculate particular features directly from the EEG, including autocorrelation, spectral band analysis, curve length, accumulated energy, and high-frequency epileptiform oscillation[78,92] nonlinear algorithms. The EEG sliding window is reconstructed in three-dimensional phase space and analyzed using techniques such as the short-term maximum Lyapunov exponent, dynamic similarity, or correlation dimension.[78,92] All of these techniques have been purported to have their advantages in seizure prediction. However, as discussed at the recent Second Annual Seizure Prediction Workshop in April 2006,[77] there is still much work to be done in terms of understanding and applying the basics of seizure dynamics. Future techniques will likely apply multichannel, multialgorithm integrated analysis, utilizing a continuous probability curve rather than binary thresholding. In addition, the relevance of high-frequency epileptiform oscillations prior to seizure onset will need to be determined and incorporated into future SPAs. It is likely that future seizure prediction and detection in an individual patient will utilize more than one SPA, and that the optimal SPA application profile will differ from patient to patient.

The Efferent Arm: Stimulation Delivery

In humans, cortical stimulation has long been known to abort spontaneous or induced epileptiform activity during brain mapping in surgical patients. Penfield and Jasper first applied focal electrical stimulation over 50 years ago to terminate spontaneous seizures detected by electrocorticography (ECoG) at the time of resective surgery. More recently, stimulation has been used to shorten or terminate epileptiform afterdischarge activity in patients implanted with intracranial subdural electrode arrays. During the brain-mapping procedures in these implanted patients, brief electrical stimulations were applied to the cortex, with the stimulus amplitude progressively increased until a clinical alteration or subclinical electrographic afterdischarge resulted. In 17 patients with subdural electrodes who underwent functional mapping, control afterdischarge duration was compared with afterdischarges that received brief bursts of stimulation.[72] A biphasic 50-Hz pulse was presented for 0.3 to 2 seconds at the same stimulus intensity used to generate the afterdischarge. The duration of the afterdischarges was significantly shorter in those patients receiving stimulation (Table 1).

Brief pulse durations (0.5 to 1 second) were more effective in terminating afterdischarges than were stimulations of longer duration. This and other studies suggest that the exact stimulation parameters and timing may be very important in determining whether stimulation will disrupt or further entrain electrographic discharges.

Closing the Loop: Combined Detection and Delivery Systems

Limited animal model and human experience pertains to responsive stimulation. In the genetic absence epilepsy rat of Strasbourg (GAERS) rat, which has a genetic disposition to spontaneous generalized absence seizures, responsive stimulation delivered to the subthalamic nucleus upon detection of

P.1418

spike-and-wave epileptiform activity was effective in suppressing seizures.[147] Interestingly, continuous stimulation had no effect on seizure frequency in this model. Responsive stimulation has also suppressed spontaneous seizures in cats[100] and in rat hippocampal slices.[94]

While still in its infancy, the field of responsive stimulation already has examples of effective clinical application in human epilepsy patients. Osorio et al.[97] at the University of Kansas applied high-frequency electrical stimulation that was delivered either directly to the epileptogenic zone (local closed loop, *n* = four patients) or to the bilateral anterior thalamic nuclei (remote closed loop, *n* = four patients) in response to every other automated seizure detection. The eight patients had a baseline video-EEG monitoring with implanted subdural and depth electrodes that localized epileptic foci and quantified seizure frequency using a linear simple genetic algorithm (SGA). Patients determined to have multifocal onsets were implanted into the bilateral thalami for remote stimulation, while local therapy was delivered to patients with a precisely localized epileptogenic focus. A total of 1,491 stimulations were delivered, 0.2% of which triggered afterdischarges. The mean reduction in seizure rate in the local closed-loop group was 55%; in the three responders the mean decrease was 86%, with two patients rendered seizure free during the local stimulation therapy. In the remote thalamic closed-loop stimulation, the mean seizure reduction rate was 41%, with a 74% reduction in the two responders.

More recently, patients undergoing subdural and depth electrode monitoring for seizure localization and functional mapping were enrolled in a trial testing an externalized version of an implantable responsive neurostimulator (eRNS, NeuroPace, Inc., Mountain View, CA).[64] This device used linear SPAs that could be tuned to patient-specific epileptiform activity to deliver electrical stimulation through up to eight contacts of a combination of subdural and/or depth electrodes implanted at the epileptogenic zone. Of 50 enrolled patients, 40 received responsive stimulation. The experience with four of these patients was subsequently reported. In this trial, electrographic seizures were altered and suppressed in these patients during trials of neurostimulation, with no major side effects. In one patient, stimulation appeared also to improve the baseline EEG.

Implantation of an internalized version of this responsive neurostimulator (RNS) system was subsequently investigated in a multicenter clinical trial assessing feasibility of the device's clinical implantation and implementation. For this trial, enrollment included subjects 18 to 65 years with intractable partial-onset seizures and localized epileptogenic-onset region or regions. Subjects with at least 12 simple partial (SP) sensory or motor, complex partial (CP), or generalized tonic–clonic (GTC) seizures over an 84-day baseline period qualified for implant. The responsive stimulator was connected to up to four contact leads (subdural and/or depth), which were targeted to the seizure focus. This trial's results have been reported in limited fashion. A single center's experience with eight implants resulted in 45% reduction in seizure frequency in seven of eight patients over more than 9 months' follow-up.[30] For the multicenter trial, efficacy was assessed during the most recent 84 days for which a subject could have received therapy. Defining response as at least a 50% reduction in seizures, the responder rate for 56 subjects was 36% for CP, 50% for GTC, and 36% for totally disabling (TD) seizures. The median percentage reduction was CP 28%, GTC 50%, and TD 30%; seizure reduction was significant for CP ($p < 0.005$), GTC ($p < 0.02$), and TD ($p < 0.001$). In 65 implanted subjects, including 17 device replacements, there were no serious unanticipated device-related adverse events. Responsive neurostimulation was well tolerated by the patients.[37]

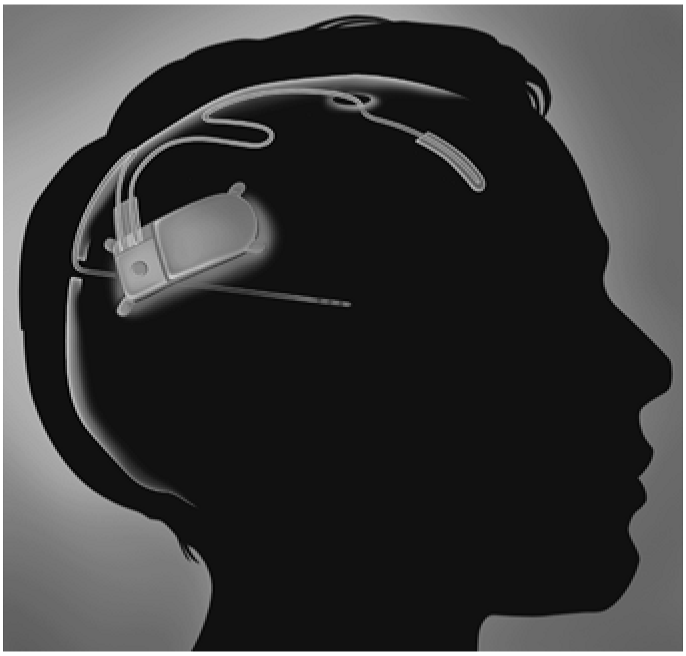

FIGURE 2. Schematic view of the implantable NeuroPace responsive stimulation device (NeuroPace, Inc., Mountain View, CA).

In follow-up to the feasibility trial, a clinical efficacy trial began enrollment in the fall of 2006. In contrast to available implantable deep brain stimulation systems, in which the pulse generator is implanted below the clavicle, the RNS system has two four-contact subdural strip and/or depth electrodes that are attached to a seizure detection and stimulation delivery device that is implanted directly into the skull (Fig. 2). In our center's experience, the most commonly encountered current applications for the RNS trial are dominant mesial temporal seizure onsets in patients with preserved hippocampal function, bitemporal epilepsy with mesial temporal onsets, and seizure onsets arising from a functionally “eloquent” area such as essential language cortex.

Future Directions

Responsive stimulation therapy for epilepsy must be efficacious, well tolerated, and safe in order to offer an alternative to resective surgery or other stimulation modalities in patients resistant to antiepileptic medication. Therapy should be targeted at the epileptogenic region or at seizure propagation pathways and leave other regions of the brain unaffected. It need not interfere with normal brain function, have an acceptable false-positive detection rate, and be stable as a therapy over time. It must also not result in chronic brain damage or the generation of new epileptic foci.

In addition to responsive stimulation, a device with accurate SPA technology will likely be paired in the future with novel treatment strategies such as convection-enhanced local drug delivery[126] or focal cooling[113] to treat epilepsy in closed-loop responsive fashion. Future therapy may be delivered to the epileptic focus, to the epileptogenic region, to propagation pathways, or to deep brain structures. Whether a local responsive treatment can both suppress seizures and inhibit epileptogenesis remains to be determined.

As discussed above, SPA technology will certainly improve and need to be optimized on a case-by-case basis. The ability of responsive stimulation to then terminate detected seizures may depend on a variety of stimulation parameters including exact timing of delivery, current intensity, stimulus duration, the stimulus waveform, pulse frequency, and the delivery of the

P.1419

stimulation in relation to the morphology of the epileptiform activity. These are all areas requiring further basic and human investigation.

The exact localization of the epileptogenic zone is critical for the future efficacy of responsive therapies. Currently, many mesial temporal and nearly all neocortical responsive stimulation patients require invasive monitoring to determine their seizure onset location or locations. Advances in techniques such as magnetic resonance imaging (MRI)–based localization of interictal and ictal activity have great promise in determining where to apply responsive treatment.

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) is a relatively new technique in neurophysiology, with its first description only approximately 20 years ago.[3,62] In contrast to the preexisting transcranial electrical stimulation, TMS provides noninvasive cerebral stimulation that is painless.[89] TMS achieves this by using electromagnetic induction to produce the neurostimulation. The induction is produced by placing a rapidly changing magnetic field adjacent to the scalp. The field is generated by a brief but large electric current through a wire loop and produces an electric current in the subjacent cerebral cortex. This results in synaptic excitation of the neurons within the region of the electric current. Because the magnetic field penetrates the tissue with negligible resistance or attenuation, it is painless. Each magnetic pulse is perceived as a touch or a tap to the scalp.

Technique

TMS has the potential for excellent spatial and temporal resolution. A 0.1-msec stimulation induces a current lasting the same duration and confined to 1 cm^2 of cortex with a maximum depth of about 2 cm.[57,112] When the motor cortex is stimulated, the excitation affects corticocortical neurons predominantly with subsequent activation of corticospinal neurons. The produced movement is a motor-evoked potential (MEP) with measurable conduction time and amplitude. Beyond the stimulation of motor cortex, all cortex that is adjacent to the cranium may be stimulated. Depending on the stimulation parameters, TMS may produce transient dysfunction for purposes of functional mapping or may temporarily alter the intrinsic excitability of the local gray matter. It is this capacity to alter the intrinsic excitability of cerebral tissue that is the foundation of TMS as a potential treatment for epilepsy.

Individual TMS pulses provide a means to measure cortical excitability through several parameters, including intensity thresholds, post-MEP (central) silent periods, and paired-pulse techniques that are similar to those used in basic neurophysiology.[131] These techniques assess different aspects of cortical excitability. Threshold studies apparently represent pyramidal cell membrane excitability as the results are affected by sodium and calcium channel–blocking medications. Central silent period studies likely represent intracortical inhibition and paired-pulse studies are influenced by networks beyond the local cortex. The results of both are dependent on glutamatergic, dopaminergic, and GABAergic (γ-aminobutyric acid) activity.

Single and paired-pulse stimulations do not produce a sustained alteration to the cortical excitability, but such alterations may occur when the stimulation is delivered in trains of pulses. This technique is called repetitive TMS (rTMS). Low-frequency rTMS (LF-rTMS) is defined as pulse trains at or below 1 Hz and high-frequency rTMS (HF-rTMS) as pulse trains above 1 Hz and usually around 20 Hz. The 1-Hz division has practical implications because LF-rTMS is associated with decreases in cortical excitability and HF-rTMS is associated with increases. The occurrence of seizures as an adverse effect of TMS most often occurs during HF-rTMS. Therefore, LF-rTMS is the technique that has been most explored as a treatment for epilepsy. This approach partly depends on abnormal excitability of epileptic cortex, as documented in clinical and animal studies. LF-rTMS delays the development of seizures in pentylenetetrazol-exposed and kindled rats.[1]

Clinical Experience for Epilepsy Therapy

In humans, the reports of rTMS efficacy for seizures have varied considerably with respect to the types of patients included and outcome. Direct electrical stimulation through subdural grid electrodes can decrease both interictal epileptiform discharges and electrographic seizures in patients.[60,116] In a case report of a patient with a focal cortical dysplasia, 100 pulses of LF-rTMS were delivered to the area over the dysplasia twice a week for 4 weeks with a resulting 70% reduction in seizure frequency and a 77% reduction in interictal epileptiform discharges.[88] A report of two patients with epilepsia partialis continua describes each receiving 15 minutes of intermittent HF-rTMS and one becoming seizure free for 2 weeks. Both patients demonstrated a decrease in seizure-related hyperperfusion on single photon emission computed tomography (SPECT).[39]

A series of five patients with intractable focal epilepsy received LF-rTMS over 3 months with modest efficacy.[11] Collective reduction in seizure frequency was 23%, but only one individual within the group demonstrated a significant reduction, which was 43%. The others showed no significant change in mean daily seizure number. In a series of nine patients with various types of focal epilepsy, 1,000 pulses of LF-rTMS were delivered to the vertex daily for 5 days. This produced a seizure frequency reduction >50% for three patients, a 20% to 50% reduction for three patients, a 20% reduction for one patient, and no improvement for the remaining two patients.[133] Those who benefited continued at the reduced frequency for 6 to 8 weeks. A series of seven patients with extratemporal lobe epilepsy received stimulation with 810 pulses of LF-rTMS daily for 5 days.[59] The average frequency of complex partial seizures decreased by 36%, but the decrease in total seizures did not reach statistical significance.

Theodore et al. delivered 30 minutes of LF-rTMS each day for a week to the scalp over the identified epileptic focus in a series of 24 patients.[135] Using a controlled, blinded study design, they observed a 36% reduction in seizure frequency for those patients with neocortical epilepsy and a 12% reduction for those with mesial temporal lobe epilepsy, but the difference was not statistically significant. A similarly designed study with baseline, intervention, and follow-up periods included four patients and observed a seizure frequency reduction >50% in three patients.[115] This study differed from the prior by focusing the stimulation with frameless stereotaxy at a well-defined epileptogenic region, which may explain its more uniform results.

Conclusion

Overall, rTMS has demonstrated promise as a treatment for some forms of epilepsy. The rapid decrement of magnetic field strength with distance suggests that rTMS might be most useful with superficial epileptogenic regions, such as with cortical dysplasias. Further development of rTMS as a treatment will require controlled studies that are designed to determine efficacy and identify patient characteristics that are most associated

P.1420

with successful treatment. Technical development of rTMS should establish optimal stimulation parameters for affecting seizure frequency by addressing the questions of stimulation intensity, frequency, duration, and targeting. If future clinical investigations identify rTMS methods that produce consistently superior seizure control results, epilepsy care would have the additional benefit of gaining a safe and highly tolerable treatment.

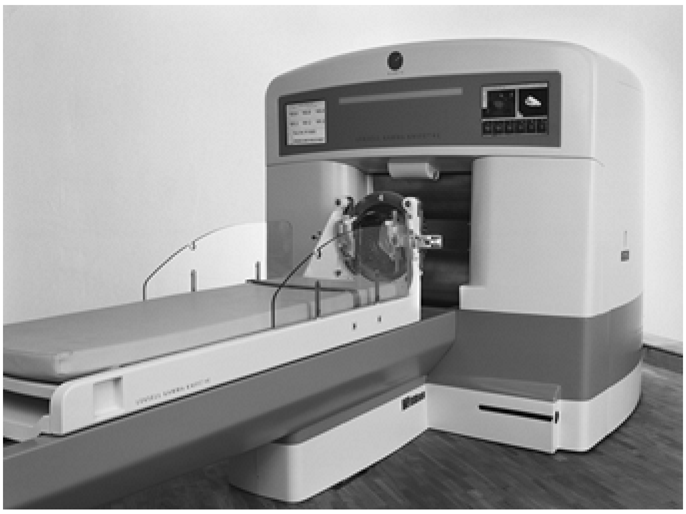

FIGURE 3. A Gamma Knife device. The large housing shields the radioactive cobalt sources. The hemispherical helmet shields the patient from extraneous radiation and contains the collimators that focus gamma radiation to create the surgical lesion. Gamma Knife Radiosurgery

Gamma Knife radiosurgery (GKS) allows performance of precise radiosurgical lesions deep or adjacent to eloquent cortex or other regions of the nervous system that cannot be accessed easily by conventional surgical approaches. In addition, its ability to target functional lesions noninvasively may be advantageous for select patients. On the other hand, use of GKS requires precise localization of the epileptogenic brain region, which means that its noninvasive advantage becomes somewhat moot in syndromes that require invasive localizing techniques.

Relevant background on Gamma Knife history and methodology can be found in the cited reviews.[33,71] Briefly, the Gamma Knife stereotactically projects multiple gamma radiation sources onto brain lesions (Fig. 3). Whereas the individual sources of radiation are too weak to damage intervening brain tissue, a lesion within the common focus is exposed to high-intensity radiation. It is not known how irradiation produces an antiepileptic effect. Massive necrosis of neuronal tissue does not seem to be a requirement, as the major pathologic findings following irradiation are endothelial damage to small blood vessels and astrocytic reactions.[150] One hypothesis, therefore, is that neuronal damage results from ischemia caused by vascular inflammation.[120] In addition, some neurons (e.g., hippocampal neurons) may show differential susceptibility to irradiation or ischemic injury.[140]

The main use of GKS is in the treatment of tumors[117] or arteriovenous malformations (AVMs)[35,47,66,127] that are inoperable with standard neurosurgical techniques. In patients with tumors, it is difficult to separate the effects of GKS as an antiepileptic procedure from its beneficial effects on the primary lesion. The potential efficacy of GKS in the treatment of symptomatic localization-related epilepsies is most evident in the treatment of AVMs. Steiner et al. reported that 69% of patients with recurring seizures due to an AVM became seizure free after GKS.[127] Nineteen percent successfully discontinued all anticonvulsant medications. Subsequent studies of both proton beam and GKS showed a combined rate of 70% seizure remission following Gamma Knife treatment of AVMs (Table 2).

Table 3 Results of Published Clinical Trials of Gamma Knife Surgery for Mesial Temporal Lobe Epilepsy[a]

[a] Treatment dose and volumes are estimated at the 50% isodose limit.

[b] Linear accelerator, dose, and volume at 57% isodose limit.

Steiner et al. noted that seizures remitted independent of radiologic remission of the AVM,[127] a finding that suggests that the focal effects of irradiation, rather than the improvement of the lesion itself, may be antiepileptogenic.

The utility of GKS has also been studied in patients with epilepsy due to lesions such as hypothalamic hamartomas[26,85,101,141,142] or cavernous angiomas[76,102] that are difficult to excise using traditional surgical techniques. Régis et al. conducted a multicenter, retrospective survey of ten patients treated with GKS for hypothalamic hamartomas.[101] Four subjects were seizure free in follow-up durations between 12 and 71 months, although two subjects required two treatments to achieve this success. Two other patients "significantly improved." No postsurgical morbidity was reported. Preliminary data from a prospective study show that in 27 patients with at least 3 years' follow-up, 37% are seizure free.[106]

There are no published data on the use of GKS for functional neocortical lesions. Because localization of seizure onset in these cases usually requires invasive techniques, the noninvasive nature of GKS loses some advantage.

Mesial temporal lobe epilepsy (MTLE) has received much attention in terms of GKS treatment. Unlike nonlesional neocortical epilepsy, MTLE is commonly diagnosed noninvasively, which makes GKS especially attractive. Furthermore, seizures caused by epileptogenic tumors within the temporal lobe remit in greater rates than seizures associated with extratemporal tumors;[117] the success of GKS in treating space-occupying temporal lesions suggested that temporal lobe epilepsy with

P.1421

functional, rather than space-occupying, lesions might benefit as well. However, initial attempts in Sweden with Gamma Knife[75] and elsewhere with the use of fractionated radiotherapy and other techniques[2] were not encouraging. The first surgical series employing radiosurgery in a systematic fashion was reported by Talairach,[129] who treated 44 patients between 1959 and 1973 with the use of yttrium.[90] With a mean follow-up of 5.7 years, Talairach reported a 75% rate of seizure freedom for patients with temporal lobe epilepsy.[129]

Régis et al. revived interest in GKS of MTLE when their preliminary studies showed short-term seizure-free rates of >80%.[103,104] These early reports suggested that GKS might offer rates of efficacy that were comparable to standard anterior temporal lobe (ATL) resection. Their prospective multicenter European trial of 21 participants demonstrated a 62% intent-to-treat seizure-free rate at a minimum of 2 years' follow-up.[105] Small case series differ in treatment protocols and results, with most failing to achieve complete remission from seizures.[16,56,86,125] Currently, a U.S. National Institutes of Health (NIH)–sponsored multicenter trial headed by Nicholas Barbaro of the University of California at San Francisco is ongoing.

Published trials are summarized in Table 3. The variability in results of GKS therapy for MTLE underscores the difficulties in clinical research in the determination of basic parameters of anatomic target, dose, and target volume. Anatomic targets in GKS of MTLE are the least variable factor. All studies in Table 3 specify that the 50% isodose volume (the volume encompassing at least 50% of the total radiation) contains regions thought most important in generation of mesial seizures, the amygdala, the head and anterior body of the hippocampus, and the parahippocampal gyrus.[149] Dose (measured in units of radiation absorbed, Gray [Gy]) and lesion volume are more variable among studies. Dose intensity and volume are difficult to extrapolate from animal[14,84] to human protocols. However, comparison of the studies listed in Table 3 suggests that low-dose protocols are less successful than are higher-dose protocols. Dose/volume-response curves extracted from early trials (Fig. 4) suggest a narrow therapeutic window between efficacy and potential toxicity.[103,104]

The ongoing NIH multicenter study will help evaluate the effect of radiation dose volume in that treatment volumes should exceed 5.5 mL, below which GKS was inefficacious, and stay below 7.5 mL, above which postoperative edema appeared too severe. In the current protocol, patients are randomized into 20-Gy or 24-Gy treatment arms. Régis et al. have outlined the typical postoperative course.[103,104,105,107] No significant changes typically occur in seizure frequency or neuroimaging for 9 to 12 months.[103,104,105,107] Nearly all patients experience transient exacerbations in auras or seizures before seizures decrease or remit.[105] The most dramatic drop in seizure rate occurs between 12 and 18 months, coinciding with the development of maximal MRI changes (Fig. 5).[105]

Morbidities of Gamma Knife therapy for MTLE include visual field deficits in 52% of patients, mostly quadrantanopsias, as to be expected after standard ATL resection. One subject had a hemianopia (indicating direct involvement of the optic tract) and another had mixed deficits.[105] Other “transient minor morbidities” consisted of headache, nausea, vomiting, and depression. Headache requires special comment, as it coincides in some subjects with postoperative edema.[105] Steroids, either in response to symptoms or in response to MRI changes, were used in the majority of patients presented in Table 3, but no clear evidence in these studies stand out either for steroid initiation, its effectiveness in treating symptoms, or its effects on eventual seizure remission. In fact, Régis reported that eight subjects were not treated with steroids at any point in the postoperative course.[105]

P.1422

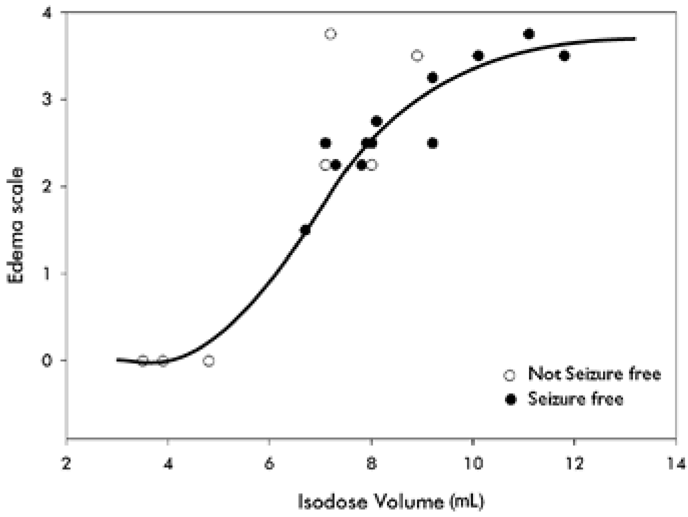

FIGURE 4. Dose-volume response curve of 24-Gy doses of Gamma Knife treatment of mesial temporal lobe epilepsy in early trials (Régis J, Peragui J, Rey M, et al. First selective amygdalohippocampal radiosurgery for 'mesial temporal lobe epilepsy.' *Stereotact Funct Neurosurg.* 1995;64[Suppl 1]:193–201; and Régis J, Bartolomei F, Rey M, et al. Gamma knife surgery for mesial temporal lobe epilepsy. *Epilepsia.* 1999;40:1551–1556). The y-axis indicates the peak severity of transient postradiation changes, mainly edema, that emerge in treated subjects 9 to 15 months postoperatively and slowly resolve. The x-axis indicates the 50% isodose volume of a 24-Gy exposure. (Figure created from data courtesy of J. Régis.)

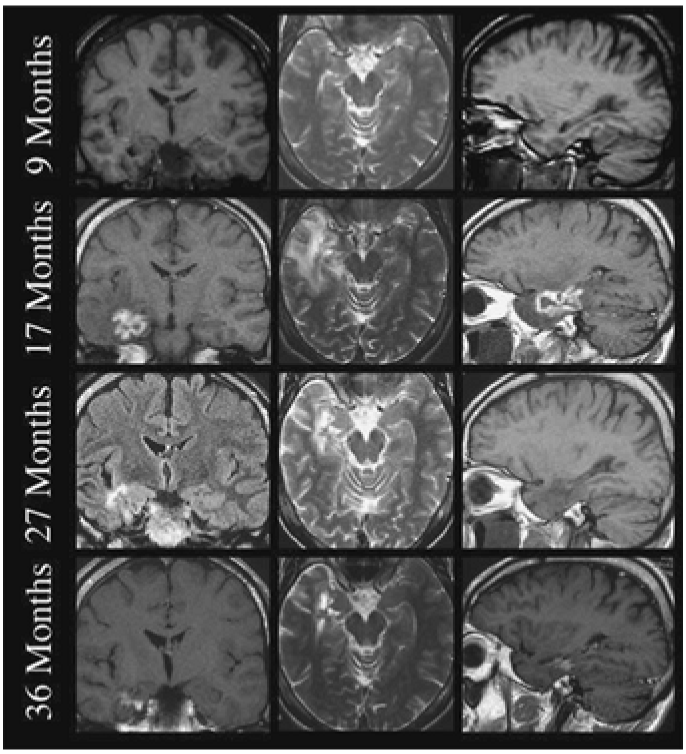

FIGURE 5. Time course of mesial and ipsilateral hemispheric changes following Gamma Knife surgery for mesial temporal lobe epilepsy at 9, 17, 27, and 36 months postoperatively. In this example, no changes are present at 9 months. At 17 months, contrast enhancement surrounded by high T2 signal changes is

evident, along with some minimal mass effect and T1 intensity changes of the temporal lobe. At 27 months and 36 months, changes begin to resolve, leaving a small region of contrast enhancement at the dose center. (From Régis J, Rey M, Bartolomei F, et al. Gamma knife surgery in mesial temporal lobe epilepsy: a prospective multicenter study. *Epilepsia.* 2004;45:504–515.)

One important factor is that the delayed effect of treatment may expose patients to the continued morbidity of ongoing seizures, including sudden death in epilepsy and traumatic injury. Two deaths occurred during the latency period in a case series of five subjects treated with "low-dose" radiation.[125] Future trials of GKS may need to consider supplementary seizure prophylaxis during the period of transient exacerbation of auras and seizures.

Beyond seizure efficacy, studies have begun to evaluate secondary outcome measures such as cognition and quality of life. There are three reports of neuropsychological outcome following GKS for MTLE: The previously noted prospective, multicenter trial[105] and two studies of small series of participants.[86,125] Prospective trial results report no mean neurocognitive changes through a 2-year follow-up period.[105] Similarly, Srikivilaikul et al. reported no group mean changes at 6 months' follow-up, although some individuals showed decline in at least one cognitive domain.[125] McDonald et al. reported on 27-month follow-up in three participants who underwent dominant hemisphere low-dose GKS treatment.[86] No long-term consistent changes in neurocognitive parameters were found, although each patient showed decline in a measure of verbal memory. They concluded that neurocognitive changes following GKS appeared similar to those of standard ATL resection.

In summary, recent trials suggest that certain protocols of GKS for MTLE may offer seizure remission. Further work is needed to clarify whether remission rates or neurocognitive outcomes following GKS are comparable to those following ATL resection. One distinct disadvantage of GKS is the approximate 12-month latency period required while the radiosurgical lesion develops. However, the noninvasive nature of GKS may prove to be an advantage to those who fear craniotomy or those with comorbid medical conditions that may prevent full anesthesia. Another potential advantage, yet to be fully explored in the clinical arena, is the ability to reduce seizures with less than a lethal effect on brain tissue in the seizure focus. Whether this will allow preservation of functions that are at risk from surgical resection remains to be determined.

Focal Delivery of Antiepileptic Drugs

Some of the side effects of antiepileptic drugs derive from actions at the periphery, for example, suppression of blood counts, hepatic or renal toxicity, or rash. Delivery of drug directly to the seizure focus in the brain might improve the therapeutic:toxic ratio of the medication. Direct delivery to the brain also could allow higher doses of drug than would be tolerated by systemic administration. Additional potential benefits include obviating the need for good oral absorption, penetration of the blood–brain barrier, and concern about drug sequestering in fat stores. Several interesting methods have been explored for focal drug delivery to the brain to better control seizures.[28]

One approach is delivery of drug to the cerebrospinal fluid, either via a ventricular catheter or a lumbar intrathecal catheter. The latter is less invasive, but may not distribute drugs to the ventricular system and periventricular brain. A key issue with intracerebroventricular delivery of medication is degree of penetration into brain. Such penetration is very slow when mediated by passive diffusion, but it may be facilitated by convection secondary to pulsatile pressure of cardiorespiratory rhythms.[10] Several studies have evaluated acute administration of antiepileptic drugs into spinal fluid during acutely induced seizures in animal models. Two studies have looked at chronic perfusion via an osmotic pump implanted subcutaneously in rats. One[119] evaluated valproic acid in a kindling model of epilepsy. Another[96] assayed efficacy of gabapentin in the fluorothyl seizure model in the rat. Both studies showed efficacy and reasonable tolerability in the model systems.

Antiepileptic drugs (AEDs) can be delivered via catheters placed over or into a seizure focus. These catheters can continuously perfuse medication, on a programmable schedule (e.g., for patients who might have more seizures during sleep), or in response to seizure detection/prediction algorithms.[126] Trials of focal drug perfusion for epilepsy have not yet been published in a clinical setting, in part because long-term safety and determination of the best medication to use are not fully accomplished. This does, however, remain a promising new approach.

A liposome is a fatty bag of medication.[138] Drug diffuses from the liposome over days to weeks. Targeting mechanisms, consisting of antibodies or receptor-binding agents, can be attached to the liposome so that the liposome adheres to a region of interest. Similar technologies exist for preparation of microsomes from synthetic materials. In neurologic disorders, a key issue is delivering a liposome across the blood–brain barrier. One strategy for doing so is to link it to a transport mechanism, such as for transferrin.[123] Liposomes and microsomes are of proven utility in some cases of infection and neoplasm, but they yet remain to be shown useful for human epilepsy.

Polymer wafers are engineered to release drug from a supporting chemical matrix over a period of months. The strategy has been useful in delivering chemotherapy for malignant brain tumors, as with the Glidel wafer.[12] Tamargo et al. showed that wafers containing phenytoin were active against seizures in a rat cobalt epilepsy model.[130] Whether the time course and efficacy of such wafers will be suitable for human AED therapy remains to be determined.

Medications can circulate systemically in a prodrug inactive state, until activated by a substance released at a seizure focus. One such interesting medication is DP-VPA, which requires action of a phospholipase to cleave a phospholipid moiety from valproic acid.[68] Phospholipase-A2 is elevated at a seizure focus, resulting in locally high concentrations of valproic acid. A small, double-blind clinical trial showed a 30% reduction in seizures during the first 28 days.[111]

Biologic machinery can be harnessed to produce locally renewable supplies of antiepileptic medications, either by cell transplantation or by genetic engineering. These approaches are considered in the subsequent sections.

Transplantation for Partial Epilepsy

Cellular engineering and transplantation have developed to a stage potentially useful for the treatment of neurologic disorders, including epilepsy.[15,38,41,53,63,80,110,121,124] Soon we will be able to use pluripotent stem cells to differentiate into any desired cellular line. Until then, work with other cell lines, such as GABAergic cells derived from neonatal pigs, may serve to test such issues as the ideal location for transplanted cells; the dose or number of cells that are necessary to give a prolonged response; whether GABAergic cells are a reasonable choice or another cellular line is preferred; and whether it is necessary to use immunosuppression on the host. This section broadly reviews the topic of cellular transplantation in the treatment of partial epilepsy in animals and in the one completed “proof of concept” study.

Transplanting cells into a region of epileptic seizure onset represents a novel approach to therapy of seizures. Cellular transplantation techniques might be a reasonable and acceptable alternative to excisional surgery for medically intractable partial epilepsy. In this scenario, the cell line that appears to be most affected by the specific seizure disorder could be grown or harvested, pretreated in such a way as to block a host rejection reaction, implanted through neurosurgical stereotactic means, and allowed to mature. With this model, the transplanted cells sprout and establish synaptic connections in the epileptic brain, allowing for that region to regain self-control over excitability. Such a therapy treats epilepsy, not just seizures, as the manifestations of the disorder.

Several questions come to mind about cellular transplantation for partial epilepsy. Many of these questions were raised during discussions of treatment of Parkinson disease with dopamine-producing cells. What are those concerns? First, what cell line is best suited to treat epilepsy? Cells that primarily produce GABA should be considered. However, dopamine-producing cells, serotonin-producing cells, and others have been tested in animal models for partial epilepsy.[49] Second, what should be the source for these cells? In the Parkinson literature, a number of studies were carried out using aborted fetal tissue.[46] Is this possible for the epilepsy patient? Can we use stem cells? In that case, should they be embryonic,[50] bone marrow,[99] or neuronal in origin? Would they need to be from related or unrelated individuals? What about cells from another species? Xenotransplantation has been used for years, yielding, for example, commonly used porcine heart valves.

Cells used for transplantation must be readily available if this is to be a widely utilized procedure. That, in conjunction with current ethical issues, makes the use of aborted fetal tissue highly unlikely for the near term.

For similar political and ethical reasons, embryonic stem cells are unlikely to be considered candidate sources even though they have many potential advantages. The cells that are transplanted should have a life expectancy similar to the recipient. This is probably not a problem for most human-derived stem cells but may be a limiting factor for xenotransplants, unless one chooses animals with fairly long life spans. The cells will need to be transplanted at a developmental time when they are no longer able to divide (postmitotic) but have not yet sent out extensive branching. Stem cell research has not yet progressed to the point where, when cells are induced to develop along a specific cell line, one can assure the recipient that there is no danger that the cells will continue to divide and reproduce in an uncontrolled fashion. Stem cell research cannot be attempted in humans as a treatment until the issue of uncontrolled reproduction is resolved. Stem cells could be harvested prior to the stage of axonal and dendritic sprouting. In so doing, the cells would be given maximum likelihood to both survive and make appropriate synaptic contact. Xenotransplant cells also can be harvested at a developmental stage when they are postmitotic but have rudimentary processes.

Would the recipient require immune system modulation to allow survival of the transplanted cells?[54] If stem cells come from unknown donors or distant relatives or if xenotransplant cells are used, some type of immunologic modulation will be required to prevent a host-versus-graph rejection reaction. On the other hand, if cells can be harvested from the recipient, grown, and differentiated, they can be given back without the need for immunologic manipulation. Immunomodulation usually utilizes one of two common approaches. In one, the physician pretreats and continues to treat the recipient with an immunosuppressive drug or drugs, for example, cyclosporine. Alternately, the physician treats the donor cells with an incomplete monoclonal antibody directed against the main histocompatibility receptor class I site (MHC-I) on the neuronal membrane. These sites are the main sites that, when activated, will trigger the rejection reaction that will ultimately kill the cell. Young cells and xenotransplant cells stand a better chance for survival than do fetal-derived cells using this technique, because of increasing membrane density of these sites with cell maturation. Studies have shown that ultimate cell survival is about the same with either of these two approaches. Lifelong immunosuppression is not benign, and some immunosuppressants are proconvulsant.

If xenotransplant cells are used, what animal should serve as the source? The considerations are that the source animal should have a reasonable life expectancy compared to humans so that the donated cells may live for the natural life of the human into whom they are transplanted. The source should be plentiful and not create undue social or ethical concerns. Higher primates have some advantages, but they are neither plentiful nor without ethical concerns. The animal should be one that has lived among humans for a long part of our natural history, so that we have been exposed to diseases that are specific to that species and vice versa. One major safety concern is that the exposure of the human recipient population to a new and previously unseen endogenous retrovirus could unleash a major public health threat. Given all these factors, the pig became the species of choice. Mankind has been exposed to pigs and their diseases for centuries. We are aware of and can treat most of the other disorders seen in pigs, and the pig's anatomic and neuronal physiology is very similar to that of humans. Pigs carry a risk of endogenous retrovirus (PERV), but this risk is well known. Humans have been exposed to and in some cases have contracted PERV infections without serious consequences. However, risks from new or previously undiscovered PERVs cannot be quantified. Pigs can be raised under favorable breeding conditions for medical needs.

GABA is present in approximately 60% to 70% of all synapses in the CNS and is the major inhibitory neurotransmitter. GABA-mediated inhibitory pathways are important in the regulation of seizure activity.

Focal-onset epilepsy appears to often be associated with loss of local inhibitory cells. Transplanting GABA-producing

P.1424

cells to the region of a seizure focus theoretically would provide a biologically active source of inhibition for an indefinite period of time, with little to no systemic side effects. GABAergic cell transplants have been evaluated as antiepileptic therapies in hippocampus, cingulate gyrus, cerebellum, olfactory regions, and septal regions[6] of animal models. Secondary epileptic brain regions also may provide useful targets for transplants.[6,24,81,83]

Fetal porcine cells for transplantation are derived from the lateral ganglionic eminence, an area rich in GABAergic cells.[51] Cells of this lineage previously were reviewed by the Food and Drug Administration (FDA) for the treatment of Huntington disease and of stroke.[114] In animal studies, fetal porcine GABAergic neurons survive following transplantation and continue to express the enzyme required for the synthesis of GABA. The gestational age E 31 to 38 is ideal for harvesting these cells because the cells are postmitotic and have not yet started to send out processes. Studies in animal systems have showed cell survival and migration within certain boundaries.[23] Cells establish synaptic contacts and functional interactions within the local environment.[32] Studies compared cyclosporine treatment and mouse monoclonal antibodies to multiple cloning site 1 (MCS-1). Techniques were developed to determine the level of cell survival and neuronal growth, as well as neuronal integration. In postmortem slides of animal work, stains that recognized porcine repetitive element DNA could easily dissociate the graft and host cells. This technique, while showing survival of the porcine cells within the transplant, did not differentiate between those that were neuronal versus those that were glial elements. Therefore, superimposed upon this stain were porcine glial stains, which identified the glial elements. Neuronal elements themselves could be stained with a specific neurofilament stain. GABAergic origin was documented with an anti–glutamate decarboxylase (GAD) stain. Finally, stains that were specific for new neuronal synapse formation (i.e., synaptobrevin) could clearly differentiate cells that established synaptic contact with existing cells.[27,51] What could not be determined is whether these cells behaved as they would in normal circumstances.

We initiated a “proof of concept” study for porcine GABAergic transplants with individuals who were 18 years of age or older, who had a longstanding history of medical refractory frontal or temporal lobe seizures. The seizure focus onset had to have been localized via invasive EEG testing and found to be surgically treatable. We asked that the exclusion criteria include anyone with a treatable etiology for their seizures, anyone with multifocal-onset seizures, or those who had a history of psychosis associated with GABAergic-enhancing medications. Anyone with a progressive CNS lesion or with a history of status epilepticus within 3 months of the transplant was excluded. Eligible patients had to agree to delay their surgery for a period of 6 months and have the implantation procedure.

Transplants were accomplished using cells from the lateral ganglionic eminence of gestational age 31 to 38 pig fetuses, microscopically dissected and treated with a mouse-derived monoclonal antibody against the MHC-1 sites. This resulted in a suspension with a concentration of 100,000 cells/μL. Approximately 4 μL of this suspension, representing about 500,000 cells, was infused along the line of the electrographically determined epileptogenic zone. A flexible cannula was passed through the depth electrode on one occasion but the tip of the electrode was occluded. Subsequent implants used a cannula guided by stereotactic techniques.

Patients were monitored for adverse events, including PERV exposure, and to obtain preliminary seizure data. At the time of excisional surgery, porcine cell survival and connectivity were evaluated in three subjects, two with mesial frontal lobe foci and one with mesial temporal-onset epilepsy. None of the three suffered any physical or neurologic deterioration during the time of the transplantation. Blood chemistries, hematologic status, and AEDs were monitored regularly. Blood specimens were sent for and then stored for evaluation of PERVs.

Two of the three patients underwent their planned surgical procedure. The patient with mesial temporal-onset seizures was found to have mesial temporal sclerosis. This patient unfortunately died an unobserved death of unknown etiology. No surviving porcine cells were found or identified. The second patient had a mesial frontal removal done at about 9 months following the implantation. He had delayed his surgical removal date because he and his family were convinced that he had fewer seizures and the ones that did occur were milder. He, too, had no visible surviving GABAergic transplanted cells. The third patient maintained a transplant for over 4 years and, for the last 3 years of that time, had no recorded seizures and required no significant medicine changes. Unfortunately, this patient died in association with acute AED withdrawal, when his pharmacy was unable to renew his prescriptions over a long holiday weekend. The family refused postmortem examination.

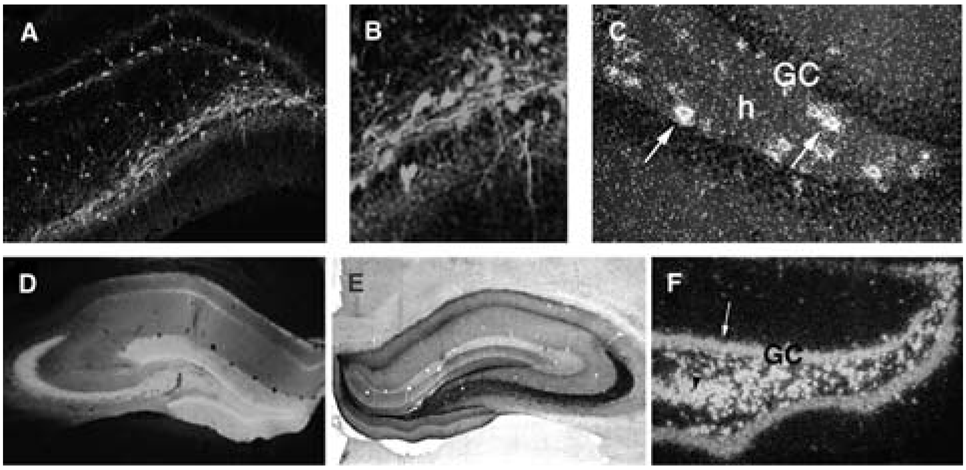

FIGURE 6. Influence of viral serotype on green fluorescent protein (GFP) and neuropeptide Y (NPY) expression in the rat hippocampus. Serotype 2 adeno-associated virus (AAV) induces transgene expression specifically in hilar interneurons with a spread of about 1.5 mm around the injection site. Panels **A** and **B** depict GFP in hilar interneurons and their fibers. Panel **C** depicts NPY mRNA in hilar interneurons (*arrows*). Note that granule cells do not express the transgene. Chimeric serotype 1/2 induces a larger transgene expression including hilar interneurons, mossy fibers, and granule cells with an extension of approximately 2.5 mm around the injection site. Panel **D** illustrates GFP distribution throughout the hippocampus. Panels **E** and **F** show NPY immunoreactivity and its mRNA, respectively. Note that an intense hybridization signal is observed in granule cells (*arrow* in **F**) and CA3 (*arrowhead* in **F**). Transgenes were selectively expressed in neurons since they were under control of neuronal enolase promoter. GC, granule cells; h, hilus. (See the color insert.)

Our "proof of concept" study suggests that it is feasible to identify a subset of potential surgical excisional patients for possible transplantation, although the numbers in the pilot study were small. Mesial frontal seizures without identifiable lesions, a condition that is relatively well known to have a higher than usual surgical failure rate, did seem to respond, whereas mesial temporal sclerosis, a condition where the surgical treatment has excellent outcome results, failed. No adverse effects resulted from the transplants themselves. No new PERV infections emerged. Cell survival and synaptic connectivity in the patients are unknown. The patients with frontal epilepsy had a response similar to that described for implanted latex beads soaked in GABA. Seizure reduction lasted for about 2 weeks, faded, and then reappeared. Speculatively, the delayed response was associated with cell survival and secretion of GABA.

A number of concerns need to be considered prior to further clinical trials. The "proof of concept" study demonstrated that this approach is feasible, but evidence was insufficient to prove that the technique produced the desired effect in the recipient. The study failed to show that these transplanted cells survived or functioned. One of the three cases, however, had a lasting improvement in seizure control, which significantly raises hope. Given the progressive nature of uncontrolled or poorly controlled partial epilepsy, techniques that use xenotransplant cells or stem cells are likely to be tried in the near future. The potential for success appears to be substantial.

Gene Therapy

Gene therapy techniques as a treatment for epilepsy involve the transfer and expression of a gene into the ictogenic brain region or regions, resulting in a long-lasting production of a "therapeutic" molecule endowed of potential antiepileptic action. In principle, patients with intractable seizures of focal onset may benefit from gene therapy approaches that are alternative to resective surgery, offering the possibility to deliver specific "therapeutic" genes directly into the brain area where seizures originate.

The generation of viral vectors transducing neurons, and of other in vivo gene transfer methods, provides attractive strategies for introducing and stably expressing novel genes into the brain.[20,93] Moreover, recent experimental evidence in rodents provided a proof of principle for the applicability of these strategies for inhibiting seizures and rescue neurons from irreversible damage. These two therapeutic outcomes should lead to sparing of function at the level of synaptic transmission, plasticity, behavior, and cognition. Crucial aspects that

contribute to determine the success of a gene therapy approach include the methods of gene delivery, the strategies for improving cell transfection, and the expression of the specific gene, and circumventing possible adverse host tissue reactions to the transgene.

Therapeutic Targets and Delivery Methods

Experimental approaches to gene therapy in rodent models of seizures have characterized several candidate genes that may provide targets to inhibit seizures, including neuropeptides, such as galanin, cholecystokinin, and neuropeptide Y; inhibitory neurotransmitters, such as GABA and adenosine; and *N*-methyl-D-aspartate (NMDA) receptors (for review see reference 95). Neuroprotection from the damaging effects of seizures or prevention of progressive cell loss that may predispose to epileptogenesis also are important aspects that should be considered in the context of a gene therapy approach to epilepsy. Using in vitro and in vivo models of cell death, neuroprotection has been achieved by inducing overexpression of antinecrotic and antiapoptotic genes, neurotrophins, and Glut-1 glucose transporters or using vectors containing a synthetic glucocorticoid-responsive promoter exploiting the high levels of adrenal stress hormones secreted in response to injury.[25,42,87,98] Transgene expression has also provided in some instances recovery from physiologic and behavioral dysfunctions.[25]

Gene transfer can be achieved in vivo using viral vectors, naked DNA, or cation–lipid DNA complexes, or ex vivo using cells previously transfected in vivo with the gene of interest. Viral vectors are generally the most efficient for in vivo transfection since they permit long-term gene expression and can be engineered to preferentially target specific neuronal populations in a controllable manner.[22,52] However, they have size limitations for transgene inclusion in the expression cassette and are potentially immunogenic. Viral vectors such as adeno-associated virus (AAV) vectors, lentivirus, and herpes simplex virus have specific tropism for postmitotic neurons; AAVs have the best safety profile.[91]

Viral Vectors in Experimental Models

Neuropeptides

Attenuation of seizure and neuronal death in rats has been reported following brain application of AAV vectors mediating galanin and NPY expression and secretion.[43,74,109] Haberman et al.[42] engineered a viral vector carrying the secretory signal of the laminar protein fibronectin together with the galanin gene. The secretory signal improved galanin secretion and significantly attenuated in vivo focal seizure sensitivity in rat inferior collicular cortex; moreover, hippocampal hilar cell loss consequent to kainate seizures was prevented. Using a doxycycline-off, regulated AAV vector, this study demonstrated the feasibility of both controllable and long-term (up to 4 weeks) seizure attenuation. Lin et al.[74] adopted an AAV vector in which the galanin gene was driven by a neuron-specific promoter. This study showed long-lasting (up to 2.5 months) functional overexpression of galanin, specifically in hilar interneurons and their terminal projection fields, thus demonstrating that the peptide can be transported along axons even long distance from its site of synthesis. This restricted galanin overexpression resulted in powerful inhibition of seizures induced by intrahippocampal injection of kainic acid.

Richichi et al.[109] induced long-lasting NPY overexpression in the rat hippocampus by local application of AAV vectors with different serotypes. This study showed that enhanced gene transfection can be achieved by varying the capsid genes: Serotype 2 AAV vector increased NPY expression in hilar interneurons only, while the chimeric serotype 1/2 vector caused far more widespread expression including mossy fibers, pyramidal cells, and subiculum (Fig. 6). NPY overexpression resulted in kainate seizures inhibition, blockade of status epilepticus, and delay in kindling epileptogenesis.

N-methyl-D-aspartate Receptors

Haberman et al.[43] cloned an antisense cDNA fragment of the constitutive NMDA receptor subunit (NMDAR1) into an AAV vector, under the control of a cytomegalovirus (CMV) promoter *with or without* a tetracycline (TET)-off cassette. Three weeks after delivery into the inferior colliculus, a well-characterized site of focal seizure genesis, the NMDA-like immunoreactivity was significantly reduced. However, the threshold current for inducing wild-running seizures by electrical stimulation of the collicular cortex was raised only in the rats that received the AAV vector *without the TET-off cassette* since this vector transduced the primary excitatory-output neurons only. A paradoxic increase in focal seizure sensitivity was instead induced by the AAV vector *carrying the TET-off controllable promoter* since this vector primarily depleted NMDA receptors on inhibitory GABA interneurons, thus reducing the GABA-mediated inhibitory drive on excitatory output neurons. Thus, without a detailed knowledge of the transduction pattern in humans, manipulation of neurotransmitter receptors, or inference of ion channels, may lead to a paradoxic increase in seizure sensitivity.

Enzyme Replacement

In humans, a mutation-dependent deficiency of the aspartoacylase (ASPA) gene leads to Canavan disease, and 63% of these patients exhibit epileptic seizures.[139] The ASPA gene is involved in the hydroxylation of *N*-acetyl-L-aspartate (NAA), which has neuroexcitatory properties. This gene was inserted into a defective recombinant adenoviral vector under the control of a chimeric promoter (CAG promoter)[118] and intracerebroventricularly injected in spontaneously epileptic rats, which were obtained from cross-breeding of the tremor rats lacking the ASPA gene. The occurrence of tonic seizures was significantly reduced in these rats; however, this protective effect was lost within 2 weeks after the vector injection, possibly due to the induction of an immune response to this first-generation adenoviral vector. A recent study has shown that delivery of the ASPA gene using AAV vectors in tremor rats persistently attenuated seizures.[61]

Nonviral Delivery Systems

One of the main alternatives to viral vectors for gene transfer into CNS cells is represented by pegylated immunoliposomes carrying the plasmid DNA for expressing the exogenous gene. Using a brain cell–specific promoter and a targeting ligand that binds to a transporting receptor on the blood–brain barrier (i.e., a monoclonal antibody to the transferring receptor), it is possible to limit the expression of the exogenous gene to the brain.[122] The advantage of this delivery system is the possibility of systemic, thus noninvasive, application. However, the persistence, level of expression, and transduction efficiency of the transgene are limited compared to viral vector–mediated gene delivery.

Zhang et al.[151] used lipofectin reagent solution to transfer the CCK gene inserted into a plasmid under the control of SV40 promoter into the ventricles of rats with congenital audiogenic seizures. Seizures were markedly but very transiently decreased, likely because the plasmid was degraded by endogenous cellular nucleases.

Transplantation of Genetically Modified Cells

Cells can be engineered *in vitro* to produce and release a therapeutic molecule after *in vivo* transplantation in specific brain areas. GABA and adenosine have been used as therapeutic targets in cell transplantation approaches because of their well-established inhibitory actions on seizures in various models of epilepsy.

Huber et al.[49] engineered conditionally immortalized fibroblasts to secrete adenosine by inactivating the adenosine-metabolizing enzymes adenosine kinase and adenosine deaminase. These fibroblasts were encapsulated into semipermeable polymers and subsequently grafted into the brain ventricle of electrically kindled rats. Generalized seizures were completely suppressed in rats receiving the adenosine-releasing grafts. An important aspect of this approach was the lack of sedation or ataxia that otherwise was observed after systemic delivery of adenosine or its analogs. However, protection from seizures was limited to the first 12 to 24 days from grafting, apparently due to a decrease in cell viability within the graft. Genetically engineered GABA-producing cells have been obtained from conditionally immortalized mouse cortical neurons and glia[137] by using a plasmid carrying the cDNA for the GABA-synthesizing enzyme glutamate decarboxylase (GAD65), under the control of doxycycline-sensitive minimal human CMV promoter. The rats receiving neuron or glia-derived cell transplants producing GABA in the anterior substantia nigra showed a delayed kindling progression, while acceleration of kindling was observed if these cells were transplanted in the posterior substantia nigra, in analogy with the effects elicited by exogenous application of GABA agonists to the same brain areas. If GABA-producing cells from immortalized cortical neurons were implanted into the piriform cortex, the rats displayed a higher threshold for the induction of generalized seizures after amygdala kindling, but they did not show any alteration in the development of kindling.[34]

The rats that received GABA-producing cells into the substantia nigra 2 weeks after the induction of pilocarpine-induced status epilepticus had significantly fewer spontaneous seizures and suppression of epileptiform spikes. The engineered cells showed evidence of integration with the host, but ongoing cell degeneration was observed within 10 days.[136]

Thus, strategies for the generation of cells with enhanced viability such as introducing survival-enhancing genes (i.e., constitutive active immortalizing oncogenes or apoptosis inhibitors) are warranted to provide long-term anticonvulsive efficacy.

Conclusions

Although the studies in experimental models of seizures and epileptogenesis have shown the potential applicability of gene therapy approaches to epilepsy, an important issue that still remains to be fully addressed is the characterization of the efficacy of gene therapy in chronic epileptic tissue using models of spontaneous and recurrent seizures. Thus, chronic epileptic tissue often is characterized by neuronal loss, synaptic plasticity, and molecular changes that affect the target or targets of the “therapeutic” gene and reduce its effects. Direct gene transfer into human epileptogenic tissue from temporal lobe epilepsy patients has been done in vitro using an AAV vector to transfer and express a reporter gene. Histologic analysis showed expression of the transgene in neurons with no obvious evidence of toxicity.[31] One recent report showed that the incidence and duration of spontaneous seizures were indeed reduced in chronic epileptic rats following hippocampal application of AAV vector overexpressing NPY, and the disease progression appeared to be arrested.[95]

Another important consideration concerns the immune reactions that may be induced by the gene transfer (i.e., production of antibodies against the vector serotypes, promoter silencing, instability of the vector genome, and loss of transduced cells).

A crucial question in the context of clinical applications is the choice of a population of epileptic patients for a clinical trial. One possibility would be to select patients with temporal lobe epilepsy. At some stage before the resective surgery, the vector could be infused into the epileptogenic area and its efficacy could be evaluated before tissue resection.

In conclusion, the inhibitory effects on seizures and epileptogenesis and the evidence for neuroprotection in experimental models by specific transgene overexpression in CNS open the possibility of developing novel therapeutic strategies for the treatment and management of seizures at focal onset, such as temporal lobe epilepsy. In principle, with the rapid advancement in recombinant AAV technology, a clinical-grade vector could be stereotactically delivered directly to the seizure focus in patients. AAV-mediated inhibitory molecule expression someday might provide an alternative to surgical resection.

Summary and Conclusions

Proliferation of interest in and studies of nonpharmacologic therapies for epilepsy serve as testimony to the limits of medication therapies. Some nonpharmacologic therapies, such as epilepsy surgery, the ketogenic diet, and vagus nerve stimulation, are now part of standard care. Others are less accepted. This chapter viewed a diverse collection of alternative therapies for people with medication-refractory seizures.

Deep brain stimulation is a promising technique, but at the time of this writing, efficacy remains unproven. Regions of stimulation include the anterior thalamic nuclei, subthalamic nuclei, hippocampi, and direct stimulation of the seizure focus in cortex or elsewhere. Stimulation can be on a regular cycle, as in the pivotal ongoing trial of SANTE, sponsored by Medtronic. Alternatively, stimulation can be responsive to detected patterns in the continually assayed EEG, as with the responsive neurostimulation trial sponsored by NeuroPace.

Stimulation also can be delivered transcranially, via magnetic pulse, which sets up electric currents in the cortex. Although this approach is attractively noninvasive, the penetration of influence into the brain is limited, and documentation of clinical efficacy is so far mainly anecdotal.

Tissue ablation is possible with radiotherapy, commonly then known as radiosurgery. A linear single-beam approach delivers substantial radiation to points along the pathway. Modern stereotactic radiosurgery utilizes beam-crossing methods, either by lead helmets (Gamma Knife) or computer-driven rotating delivery arms (CyberKnife), to focus the high energy only where desired. In animal models and perhaps in humans, doses of radiation too low to cause tissue necrosis can have antiepileptic efficacy. If borne out by controlled studies, now under way, this would be a truly novel therapy. Skeptics note that adverse reactions from radiation are not evident in some instances for many years.

Focal delivery of AEDs to the brain seems to be a promising approach, mainly in terms of permitting very high local concentrations at a seizure focus, without engendering much distant toxicity. Animal experiments have been favorable in terms of reducing epileptiform spikes and seizures at a cortical or hippocampal seizure focus, but several practical issues are unresolved. How easy is it to localize a seizure focus and infuse it with drug? Can superficially applied drug eventually penetrate enough brain to make a difference? How can the catheters be kept open and working? Which drug should be infused? Will long-term exposure of brain tissue to drug lead to compensatory undesirable “rebound”? Much remains to be done before local infusion can be considered effective and safe.

Liposomal or microsomal delivery of drug is a natural extension of a delivery mechanism that is used now for antibiotics and antineoplastic medications. These delivery vehicles are “bags of drug” with a targeting device, either an antibody or receptor-binding agent. A liposome then homes to a site of interest, sticks, and slowly releases drug. No liposomal products are yet available for epilepsy, because of uncertainty about how to target a seizure focus and how to penetrate the blood–brain barrier. Strategies exist to surmount both of these problems and products may be expected in the future.

Two strategies have the potential of delivering renewable drug or neuromodulators to brain tissue: Cell transplants and gene vectors. Cell transplants tend to be eliminated by the immune system (possible exception in the case of stem cells) unless they are encased in protection. One study of treated porcine GABAergic neurons into the hippocampus of patients has provided proof of concept, but not yet evidence for efficacy.

Gene therapy can use viral vectors to introduce GABA, inhibitory neuropeptides, or antisense signals to excitatory receptors into the CNS. Viral vectors derived from adeno-associated or herpes virus are accumulating a safety record, despite well-publicized initial safety failures. An unsettled issue for clinical application is the efficiency of transfection, that is, how many brain cells incorporate the gene and produce product. What is the duration of production, since frequent brain injections would be impractical? Genes and resulting gene products have been documented in human brain tissue *in vitro*. The next step will be to extend the lessons learned to *in vivo* protocols.

This chapter does not attempt to provide a complete list of upcoming studies of nonpharmacologic therapies for epilepsy. Such an exposition is prohibited by space and by constant emergence of new ideas: Brain cooling, trigeminal nerve stimulation, biofeedback, and many more. If effective and safe, the therapies mentioned in this chapter will move from alternative to complementary.

Chapter 135

Overview: Antiepileptic Drugs

Jacqueline A. French

Elinor Ben-Menachem

Introduction

This section addresses pharmacologic treatment of the epilepsies. Despite the availability of other treatments, including surgery, various devices, and behavioral/homeopathic treatments, antiepileptic drugs (AEDs) continue to be the mainstay of therapy for people with epilepsy. The overwhelming majority of individuals diagnosed with epilepsy will take AEDs for some period of time during the course of their illness, when they are available. Often, this treatment will last for decades and have a major impact on quality of life. There are currently over 20 drugs available for the treatment of epilepsy, and 10 were approved for use within the last 15 years. The availability of a large number of therapeutic options is advantageous for patients, but at the same time, this array increases the complexity of appropriate drug selection and management. The selection of antiepileptic drug is critical to the long-term well-being of the person with epilepsy, and this selection must be made with great care. In the absence of the "ideal" antiepileptic drug, it is optimal to have several reasonable choices in order to cover the great variability in types of epilepsy as well as individual patient characteristics. It is the intent of this section to provide important and useful information that will facilitate the selection of optimal treatment strategies.

Pharmacologic treatment of epilepsy has come a long way in the last century. Before the discovery in the mid-19th century that bromide could be used as a treatment for epilepsy, there was no useful treatment available for the disorder. Of interest, valproic acid existed as a solvent but was not identified as an antiepileptic drug for another 100 years.

Bromide was suggested as an AED in 1857, but for the wrong reasons. When Edward Sieveking presented 52 cases of epilepsy at the Royal Medical and Chirurgical Society in London, one physician, Charles Locock, mentioned that he had used potassium bromide to treat "hysterical" epilepsy, which usually occurred around menstruation (catamenial epilepsy today). It had also been reported that potassium bromide caused impotence in males, and the idea was that bromide would reduce sexual excitement in women and calm down epileptic activity, which, in fact, it did.[7] In 1912 phenobarbital was discovered, and it remains a useful AED today. It is also the major anticonvulsant agent used in veterinary medicine.

The German chemist Adolph von Baeyer synthesized "malonylurea" from a reaction of urea with malonic acid, a chemical found in apples. This became known as "barbituric acid." Its discovery led to various derivatives, and by 1903 Fischer and von Mering had synthesized a therapeutic barbiturate that induced sleep.

Further development focusing on barbituric acid led to the synthesis of phenobarbital. Hauptmann's clinical studies in 1912 demonstrated both sedative action and anticonvulsant activity.[7] Various alterations in the phenobarbital molecule led to the discovery of benzodiazepines.[10]

The idea that compounds could be tested for anticonvulsant activity now gained a foothold among neurologists and psychiatrists, and this eventually led to more new treatments for epilepsy. After phenobarbital, the next drug to appear was phenytoin. Phenytoin (diphenylhydantoin) was first synthesized in 1908 by a German physician named Heinrich Biltz. He sold his discovery to Parke-Davis, which did not find an immediate use for it. In 1936, H. Houston Merritt and Tracy Putnam discovered phenytoin's usefulness for controlling seizures. Using an animal model of maximal electroshock (MES), Merritt and Putnam found that phenytoin could control seizures without the sedation of phenobarbital, and by 1938 it was marketed as a new antiepileptic drug in the form of Dilantin sodium. Nearly 75 years later, phenyt-oin remains one of the most effective AEDs for partial-onset seizures and is used as a main agent in the treatment of status epilepticus.

After the development of phenytoin, other drugs entered the market, with primidone being introduced in 1952.[11] It was synthesized by making a minor alteration in the phenobarbital molecule. Primidone's efficacy, like that of phenytoin, was established in the MES test developed by Merritt and Putnam. It appeared to have anticonvulsant activity that was independent of phenobarbital and also more effective.

Ethosuximide appeared in 1960, and carbamazepine in 1974. Valproate was accidentally recognized as an AED in the 1960s. As already noted, it had been available as a solvent for other AEDs for some time, but during testing in animal models it was found to be more effective alone than the experimental drugs thought to be of interest. Today, valproic acid is still among the most effective broad-spectrum AEDs available.

In 1969, the National Institutes of Neurological Disorders and Stroke (NINDS) initiated the Anticonvulsant Drug Development (ADD) Program under the leadership of J. Kiffen Penry. In 1975, as a response to the dearth of new compounds being identified for use in epilepsy, the Epilepsy Branch of the NINDS established the Anticonvulsant Screening Project (ASP) in collaboration with investigators at the University of Utah.[12,13] The problem at the time was that the pharmaceutical industry had almost no interest in developing AEDs, and the NINDS believed it had the responsibility of trying to stimulate corporate interest by identifying promising compounds through the drug screening program. The ASP's role was and still is to identify possible drug candidates and evaluate their antiepileptic potential in animal models. Subsequently, the ADD program would (and, to some extent, still does) take these candidate drugs forward into clinical testing. This collaboration was the first attempt to screen organic compounds systematically on a large scale in animal models as a means of discovering and then developing new therapies for epilepsy. To date, the ASP has

screened more than 24,000 compounds. The fact that we have a new generation of antiepileptic drugs available is in large part due to the direct influence and inspiration of the ADD program and the ASP.

There was a long gap between the introduction of valproate and carbamazepine and the next AED that received Food and Drug Administration (FDA) approval. The first of this “second generation” of AEDs was vigabatrin, whose development started in the 1970s in France. It was registered as an AED in 1989 in the United Kingdom. Vigabatrin represented one of the first attempts at mechanism-based drug development. It was designed specifically to increase brain γ-aminobutyric acid (GABA) levels by blocking the enzyme GABA transaminase, based on the underlying hypothesis that increasing the brain's major inhibitory neurotransmitter would control seizures. Progabide actually reached the market before vigabatrin, and it too was a GABA agonist developed based on mechanism. Progabide was marketed in France but never gained popularity because of its perceived weak efficacy. Vigabatrin, however, is still available. Because of serious toxicity causing concentric visual field deficits, it is rarely used now except for treatment of infantile spasms. Tiagabine, a GABA receptor uptake inhibitor, was also designed to increase GABA concentration and is an effective drug for partial-onset seizures. In recent years there has been an explosion in the development of new AEDs Gabapentin, felbamate, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, topiramate, and zonisamide have all reached the market since 1994. None of these has been developed exclusively based on a predetermined hypothesis of mechanism of action, although we have subsequently learned much about the anticonvulsant effects of these drugs.

Perhaps surprisingly, this wealth of newly available AEDs, many associated with novel mechanisms and improved pharmacokinetics, have not demonstrated superior efficacy compared to the older drugs in head-to-head clinical trials of newly diagnosed epilepsy. Rather, these trials have shown efficacy of the old and new AEDs to be equivalent.[1,2,3,4,5,6,14,16] The newer drugs often appear to have advantages related to safety, long-term side effects, and pharmacokinetics, but their benefit is harder to prove. In refractory patients, the newer AEDs reduce seizure frequency by up to 50% when added to pre-existing AEDs, but it is still rare for previously refractory patients to become seizure free.[9]

There are many questions to ponder regarding the future of AED therapy. Are better drugs in the pipeline? Is there a new “blockbuster” on the horizon? If so, where will it come from? Our understanding of the basic mechanisms of epilepsy and epileptogenesis is growing rapidly. Yet it is still unclear how these advances will lead to better drug development and improved seizure control in patients. Is selection based on efficacy in animal models the optimal way to search for new AEDs? Is the search for new mechanisms a methodology that will lead to more potent and safer therapies? Will the solution to drug resistance be better selection of drugs based on individual patient characteristics, or one drug that will benefit all? Perhaps the answer will not be the drug itself, but how it is delivered to its target. There has been great interest recently in addressing transport of AEDs across the blood–brain barrier, as well as in directed delivery of drugs to appropriate targets in the central nervous system.[8,15] Alternatively, targeted therapy that recognizes differences in individual patient response through pharmacogenomics may be an essential component to better therapy.[17] Until these advances are realized, however, optimal care will require a thorough understanding of available drugs, and how they can best be utilized on patient characteristics. The following chapters should prove useful in achieving that goal.

Summary and Conclusions

After a slow 100 year start in antiepileptic drug development, the last two decades of intense focus have substantially increased the number of antiepileptic drugs that are available to clinicians. It will be up to clinicians and clinical researchers to determine how to optimally utilize this resource. It is now more possible than ever to target therapy to individual patient needs and characteristics. Nonetheless new drugs are needed, particularly ones that target refractory patient populations.

Chapter 136

Cellular Effects of Antiepileptic Drugs

Robert L. MacDonald

Michael A. Rogawski

Introduction

Antiepileptic drugs (AEDs) protect against seizures through interactions with a variety of cellular targets, which include various ion channels, a neurotransmitter transporter, a neurotransmitter metabolic enzyme, and a synaptic vesicle protein. AED actions on these targets can be categorized into four broad groups:

1. Modulation of voltage-dependent ion channels (mainly sodium [Na] but also calcium [Ca] channels)
2. Effects on γ-aminobutyric acid (GABA) systems, including alterations in the cellular disposition of GABA and enhancement of synaptic inhibition mediated by $GABA_A$ receptors
3. Inhibition of synaptic excitation mediated by ionotropic glutamate receptors
4. Modulation of neurotransmitter release, particularly of glutamate, through presynaptic mechanisms.

A critical downstream effect of drugs that target voltage-dependent Na and Ca channels may be to selectively modulate glutamate release while only weakly affecting GABA release.[132] Thus, group 1 and group 4 actions overlap in that they represent mechanisms for the presynaptic regulation of glutamate release. The ultimate effects of the interactions at these diverse targets are to modify the bursting properties of neurons and to reduce synchronization in localized neuronal ensembles. In addition, AEDs inhibit the spread of abnormal firing to distant sites, which is required for the expression of behavioral seizure activity in localization-related epilepsies. Generalized absence seizures, unlike other seizure types, are believed to result from thalamocortical synchronization. Interference with the intrinsic rhythm-generating mechanisms that underlie the synchronized activity in this circuit is necessary to abort these seizures. This chapter discusses the specific actions or combinations of actions that are believed to account for the anticonvulsant activity of marketed AEDs. Each of the AEDs has its own unique pharmacodynamic properties. In some cases, the uniqueness results because the biophysical parameters governing the drug's interaction with its target are distinct. For example, phenytoin and carbamazepine both interact with voltage-gated Na channels, but the kinetic properties of the interaction are subtly different. In other cases, the AEDs act selectively on unique targets. For example, ethosuximide targets T-type Ca channels, vigabatrin targets GABA transaminase, tiagabine targets the GAT-1 GABA transporter, gabapentin and pregabalin target α2-δ proteins, and levetiracetam targets the SV2A synaptic vesicle protein. Finally, in other cases still, AEDs such as phenobarbital, felbamate, and topiramate have mixed actions on various targets; their unique properties as anticonvulsants result from the combination of effects on these targets. These various diverse actions confer on each AED a characteristic and unique clinical profile.[147]

Mechanisms of Action of Established AEDs

Phenytoin and Carbamazepine

Phenytoin and carbamazepine interact with voltage-dependent Na channels at concentrations found free in plasma in patients being treated for epilepsy.[96] Both drugs are highly protective against tonic seizures in animal models (as in the maximal electroshock [MES] test), but do not protect against clonic seizures (as in the pentylenetetrazol [PTZ] test). This profile of activity is typical of AEDs that act as Na channel modulators. Na channels are composed of an α subunit (Na_V1.1–1.9) associated with auxiliary β1-, β2-, or β3-subunits. An α-subunit is sufficient to form the channel and allow functional expression, but the kinetic properties and voltage-dependence of channel gating are modulated by the β-subunits.

Phenytoin and carbamazepine were demonstrated to reduce the frequency of sustained repetitive firing of action potentials.[106,107] The characteristic property of these drugs is that they do not reduce the amplitude or duration of single action potentials but reduce the ability of neurons to fire trains of action potentials at high frequency. The limitation of high-frequency repetitive firing is voltage-dependent, with limitation of firing increasing after depolarization and reducing after hyperpolarization. Once developed, the limitation of firing is prolonged, lasting several hundred milliseconds. The action of the AEDs appear to be due to a shift of Na channels to an inactive state from which recovery is delayed.

On mammalian myelinated nerve fibers, both phenytoin and carbamazepine produced a voltage-dependent block of sodium channels that could be removed by hyperpolarization, a shift of the steady-state sodium channel inactivation curve to more negative voltages, and a reduction in the rate of recovery of sodium channels from inactivation.[155] Sodium channels recovered from complete inactivation in a few milliseconds after a 500-ms depolarization to 25 mV. In the presence of 100 μmol/L phenytoin or carbamazepine, however, recovery was prolonged to 90 or 40 ms, respectively. At 50 μmol/L, phe- nytoin and carbamazepine each produced a frequency-depen- dent block. However, the frequency-dependent block produced by carbamazepine was somewhat less pronounced than that produced by phenytoin. Of interest was the finding that phenytoin had a longer time-dependence for frequency-dependent block and for recovery from block than did carbamazepine, which would result in a more pronounced frequency-dependent block for phenytoin than for carbamazepine. Thus, although phenytoin and carbamazepine have qualitatively similar actions on sodium channels, their actions are quantitatively somewhat different. This may explain, at least in part, differences in efficacy for these two drugs in different patients.

In rat hippocampal neurons, phenytoin (200 μmol/L) produced a 20-mV negative shift in the steady-state inactivation

curve for Na channels and produced frequency-dependent block of Na channels.[191] Frequency-dependent block was shown at frequencies as low as 1 Hz, and the block increased to 50% at 10 Hz.[191] It has been suggested that unbinding of phenytoin from the Na channel is driven by channel deactivation, and that phenytoin may not stabilize the "normal" inactivation state.[78] The delay in recovery from apparent inactivation may be due to phenytoin blocking the Na channel by binding to a blocking site on the Na channel that is formed during activation and removed during deactivation and only slowly dissociating from the blocking site after deactivation. The phenytoin block is thus due to the voltage-dependency of deactivation. The slow dissociation, in part, accounts for phenyt- oin's selective ability to block high-frequency firing: When recovery is slow, the block can accumulate during repetitive activation of the channel. Another important feature of the block of Na channels by phenytoin is its slow onset. Slow binding has two important implications. First, the time course of fast Na currents is not altered in the presence of the drug, and therefore, the kinetic properties of normal action potentials are not perturbed. Second, slow binding means that action potentials evoked by synaptic depolarizations of ordinary duration are not blocked. Even interictal discharges, characterized by depolarizations lasting 50 to 200 ms, are not sufficiently long for drug binding and block of Na channels. Consequently, the frequency of interictal discharges in unaffected by phenytoin. In focal epilepsies, seizure discharges are associated with more sustained depolarizations than those occurring during interictal discharges. Only depolarizations that are as long as those occurring during ictal discharges provide the conditions required for drug binding and block.

Benzodiazepines and Barbiturates

Benzodiazepines and barbiturates enhance GABAergic inhibition at the free serum concentrations found in ambulatory patients[96] by interacting directly with $GABA_A$ receptors. $GABA_A$ receptors are formed by the assembly of multiple subunit subtypes (α1–α6, β1–β3, γ1–γ3, δ, ε, π, θ, and ρ1–ρ3) into a pentamer, although the most common and likely subunit composition has been determined to contain two α-subunits, two β-subunits, and a γ-subunit.[10] The five subunits are arranged in a counterclockwise sequence (as seen from the synaptic cleft) γβαβα.[10] Once assembled, $GABA_A$ receptors form chloride (Cl) ion channels, and the current carried by these channels can be modulated by a number of AEDs, including barbiturates and benzodiazepines.

$GABA_A$ receptors have been shown to be involved in both phasic, inhibitory synaptic transmission and tonic, perisynaptic inhibition[36,98] (see Chapter 23). GABA regulates gating (opening and closing) of the ion channel.[96,186,197] Binding of GABA increases the probability of channel opening, and the open channel can close and rapidly reopen to create bursts of openings.

Barbiturates enhance $GABA_A$ receptor current by binding to an allosteric regulatory site on the receptor, but the specific residues that constitute the allosteric binding site are unknown.[126] Mutagenesis studies have demonstrated that a glycine residue in the first transmembrane domain[21] and a tryptophan residue in the third transmembrane domain[2] of the β-subunit may be involved in barbiturate actions. All $GABA_A$ receptor isoforms containing at least an α- and β-subunit have been shown to be sensitive to barbiturates; in general, only minor differences in sensitivity are noted for different isoforms. However, $GABA_A$ receptors that contain a δ-subunit instead of the more common γ2-subunit and that are believed to be localized perisynaptically, where they mediate tonic inhibition, are more sensitive to barbiturates than are those containing γ2-subunits that are synaptically localized.[1] Single-channel recordings of barbiturate-enhanced single $GABA_A$ receptor currents have directly demonstrated that barbiturates increase mean channel open duration but do not alter receptor conductance or opening frequency.[96,185]

The sensitivity of $GABA_A$ receptors to benzodiazepines requires the presence of a γ-subunit coexpressed with an α1-, α2-, α3-, or α5-$GABA_A$ receptor subtype.[134] Expression of the α4- or α6-subtypes with β1- and γ2-subtypes results in receptors that are insensitive to benzodiazepines.[203] Thus, benzodiazepine sensitivity of $GABA_A$ receptors depends on both γ-subunit and α-subtypes. The single high-affinity binding site for benzodiazepines is located at the α/γ-subunit interface, whereas the two binding sites for GABA are at the α/β-interfaces. These two binding sites are allosterically coupled.[126] Benzodiazepines increase $GABA_A$ receptor current, and single-channel recordings have demonstrated that they increase $GABA_A$ receptor opening frequency without altering mean open time or conductance.[148,189]

Ethosuximide and Trimethadione

Ethosuximide and trimethadione, which are effective in the treatment of generalized absence seizures, have been shown to interact with voltage-dependent T-type Ca channels (Table 1). The multiple Ca channel types[22,122] are designated as L (Ca_v1.1–1.4), P/Q (Ca_v2.1), N (Ca_v2.2), R (Ca_v2.3), and T (Ca_v3.1–3.3), each with different voltage ranges and rates for activation and inactivation. Each channel type is composed of an ion conducting α-subunit (Ca_v1.1–1.4, Ca_v 2.1–2.3) and may include smaller accessory subunits, β- (Ca_v1–4) and α2δ1–4, which are not required for function but do modify gating.[81,22]

Table 1 Molecular targets of antiepileptic drugs

Drug	Molecular target			
	Na channels	Ca channels	GABA system	Glutamate receptors
	Predominant Na (and Ca) channel activity			
Phenytoin	I_{NaF} (↓) I_{NaP} (↓)			
Carbamazepine	I_{NaF} (↓)			
Oxcarbazepine	I_{NaF} (↓)			

Lamotrigine	I_{NaF} (↓)	HVA (↓)		
Zonisamide	I_{NaF} (↓)	T-type (↓)		
Predominant Ca channel activity				
Ethosuximide	? I_{NaP} (↓)	T-type (↓)		
GABA systems				
Benzodiazepines			$GABA_A$R (↑)	
Vigabatrin			GABA-T (↓)	
Tiagabine			GABA transporter (↓)	
Mixed				
Valproate	? I_{NaF} (↓) I_{NaP} (↓)	? T-type (↓)	GABA turnover (↑)	
Felbamate	I_{NaF} (↓)	HVA (↓)	$GABA_A$R (↑)	NMDA (↓)
Topiramate	I_{NaF} (↓) I_{NaP} (↓)	HVA (↓)	$GABA_A$R (↑)	KA/AMPA (↓)
Phenobarbital		HVA (↓)	$GABA_A$R (↑)	AMPA (↓)
Novel targets				
Gabapentin	α2δ protein (Ca channel subunit)			
Pregabalin	α2δ protein (Ca channel subunit)			
Levetiracetam	SV2A synaptic vesicle protein			

↑, Indicates increase in activity of target; ↓, indicates decrease in activity of target. *Abbreviations:* AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid; GABA, γ-aminobutyric acid; GABA-T, GABA aminotransferase; $GABA_A$R, $GABA_A$ receptor; HVA, high voltage activated; I_{NaF}, fast Na current; I_{NaP}, persistent Na current; KA, kainate; NMDA, *N*-methyl-D-aspartate.

Adapted from Rogawski MA, Löscher W. The neurobiology of antiepileptic drugs. *Nat Rev Neurosci.* 2004;5:553–564, with permission.[145]

Generalized absence epilepsy is characterized clinically by brief periods of loss of consciousness and electrically by generalized 3-Hz spike-and-wave discharges recorded on the electroencephalogram. Thalamic relay neurons play a critical role in the generation of the abnormal thalamocortical rhythmicity that underlies the 3-Hz spike-and-wave discharge. Whole-cell voltage clamp recordings from acutely dissociated relay neurons from the rat thalamus have demonstrated the presence of low-threshold (T-type) and high-threshold Ca currents.[174] The T-type currents had properties such that channel activation was necessary and sufficient to cause the generation of low-threshold Ca spikes in thalamic relay neurons. Ethosuximide and dimethadione, the active metabolite of trimethadione, both reduced T-type Ca currents of thalamic neurons isolated from guinea pigs and rats[27,28] at clinically relevant concentrations. Phenytoin and carbamazepine, which are ineffective in the control of generalized absence seizures, had minimal effects on T-type current. Dimethadione reduced T-type Ca current by a mechanism similar to that of ethosuximide. Another anticonvulsant succinimide, α-methyl-α-phenylsuccinimide, also reduced T-type currents, whereas a convulsant succinimide, tetramethylsuccinimide, only reduced the T-type current at very high concentrations.[29] These results suggest that anticonvulsant succinimides and dimethadione may have their primary action by reducing the T-type Ca current in thalamic relay neurons. More recent studies have largely confirmed these effects of ethosuximide in additional preparations, although variability in responsiveness occurs.[55,184,183] It has been proposed that certain factors regulating pharmacologic sensitivity, such as the presence of accessory Ca channel subunits, may contribute to the variability. Recent studies with recombinant human T-type Ca channels indicated that the action of ethosuximide is more complex than previously appreciated.[45] There may be two binding sites, one with high-affinity (~0.1 mM) that accounts for ~20% of total channel blockade and a low-affinity site (~10 mM) that accounts for the remainder. Although

ethosuximide did not alter the voltage-dependency of steady-state inactivation or the time course of recovery from inactivation of the T-type Ca current, the drug did inhibit the current in a voltage-dependent manner, with current reduction most prominent at negative membrane potentials and less prominent at more positive membrane potentials.[45] Thus, under conditions in which neurons are normally hyperpolarized (resting membrane potentials varying between –55 and –70 mV), the sensitivity of T-type Ca channels to succinimide block will be enhanced. In particular, these agents would be expected to block T-type Ca currents during slow, GABA-dependent network activity, as is believed to occur during absence seizures.[55]

Valproate

Valproate has many pharmacologic actions, none of which by itself can completely account for its clinical activity in epilepsy and the other conditions for which it is used, including bipolar disorder and migraine headache. It has therefore been proposed that valproate acts through a combination of neurophysiological and neurochemical actions.[88] Among these diverse actions, effects on GABA systems may play a leading role. Although the precise mechanism is obscure, in some specific brain regions thought to be involved in the control of seizure generation and propagation, valproate increases the turnover of GABA and presumably enhances GABAergic function. Indeed, valproate has actions in animal epilepsy models that overlap with drugs that are believed to act on GABA systems. Thus, valproate is especially active in genetic models of absence seizures, such as the genetic absence epilepsy rat from Strasbourg (GAERS).[100] It is also protective against seizu- res induced by methyl 6,7-dimethoxy-4-ethyl-β-carboline-3-carboxylate (DMCM)[129] and in the 6-Hz model, an alternative electroshock model that is sensitive to GABAergic agents.[8,67] Valproate also exhibits protective activity in virtually all other animal AED screening models including the MES and PTZ models, but its potency in any specific model varies depending on the species and route of administration.[88] In view of the activity of valproate in the MES model, which is shared with drugs like phenytoin, carbamazepine, and lamotrigine that are well recognized to modulate voltage-gated Na channels, it has been proposed that valproate might also have an action on Na channels. Indeed, valproate does block sustained high-frequency repetitive firing of neurons in culture.[106] However, detailed voltage clamp experiments of valproate actions on Na currents have not been performed; therefore, it cannot be concluded that valproate has a mechanism of action similar to that of the classical Na-channel AEDs.

Although valproate is effective in the treatment of generalized absence seizures, studies in rat thalamic neurons did not demonstrate any effect on T-type Ca current, but subsequently, the drug was shown to reduce T-type currents in primary afferent neurons.[70] This effect occurred over a concentration range of 100 to 1,000 μmol/L. However, the magnitude of block was modest, with a 16% reduction seen at 1 mmol/L. Whether this modest reduction in T-type Ca current is sufficient to

explain the effect of valproate on generalized absence seizures is unclear. Furthermore, the basis for the discrepancy between the results obtained in thalamic neurons and primary afferent neurons remains uncertain. Whether this is a relevant mechanism of action for valproate will have to be determined by future investigation.

Mechanisms OF Action of Newer AEDs

Felbamate

Felbamate is a dicarbamate, which is an analog of the sedative-hypnotic drug meprobamate (2-methyl-2-propyl-1,3-propanediol dicarbamate). Despite its idiosyncratic toxicities, felbamate is a highly effective AED with a broad spectrum of activity, and is one of only three AEDs for which there is evidence, from a controlled clinical trial, of efficacy in the treatment of the Lennox-Gastaut syndrome.[5] Felbamate has been reported to inhibit sustained repetitive action potential firing in cultured neurons, suggesting that it modulates voltage-gated Na channels.[201] Although an effect on recombinant Na channels is observed only at relatively high (1 mM) concentrations,[175] inhibition of Na-channel function could, at least in part, contribute to felbamate's anticonvulsant activity. Felbamate has also been reported to inhibit high voltage–gated Ca channels,[167,168] but the significance of this action for seizure protection is uncertain. Like meprobamate, felbamate potentiates $GABA_A$ receptor currents via an interaction with a site on the $GABA_A$ receptor that is distinct from the benzodiazepine recognition site.[77,137] The threshold concentration for felbamate modulation of $GABA_A$ receptor currents is ~100 μM, and the IC_{50} value for allosteric inhibition of *t*-[^{3}H]butylbicycloorthobenzoate binding to $GABA_A$ receptors in rat brain slices is 250 μM.[77] Because low therapeutic (anticonvulsant) serum concentrations of felbamate are in the range of 100 to 300 μM, the action of felbamate on $GABA_A$ receptors is probably relevant to its anticonvulsant activity. In addition, felbamate at a concentration of 100 μM has been found to block *N*-methyl-D-aspartate (NMDA) receptor-mediated synaptic responses[135] and to inhibit NMDA-receptor currents in cultured neurons (K_d, ~1 mM[137,171]). It has been proposed that felbamate may act as a competitive antagonist at the glycine recognition site of NMDA receptors,[105,193] and studies in animal models seemed to support this concept.[26,200] However, several studies directly examining the interaction between felbamate and the NMDA receptor have shown conclusively that felbamate does not act at the glycine site per se.[73,135,137,171,181] On the basis of whole-cell and single-channel recordings, Subramaniam et al.[171] concluded that felbamate acts both by a channel blocking mechanism and also by distinct effects on channel gating. Details of the effects on gating have been defined by Kuo et al.,[79] who found that low, submillimolar concentrations of felbamate more readily blocked the late sustained phase of NMDA receptor responses but not the initial onset of the response. This phenomenon was ascribed to an acceleration of the decay of responses. It can be speculated that this property would confer selectivity on felbamate to block seizures, because the prolonged pathologic activation that occurs during seizures would be suppressed more strongly than normal (rapid) synaptically generated NMDA responses. In addition, NMDA receptor blockade responses was greater with high concentrations of NMDA, another factor that would allow the drug to selectively block seizure discharges associated with strong activation of NMDA receptors. Kuo et al. further found that felbamate selectively binds with higher affinity to the desensitized state of NMDA receptors (55 μM) than to the resting or activated states (200 and 110 μM, respectively), so that the allosteric blocking action relates to stabilization of the desensitized state.[79]

Felbamate also selectively blocked currents from recombinant NMDA receptors composed of NR2B subunits at lower concentrations (IC_{50}, 0.5 mM) than it blocked currents from NMDA receptors formed from other subunit combinations.[52,73] This selectivity could contribute to the relatively low neurobehavioral toxicity of felbamate in relation to other NMDA receptor antagonists. Unlike the NR2A subunit that is distributed ubiquitously in the central nervous system (CNS), expression of the NR2B subunit in the adult is largely restricted to the forebrain.

Thus, felbamate may selectively target NMDA receptors in forebrain areas critical to seizure generation, with less effect on nonforebrain structures that could mediate side effects. The subunit selectivity could also account for the clinical utility of felbamate in seizure disorders affecting the immature brain, such as Lennox-Gastaut syndrome, because NR2B subunits are more abundant in the developing brain.

Gabapentin and Pregabalin

Gabapentin, the lipophilic 3-cycylohexyl analog of GABA, was originally synthesized in an attempt to develop a brain-penetrant GABA agonist. Pregabalin [*S*(+)-3-(aminomethyl)-5-methylhexanoic acid; *S*(+)-3-isobutyl GABA] is a congener of gabapentin with similar properties. Although both gabapentin and pregabalin are based on a GABA backbone, bulky aliphatic substituents in the molecules preclude binding to the GABA recognition site on $GABA_A$ receptors. The drugs also do not interact with other sites on $GABA_A$ receptors, including the benzodiazepine recognition site.[172] Although there are reports of agonist activity at $GABA_B$ receptors, the preponderance of evidence indicates that $GABA_B$ receptors are not a pharmacologic target.[178] Additional studies have shown that gabapentin does not inhibit GABA uptake or GABA catabolism, although it may enhance GABA turnover.[91] Increases in GABA levels have been reported in humans using noninvasive spectroscopic techniques,[80,131] but neither gabapentin nor pregabalin affect brain GABA levels in the rat,[40] and thus the significance of these alterations in GABA metabolism are uncertain. Nevertheless, there is little doubt that the therapeutic activities of gabapentin and pregabalin do not reside in effects on GABA systems. Indeed, the molecular targets of gabapentin and pregabalin are almost certainly α2δ-proteins, which are believed to be auxiliary subunits of voltage-activated Ca channels. Strong evidence for this concept is the observation that the binding affinities of gabapentin, pregabalin, and related structures to α2δ-subunits correlate in a stereoselective fashion with their anticonvulsant potencies.[12,19] In addition, knockin of a mutation (R217A) in the α2δ-1 subunit in mice, which results in markedly reduced binding of gabapentin and pregabalin, reduces the anticonvulsant activity of pregabalin and eliminates its analgesic activity.[148] Because the anticonvulsant actions of phenytoin and the analgesic actions of morphine are not altered by the same mutation, it is likely that the α2δ-1 protein is a target for the pharmacologic effects of pregabalin. However, since the mutation does not completely eliminate the anticonvulsant activity of pregabalin, it is plausible that effects occur on targets other than α2δ-1. Because gabapentin and pregabalin also bind to α2δ-2, this is a logical second target; but until experiments with mice bearing mutations in both α2δ-1 and α2δ-2 are available, the possibility that the drugs confer anticonvulsant activity through interactions with non-α2δ targets cannot be eliminated.

The α2δ-subunits are highly glycosylated proteins having a molecular mass of ~150 kD (997 to 1150 amino acid residues). Four homologous forms exist, but only subtypes 1 and 2 bind gabapentin and pregabalin with high affinity.[75] Each of the α2δ-subunits are products of a single gene that is posttranslationally cleaved into α2- and δ-peptides, which are then covalently linked by a disulfide bridge. Within the multimeric complex that forms the functional Ca channel, the α2δ-subunit is adjacent to or embedded in the pore forming α1-subunit. The δ-subunit portion of α2δ is in close association with the channel and serves as an anchor for the α2-subunit, which is located largely extracellularly.[204] Mutagenesis experiments have shown that the gabapentin binding site is probably confined to the α2-subunit protein and the external portion of the associated δ component.[18,195] The α2δ-1 and α2δ-2 subunits are believed to form complexes with many voltage-dependent Ca channel types, but it is not yet clear which Ca channels are important for the therapeutic activity of gabapentin and pregabalin, nor is the functional role of the α2δ subunit complex fully understood. However, for some Ca channel types, the α2δ subunit complex has been shown to allosterically enhance current amplitude and also promote channel trafficking to the membrane.

Functional studies of the effects of gabapentin on Ca channel activity have yielded divergent results[178]; however, the general consensus is that gabapentin and pregabalin reduce the release of neurotransmitters from neural tissue, with effects on glutamate release being of particular relevance in epilepsy.[11,38] Thus, in various preparations, gabapentin and pregabalin have been shown to reduce the amplitude of evoked and spontaneous excitatory postsynaptic currents. Surprisingly, however, a reduction also occurs in the frequency of miniature excitatory synaptic currents.[3,128] Because these events do not depend on Ca entry through voltage-sensitive Ca channels, gabapentin and pregabalin do not seem to be acting simply by inhibiting Ca channels in presynaptic terminals. Rather, it has been speculated that binding of the drugs to α2δ-subunits directly influences the release machinery,[147] possibly by affecting physical interactions between presynaptic Ca channels and proteins mediating exocytosis.[165]

Gabapentin and pregabalin are absorbed in the gut and pass across the blood–brain barrier via the system L transporter, which is specialized for the transport of large, neutral amino acids.[170] The fact that these drugs are substrates for this transporter is essential to their anticonvulsant activity because it allows them to gain access to the CNS.[12] However, an interaction with the transporter is not responsible for seizure protection or other pharmacologic activities of the drugs.

Both gabapentin and pregabalin are highly effective in the rat MES test and also are protective against tonic seizures induced by chemoconvulsants, with pregabalin being modestly more potent than gabapentin.[20,178,202] Neither agent is as effective in the mouse, which is unusual, because most AEDs show the reverse species selectivity. Both drugs are effective in protecting against seizures in kindled rats, and are highly potent against audiogenic seizures in genetically susceptible mice. The drugs are only weakly active against chemoconvulsant-induced clonic seizures. They are not protective in models of absence epilepsy, and can even promote absence seizures at high doses.[178] Overall, the preferential activity against tonic seizures, in the MES test and other models, and lack of protective activity against absence seizures, is consistent with the presumed mechanism of action, which is to inhibit synaptic release. This conclusion is based on a comparison with other AEDs with a similar profile in animal seizure models, most notably Na-channel blocking AEDs. Although Na-channel blocking AEDs do not directly alter synaptic responses, as noted earlier, their inhibitory action on Na channels translates into reduced transmitter output at synapses, with a preference for the release of glutamate.

Lamotrigine

Lamotrigine [3,5-diamino-6-(2,3-dichlorophenyl)-1,2,4-tria- zine] is a phenyltriazine with weak antifolate activity. Lamotrigine was developed after it was observed that the use of phenobarbital, primidone, and phenytoin resulted in reduced folate levels, and that folates could induce seizures in experimental animals.[136] It was proposed that antifolate activity may be related to the anticonvulsant properties of these AEDs; however, this has not been confirmed in structure-activity studies.[146] Lamotrigine has anticonvulsant activity against tonic seizures in the MES test and also against tonic seizures induced by PTZ, but it is not active in the conventional PTZ test in which clonic seizure activity is the end-point.[110] Lamotrigine is also inactive in rat models of absence epilepsy.[188] Therefore, its profile in animal models is similar to that of Na-channel modulators such as phenytoin and carbamazepine.

Early studies of the mechanism of action of lamotrigine examined its effects on the release of endogenous amino acids from rat cerebral cortex slices in vitro. As is the case for AEDs that act on voltage-dependent Na channels,[87] lamotrigine inhibited the release of glutamate and aspartate evoked by the Na-channel activator veratrine and was less effective in the inhibition of acetylcholine or GABA release.[85] At high concentrations, lamotrigine had no effect on spontaneous or potassium (K)-evoked amino acid release. These studies suggested that lamotrigine acts presynaptically on voltage-gated Na channels to decrease glutamate release. In radioligand studies, the binding of [^{3}H]batrachotoxinin A 20-α-benzoate, a neurotoxin that binds to receptor site 2 on voltage-dependent Na channels, was inhibited by lamotrigine in rat brain synaptosomes.[25] Several electrophysiological studies have investigated the effects of lamotrigine on voltage-dependent Na channels. Lamotrigine blocked sustained repetitive firing in cultured mouse spinal cord neurons in a concentration-dependent manner at concentrations therapeutic in the treatment of human seizures.[25] In cultured rat cortical neurons, lamotrigine reduced burst firing induced by glutamate or K, but not unitary Na action potentials evoked at low frequencies.[86] In cultured hippocampal neurons, lamotrigine reduced Na currents in a voltage-dependent manner, and at depolarized potentials showed a small frequency-dependent inhibition.[115] Lamotrigine increased steady-state inactivation of rat brain type IIA Na channel α-subunit currents expressed in Chinese hamster ovary cells[180] and produced both tonic and frequency-dependent inhibition of voltage-dependent Na channels in clonal N4TG1 mouse neuroblastoma cells, but had no effect on cationic currents induced by stimulation of glutamatergic receptors in embryonic rat hippocampal neurons.[194]

In cultured rat cortical neurons, lamotrigine at high concentrations was able to inhibit peak high-threshold Ca currents and appeared to shift the threshold for inward currents to more depolarized potentials.[86] In clonal rat pituitary GH3 cells, lamotrigine at the same concentration did not inhibit high-threshold Ca currents, caused only slight inhibition of low-threshold Ca currents, reduced rapidly inactivating voltage-dependent K currents, and had no significant effect on Ca-activated K currents.[82] In cultured rat cortical neurons, lamotrigine did not appear to mimic the effect of diazepam when tested on GABA-evoked Cl currents.[86]

These results indicate that the antiepileptic effect of lamotrigine, like that of phenytoin and carbamazepine, is at least in part due to use- and voltage-dependent modulation of fast voltage-dependent Na currents. However, lamotrigine has a

broader clinical spectrum of activity than phenytoin and carbamazepine and is recognized to be protective against generalized absence epilepsy and other generalized epilepsy syndromes, including primary generalized tonic–clonic seizures, juvenile myoclonic epilepsy, and Lennox-Gastaut syndrome.[16,41,133] The basis for the broader spectrum of activity of lamotrigine is unknown, but could relate to actions of the drug on voltage-activated Ca channels.[145] Lamotrigine blocks T-type Ca channels weakly, if at all.[44,49] However, it does inhibit native and recombinant high-voltage–gated Ca channels (N- and P/Q/R-types) at therapeutic concentrations.[49,167,196] Whether this activity on Ca channels accounts for lamotrigine's broader clinical spectrum of activity in comparison with phenytoin and carbamazepine remains to be determined.

Levetiracetam

Levetiracetam [(S)-α-ethyl-2-oxo-pyrrolidine acetamide], the *S*-enantiomer of the ethyl analog of the nootropic agent piracetam, differs from other AEDs in its profile of activity in animal seizure models. Notably, levetiracetam is inactive against both the MES and subcutaneously administered PTZ seizures.[74,89] Nevertheless, the drug does have activity in many acute seizure models. For example, it confers protection against sound-induced clonic seizures and also against clonic seizures induced by pilocarpine and DMCM, but not against seizures induced by other chemoconvulsants such as the $GABA_A$ receptor antagonists bicuculline or picrotoxin or by intracerebroventricular injection of the excitatory amino acid agonists NMDA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), or kainate.[74] Levetiracetam also confers protection against kindled seizures,[89] and it can inhibit the development of the seizure-prone state in various kindling models.[47,90] Levetiracetam can also inhibit the developmental expression of tonic convulsions in a genetic epilepsy model.[207] The anticonvulsant activity of levetiracetam is stereoselective (the *R*-enantiomer is very weak or inactive,[47] indicating an interaction with a structurally specific recognition site). In line with the atypical profile of levetiracetam in animal models, the drug also behaves distinctly in brain slice epilepsy models. Unlike conventional AEDs that inhibit high-frequency action potential firing, presumably through effects on Na channels, levetiracetam specifically suppresses synchronized network bursting, indicating an effect on synchronization mechanisms.[120] In this regard, it is noteworthy that levetiracetam has a much larger therapeutic window than do other AEDs (only very large doses ~1,000 mg/kg cause impairment of motor performance), which is consistent with a more specific action on epileptiform activity than that of other AEDs. The various differences between levetiracetam and other AEDs suggest that levetiracetam protects against seizures by a novel mechanism. However, until recently, a reasonable candidate was not at hand. Levetiracetam has been shown to inhibit voltage-activated Ca[119] and K[99] currents at high concentrations. In addition, recognizing that levetiracetam is protective against seizures induced by the benzodiazepine receptor inverse agonist DMCM, it was observed that levetiracetam can reverse DMCM inhibition of $GABA_A$ and glycine receptor responses in cultured neurons.[140] However, none of these actions has been convincingly linked to the anticonvulsant activity of the drug. In 1995, Noyer et al.[123] described a saturable and stereoselective specific binding site for $[^3H]$levetiracetam in brain membranes. The binding site was found to be an integral membrane protein, having an apparent molecular mass of ~90 kDa, which is widely distributed in brain and localized to the synaptic vesicle membrane fraction in neurons. Although the binding site was only of moderate affinity (K_d, 0.8 μM), a series of stereoisomer homologs of levetiracetam demonstrated a rank order of affinity for the $[^3H]$levetiracetam binding site that was highly correlated with their anticonvulsant activity, indicating that the binding was relevant for the anticonvulsant properties of levetiracetam and related structures. Further studies indicated that the binding protein is the ubiquitous synaptic vesicle protein SV2A.[95] Thus, levetiracetam has a target that is distinct from that of other AEDs. SV2A was originally described by Bajjalieh et al.[6] as a 12-transmembrane domain glycoprotein homologous to membrane transporters. However, to date, a transporter activity for the protein has not been established. Rather, SV2A seems to interact with synaptotagmin, which is believed to be the Ca sensor in exocytosis.[153] It is now recognized that SV2A is a member of a small family of homologous proteins that also includes SV2B and SV2C; but only SV2A, the most ubiquitous form, binds levetiracetam. Studies with mice in which the SV2 proteins have been deleted by gene targeting are consistent with a possible role of SV2A in regulating seizure susceptibility, but they have not yet provided answers to the key questions of the function of SV2A and how levetiracetam binding confers seizure protection. In SV2A knockout mice, brain morphology—and indeed the morphology of synapses—is normal.[30,60] However, homozygous SV2A knockout mice experience severe seizures and die between postnatal weeks (P)12 and P23; heterozygous animals are also susceptible to seizures but have nearly normal survival. The SV2 proteins do not appear to be required for synaptic transmission or for the uptake or storage of neurotransmitters, although they may play a subtle role in the release process during repetitive synaptic activation (as occurs during seizure activity) by regulating nerve terminal Ca dynamics.[60] Although there is still much to be learned about the mechanism of levetiracetam, it is now clear that its target is a component of the synaptic release machinery, which supports the unifying concept that the ultimate action of many AEDs, whatever their molecular targets, is to modulate neurotransmitter release. Levetiracetam is the first AED that targets the synaptic release machinery directly. Through this direct mechanism, the drug seems to be able to exert a protective action on seizures with a favorable side-effect profile.

Oxcarbazepine

Oxcarbazepine (10,11-dihydro-10-oxo-carbamazepine) is a dibenzazepine that is structurally similar to carbamazepine, except that is has a keto substitution at the 10 position of the dibenzazepine nucleus. The keto substitution prevents the formation of the 10,11-epoxide, which, in the case of carbamazepine has been hypothesized to contribute to toxicity. Rather, oxcarbazepine is rapidly and nearly completely reduced to 10,11-dihydro-10-hydroxy carbamazepine (licarbazepine; GP 47779; LIC477).[31] Licarbazepine is a racemate, with the *S*(+)-enantiomer (BIA 2-093) about four times as abundant in the urine as the *R*(–)-enantiomer; both enantiomers have approximately equal anticonvulsant activity.[13,154]

Oxcarbazepine and licarbazepine are effective in inhibiting the hind limb extension in rats and mice elicited by MES, but are approximately two to three times less effective against PTZ-induced seizures in mice.[7] In studies using rats at different developmental ages, oxcarbazepine, licarbazepine, and carbamazepine dose-dependently reduced the tonic phase of generalized seizures induced by PTZ and appeared to have identical anticonvulsant profiles in this model.[76] Oxcarbazepine and licarbazepine have relatively poor anticonvulsant efficacy against picrotoxin- and strychnine-induced seizures in mice.[7] Oxcarbazepine was able to completely suppress seizures in rhesus monkeys in a chronic aluminum foci model of partial seizures. At comparable doses, licarbazepine was less effective in suppressing seizures in this model.[61] Oxcarbazepine is effective in

P.1439

the treatment of human partial seizures and generalized tonic–clonic seizures with and without secondary generalization.[33]

In electrophysiologic studies in rat hippocampal slices, oxcarbazepine and licarbazepine enantiomers dose-dependently decreased epileptic-like discharges induced by penicillin.[154] In addition, the compounds reduced sustained high-frequency repetitive firing of voltage-dependent Na action potentials in mouse spinal cord neurons.[194] Oxcarbazepine is slightly more potent than carbamazepine in displacing [^{3}H]batrachotoxinin A 20-α-benzoate from voltage-dependent Na channels in rat cortical synaptosomes and also slightly more potent in inhibiting[22] Na^+ uptake.[13] Together, these observations indicate that the anticonvulsant mechanism of oxcarbazepine is similar to that of carbamazepine, and depends on the modulation of voltage-dependent Na channels.

Tiagabine

Tiagabine [(*R*)-N-(4,4-di(3-methylthien-2-yl)but-3-enyl) nipe-cotic acid hydrochloride] is a nipecotic acid analog with an incorporated lipophilic anchor to facilitate crossing of the blood–brain barrier after oral administration.[84] Like nipecotic acid, tiagabine is a potent and specific competitive inhibitor of the neuronal and astrocytic GABA transporter GAT-1.[17] Tiagabine binds with high affinity to the transporter, thus preventing GABA uptake without itself being transported. By slowing the reuptake of synaptically released GABA, tiagabine increases synaptic GABA levels and prolongs inhibitory post-synaptic potentials.[39,59,150,169,182] The prolongation of inhibitory GABA-mediated synaptic responses by tiagabine may be enhanced with repetitive activation, such as occurs occur during the synchronous discharge of GABAergic interneurons during epileptic activity. This may minimize the behavioral depression that would accompany indiscriminate enhancement of GABA inhibition.

Tiagabine has a unique spectrum of activity in animal seizure models. The drug is highly potent against tonic and also clonic seizures induced by PTZ and DMCM,[32] and is also effective against various types of kindled[113] and reflex seizures.[163] It is only weakly active, if at all, against tonic hind-limb extension in the MES model.[32,118] In addition, tiagabine is effective against status epilepticus (SE) in cobalt-lesioned rats but also produced a hyporeactive state associated with a rhythmic EEG pattern suggesting a generalized convulsant action.[192] In fact, in patients who were not previously recognized as having epilepsy, tiagabine use has rarely been associated with new-onset seizures and SE. Interestingly, tiagabine was also shown to exert an antepileptogenic effect in amygdala kindling[32] and to prevent seizures and neuronal damage in experimental SE.[50]

Topiramate

Topiramate (2,3:4,5-*bis-O*-[1-methylethylidene]-β-D-fructo-pyranose sulfamate) is a sulfamate derivative of the naturally occurring monosaccharide D-fructose. The drug is active against MES seizures in rats and mice, in amygdala-kindled seizures in rats, and sound-induced seizures in mice.[159] It is ineffective against seizures induced by PTZ, bicuculline, or picrotoxin.[42,159] It therefore has a profile of activity in animal models that is similar to that of Na channel–blocking AEDs[143]; the profile also resembles that of glutamate receptor antagonists.[93] However, the drug has several properties that are atypical for Na channel–blocking AEDs in that it is effective in a rat genetic model of absence epilepsy[117] and can also raise the threshold for clonic seizures induced by intravenous PTZ in mice.[198] Several cellular mechanisms have been proposed to underlie the therapeutic activity of topiramate: (a) activity-dependent attenuation of voltage-dependent Na currents[177,212]; (b) inhibition of high-voltage–activated Ca channels[210]; (c) potentiation of $GABA_A$ receptor-mediated currents[46,68,198,199]; (d) inhibition of AMPA/kainate receptors[43,162,164]; (e) inhibition of types II and IV carbonic anhydrase isoenzymes[37]; and (f) activation of a steady K current.[53] The effects on Na channels occur at relatively low, therapeutically relevant concentrations (25–30 μM). Trough serum concentrations of topiramate associated with antiepileptic activity in clinical trials range from 6 to 35 μM. The biophysical details of the modulation of fast Na currents are similar to that of classical Na-channel blocking anticonvulsants, particularly phenytoin. Thus, the degree of block is enhanced with the long membrane depolarizations as are believed to occur during epileptiform activity. However, the unblock upon membrane hyperpolarization is more rapid than with phenytoin (comparable to carbamazepine and lamotrigine). It has been suggested that the faster recovery is desirable because it would allow ongoing neuronal activity to resume quickly after epileptiform activity is aborted. In addition to effects on fast Na currents, topiramate, like phenytoin, blocks persistent Na currents at low concentrations. Because persistent Na current may contribute to the initiation and maintenance of epileptiform activity,[156] this could represent an important factor in topiramate's anticonvulsant properties. The pharmacologic effect of topiramate on high-voltage–activated Ca current is of uncertain relevance, because the drug was specific for L-type Ca currents[210] and L-type Ca channel blockers are not effective as anticonvulsants.

Effects of topiramate on $GABA_A$ receptors could contribute to the broad spectrum of activity of topiramate, but the evidence is imperfect. Topiramate is not active in those animal models, such as the PTZ test, that are typically sensitive to drugs that positively modulate $GABA_A$ receptors. Nevertheless, the drug does have activity in an absence epilepsy model and on PTZ threshold, consistent with effects on $GABA_A$ receptors.[34] However, the ability of the drug to enhance $GABA_A$ receptor currents within in vitro systems is inconsistent and variable among preparations and does not show ordinary concentration-dependence,[46,53] making the effect difficult to study. The variability could be due in part to subunit selectivity, inasmuch as some $GABA_A$ receptor subunit combinations expressed in *Xenopus* oocytes were potentiated, whereas others were inhibited.[46] The potentiation, when it occurs, is independent of an interaction with the GABA or benzodiazepine recognition sites of the $GABA_A$ receptor, and effects on slow desensitization kinetics are more substantial than on the peak amplitude.[46,199] Modulation of slow $GABA_A$ receptor desensitization could influence seizure susceptibility,[15] but the way in which this might occur with topiramate has yet to be defined. Evidence suggests that topiramate may alter the activity of the various receptors and ion channels with which it interacts by affecting their phosphorylation state.[159] Phosphorylation does influence the kinetic properties of $GABA_A$ receptors,[54] raising the possibility that this mechanism could be relevant to their modulation by topiramate.

As noted, the activity of topiramate in animal models is compatible with effects on glutamate receptors, including NMDA and AMPA/kainate receptors.[143] There is no evidence that to- piramate blocks NMDA receptors.[44] However, in cultured neurons, it does inhibit responses to kainate, an agonist of AMPA and kainate receptors.[44] Recently, topiramate was found to be a more potent and efficacious inhibitor of GluR5 kainate receptor currents in basolateral amygdala principal neurons than of AMPA receptor currents.[48] AMPA receptors are crucial for excitatory synaptic transmission throughout the CNS, and drugs that substantially block AMPA receptors produce dramatic neurobehavioral impairment.[206] Thus, the finding

P.1440

that topiramate is weak and has low efficacy as an AMPA receptor antagonist corresponds with the clinical observation that the drug is reasonably well tolerated. Kainate receptors represent a new potential anticonvulsant drug target.[145] Blockade of GluR5 kainate receptors is not associated with the side effects associated with blockade of AMPA receptors and, in fact, transgenic mice that lack GluR5 are grossly normal neurologically. The inhibitory action of topiramate on GluR5 kainate receptors develops slowly, suggesting that it acts indirectly. Recently, it has been found that topiramate inhibits phosphorylation of serine 845 of the AMPA receptor GluR1 subunit,[4] suggesting that the effect of the drug on AMPA and perhaps kainate receptors is due to an alteration in the phosphorylation state of the protein. The relevance of the GluR5 kainate receptor–blocking activity of topiramate was confirmed using in vivo experiments in mice with selective glutamate receptor antagonists, in which anticonvulsant doses of topiramate blocked clonic seizures induced by a selective GluR5 kainate receptor agonist but not by an agonist of AMPA receptors.[67] In addition to effects on GluR5 kainate receptors, the drug may also affect the more abundant GluR6-containing kainate receptors.[66]

The action of topiramate on carbonic anhydrase has been assumed not to contribute to its clinical efficacy because cross-tolerance to the anticonvulsant activity of topiramate does not occur with the classical carbonic anhydrase inhibitor acetazolamide in mice.[160] Moreover, topiramate is only a moderate-potency inhibitor of carbonic anhydrase isoenzymes.[121] However, it is noteworthy that acetazolamide, like topiramate, has a preferential activity against MES seizures.[3] Recently, evidence supporting a role for carbonic anhydrase inhibition in the action of topiramate has come from studies of $GABA_A$ receptor–mediated depolarizing responses, which can be elicited by high-frequency stimulation of GABAergic synapses.[53] Such depolarizing GABA currents may promote the generation of seizure discharges. The efflux of intracellular bicarbonate formed by carbonic anhydrase is believed to be a major factor underlying depolarizing GABA currents.[62,166] Topiramate at clinically relevant concentrations strongly inhibited depolarizing GABA currents without affecting hyperpolarizing GABA-mediated inhibitory postsynaptic currents. This effect is assumed to be due to carbonic anhydrase inhibition, because it was mimicked by acetazolamide.

Overall, topiramate's broad spectrum of anticonvulsant activity is likely to result from effects on multiple target sites, including Na channels, kainate receptors, and possibly also $GABA_A$ receptors and carbonic anhydrase isoenzymes. The effects on ion channels are complex and are unlikely to occur through direct effects on channel gating, but are more likely to be mediated indirectly, possibly through inhibition of channel phosphorylation.

Vigabatrin

Vigabatrin (γ-vinyl GABA; 4-amino-hex-5-enoic acid) is a structural analog of GABA that acts as an enzyme-activated ("suicide") inhibitor of GABA-transaminase (γ-aminobutyrate-α-oxoglutarate aminotransferase; GABA-T), a pyridoxal-5′-phosphate–dependent enzyme localized to mitochondria that is the main degradative enzyme for GABA. The drug initially binds reversibly to the pyridoxal-5′-phosphate cofactor and then binds irreversibly to the enzyme.[35] Because GABA-T inhibition is irreversible, recovery of GABA transaminating activity requires resynthesis of the enzyme. Vigabatrin is a racemic mixture of *S*(+)- and *R*(–)-enantiomers; only the *S*(+)-enantiomer inhibits GABA-T.[83] There is a corresponding stereoselectivity for the anticonvulsant activity of vigabatrin.[108] Administration of vigabatrin leads to large elevations in brain GABA levels in animals[92] and humans.[130] In addition, the drug causes a dose-dependent increase in cerebrospinal GABA in human subjects with epilepsy, without affecting the levels of other neurotransmitters, including monoamines.[139,152] The extent to which vigabatrin increases GABA concentrations differs among brain regions, depending on the density of GABAergic neurons.[24] Although GABA-T is present in both neurons and glia,[23] the increase in brain GABA levels is predominantly due to inhibition of GABA-T in neurons.[149]

The antiepileptic properties of vigabatrin have been attributed to enhanced GABA-mediated inhibition. Paradoxically, however, vigabatrin does not lead to larger $GABA_A$ receptor-mediated synaptic responses, and it has generally been found to inhibit spontaneous and evoked synaptic GABA currents.[58,127,205] In contrast to the effects on synaptic GABA responses, vigabatrin potently increases tonic current resulting from the action of ambient GABA on extrasynaptic $GABA_A$ receptors.[138,205] The increased extracellular GABA levels are attributed to efflux of GABA from neurons via GABA transporters operating in a reverse fashion due to high intracellular GABA. The enhanced activation of extrasynaptic $GABA_A$ receptors produced by the elevated extracellular GABA is believed to produce an anticonvulsant effect through reduced network excitability, although the details of how this occurs remain to be defined. An alternate hypothesis is that vigabat- rin prevents the fading of GABA responses during repetitive activation of inhibitory pathways, through reduced function of release-regulating presynaptic $GABA_B$ receptors.[58] Such fading is believed to be an important factor that permits focal epileptiform activity to develop into a full-blown seizure.

Vigabatrin is indicated primarily for the treatment of partial seizures and is also a first-line treatment for infantile spasms. Therefore, its clinical indications differ from other drugs, such as benzodiazepines, that act on GABA systems. No uniform agreement exists on the profile of vigabatrin in animal epilepsy models. The variability in efficacy that has been observed can be attributed in part to differences in dosing and route of administration, because in some studies the drug was administered directly into the brain. The preponderance of evidence indicates that systemically administered vigabatrin is active against seizures induced by chemoconvulsants including strychnine, PTZ, picrotoxin, and isoniazid.[14,33,71,94] It is also effective against sound-induced seizures in mice,[109] epileptic responses in photosensitive baboons,[108] and against amygdala-kindled seizures.[64,161] In fact, as with other drugs that enhance GABAergic function, vigabatrin retards the development of kindled seizures, indicating that it has antiepileptogenic properties, at least in the kindling model.[161] Despite the clinical efficacy against partial seizures, systemically administered vig- abatrin has generally been found to be inactive in the MES test.[14] It is also ineffective in genetic absence epilepsy models,[100] which corresponds with it lack of clinical antiabsence activity. Overall, vigabatrin has a unique profile of activity in animals models and in clinical use, which is not surprising because its mechanism of action differs from other marketed AEDs.

Zonisamide

Zonisamide (1,2-benzisoxazole-3-methanesulfonamide) is an AED with a unique chemical structure consisting of an aromatic fused benzene-isoxazole ring structure and a sulfonamide side chain. Zonisamide has a profile of activity in animal seizure models that is similar to that of AEDs that modulate voltage-dependent Na channels, including phenytoin, carbamazepine, and lamotrigine. Like these AEDs, zonisamide is protective in the MES test and inactive against subcutaneous PTZ seizures in both mice and rats[102,179,202]; it is also inactive against seizures induced by bicuculline and picrotoxin. Zonisamide has activity

P.1441

in various kindling models,[51,63,65,190] and is also effective against tonic–clonic and myoclonic seizures in the Mongolian gerbil, a genetic animal model of reflex epilepsy.[9] In a strain of spontaneously epileptic rats, it suppressed tonic, but not absence-like seizures, and inhibited sound-induced seizures in DBA/2 mice.[117] However, zonisamide did not completely suppress spontaneous seizures in the EL mouse.[116]

Zonisamide prevented spread of epileptiform activity in the cortex of experimental animals, suppressing focal seizure activity induced by direct electrical stimulation of the cat visual cortex and increasing afterdischarge threshold[190]; following unilateral injection of kainic acid into the amygdala of the rat, it reduced the spread of seizures to the contralateral side.[176] Zonisamide also suppressed epileptogenic focal activity induced in the cortex of experimental animals. Zonisamide reduced spiking activity induced by cortical freezing in cat cortex and interictal spikes induced by tungstic acid gel in rat cortex.[56,57]

Multiple mechanisms of action for zonisamide have been proposed. These include (a) modulation of voltage-dependent Na channels, (b) inhibition of T-type voltage-dependent Ca channels, (c) presynaptic inhibition or facilitation of neurotransmitter release, (d) alteration in neurotransmitter turnover and metabolism, and (e) inhibition of carbonic anhydrase. Although some experimental data demonstrate pharmacologic activity relating to all these mechanisms, the effects on voltage-dependent Na channels and T-type Ca channels may be most relevant to the anticonvulsant activity of zonisamide.

The first study of the effects of zonisamide on Na channels was carried out in voltage-clamped *Myxicola* giant axons.[151] Zonisamide had no effect on Na channel activation but produced a shift in the steady-state fast inactivation curve to more negative voltages, and it slowed recovery from both fast and slow inactivation. The effect of zonisamide was only produced with intracellular zonisamide; extracellular zonisamide did not affect Na channel inactivation. The zonisamide effect on fast inactivation occurred at relatively low concentrations (1 to 100 μM) with a half-maximal concentration of 12 μM producing a 20 mV shift in the steady-state inactivation curve. The effect of zonisamide to slow recovery from slow inactivation occurred at even lower concentrations (0.1 to 10 μM). Thus, this early study demonstrated that zonisamide directly affects Na channels at low concentrations.

Recordings from cultured mouse spinal neurons have further indicated that zonisamide modulates voltage-dependent Na channels.[142] Concentrations above 2 μM caused a concentration-dependent limitation of high frequency action potential firing, with half-maximal inhibition at 17 μM. The minimum effective plasma concentration of zonisamide that is protective in the MES test is 10 μg/mL (47 μM), whereas concentrations greater than 70 μg/mL (330 μM) are associated with neurotoxicity.[104] In clinical studies, therapeutic serum concentrations of zonisamide are in the range 20 to 30 μg/mL (94–141 μM).[158] Zonisamide readily crosses the blood–brain barrier, and cerebrospinal fluid concentrations are similar to the free fraction in serum. Because zonisamide is approximately 50% bound to human serum albumin, minimum therapeutic brain concentrations are estimated to be in the range of 50 μM. Thus, the effect of zonisamide to limit the sustained, high-frequency, repetitive firing of action potentials occurred at concentrations that are therapeutically relevant. Although voltage-clamp studies have not been carried out in mammalian neurons, it can be inferred that zonisamide acts on voltage-dependent Na channels in a similar fashion to other Na-channel–modulating AEDs. That is, the drug likely produces use- and voltage-dependent blockade by binding to Na channels in the inactive state and slowing the rate of recovery of these channels from inactivation.

Unlike other Na-channel blocking AEDs, zonisamide also has specific effects on T-type Ca channels that are similar to those of ethosuximide. Thus, in cultured fetal rat cortical neurons, zonisamide produced a concentration-dependent inhibition of T-type Ca current without affecting L-type Ca current.[173] The zonisamide reduction in peak T-type Ca current occurred in a concentration-dependent fashion with zonisamide concentrations in the range of 1 to 500 μM. T-type Ca currents were inhibited 10% to 25% at therapeutic concentrations of 10 to 50 μM, and the maximum inhibition obtained was 60%. Zonisamide also reduced the T-type Ca current recorded from cultured neuroblastoma cells, producing a 38% reduction in current at a concentration of 50 μM and a shift in the inactivation curve to more negative potentials by 20 mV.[72] It seems plausible that the broader clinical spectrum of activity of zonisamide, including its activity in generalized absence seizures,[157] could relate to this action on T-type Ca current.

As is the case for other Na-channel modulating AEDs, the ability of zonisamide to modulate voltage-dependent Na channels is expected to reduce the action potential–evoked release of glutamate through a presynaptic action. In fact, recordings from hippocampal neurons in rat brain slices demonstrated that 20 μM zonisamide suppressed the amplitude of spontaneous action potential–dependent excitatory postsynaptic currents without affecting action potential–independent (miniature) synaptic currents.[144] Thus, these electrophysiologic studies demonstrate that zonisamide is able to block glutamate release through a presynaptic action, and they suggest that this occurs through an interaction with Na channels, and not through downstream components of the vesicular release machinery.

Studies with microdialysis in freely moving rats have indicated that zonisamide has complex actions on the release of various neurotransmitters, and that these effects could be mediated through actions distinct from the interaction with Na channels. The transmitters studied have included GABA, dopamine, serotonin, and acetylcholine. Zonisamide in some cases was found to increase release and in other cases to inhibit it.[69,124,211] The extent to which these effects could contribute to the anticonvulsant activity of zonisamide is not well understood. However, it is interesting that zonisamide can enhance the basal release of GABA.[208] Another observation suggesting that zonisamide could influence GABA systems is that chronic treatment of rats with zonisamide leads to downregulation of the GAT-1 GABA transporter.[187] In addition, there is evidence from radioligand binding suggesting that zonisamide could directly interact with $GABA_A$ receptors. Thus, reports from one research group demonstrated that zonisamide displaced [^{3}H]flunitrazepam and [^{3}H]muscimol binding in rat brain, albeit at relatively high concentrations (100–1,000 μM).[111,112] In addition, [^{3}H]zonisamide was found to bind to a stereospecific binding site in a crude synaptosomal fraction of whole rat brain with a K_d of 90 nM.[112] Clonazepam reduced and GABA increased [^{3}H]zonisamide binding, suggesting that the zonisamide binding site was coupled to benzodiazepine receptors. However, in spinal cord neurons in cell culture, zonisamide did not affect electrophysiologic responses to GABA.[142] Overall, it seems unlikely that effects on GABAergic systems contribute in a major way to the anticonvulsant actions of zonisamide.

In a large number of additional studies, zonisamide has been reported to have various effects on monamine turnover and metabolism (reviewed by Macdonald[98]). Effects on dopamine systems have been particularly well studied, with several reports that zonisamide enhances dopamine turnover at therapeutic concentrations[125] but it is unlikely that these effects contribute to the therapeutic activity of zonisamide in epilepsy.[114]

Zonisamide has a sulfonamide side chain that is a common element of many carbonic anhydrase inhibitors, including acetazolamide, and zonisamide is well recognized to inhibit carbonic anhydrase isoenzymes.[101] At least 15 human carbonic

anhydrase isoenzymes have been described, including forms that are cytoplasmic (I, II, III, and VII), mitochondrial (VA and VB), secreted (VI), and membrane-associated (IV, IX, XII, and XIV). Although zonisamide is a very weak inhibitor of membrane-associated isoenzyme XII, it inhibits isoenzyme IX with high affinity (K_I, 5.1 nM).[121] Given the emerging evidence that carbonic anhydrase regulates GABA signalling,[141] this effect is intriguing. However, a role for carbonic anhydrase inhibition in the anticonvulsant mechanism of zonisamide has been discounted on the basis of structure-activity studies. Thus, both zonisamide and its 7-methyl analog have similar carbonic anhydrase inhibitory activity, but only zonisamide was protective in the mouse MES test.[103] This observation indicates that carbonic anhydrase inhibition is not the sole or major mechanism underlying the anticonvulsant activity of zonisamide; whether it is a contributory factor remains to be determined.

Summary and Conclusions

In summary a key action of zonisamide that likely contributes to its anticonvulsant activity is the modulation of voltage-gated Na channels to limit sustained, high-frequency, repetitive action potential firing. In addition, and in distinction with conventional Na-channel blocking AEDs, zonisamide can inhibit T-type Ca channels. Both effects occur at clinically effective free serum concentrations. By virtue of its action on Na channels, zonisamide inhibits the release of glutamate and other neurotransmitters through a presynaptic action. In addition, zonisamide has complex actions on dopamine, serotonin and acetylcholine metabolism; the relationship of these actions to anticonvulsant activity is obscure. Finally, zonisamide is a potent inhibitor of some carbonic anhydrase isoenzymes, but this action has not yet been linked to its therapeutic activity. The complex cellular actions of zonisamide, including its effects on T-type Ca channels, likely account for its broader clinical spectrum of activity than conventional Na channel blocking AEDs.[209] The multiple mechanisms may extend its range of clinical utility not only to generalized absence seizures, but also to myoclonic seizures (including those in juvenile myoclonic epilepsy), infantile spasms, and the Lennox-Gastaut syndrome.

Chapter 137

Basic Principles of Medicinal Chemistry

Donald F. Weaver

Raman Sankar

Introduction

Medicinal chemistry is the branch of applied organic chemistry that deals with the design and synthesis of new chemical entities for the symptomatic or curative treatment of human disease states.[30] Medicinal chemistry is a multidisciplinary endeavor. It has as its basis a firm understanding of all branches of chemistry (in particular synthetic organic chemistry), but also embraces many elements of other disciplines that are necessary tools for the practicing medicinal chemist, including pharmacology, pharmacy, physiology, biochemistry, and medicine. The primary objective of medicinal chemistry is to discover new prototype molecules as prospective drugs, and subsequently to optimize any promising drug candidate by improving its beneficial therapeutic effects and minimizing its undesirable side effects. As applied to epilepsy, the role of medicinal chemistry is to discover new drugs to treat seizures with improved efficacy and decreased toxicity.

The medicinal chemistry of anticonvulsants has a long history, and it will probably have a long future. During the past 2,000 years, many compounds have been suggested as potential therapeutic agents for epilepsy. The history of the medicinal chemistry of anticonvulsant drugs can be categorized into three distinct eras: The era of charlatanism (prehistory to 1857), the era of serendipity (1857 to 1980), and the era of rational drug design (1980 to the present). The future of anticonvulsant medicinal chemistry will also hold a number of distinct changes.

The Era of Charlatanism: Ancient Times to 1857

Epilepsy was described by the school of Hippocrates in the book *On the Sacred Disease*, written in 400 BC. Although the role of heredity as well as the relationship between focal head trauma and contralateral seizures was recognized at the time, the overwhelming emphasis on the role of possession by evil spirits and excess accumulation of cold phlegm resulted in therapeutic approaches that focused on occult or magical powers to render a cure. The therapy of that time was dominated by superstition and charlatanism and relied on agents such as gladiator blood, seal penis, mistletoe, and dried human skull extract. Not surprisingly, such cures were of negligible value.

It was not until the “era of serendipity” that truly useful chemical agents to treat seizures first emerged.

The Era of Serendipity: 1857 to 1980

Many important drugs have had their origin in an accident, either in the laboratory or the clinic. The so-called serendipity factor looms large in the history of medicinal chemistry and accounts for several major discoveries, from penicillin as an antibacterial agent to imipramine as an antidepressant. Although this is a humbling realization, the evolution from penicillin to the large number of synthetic *B*-lactams and cephalosporins in use today is a direct result of the application of concepts of drug design. Design concepts that build on a serendipitous lead to generate a large number of synthetic analogs have played a role in the development of several anticonvulsant drugs. One of the authors[30] has stressed the critical importance of serendipity in a historical analysis of antiepileptic drug development, urging investigators to look sideways for the unexpected. From 1857 to 1980, serendipity was the major discoverer of anticonvulsant drugs.

The first application of effective chemotherapy to control seizures was undertaken by Sir Charles Locock, an obstetrician in the mid-19th century. In those days, bromide preparations were known for their sedative and antiaphrodisiac properties, and epilepsy was thought to result from excessive masturbation and hysteria. These factors caused Locock to introduce bromides for the treatment of seizures related to menses and seizures considered to be venereally induced. Although his reasoning was quite erroneous, this inorganic agent was the first effective pharmacotherapeutic agent for epilepsy.

The first synthetic organic medicinal agent to control seizures was phenobarbital, a ureide (a derivative of urea, synthesized by the combination of urea and substituted malonic acid) that was introduced in 1912.[15] The discovery of the anticonvulsant potential of phenobarbital was quite accidental, as the drug had been administered mainly to sedate a ward of noisy epileptic patients during the night. From that point on, the increasing ability of chemists to tinker with the basic ring structure of phenobarbital, combined with new animal models of seizures, became the driving force behind the development of anticonvulsant drugs.

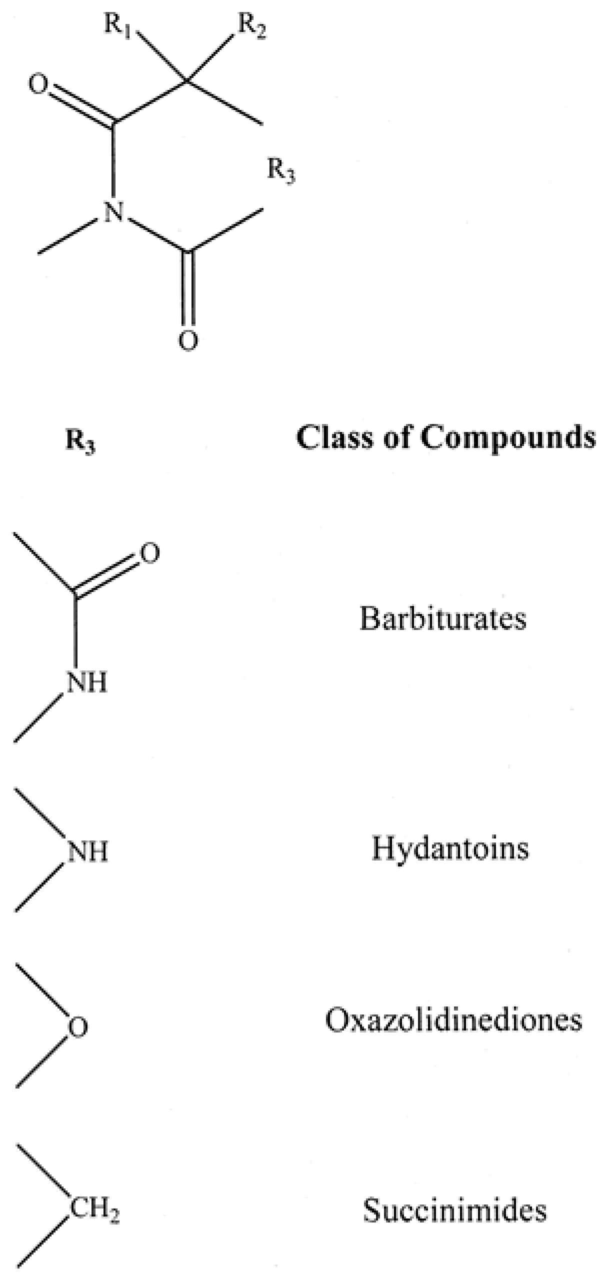

FIGURE 1. Structure common to antiepileptic drugs containing the ureide moiety.

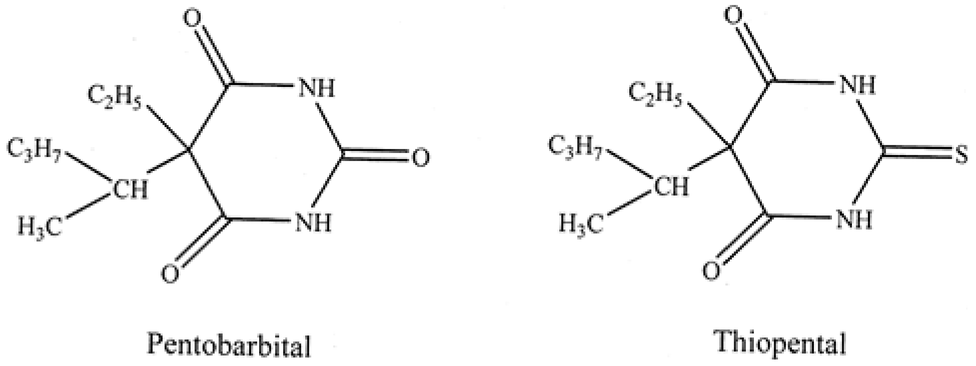

FIGURE 2. Substitution of the urea oxygen on pentobarbital with sulfur to create thiopental results in a compound with increased lipid solubility; this in turn leads to extremely rapid distribution of thiopental into the central nervous system and rapid redistribution to adipose tissue, thus making it a member of the ultra-short series.

The first epochal result of such an approach was the discovery of phenytoin by Merritt and Putnam.[19] The development of the maximal electroshock model by Merritt and Putnam,[20] with its subsequent use as a screening model, was crucial to the availability of phenytoin in 1938. The close structural relationship between phenobarbital (a barbiturate) and phenytoin (a hydantoin) can be discerned from FIGURE 1. The expansion of the barbiturate and hydantoin families came about because the side chains (aryl, alkyl, cycloalkyl) could be varied and *N*-alkyl groups could be introduced to the basic structure of phenobarbital and phenytoin, giving rise to a number of compounds that differed in their onset and duration of action. The subsequent availability of the pentylenetetrazol model gave rise to the development of trimethadione, an oxazolidindione, as a specific agent for absence (then call petit mal) seizures. This compound was originally studied as an analgesic; it was systematic screening using available animal models that resulted in its accidental discovery as an antiabsence drug. The development of the succinimides, especially ethosuximide, yielded effective antiabsence compounds that were also less toxic. The close structural

P.1448

relationship among the barbiturates, hydantoins, oxazolidindiones, and succinimides (families of compounds in the ureide dynasty), all of which possess a cyclic structure, is clearly seen in FIGURE 1. All these compounds resulted from the serendipitous clinical observation of phenobarbital as an anticonvulsant.

A wealth of lessons in medicinal chemistry was learned from the initial studies with ureides. For example, it was noted that the lipid solubility of a given compound within the ureide family could be increased according to the size of the alkyl (cycloalkyl) and aryl side chains, by the introduction of *N*-alkyl groups (which alter the pKa of the compound and hence the extent of ionization), or by replacing an oxygen in the ureide ring with a sulfur (Fig. 2).

The lipid solubility of a compound correlates with the rapidity with which therapeutic levels may be achieved in the brain. Other chemical modifications influenced the rate of drug clearance by affecting plasma protein binding, affinity for the hepatic cytochrome P450/mixed-function oxidase system, and the rate of the oxidative reaction in that matrix. Accordingly, the structural congeners developed via medicinal chemistry gave rise to drugs with distinctive onsets of action as well as duration of action.

The ureides dominated the anticonvulsant drug scene until the arrival of the benzodiazepines, carbamazepine, and valproic acid. All three of these classes of drug were discovered by serendipity. For example, chlordiazepoxide was discovered when it was accidentally synthesized in an attempt to produce antipsychotic tricyclic drugs; its sedative and anxiolytic properties were then observed serendipitously, and only later were the anticonvulsant properties of benzodiazepines realized. Similarly, carbamazepine was designed as a psychotropic tricyclic; its unanticipated anticonvulsant properties were revealed at a later time.

However, the importance of serendipity in drug discovery is most clearly illustrated by the circumstances in which the anticonvulsant activity of valproate was recognized. In 1963, a graduate student in France prepared a series of heterocyclic molecules that were subsequently submitted to a local pharmaceutical company for screening in a variety of biologic assays. Because of the poor solubility of these compounds, they were somewhat randomly dissolved in a series of solvents, of which valproic acid was one. When it was noted that one of the compounds seemed to have anticonvulsant activity, subsequent work revealed that all such activity was located in the serendipitously selected valproic acid solvent.[4,5] Thus, valproate was discovered completely by accident.

As is apparent, the major traditional anticonvulsant drugs (phenobarbital, phenytoin, carbamazepine, valproate, benzodiazepines) were all discovered through serendipitous observations. Because of this element of chance, the medicinal chemistry of these important compounds remains incomplete. For example, modern electrophysiologic studies suggest that phenytoin, carbamazepine, and valproate probably function at the level of the voltage-gated sodium channel; however, the structure of the receptor site, the nature of the drug–receptor interaction, and the portion of the drug molecule interacting with the receptor all remain incompletely elucidated.

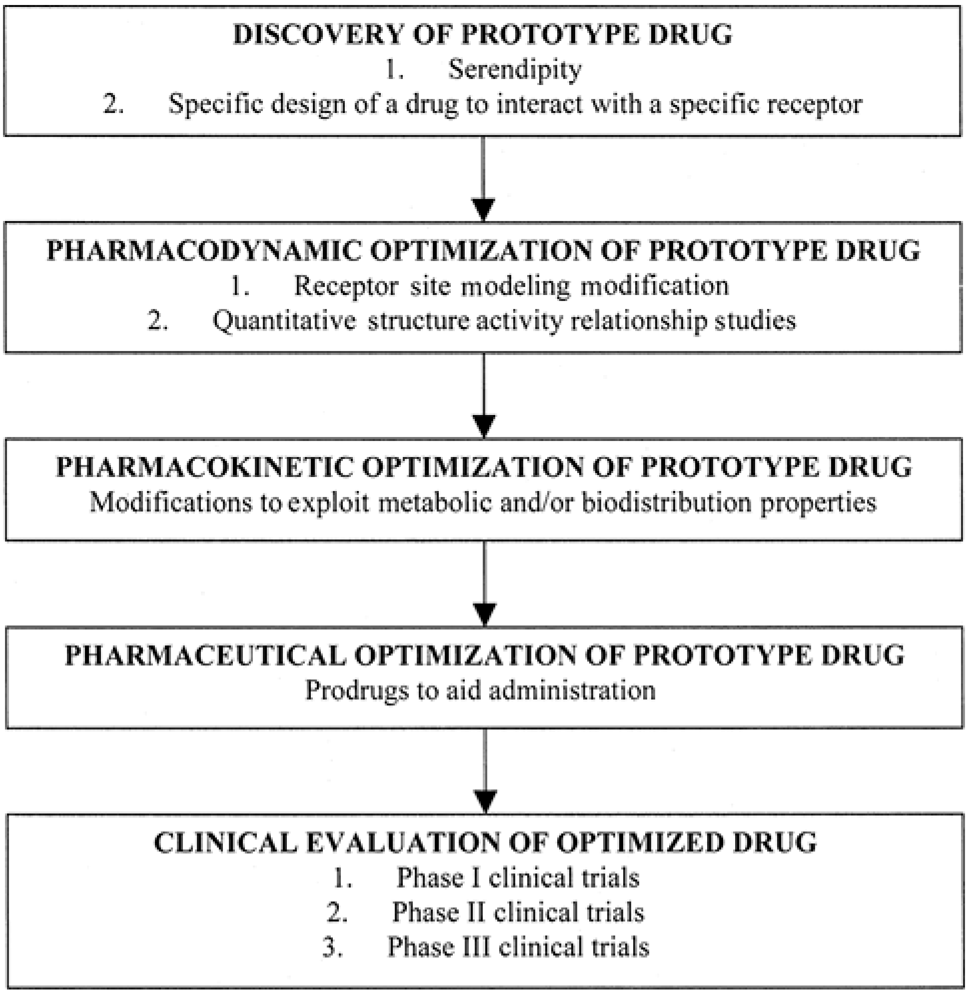

FIGURE 4. Modern antiepileptic drug design and optimization.

Although the discoveries may have been accidental, advances in the medicinal chemistry of anticonvulsant drugs made

P.1449

accidentally during the era of serendipity paved the way to the present era of rational drug design.

The Era of Rational Drug Design: 1980 to the Present

Over the past 25 years, a number of new chemical entities have been introduced as new agents for the treatment of epilepsy, with many more on the drawing board.[18] Some of these new agents are shown in FIGURE 3. This past quarter-century has been an era of rational drug design.

Strictly defined, rational drug design is a process whereby the three-dimensional structure of some biologic macromolecular receptor involved in the etiology and pathogenesis of a given disease process is determined, thus permitting the intelligent engineering of molecules specifically developed to dock with and alter the function of the receptor macromolecule. Operationally defined, rational drug design is the process of optimizing a prototype drug to yield the best possible clinical candidate. A flow chart describing this process is shown in FIGURE 4.

Rational drug design starts with the identification of a prototype or lead compound. This may be done using several approaches, including random screening and specific design. The

P.1450

lead compound is then optimized at three distinct levels: Pharmacodynamic, pharmacokinetic, and pharmaceutical. At the pharmaceutical level, the route of administration and the adequacy of solubility and penetration into the organism are determined. The pharmacokinetic level concerns the metabolism of the drug (including first-pass effect through the liver) and its biodistribution to the receptor microenvironment. The pharmacodynamic phase involves the interaction of the drug with its receptor at the molecular level of conceptualization.

Discovering the Prototype Drug

Craig[6] described several methods of "drug discovery" to convey the fact it is usually not restricted to de novo drug design. The general approaches to the identification of prototype compounds include the three described below:

1. Specific design of a drug to interact with a receptor site after the structure of the receptor site has been rigorously determined by x-ray crystallography or other means
2. Preparation of structural analogs of synthetic chemicals with interesting biologic activity
3. Preparation of novel chemicals based on the known structures of naturally occurring, biologically active substances of plant and animal origin

Approach 1: This ultimate ideal in rational drug design involves the isolation, purification, and crystallization of receptor proteins. As many of the relevant antiseizure receptor targets (such as the transmembrane voltage-gated sodium channel) are not amenable to such biochemical manipulations, this approach remains unrealized as far as anticonvulsant drug discovery is concerned. Nevertheless, ion channels remain as an important target for anticonvulsant drug design.[31] Also, recent pioneering work by McKinnon (for which he was awarded the 2003 Nobel Prize in Chemistry) is starting to provide insights into the structure of voltage-gated ion channels.

Approach 2: For years it was believed that folate deficiency was a mechanism of anticonvulsant activity. For instance, many workers suggested that the mechanism of phenytoin might be exerted through this route. Using this as a starting point, attempts were made to design novel anticonvulsant drugs as analogs of compounds with known antifolate activity. Lamotrigine, which was developed as a congener of methotrexate, demonstrated significant anticonvulsant activity. Unfortunately, the success of lamotrigine as an anticonvulsant drug does not occur via a folate mechanism, but rather through a sodium channel blockade—the importance of the serendipity factor persists even in the era of rational drug design.

Approach 3: In rational drug design, discovering a prototype drug usually requires that the underlying biochemistry be understood at some reasonable level of refinement. Seizures occur when an imbalance in the two principal neurotransmitters occurs: L-glutamic acid, an excitatory amino acid neurotransmitter, and γ-aminobutyric acid (GABA), an inhibitory amino acid neurotransmitter. Of these two neurotransmitters, GABA is particularly important in epilepsy. The concentration of GABA is regulated by two pyridoxal-5-phosphate (PLP)-dependent enzymes: L-glutamic acid decarboxylase (GAD, glutamate decarboxylase), which converts glutamate to GABA, and GABA aminotransferase (GABA-T), which catabolizes GABA to succinic semialdehyde. (Although succinic semialdehyde is cytotoxic, it is rapidly and efficiently metabolized to succinic acid by the enzyme succinic semialdehyde dehydrogenase [SSADH].)

Because GABAergic dysfunction seems to play a role in the pathogenesis and etiology of seizures and epilepsy, it seems understandable that GABA or some related analog might be a profitable prototype drug. A wealth of experimental data supports this assertion. For example, when GABA levels fall below a certain threshold level, seizures may occur; likewise, direct injection of GABA into the brains of experimental animals can stop seizure activity. Accordingly, it would seem reasonable that GABA should be an ideal prototype anticonvulsant drug. Nevertheless, when GABA is administered orally, it is devoid of anticonvulsant activity, as it is not bioavailable to the brain; GABA does not cross the blood–brain barrier. Another approach for increasing brain GABA levels would be to discover a compound capable of crossing the blood–brain barrier and inactivating the GABA-T enzyme implicated in the biodegeneration of GABA. Provided the glutamate decarboxylase was not simultaneously inhibited, GABA levels would rise to effective anticonvulsant concentrations. Vigabatrin, a structural analog of GABA, is such a molecule. Vigabatrin is a molecule that functions as a mechanism-based inactivator of GABA-T. Vigabatrin is an unreactive compound that is converted by the normal catalytic mechanism of GABA-T to a reactive intermediate compound that attaches to the GABA-T, thereby inactivating the enzyme.

It is surprising that GABA does not cross the blood–brain barrier, but vigabatrin, which is also a small, charged molecule, is capable of diffusing across the lipophilic blood–brain barrier. There are two reasons for this seeming paradox. First, the attachment of a vinyl substituent increases the lipophilicity of the molecule. Second, the vinyl group is an electron-withdrawing substituent that lowers the pKa of the amino group; this in turn increases the concentration of the uncharged, nonzwitterionic form, which is more lipophilic than the charged, zwitterionic form.

Optimizing the Pharmacodynamic Level

One of the first steps in rational drug design is to optimize a candidate drug at the pharmacodynamic level, that is, at the level of the drug–receptor interaction. In anticonvulsant drug design, the nature and structure of the receptor are not clearly known. For example, although it is known that most current anticonvulsant drugs work at the level of the voltage-gated sodium channel, the structure of this protein remains unsolved. Accordingly, it is necessary to synthesize many analogs (hundreds or thousands!) of a prototype drug in an attempt to discover analogs with improved anticonvulsant activity. The systematic approach employed for this purpose is termed quantitative structure-activity relationship studies.[26]

Quantitative Structure-Activity Relationship Studies

Quantitative structure-activity relationship (QSAR) studies are central to drug optimization. A QSAR study answers the following question: What is it about the structural, physical, and chemical properties of the drug molecule that impart its biologic activity, and how is the biologic activity modified by systemic variations of molecular structure?[13] The phenobarbital molecule may be considered an example.

There are many ways of approaching a QSAR study of barbiturates. Bikker et al.[2] have published a theoretic quantum pharmacologic QSAR study of barbiturates. These authors identified 48 barbiturates with varying anticonvulsant activities, which had been assessed using comparable biologic assays. Each barbiturate, regardless of its activity, was analyzed according to a series of descriptors. These descriptors were divided into four groups: Geometric, electronic, topologic,

and physiochemical. Geometric descriptors (e.g., bond lengths, bond angles, interatomic distances) reflect the shape and size properties of the molecules.[21] Electronic descriptors (e.g., atomic charges, molecular dipole) encode the electron distribution properties within the drug. Topologic descriptors are numeric representations of molecular branching and complexity.[16] Physiochemical descriptors (e.g., log P, the octanol-water partition coefficient) reflect the capacity of the drug to traverse biologic membranes and barriers.[14] These groups of descriptors are calculated, using classic mechanics and quantum mechanics, for each drug molecule. Statistical algorithms are then employed to discern the minimal number of descriptors capable of distinguishing activity from inactivity. As a corollary, it is possible to gain insights into the nature of the drug receptor site. This study clearly demonstrated that there are different portions of the phenobarbital molecule necessary for activity against maximal electroshock seizures and against pentylenetetrazol-induced seizures. The portion of the molecule responsible for its bioactivity is its *bioactive face* or *pharmacophore* (the three-dimensional arrangement of atoms necessary for biologic activity).

Once the QSAR studies permit the structure of the pharmacophore to be deduced, it is possible to optimize the drug by refining its structure.

Optimizing the Pharmacokinetic Level

Metabolic Masking: Carbamazepine Versus Oxcarbazepine

The oxidation of the 10,11-double bond of the seven-membered azepine ring in carbamazepine (CBZ) to form epoxy-CBA is quantitatively the most important pathway in the biotransformation of CBZ.[9] Although the anticonvulsant efficacy and neurotoxicity of this epoxide metabolite are comparable with those of the parent drug,[3] it has long been implicated as a significant contributor to the clinical toxicity of therapy with CBZ. This is because epoxy-CBZ is inactivated by conversion to the *trans*-diol by an epoxide hydrolase that is less inducible by repeated doses of CBZ than the P450 isoforms that produce the epoxy-CBZ.[7] Oxcarbazepine (OCBZ), the 10-keto derivative of CBZ, was developed to overcome this problem. This compound is rapidly converted to a monohydroxyl derivative, 10-hydroxy-CBZ, which is responsible for the anticonvulsant effect. In this sense, oxcarbazepine is a bioprecursor and is activated by an enzymatic reduction to the active metabolite. Oxcarbazepine compares with CBZ in efficacy and appears to produce fewer adverse effects. Allergic reactions may also be less frequent with OCBZ and CBZ, as covalent interaction of the epoxide with cellular macromolecules may be responsible for the generation of haptens that produce immunologic responses.

Optimizing the Pharmaceutical Level

Bioprecursors Versus Prodrugs: Fosphenytoin

It is possible to create a temporary linkage between an active drug and a carrier moiety to modify strongly the lipophilicity or water solubility of a drug. The carrier group may be readily hydrolyzed on administration by chemical or enzymatic processes for rapid release of the active moiety (parent drug molecule). An example of this approach is seen in the design of fosphenytoin. Phenytoin, even as the sodium salt, has very limited water solubility. The intravenous preparation has a pH of approximately 12 and employs a vehicle that includes 40% propylene glycol and 10% ethanol, making it a highly irritating solution. The limited solubility also precludes the possibility of using the solution intramuscularly. Fosphenytoin is the disodium phosphate ester of 3-hydroxymethyl-5,5-diphenylhydantoin (Fig. 5). It has significantly better solubility than phenytoin sodium, and the intravenous preparation has a pH of 8.8 (approximately 1,000-fold less alkaline than a solution of sodium phenytoin). This compound may be used with ease intravenously with far less irritation than that caused by phenytoin sodium. It may also be used safely as an intramuscular injection. The ester is rapidly converted by serum alkaline phosphatase to free phenytoin, and the C_{max} and T_{max} of free phenytoin achieved by infusion at 100 mg/min are comparable with those attained by a 50-mg/min infusion of phenytoin sodium; the incidence of pain and burning immediately after infusion are dramatically reduced.[10]

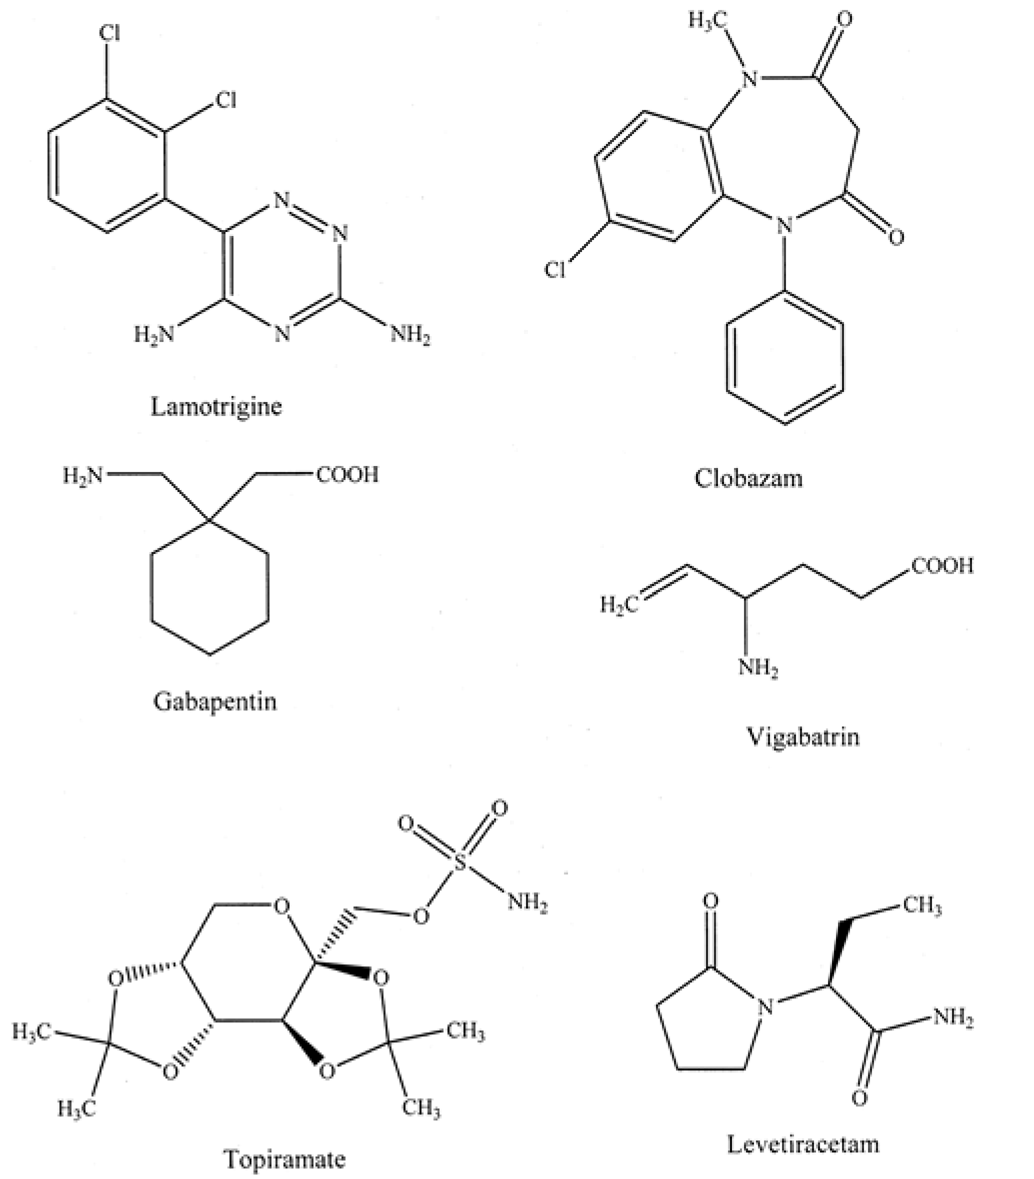

FIGURE 5. Hydrolytic conversion of fosphenytoin to phenytoin. The disodium phosphate moiety provides for a more water-soluble, less alkaline, and less irritating product.

The Future of Anticonvulsant Medicinal Chemistry

The future of anticonvulsant medicinal chemistry holds significant promise.

Anticonvulsant Discovery by High Throughput Screening

Modern drug discovery through screening is emerging as an ever-improving technologic tour de force.[30] If a reliable bioassay is available, it is possible to screen thousands or even millions of compounds in this bioassay. The crystal structures of key protein receptors involved in the disease process do not have to be known; indeed, the proteins do not even have to be identified. If the bioassay is fast and efficient, and if the library of compounds being screened is diverse and comprehensive, then in principle it should be possible to identify a lead compound. However, the key to success lies in the “diversity of the library of compounds” (i.e., a combinatorial chemistry library) and in the efficiency of the screening bioassay (i.e., high throughput screening methods).

The first key to success in drug discovery by screening is the availability of a large and structurally diverse library of compounds. If the library contains a million compounds that are all analogs of each other, then it may be large, but it is probably not sufficiently diverse. The library should have the full range of chemical functionalities displayed in all possible combinations in three-dimensional space. Creating such a library is not a trivial task.

Combinatorial chemistry is both the philosophical and the practical method with which to create such structurally diverse compound libraries. Combinatorial chemistry is defined as that branch of synthetic organic chemistry that enables the concomitant synthesis of large numbers of chemical variants in such a manner as to permit their evaluation, isolation, and identification. Historically, the first major libraries were oligomers of naturally occurring monomers. A good example would be a library of all possible tripeptides. Using the 20 naturally occurring amino acids, it is possible to produce 8,000 different tripeptides. Such peptide libraries are easy to synthesize, and, since amino acid side chains possess a wide variety of different functional groups, it is possible to achieve a good measure of structural diversity. However, in general, peptides are not drugs and a peptide lead would have to be modified into a druglike molecule.

P.1452

A step beyond the naturally occurring oligomeric libraries is to create libraries from nonnaturally occurring monomeric building blocks. The medicinal chemistry literature contains a fair number of examples of such libraries. Although these libraries overcome the limitations of naturally occurring oligo- meric libraries, most drugs are not polymers. To address this problem, new libraries are emerging in which the central moiety is a small organic molecule, not a polymer. The diversity library is then constructed by attaching many different substituents to this central moiety. Through these various techniques, large and structurally diverse libraries of compounds are becoming available.

The second key to success in drug discovery by screening is the availability of a high throughput bioassay with which to screen the large, chemically diverse library of molecules in a time-efficient manner. If a 200,000 compound library is available, the biologic evaluation assay must be rapid and reliable. If the assay were capable of testing five compounds per day, it would take 110 years to evaluate the entire library. Clearly, this is not the time for elaborate in vivo testing. Fast, efficient in vitro assays are required. The ability to inhibit an enzyme is a good example of a potentially useful assay for high throughput screening. This issue is crucial in anticonvulsant drug discovery. Most models of seizures are slow, tedious animal models (maximal electroshock, pentylenetetrazole models), which are not amenable to high throughput screening (HTPS). If future anticonvulsant drug discovery is to employ HTPS, then efficient bioassays relevant to epilepsy must be identified.

A variety of high throughput assays have been developed and perfected over the past 10 to 20 years. These include the following three basic types of assay:

1. Microplate activity assays (assay is in solution in a well; the result of the assay, such as enzyme inhibition, is linked to an experiment observable to enable identification of bioactivity)
2. Gel diffusion assays
3. Affinity selection assays

Of these, microplate assays are probably the most widely used. Screening combinatorial libraries on microplates containing 96 or 384 (or more) wells is time and cost efficient. Using robotic techniques, it is possible to perform more than 100,000 bioassays per week in a microplate system (permitting the above-described 200,000 compound library to be screened in 2 weeks, rather than over a century).

In addition to selecting an appropriate assay, it is also necessary to have a pooling strategy. It is more efficient to test many compounds per well on the microplate, rather than one compound per well. If one could test 100 compounds per well, then the standard 96-well plate would enable almost 10,000 compounds to be evaluated in one experiment.

P.1453

The evolution of methods for combinatorial syntheses and high throughput screening will be necessary to address the explosion of druggable targets soon to be identified by the genomics and proteomics revolutions. Genomics and proteomics represent the future of lead compound identification for drugs in general and perhaps anticonvulsants in particular.

Genomics is the study of genes and their functions. On June 26, 2000—the dawning of the present century—a historic milestone in genomic science was attained when researchers involved with the Human Genome Project jointly announced that they had sequenced 97% to 99% of the human genome. The human genome consists of 23 pairs of chromosomes with 3 billion base pair codes for approximately 24,000 to 30,000 functional genes.

Determining gene structure and function through genomics definitely does illuminate the path for linking specific genes to specific disorders, such as epilepsy. Although genomics did deliver phenomenal masses of raw information, the pathway to using genomics for anticonvulsant drug discovery is not immediately apparent. Such an endeavor will require postgenomics technologies. Taking genomics one step further for the purpose of anticonvulsant drug discovery will require linking specific proteins to those specific genes. Clearly, there exists a vast gap between genomics and drug discovery. Bridging this gap will ultimately be a daunting task that lies within the domain of proteomics.

Proteomics is a protein-based science that seeks to provide new, fundamental information about proteins on a genome-wide scale. Proteomics seeks to elucidate the structure and function profiles of all proteins encoded within a specific genome; this collection of proteins is termed the proteome. The proteomes of multicellular organisms present an immense challenge in that more than 75% of the predicted proteins have no apparent cellular function. Furthermore, although the human proteome has more than 100,000 proteins, only a fraction of these proteins are expressed in any individual cell type. If epilepsy is to be linked to specific proteins, it is imperative that ways be developed to deduce which individual protein is expressed in which individual cell.

Since protein and mRNA concentrations tend to be correlated, DNA microarray technology is a powerful technique with which to monitor the relative abundance of a specific mRNA in an individual cell and to correlate this with a specific protein. In addition to these microarray technologies, many other technologies will be required if proteomics is to deliver the drugs promised by genomics. For example, drug design requires much more than merely knowing the primary amino acid sequence of a protein—it requires a precise knowledge of the protein's three-dimensional structure, down to the level of the Angström. To date, science has no technology that enables one to use the information coded in a protein's primary amino acid sequence to deduce the overall tertiary structure of the protein. This is the protein folding problem. The need to solve this problem has given rise to the subdiscipline of structural proteomics, a technology that is based upon the principle that structure underlies function and that endeavors provide three-dimensional structural information for all proteins.

Despite these advances, the pathway to the awaiting plethora of anticonvulsant drugs is still far from perfect. In general, anticonvulsant drugs are small organic molecules. Obtaining these drug molecules will require yet another step in the “from genomics to proteomics to disease” cascade. Just as proteomics is a crucial bridge uniting genomics to disease, so too will an equally crucial bridge be needed to unite proteomics with therapeutics. The bioinformatics/cheminformatics spectrum may be that bridge.

Bioinformatics/cheminformatics constitute an *in silico* science that endeavors to predict the phenomenology of cellular physiology and pharmacology at a molecular level using computational methods. Using databases of compounds and other theoretic molecular design techniques, bioinformatics and cheminformatics will attempt to identify novel molecules to alter the function of various proteins defined by the genome-based proteome. Bioinformatics/cheminformatics will apply knowledge-discovery and pattern-recognition algorithms to the genome-wide and proteome-wide experimental data, thereby facilitating anticonvulsant drug design. If structural proteomics has identified the functional portion of an important protein, cheminformatics will search large databases of druglike molecules to identify one that has the right shape and properties to dock with the protein.

Adopting New Methodologies of Drug Design

The ways in which drugs are designed and synthesized are changing. In the future, anticonvulsant drugs will be designed in part using *quantum pharmacology* calculations, also called *molecular modeling studies* or *computer-assisted molecular design (CAMD)*. Indeed, CAMD is emerging as a biotechnology of the future. CAMD calculations are performed using molecular mechanics, molecular dynamics, and semiempirical molecular orbital and *ab initio* quantum mechanics calculations. Molecular mechanics calculations employ a classic mechanical approach, in which an empiric force field equation describes the shape of a molecule as a function of energy. Molecular mechanics conceptualizes atoms as distensible spheres, focusing on the position of nuclei and not considering electrons explicitly. Quantum mechanics, on the other hand, treats electrons explicitly, using the nonempiric Schroedinger equation in preference to a force field equation. Regardless of the mathematical method employed, all these techniques permit energy to be calculated for some shape (conformation) of the molecule. These methods are then used to optimize the shape of the drug molecule, the shape of the receptor protein, and the nature of the interaction between the drug and its receptor.

Designing Rational Polypharmacy in a Single Drug

Existing methods for CAMD attempt to optimize the drug molecule to a receptor with which it may interact. Emerging understanding of the patterns of abnormal neuronal excitability that underlie many models of the epilepsies suggests that multiple neurotransmitters and subtypes of their receptors are involved. For instance, strong evidence from both in vitro and in vivo studies of the glutamatergic system suggests that both *N*-methyl-D-aspartate (NMDA) and non-NMDA mechanisms have important roles to play in several models; epileptiform activity may be abolished by drugs that act at nonglutamatergic sites (modulators of GABA activity). The possibility then exists that a drug that has suitable low-affinity interactions at multiple receptors may provide considerable efficacy with low neurologic toxicity.[23]

Topiramate is an example of a drug that has at least three interesting interactions built into one molecule: (a) use-dependent blockade of voltage-dependent sodium channels; (b) blockade of sodium currents mediated by activation of non-NMDA α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA) receptors;[24] and (c) enhancement of GABA-mediated chloride currents. In addition, topiramate also exhibits weak carbonic anhydrose antagonism; the contribution of this activity to the overall anticonvulsant activity of topiramate may not be significant.

The conventional view in drug design has been that reduction of side effects is best achieved by high selectivity and

potency. On the other hand, it seems logical that in the case of anticonvulsant drug molecules that modulate excitability mechanisms critical to normal brain function, agents with high potency and efficacy may carry the liability of unacceptable toxicity. The strategy of searching for drugs that exert low-efficacy effects on more than one receptor seems to be a worthwhile one. It should be kept in mind that both felbamate and topiramate are products of extensive screening. From the point of view of CAMD, once optimal structural features for specific drug interactions have been defined, further algorithms may become important in looking into the possibility of building multiple pharmacophores and the requisite conformational freedom to facilitate multiple interactions in a single molecule.

Designing "Curative" Antiepileptogenic Drugs

The drugs currently available for treating epilepsy are little more than symptomatic agents, suppressing the symptoms of epilepsy (i.e., seizures) while failing to contend meaningfully with the fundamental pathologic process that initially causes (and continues to cause) the underlying susceptibility to seizures. Furthermore, the current drugs for the symptomatic suppression of seizures are effective in <65% of patients. The direction to be pursued in the development of these new agents is not apparent. With an existing drug selection populated by a diversity of old agents (e.g., phenytoin, carbamazepine) and newer agents (e.g., vigabatrin, lamotrigine), the interests of the patient population will not be served best by simply more of the same. Central to the rational design of truly novel new compounds will be the evolution of concepts concerning the etiology and pathogenesis of epilepsy. The new agents developed to interact with target receptors based on these concepts must have the capacity to influence the natural history of epilepsy in a curative sense, not merely mask the symptoms.

An important first conceptual step in target selection for future curative drug design will be differentiating between the notions of ictogenesis and epileptogenesis.[29] A seizure (Latin, *ictus*) is a single, discrete clinical event caused by an excessive electrical discharge from a collection of neurons. A seizure is merely a symptom of epilepsy. Epilepsy, on the other hand, is a dynamic and frequently progressive process characterized by an underlying sequence of pathologic transformations whereby normal brain is altered, becoming susceptible to recurrent seizures. Ictogenesis (the initiation and propagation of a seizure in time and space) is a rapid and definitive electrical/chemical event occurring within seconds or minutes. Epileptogenesis (the gradual process whereby normal brain is transformed into a state susceptible to spontaneous, episodic, time-limited, recurrent seizures through the initiation and maturation of an epileptogenic focus) is a slow biochemical/histologic process occurring insidiously through a period of months to years. Obviously, the chemistries of ictogenesis and epileptogenesis have unique differences, and not surprisingly, therapeutics targeting these two processes may also have definite differences. For the purposes of rational drug design, both processes must be explicitly understood at the molecular level.

Ictogenesis is a fast, short-term event. Heuristically, ictogenesis can be divided into the rapidly sequential phases of initiation and elaboration; elaboration arises from the extension of the seizure in time and space. Ictogenesis involves excessive brain electrical discharges propagated by a cascade of chemical events initiated by the sequential opening of Na^+ channels and subsequent involvement of K^+ channels and the Na^+/K^+ATPase pump. The electrical activity passes from neuron to neuron via the CA^{2+} channel-mediated release of neurotransmitters. Logically, diverse approaches exist for the rational design of anti-ictogenic (anticonvulsant, antiseizure) drugs, including agents that (a) block voltage-gated ion channels, (b) antagonize excitatory neurotransmitters, and (c) mimic inhibitory neurotransmitters. The obvious central role of the transmembrane voltage-gated Na^+channel protein in ictogenesis has resulted in the majority of currently available anticonvulsant drugs (e.g., phenytoin, carbamazepine, lamotrigine) being targeted against this receptor site.

Epileptogenesis, unlike ictogenesis, is a gradual, two-phase process showing dynamic changes over the course of time. Phase 1 is the initiation of the epileptogenic focus/predisposition, and phase 2 is the maturation of the epileptogenic focus/predisposition. Phase 1 epileptogenesis denotes the events that take place before the occurrence of the first seizure. There may be a considerable delay of months to years between the occurrence of the brain injury (e.g., stroke, trauma) and the onset of spontaneous, recurrent seizures; during this latent period, epileptogenesis is taking place, culminating in active epilepsy characterized by recurrent seizures. Phase 2 epileptogenesis denotes the events that take place after the first seizure has occurred. This also is a long, protracted process, in which seizures may become more frequent, more severe, more refractory to treatment, or phenomenologically different in their clinical manifestations. As the design of antiepileptogenic drugs is central to the discovery of truly curative agents, understanding the pathogenesis of epilepsy at the molecular level is crucial.

The cascade of histologic and biochemical events that characterize epileptogenesis differs from those of ictogenesis. At the histologic level, epileptogenesis involves cellular alterations that, in the clinically important partial epilepsies, are usually at the level of the limbic system. Morphologically, epileptogenesis is accompanied by neuronal loss in a variety of limbic structures, including the entorhinal cortex, the endopyriform nucleus, and the CA3 and CA1 pyramidal cell fields and granule cell layer of the dentate gyrus in the hippocampal formation. At the biochemical level, studies of partial seizures originating in limbic structures indicate that epileptogenesis involves abnormalities of synaptic chemistry. From these morphologic, physiologic, and biochemical studies, two theories of epileptogenesis have emerged: (a) the mossy fiber sprouting hypothesis and (b) the dormant basket cell hypothesis. The mossy fiber sprouting hypothesis, which has emerged from work by Sutula et al.,[27] postulates an upregulation of excitatory coupling between neurons. This excitatory upregulation is mediated by NMDA glutamatergic receptors, which are activated in chronic epileptic brain under circumstances that would not lead to activation in normal brain. In contrast, the dormant basket cell hypothesis suggests a downregulation of inhibitory coupling between neurons. This hypothesis postulates that the connections that normally drive GABA-releasing inhibitory interneurons are disturbed, thereby rendering them functionally disconnected or dormant. Studies by Sloviter[25] and Bekenstein and Lothman[1] support this hypothesis. The mossy fiber sprouting hypothesis invokes augmentation of glutamatergic excitation, whereas the dormant basket cell hypothesis invokes diminution of GABAergic inhibition. Although either abnormality could in isolation predispose an individual to epileptiform paroxysms, the fundamental disturbance that yields epileptogenesis seems to represent a combined, concurrent imbalance of both excitation (too much) and inhibition (too little).

Although glutamatergic and GABAergic processes are leading candidates for the mechanisms of epileptogenesis, there are other molecular pretenders to the throne. For example, recent studies have shown that in animal models of limbic seizures and of the experimental form of epileptogenesis known as *kindling* (in which repetitive, subconvulsive, subcortical electrical stimulation evokes progressively prolonged electroencephalographic and behavioral responses that culminate in

P.1455

generalized seizures), expression of nerve growth factor (NGF) protein is enhanced in the dentate gyrus;[8,12] moreover, the intracerebroventricular administration of antibodies to NGF delays the onset of kindled seizures.[11,28] Nerve growth factor is also required for hippocampal sprouting in response to a proconvulsive head injury. A synthetic peptide designed to interfere with the binding of NGF to receptors has been shown to retard seizure development and inhibit mossy fiber sprouting.[22] These various observations suggest that neurotrophic peptides like NGF play a facilitating role in hippocampal synaptic reorganization, thereby contributing to the evolution of the epileptogenic state. Clearly, the future design of much needed antiepileptogenic agents must identify the full range of target molecules, extending from the small (NMDA antagonists, GABA agonists) to the large (NGF antagonists).

Summary and Conclusions

Future rationally designed drugs for epilepsy must extend beyond the scope of simple ictogenesis and should encompass the greater mandate of epileptogenesis. Just as staphylococcal meningitis is treated with penicillin in preference to aspirin, so too must epilepsy be treated more than simply symptomatically. Achieving this goal will require changes in antiepileptic drug design and testing; it is hoped that the final result will be a truly curative agent for epilepsy—an agent that will revolutionize the therapeutic expectations of this large and significant patient population.

Chapter 138

Molecular Targets for Novel Antiepileptic Drugs

Brian S. Meldrum

Introduction

The majority of antiepileptic drugs (AEDs) introduced since 1938 have been identified as anticonvulsants by means of screening tests using in vivo models of seizures. The most widely applied models have been electrically or chemically induced seizures in normal animals. The maximal electroshock (MES) test in mice and rats and the “threshold” pentylenetetrazol (PTZ) test in mice have been rigorously standardized since 1978.[52] This has had several predictable consequences. Drugs functionally similar to phenytoin appear to be preferentially identified by the MES test. Thus, most AEDs introduced since 1978 suppress sustained rapid repetitive firing in cultured neurons, apparently by prolonging inactivation of voltage-dependent sodium channels (e.g., lamotrigine, zonisamide, topiramate, felbamate, and oxcarbazepine).

The other most widely used anticonvulsant screen is the “threshold” pentylenetetrazol test, which is used to identify drugs potentially active against absence seizures[52] (see Chapter 139). This is particularly sensitive to benzodiazepines and some other agents acting via the γ-aminobutyric acid $(GABA)_A$/benzodiazepine receptor and to drugs acting on T-type calcium channels.

Thus, a key criticism of the traditional anticonvulsant screens is that they tended to identify drugs with the same mechanism of action as existing drugs because they have been validated in terms of their capacity to select existing AEDs. This applies both in a precise mechanistic sense (i.e., in terms of their molecular targets) but also in the broad sense that most currently used drugs are direct-acting agents with a close temporal correlation between plasma or brain levels and action at the target molecule and antiepileptic effect (with only vigabatrin, gabapentin, and valproate as partial exceptions). Thus, our current acute models may miss compounds that have indirect actions with potential delays in antiepileptic effect, as is possible for compounds acting via metabotropic receptors, protein kinases, neurotrophins, or changes in gene expression.

A further problem is that the epileptic brain differs from the normal brain. Elements thought to play a critical role in acute ictogenesis (i.e., events initiating a spontaneous seizure) include the transmembrane movement of ions (Na^+, K^+, Ca^{2+}, Cl^-) and the release, postsynaptic action, and reuptake of excitatory and inhibitory neurotransmitters. The assumption that these processes are abnormal in the epileptic brain is supported by substantial data obtained in kindled animals[71] and tentative data from patients with epilepsy.[3,4,6,64] It follows that drugs modifying acute ictogenesis need to be studied in the epileptic brain, not in the normal brain. The genuinely epileptic model that has been most extensively used for screening is sound-induced seizures in DBA/2 or Fring's mice. These are highly sensitive screens that identify a wide range of AEDs; they also identify some agents acting on monoaminergic systems that are relatively effective in reflex epilepsies but are not notably effective against other epileptic syndromes.[16]

Electrically kindled seizures would appear to be highly appropriate for pharmacologic studies because of their multiple abnormalities in ion channel and neurotransmitter receptor function.[71] They are perhaps one of the better models of complex partial seizures, including the drug-resistant cases.[58] However, the time-consuming nature of this model means that it is used not as a primary screen, but at a late stage in the evaluation of compounds identified by other anticonvulsant screens. A simplified procedure not involving electrode implantation (corneal kindled seizures) has been used as a tertiary screen[14,51] (see also Chapter 139).

There are also genetically determined models of absence seizures in mice and rats that are responsive to antiabsence drugs and could be used to screen novel agents. These include the GAERS (genetic absence epilepsy rat Strasbourg) and several single gene mouse mutants (e.g., lethargic, stargazer, totterer).[11]

In contrast to the approach of in vivo screening of novel compounds with seizure models or epilepsy models is the mechanism-based approach, in which a molecular target is first defined and compounds are synthesized to optimize the action at this target and tested on a variety of in vitro systems before in vivo evaluation. This approach is totally dependent on our understanding of the causes of epilepsy and the mechanisms of chronic and acute ictogenesis. If attention is focused on mechanisms of action of existing drugs, this approach will have defects similar to in vivo screening. It is clearly important to focus attention on mechanisms of ictogenesis that have not yet been exploited therapeutically.

The following account attempts to describe some of the potential targets for novel therapies, putting them in the context of what is known about the mechanism of action of existing drugs and some novel agents currently in preclinical development whose clinical value is presently unknown.

The molecular targets for AEDs have recently been reviewed by Meldrum and Rogawski.[69]

Drugs Acting on Ion Channels

Table 1 Genetic Mutations Involving Voltage-gated and Ligand-gated Ion Channels and Epileptic Syndromes

Gene	Gene product (Channel)	Epilepsy syndromes
SCN1A	*α* subunit of Nav1.1	GEFS+ (type 2), SMEI, ICEGTCS
SCN2A	*α* subunit of Nav1.2	GEFS+ (type 2), BFNIS
SCN1B	*β* subunit of Nav1.1 to 1.4	GEFS+ (type 1)
CACNA1A	*α*1 subunit of Cav2.1 P/Q type	EAT2 + E, AEA
EFHC1	Coassembles with Cav2.3 R type	JME
CACNA1H	*α*1 subunit of Cav3.2 T type	CAE
CACNB4	*β*4 subunit of P/Q and other channels	IGE + EA
KCNA1	*α* subunit of Kv1.1	EAT1, MK, PS
LGI1	Coassembles with Kv1.1, 1.4, and Kv*β*1	ADTLE
KCNAB2	*β* subunit (Kvβ2) combines with *α* subunit of Kv1.1 and Kv1.4	Epilepsy

KCNMA1	*α* subunit of Kca1.1 (BK)	GEPD
KCNQ2 KCNQ3	*α* subunit of Kv7.2 *α* subunit of Kv7.3	BFNC BFNC
KCNJ3	*α* subunit of Kir3.1 (Girk1)	Absence
CLCN2	CLC2 Cl^- VG channel	JME, CAE, JAE, EGMA
CHRNB2	*β*2 subunit nicotinic ACh receptor	ADNFLE
CHRNA4	*α*4 subunit of nicotinic Ach receptor	ADNFLE
GABRA1	*α*1 subunit, $GABA_A$ receptor	JME
GABRBD	*β* subunit $GABA_A$ receptor *β*3 subunit $GABA_A$ receptor	JME Angelman syndrome
GABRG2	γ subunit $GABA_A$ receptor	GEFS+, CAE, SME1
GABRD	*δ* subunit $GABA_A$ receptor	GEFS+

ATLE, autosomal dominant temporal lobe epilepsy; AEA, absence epilepsy with ataxia; BFNC, benign familial neonatal convulsions; BFNIS, benign familial neonatal-infantile seizures; CAE, childhood absence epilepsy; EAT1, MK, PS, episodic ataxia type 1 with myokymia; EAT2 + E, episodic ataxia type 2 with epilepsy; EGMA, epilepsy with grand mal seizures on awakening; GEFS+, generalized epilepsy with febrile seizures plus syndrome; GEPD, generalized epilepsy with paroxysmal dyskinesia; ICEGTCS, intractable childhood epilepsy with generalized tonic–clonic seizures, IGE + EA, idiopathic generalized epilepsy with episodic ataxia (Escayg et al. 2000); JAE, juvenile absence epilepsy; JME, juvenile myoclonic epilepsy; SMEI, severe myoclonic epilepsy of infancy.

Voltage-gated or ligand-gated ion channels in the neuronal membrane generate the electrical currents associated with the normal and abnormal functioning of the nervous system. The abnormal pattern of neuronal firing associated with epileptic seizures thus depends on abnormal functioning of these ion channels. They are thus the primary target for AEDs. This is confirmed by our present understanding of the mechanism of action of the established AEDs (see Chapter 136 and references 69 and 84). It is also broadly confirmed if we look at genetically determined syndromes of epilepsy, either those occurring spontaneously in man and rodents or those induced

P.1458

by genetic manipulations in mice.[2,35,99] These studies (Table 1) clearly identify the voltage-gated Na^+, Ca^{++}, and K^+ ion channels as playing a critical role in causing idiopathic generalized seizures (and possibly some partial seizures in the case of K^+). They do suggest that the VG K^+ channels are of equivalent significance to the Na^+ and Ca^{++} channels. They also identify the $GABA_A$ receptors as crucial contributors to generalized epilepsies.

Voltage-Gated Sodium Channels+

The majority of AEDs introduced since 1938 have properties that suggest they act on voltage-dependent sodium channels (Table 2). As suggested above, this emphasis on Na^+ channel inactivation may be a consequence of the screening procedures employed.

Advances in the molecular biology of voltage-dependent Na^+ channels now permit a precise definition of potential target sites for anticonvulsant drug action.[24,55]

The principal element of a voltage-dependent Na^+ channel is the *a* subunit (260 kDa), which has four domains, each with six transmembrane helices, four of which form the voltage sensor and two (S5 and S6 connected by the P-loop that confers the ion-selectivity) forming the "pore domain." The α subunit is assembled with subsidiary β1 to β4 subunits. Different cells express different *a* subunits; in the brain, I, II, IIA, and NaCh6 *a* subunits are found. Following an action potential, there is a transient process of inactivation during which the Na^+ channel is unresponsive to voltage. This inactivation has fast and slow components that have been shown by site-directed mutagenesis to have distinct structural correlates. The loop linking domains III and IV act as a mechanical gate—"hinged lid"—producing fast inactivation. It can be rendered inoperative by proteolysis or site-directed mutagenesis.

Site-directed mutagenesis was also used to establish that three amino acids in the sixth transmembrane segment in domain 4 play a critical role in the binding of local anesthetics, phenytoin, and carbamazepine.[12,82] Recently it has been shown that binding of lamotrigine and some related compounds is dependent on the same three amino acid residues in IV6 and also two in III6.[12,82,119]

Table 2 Voltage-gated Sodium Channels: Genes, Currents and AED Actions

Gene	Channel current	AED action
SCN1A	Na_V 1.1 transient I_{Na} persistent I_{Na}	Phenytoin, carbamazepine, and lamotrigine prolong inactivation of transient I_{Na}
SCN2A	Na_V 1.2 transient I_{Na} persistent I_{Na}	Phenytoin, carbamazepine, and lamotrigine prolong inactivation of transient I_{Na}
SCN8A	Na_V 1.6 transient I_{Na} persistent I_{Na}	Phenytoin, topiramate, and valproate decrease persistent I_{Na}

AED, antiepileptic drug.

Table 3 Voltage-gated Calcium Channels: Genes, Channels, and AED Actions

Gene	Channel current	AEDs decreasing current

CACN A1S	Ca_V 1.1 L-type HVA	(Barbiturates, felbamate)
CACN A1C	Ca_V 1.2 L-type HVA	(Dihydropyridines block)
CACN A1D	Ca_V 1.3 L-type HVA	
CACN A1F	Ca_V 1.4 L-type HVA	
CACN A1A	Ca_V 2.1 P/Q type HVA	Lamotrigine (gabapentin)
CACN A1B	Ca_V 2.2 N-type HVA	Lamotrigine (gabapentin)
CACN A1E	Ca_V 2.3 R-type HVA	Topiramate (gabapentin)
CACN A1G	Ca_V 3.1 T-type LVA	Ethosuximide, zonisamide (modest reduction in I_{Ca})
CACN A1H	Ca_V 3.2 T-type LVA	
CACN A1I	Ca_V 3.3 T-type LVA	
ACNA 2D1	α2δ1 subunit in Cav X.X	Gabapentin, pregabalin
CACN A2D2	α2δ2 subunit in CavX.X	Gabapentin, pregabalin

AED, antiepileptic drug.

Thus, there are specific sites within the α subunit that provide targets for AEDs, prolonging inactivation of voltage-sensitive Na^+ channels. The four different α subunits expressed in the brain also may be seen as distinct targets.

There is a further function of Na^+ channels that is a target for AEDs. They provide persistent, noninactivating Na^+ currents that contribute to certain patterns of burst firing.[103] Phenytoin diminishes these currents,[15] as do topiramate and valproate.

Thus, Na^+ channels provide a multiplicity of targets. Acting on two families of sodium channels may be advantageous for anticonvulsant efficacy. There are homologies of sequence and morphology between voltage-sensitive Na^+, Ca^{2+}, and K^+channels, and some known Ca^{2+} channel blockers also act on Na^+ channels (e.g., flunarizine). Thus, designing compounds that block both classes of ion channel may lead to improved AED efficacy.

Voltage-gated Calcium Channels

These Ca^{2+} channels were originally classified in terms of biophysical measurements across neuronal membranes, determining voltage activation threshold, conductance per channel, and inactivation kinetics, giving T-, N-, and L-type Ca^{2+} channels. Other channels (P/Q, N, and R) were later identified (Table 3).[13,105] The role of voltage-gated calcium channels in immunoglobin (IG) E has recently been reviewed.[43,50]

As explained in Chapter 136, there is an apparent link between action against 2- to 3-Hz absence attacks and a partial suppression of Ca^{2+} T-channel conductance.[22] The T-type calcium current makes a specific contribution to oscillatory responses in thalamic neurons, and these oscillations play a critical role in 2- to 3-Hz discharges in the cortex and thalamus.[122] Thus, the suppression of absence attacks by ethosuximide and dimethadione has been attributed to the reduction in T Ca^{2+} currents they produce, although a variety of other effects on ion channels may also be involved. High concentrations of valproate reduce T currents in primary afferent neurons.[46] Zonisamide also reduces T Ca^{2+} currents. Perhaps T-type Ca^{2+} channels are best regarded as an auxiliary or supplementary target to broaden the spectrum of activity of a compound intended to affect more than one molecular mechanism.

The greatest interest in terms of targets for novel drugs are the high-voltage-activated channels designated as P/Q, N, and R type (Cav 2.1 to 2.3), because of their presynaptic role controlling release of neurotransmitters. N-type channels appear to be important for synaptic release of monoamines and some peptides.[109] The P/Q-type Ca^{2+} channels are important for the release of monoamines, glutamate, and GABA.[37] There is evidence suggesting that some established and novel AEDs act on presynaptic Ca^{2+} channels.[30,53,98,111] Thus, P/Q-, N-, and R-type calcium channels appear to be key targets for the development of novel AEDs. It should be remembered, however, that mutations leading to impaired function of P/Q-type channels produce ataxia and absence seizures in man and mouse.

Table 4 Potassium Channels: Genes, Channels, and AED Actions

Gene	Channel current	AED action
KCNA1	K 1.1 delayed rectifier (A-type)	
KCNQ2	K 7.2 M-type	Retigabine
KCNQ3	K 7.3 M-type	
KCNQ5	K 7.5 M-type	
KCNJ3	Kir 3.1 Girk1	
KCNJ6	Kir 3.2 Girk2	
KCNJ10	Kir 4.1	
KCNJ11	Kir 6.2	
KCNMA1	K_{Ca} 1.1 BK or slo1	

AED, antiepileptic drug.

Voltage-gated and Other Potassium Channels

Potassium selective ion channels were originally differentiated in biophysical studies and are found in all mammalian cells. Today they are classified partially on the basis of their functional properties and partially on the basis of their evolutionary origin and molecular morphology[120,121] (see Tables 1 and 4). The 75 or more distinct α subunits identified in genetic studies provide four main families: Voltage gated (Kv1 to Kv10); calcium activated (Kca2.1 to 2.3, Kca1.1); inwardly rectifying (kir); and the two-pore K^+ channels that provide the "leak" currents (K_{2P}). The voltage-gated and calcium-activated K^+ channels are part of the S4 superfamily and have an *a* subunit with a core formed by six putative transmembrane helices. The S1 to S4 segment provides the voltage sensor domain homologous with that of the Na^+ and Ca^{++}ion channels. A linker helix connects this to the S5 and S6 segments, which, with their P-loop, form the ion-selective channel.[21,56,57] Opening K^+ channels has the effect of hyperpolarizing neurons or reversing depolarizing actions. At least two different calcium-activated K^+ channels underlie afterhyperpolarizations.[89] One, SK_{Ca}, with a fast time course, is mediated by small conductance channels; the other has a slow time course and is modulated by numerous G-protein–coupled neurotransmitters. Studies of dentate granule cells isolated from patients with temporal lobe epilepsy show a prominent delayed rectifier outward current (I_K) whose steady-state voltage dependence differs according to whether the specimen shows Ammon horn sclerosis or not.[3]

Many compounds that act as potassium channel blockers are convulsant, for example, 4-aminopyridine and various scorpion and sea anemone toxins such as dendrotoxin I and pandinus toxin.[44,108] In in vitro systems, 4-aminopyridine–induced discharges are commonly used as a model for analyzing seizure activity. Several drugs thought to act as potassium channel openers such as chromakalim, minoxidil, diazoxide, and pinacidil show antiepileptic effects when injected intracerebroventricularly in rodent models of epilepsy.[32,80] The most definitive data concern a drug retigabine, developed as a GABA modulator but shown in 2000 to activate Kv7.2 and Kv7.3 channels responsible for the M-type current on soma and dendrites and the slow K^+ current (I_{ks}) on axons.[88,115] Mutations involving the genes encoding these channels (KCNQ2/KCNQ3) are responsible for benign familial neonatal convulsions.[19,96] Retigabine shifts the voltage dependence of the M current to hyperpolarized potentials, speeds the rate of activation, and slows inactivation. It has a similar effect on Kv7.4 and Kv7.5, which are also expressed in the brain, but is inactive on Kv7.1, the cardiac homolog. Experiments with chimeric channels and point mutations[90,118] have shown that the pore domain is the site of action of retigabine and that its action is dependent on a tryptophan residue on S5 found in KCNQ2 to 5 but not in KCNQ1. Further compounds have been identified with a similar channel-opening effect and activity in rodent models of epilepsy.[117] Thus, the potassium channels responsible for the M current are clearly identified as a target for AEDs. Genetic and pharmacologic data suggest that the voltage-gated K channels responsible for the A-type K^+ currents, which play an important role in controlling the excitatory threshold in synaptic terminals, are also an important potential target for novel AEDs,[21,69] but drugs potentiating these currents have yet to be identified. The calcium-activated channels and the inwardly rectifying and leak currents may also be targets, but evidence is less clear.

Many reports describe effects of established AEDs (such as phenytoin, carbamazepine, lamotrigine, and levetiracetam) on various K^+ currents,[69] but the significance of these for antiepileptic effect remains uncertain.

Carbonic Anhydrase Inhibition

A possible mechanism for the antiepileptic action of carbonic anhydrase inhibition involves GABA-mediated inhibitory potentials.[97] $GABA_A$receptors open ion channels that are permeable to HCO_3 as well as to Cl. HCO_3 moves outward, producing a depolarizing effect that is normally smaller than the hyperpolarizing action of the inward flux of Cl. With strong $GABA_A$ receptor activation, the Cl gradient in dendrites collapses sooner than does the HCO_3 gradient (which is preserved by the inward flux of CO_2 and carbonic anhydrase activity). GABA thus develops a depolarizing effect that can be blocked or diminished by carbonic anhydrase inhibitors. The conversion of GABA's effect to depolarization may contribute to several epileptic manifestations, and carbonic anhydrase inhibitors may be beneficial.

Table 5 AEDs and Related Compounds Potentiating GABA-Mediated Inhibition

Drug	Molecular target	Functional effect	Action in GTCS and TLE	Action in absence
Vigabatrin	GABA-transaminase	Increases extracellular	Benefit	Exacerbates

		[GABA], enhances tonic inhibition		
Tiagabine	GAT-1 (forebrain neuro- and glial GABA transport)	Prolongs IPSPs, potentiates tonic inhibition	Benefit	Exacerbates
THIP (gaboxodol)	$GABA_A$ receptor (agonist site)	Agonist-opens Cl^- channels		Exacerbates
Phenobarbitone	$GABA_A$ receptor (barbiturate site)	Directly opens Cl^- channels Potentiates GABA action at phasic and tonic receptors	Benefit	No benefit
Diazepam Clobazam Clonazepam	$GABA_A$ receptor (BZD site)	Potentiate GABA at phasic receptors containing α1, α2, α3, and α5 subunits, and γ1 or γ2	Benefit	Suppresses
Ganaxolone Alphaxalone	$GABA_A$ receptor (neurosteroid site)	Potentiates GABA action at tonic $GABA_A$ receptors		
Chlormethiazole	$GABA_A$ receptor (chlormethiazole site)	Direct action at $GABA_A$	Potentiates GABA action	
Topiramate	$GABA_A$ receptor (topiramate site)	Potentiates GABA action	Benefit	Suppresses
Felbamate	$GABA_A$ receptor (felbamate site)	Potentiates GABA action at phasic receptors	Benefit	Weak action
Loreclezole	$GABA_A$ receptor (loreclezole site)	Direct action plus potentiates GABA		

AED, antiepileptic drug; GABA, γ-aminobutyric acid; GTCS, generalized tonic-clonic seizure; TLE, temporal lobe epilepsy.

Drugs Enhancing GABA-mediated Inhibition

In the 1970s, evidence that barbiturates and benzodiazepines potentiate GABA-mediated inhibition by acting on $GABA_A$ receptors accumulated. In addition, it became clear that any impairment of GABA-mediated inhibition was associated with a lowered seizure threshold or spontaneous seizures. There was tentative evidence that GABAergic neurons or GABAergic

P.1461

functions were lost in situations favoring epileptic discharges. Beginning around 1975, enhancing GABA-mediated inhibition became the preferred rational approach to AED design.[66] It is now clear that GABA provides two forms of inhibition via $GABA_A$ receptors (phasic and tonic involving synaptic and extrasynaptic receptors)[28] and two forms of inhibition via $GABA_B$ receptors (see below).

Potential means of enhancing GABA-mediated inhibition are listed in Table 5.

Inhibition of GABA Uptake

GABA uptake after synaptic release is provided by specific carriers in neuronal and glial membranes that are coupled to Na^+/Cl^-.[83] Four genes and transporter proteins have been identified in mammalian brain. Their nomenclature differs in mice, rats, and humans. The distribution of these four transporters varies markedly, with GAT-1 being predominant in the rat forebrain and hippocampus.

Nipecotic acid and guvacine were initially identified as GABA uptake inhibitors, and subsequent compounds were designed to incorporate their molecular features. Early compounds encountered difficulties relating to brain penetration and to neurologic and cognitive side effects. These problems have been largely overcome by tiagabine, which has been shown to be effective in drug-refractory cases of complex partial epilepsy.[70] Tiagabine and several related compounds are apparently specific for GAT-1.[9] Tiagabine increases the extracellular concentration of GABA in the hippocampus. It prolongs the postsynaptic inhibitory effect of synaptically released GABA.[100] It also enhances tonic (extrasynaptic) inhibition. In prolonged seizure activity, synaptically available GABA may become depleted, and blockade of glial GABA uptake may be more effective for suppressing discharges than blockade of neuronal uptake.[77] It is possible that other GABA transporters (GAT-2, GAT-3) expressed more strongly in the brainstem represent a target for agents acting on primary generalized seizures. Synergistic antiepileptic effects have been demonstrated for the combination of GAT-1 and GAT-2/GAT-3 inhibition.[114]

Inhibition of GABA-Transaminase

GABA-transaminase inhibition blocks the further metabolism of GABA to succinic semialdehyde and increases brain GABA content as well as seizure threshold. Irreversible or catalytic inhibitors of GABA-transaminase have the advantage of a more sustained effect. Total inhibition of GABA-transaminase is highly toxic. Vigabatrin is the first novel AED developed on a rational mechanistic basis (i.e., irreversible inhibition of GABA-transaminase).[54] Brain and cerebrospinal fluid (CSF) GABA are increased in man. This leads to some desensitization of phasic $GABA_A$ receptors, but increased tonic inhibition. The high incidence of visual field defects in patients receiving vigabatrin has led to doubts about the safety of GABA-transaminase inhibition.

Potentiation of GABA at $GABA^A$ Receptors: Benzodiazepines

Potentiation of the Cl conductance change induced by GABA has long been recognized as a principal anticonvulsant mechanism for 1,4-benzodiazepines such as diazepam and clonazepam and 1,5-benzodiazepines such as clobazam (see Chapter 136). The $GABA_A$/benzodiazepine receptor is formed from five peptide subunits selected from 19 isoforms that belong to various subfamilies (α1 to 6; β1 to 4; γ1 to 4; δ; ε; θ; π; ρ1 to 2).[95]

P.1462

The subunit composition of $GABA_A$/BZ receptors varies in different parts of the brain and in different cell lines.[60,116] Native $GABA_A$/BZ receptors conform to about ten patterns in terms of subunit composition.[60] In the rat brain receptors containing α1, β2, and γ2 subunits are the most abundant and widely expressed. The subunit composition critically influences the pharmacology of the $GABA_A$receptor.[42,87] In particular, for different benzodiazepines and related compounds acting at the same site, the strength and nature of their effect depends on the α and γ subunit components.[59,87] Benzodiazepine responsiveness is dependent on the presence of an α subunit chosen from *α*1, *α*2, *α*3, *α*5 (possessing a histidine residue at 101), and a *γ* subunit (from *γ*1 to *γ*3). The α subunit also largely determines the neurologic side effects of the benzodiazepines. The anxiolytic effect is mediated by receptors containing *α*2 and *α*3 subunits. In rodents, sedative and myorelaxant effects are mediated by receptors with *α*1 subunits. GABA receptors mediating tonic responses have *δ* rather than *γ* subunits and are not potentiated by benzodiazepines.

It may be important to use human isoforms to make recombinant receptors for studies of this kind. A β-carboline derivative, abecarnil, with a highly selective pattern of action at recombinant receptors that sharply differentiates between receptors with different α subunits[81] shows high antiepileptic potency in rodents and primates with reflex epilepsy with an exceptionally good therapeutic ratio.[106] This superior therapeutic index is not found in humans, suggesting that the regional and functional differentiation of $GABA_A$ receptors in rodents and nonhuman primates is not replicated in humans. Considerable attention is now being devoted to the development of compounds acting on the BZ receptor site that may have a better side effect profile than existing drugs.

Potentiation of GABA: Neurosteroids

An antiepileptic effect of adrenal steroids was known[23] long before it was shown to be mediated by an action on $GABA_A$ receptors.[49] Neurosteroids include endogenous metabolites of deoxycorticosterone and progesterone, which may contribute to mood changes in the menstrual cycle and to catamenial epilepsy. Various synthetic steroids, such as the anaesthetic alphaxalone and the experimental compound ganaxolone, act at this site to potentiate tonic inhibition. Ganaxolone is a 3β-methyl-substituted analog of 3α-hydroxy-5-α-pregnan-20-one that shows a broad spectrum of anticonvulsant activity in preclinical tests and has entered clinical trials.[85]

Potentiation of GABA: Other Compounds

There are a large number of sites (at least 12)[42] at which a very wide range of synthetic and natural products can act to enhance the action of GABA at $GABA_A$ receptors, either directly or by potentiating GABA. These include the sites at which alcohol, loreclezole, chlormethiazole, felbamate, and topiramate act.[36,110] There is clearly still scope for the identification of agents acting on the $GABA_A$ receptor with a subtype selectivity that confers superior therapeutic benefits.

$GABA_B$ Receptors

$GABA_B$ receptors act presynaptically to decrease GABA release by decreasing Ca^{2+} entry but act postsynaptically to provide a slow afterhyperpolarization by increasing K^+ conductance. $GABA_B$ receptors are overexpressed in lethargic mice,[41] and enhanced activity at the $GABA_B$ receptors contributes to the spike-and-wave activity in this absence model. In the thalamus, $GABA_B$ receptors occur pre- and postsynaptically and contribute to excitatory, inhibitory, and oscillatory membrane responses.[26] Selective $GABA_B$ agonists, such as baclofen, have long been known to induce spike-and-wave discharges in animal models.[68] $GABA_B$ antagonists, such as CGP 35348, suppress spike-and-wave discharges in genetic and chemical models of absence attacks. Thus, the $GABA_B$ receptor is a target for AEDs with a selective action against 2- to 3-Hz discharges.

Spectrum of Anticonvulsant Activity of GABA-related Antiepileptic Drugs

Drugs potentiating GABA have a characteristic preclinical and clinical spectrum of anticonvulsant action, except that benzodiazepines and some related compounds are anomalous.

All GABA-potentiating agents are active against threshold PTZ seizures; they are mostly weak against MES seizures. (When they do show activity, it may be due to additional mechanisms of action, i.e., Na^+ channel inactivation by diazepam.) Clinical trials show that GABA-potentiating drugs are nevertheless effective in complex partial seizures, a result not predicted on the basis of the MES tests. Their effects in 2- to 3-Hz absence attacks are divergent—pure GABA agonists and compounds increasing extracellular GABA concentration are not therapeutic and may facilitate spike-and-wave discharges. Benzodiazepines are, however, therapeutic. This difference is not fully explained; the role of $GABA_B$ receptors in the corticothalamic discharges of absence epilepsy may be part of the explanation,[61] but pure $GABA_A$ agonists such as muscimol and 4,5,6,7-

tetrahydroisonazolo[5,4-c]pyridrin-3-ol (THIP) can facilitate cortical spike-and-wave discharges.[122]

Drugs Diminishing Excitatory Transmission

Around 1980 it became widely accepted that glutamate is the principal excitatory neurotransmitter in the brain.[112] There is still uncertainty about the role of aspartate and various sulphinic and sulphonic analogs of glutamate and aspartate. Also at that time it was proposed that glutamate acted postsynaptically on three classes of ion channel–linked receptors, named after their preferred agonists: *N*-methyl-D-aspartate (NMDA), *α*-amino-3-hydroxy-5-methylisonozole-4-proprionitic acid (AMPA), and kainate. Subsequently, molecular biologic studies confirmed the existence of these three families of receptors, each receptor complex being composed of subunits with a high degree of homology[27,39,65] (Table 6). The properties of each receptor are determined not only by the particular subunits, but also by splice variants, RNA editing, and phosphorylation.

Table 6 Glutamate Inotropic Receptors as AED Targets

Receptor subunit	Agonists	Antagonists: competitive	Open channel blockers	Antagonist AEDs
GluR1(A)	AMPA ACPA Kainate	NBQX GYKI 52466 Talampanel		Phenobarbital Topiramate
GluR2 (B)	AMPA	NBQX GYKI 52466

NR3B	NMDA			

AED, antiepileptic drug.

Glutamate/NMDA Antagonists

NMDA receptor ion channels are permeable to Na^+, K^+, and Ca^{2+} and are subject to a voltage-dependent block by magnesium, which means that they only become operative when the cell is partially depolarized (e.g., by AMPA receptor activation). For activation, NMDA receptors require occupation of both a site recognizing glutamate or aspartate and a site recognizing glycine or D-serine. Thus, NMDA receptors can be blocked by competitive antagonists acting either at the glutamate or the glycine recognition site. The properties of NMDA

P.1463

receptor channels are altered in hippocampal neurons from kindled rats.[48]

In 1982 it was shown that selective NMDA receptor antagonists were potent anticonvulsants in reflex epilepsies and in chemically induced seizures[25] (Table 6). Similar activity is shown by glutamate competitive and glycine-site competitive antagonists.[67] Noncompetitive open-channel blockers such as phencyclidine and dizocilpine (MK-801) are also potent anticonvulsants but have a poor therapeutic index, producing enhanced motor activity and stereotypies at anticonvulsant doses.[17] Lower-affinity channel blockers such as memantine appear less toxic.[75]

The competitive antagonist 3-(2-carboxypiperazin-4-yl)propenyl-1-phosphonic acid (D-CPPene) has a potent and prolonged anticonvulsant activity in animal models.[76] In a preliminary trial as an add-on treatment in refractory complex partial seizures, however, it failed to show efficacy but augmented neurologic and cognitive side effects.[101] Early clinical trials of the noncompetitive NMDA antagonists dizocilpine and dextromethorphan also failed to give evidence of therapeutic action.

There remains scope for the development of (a) low-affinity, noncompetitive antagonists, (b) subtype-selective glutamate competitive antagonists, and (c) glycine site antagonists.[47,75] It is also possible that other allosteric sites on the NMDA receptor, such as the redox site, are potential targets for AED development.

Glutamate/AMPA Antagonists

AMPA receptors are responsible for the fast depolarizing actions of glutamate and make the major contribution to fast excitatory transmission in the central nervous system (CNS). In spike discharges and paroxysmal depolarizing shifts in in vitro models of epileptic activity, the AMPA receptors are responsible for the early component of the discharge, with NMDA receptors commonly contributing to later elements. The first AMPA receptor antagonists to be developed were the quinoxalinediones.[40] One of these, 1,2,3,4-tetrahydro-6-nitro-2,3-diono-benzo[f]quinoscaline-7-sulfonamide (NBQX), is systemically active and is anticonvulsant in reflex epilepsy models, MES, and some chemical seizures.[18,102] Subsequently, anticonvulsant activity was reported for some structurally related AMPA antagonists (e.g., YM 900) and for some novel structures (e.g., LY 293558 and the isatin oxamines).[112] A further class of AMPA antagonists is provided by the 2,3-benzodiazepines, GYKI 52466, GYKI 53455, and GYKI 53733 (Talampanel), which are noncompetitive allosteric inhibitors of AMPA receptors. They also are anticonvulsant in reflex epilepsies and in some other models.[18] Talampanel is in phase III clinical trials in humans.[85]

Table 7 Metabotropic Receptors (Glutamate, $GABA_B$, A1, M2) as Potential AED Targets

Gene	Receptor	Site	Agonists (*effect*)	Antagonists (*effect*)
	mGluR1	Postsynaptic, perisynaptic	DHPG *(convulsant)*	LY 367385, LY 456236, AIDA (*anticonvulsant)*
	mGluR5	Postsynaptic, perisynaptic	CHPG, DHPG *(convulsant)*	MPEP, SIB-1893 *(anticonvulsant [CHPG])*
	mGluR2	Presynaptic	LY 354740 *(anticonvulsant)*	Ethylglutamate *(convulsant)*
	mgluR3	Presynaptic (axonal)	LY354740	Ethylglutamate
	mGluR4	Presynaptic	ACPT-1,(RS)PPG	MAP-4, MSOP. MPPG (*convulsant)*
	mGluR7	Presynaptic	AMN082	MAP-4,MSOP, MPPG
	mGluR8	Presynaptic	ACPT1,(RS)PPG (S)3,4-DCPG	MAP-4,MSOP,MPPG

GABAB1	Presynaptic, postsynaptic	Baclofen, APPA (*augment SWD)*	Phaclofen, Saclofen *(reduce SWD)*
GABAB2	Presynaptic, postsynaptic	CGP7930	
Adenosine A1	Presynaptic	N(6)-cyclopentyladenosine	8SPT, DPCPX
mACh R,M2	Presynaptic	Carbachol	Atropine

AMPA receptors are assembled from four peptide subunits (known either as GluR1, 2, 3, and 4 or as GluRA, B, C, and D), which are differentially expressed in particular cell types.[33]

P.1464

Receptors containing the GluR2 subunit have a low Ca^{2+} permeability and show a linear or outwardly rectifying current voltage relationship, whereas receptors lacking this subunit show a significant Ca^{2+} permeability and are inwardly rectifying. This effect of the GluR2 subunit is linked to a process of messenger RNA editing, whereby a glutamine is converted to an arginine through the site-selective action of an adenosine deaminase acting on the codon. In genetically engineered mice in which this editing process is partially impaired, the calcium fluxes induced by AMPA are modestly enhanced.[10] Such mice show a wide variety of seizures early in life. This suggests that agents that selectively block AMPA receptors not containing GluR2 (and therefore showing Ca^{2+} permeability) might be good antiepileptics.

The availability of selective kainate receptor antagonists has recently improved,[7] including the development of some agents with selectivity for GluR5 versus GluR6/7 subunits.[65a] Among AMPA antagonists, NBQX also acts as an antagonist at GluR5 and GluR6, GYKI 52466 acts at neither, and LY 293558 antagonizes GluR5 but not GluR6.[8] The significance of this differential effect for antiepileptic activity is not known, but it may be relevant for specific syndromes involving altered glutamatergic receptor function.

Glutamate Transporters

Five glutamate transporters in neuronal and astrocytic membranes mediate high-affinity uptake of glutamate and aspartate. The transporters control extracellular levels of glutamate and its activity at nonsynaptic NMDA receptors and presynaptic metabotropic receptors. GLT-1 (EAAT2) expressed in astrocytes is the predominant transporter in the adult mammalian brain. Seizures are seen in GLT-1 knockout mice and following its inhibition. Compounds that enhance the function or expression of GLT-1 have been identified.[29,86,93] Thus, glutamate transporters are significant targets for novel AEDs.

Drugs Acting on Metabotropic Receptors

Metabotropic receptors are found in the plasma membranes of neurons and glia and respond to their ligands by generating second messengers rather than opening ion channels, although they have important actions on calcium and potassium conductances.[20,78] They are coupled through G proteins to enzyme systems in two broad categories, either modifying activity of adenylate cyclase or guanylate cyclase (changing the availability of cyclic adenosine monophosphate [cAMP] or cyclic guanosine monophosphate [cGMP]) or acting on phospholipase C or D, producing diacylglycerol, inositol triphosphate, or free fatty acids as second messengers, with important effects on protein kinases. Thus, there are significant effects on the phosphorylation of membrane receptors, transporters, and other enzymes, modifying their function over short or long periods.

Thus, metabotropic receptors can produce transient or sustained changes in neuronal excitability and are potentially important targets for novel AEDs.

Some of the metabotropic receptors for glutamate, acetylcholine, GABA, and adenosine are listed in Table 7. This table shows that some of these receptors are found presynaptically at which site they modify the synaptic release of glutamate and/or GABA.

Recent studies have drawn attention to the possible role of glutamate metabotropic receptors in acute and chronic epileptogenesis. Group I reponses, as judged by phosphoinositide hydrolysis induced by quisqualate, AMPA, or glutamate, are potentiated in the amygdala or hippocampus of the kindled rat.[1,45]

The variety and selectivity of pharmacologic agents acting on glutamate metabotropic receptors has been progressively augmented[91] and now includes many allosterically acting drugs with high subtype selectivity.[62,94] Extensive studies in rodent models of epilepsy show a consistent pattern of effects.[72] Group I mGluR agonists such as 1S,3R-aminocyclopentane-1,3-dicarboxylic acid (1S,3R ACPD) and

3,5-dihydroxy-phenylglycine (3,5-DHPG) are powerful convulsants when given intracerebroventricularly.[34]

Group I antagonists, such as LY 367385 ((+)2-methyl-4-carboxyphenylglycine) and AIDA ((R,S)-1-aminoindan-1,5-dicarboxylic acid) given intracerebroventricularly, or MPEP and SIB1893 (mGluR5 allosteric antagonists, given intraperitoneally) are anticonvulsant in several types of rodent seizure models. Group II (LY 354740, LY379268) and group III agonists (ACPT-1, (R,S)PPG) are also anticonvulsant.

mGluRs are important potential targets for novel AEDs. Now that the human receptors have been cloned and expressed in cell systems, they provide an excellent means for identifying selective agonists and antagonists for each receptor subtype. The availability of positive and negative allosteric modulators with high subtype selectivity allows precise targeting of specific systems. Such compounds need to be tested in a wide range of seizure models because the antiepileptic effects might be very syndrome specific. They also need to be tested over a wide range of doses and time courses.

Acetylcholine acting on muscarinic receptors, GABA acting on $GABA_B$ receptors, and adenosine acting on A1 receptors can produce presynaptic effects modifying neurotransmitter release, with varying specificity for excitatory or inhibitory synapses. They may show complex interactions with other presynaptic receptor systems.

Novel Approaches

Growing understanding of the molecular biology of acute and chronic ictogenesis suggests many possible novel molecular targets for antiepileptic drugs. These include novel ion channels such as the HCN channel responsible for the I_h.

HCN Channels

Hyperpolarization-activated cyclic nucleotide-gated cation channels play an important role in determining excitability in the hippocampus and neocortex, and their expression and function is modified during epileptogenesis in several models.[79] The HCN channels may thus be significant targets.

Connexins

Gap junctions between glia and between neurons have been shown to play a significant role in the synchronization of epileptic discharges in in vitro and in vivo models.[73] Thus, the connexins (such as Cx43 in astrocytes and Cx36 and Cx45 in neurons) provide potential molecular targets.

Protein Kinases

There are more than a thousand protein kinases expressed in the brain. They change the excitability and function of neurons and glia over short or long periods by phosphorylating receptor molecules, ion channels, transporter molecules, and enzymes. Protein kinases may play a crucial role in epileptogenesis in several different syndromes. A CAM-kinase II knockout mouse shows limbic seizures. The extremely diverse effects of topiramate on synaptic function (including effects on AMPA/kainate receptors, GABA receptors, and Na^+ and Ca^{++} channels) may be explained by a primary effect on phosphorylation sites.[53,92] Modifying kinase activity by pharmacologic or molecular genetic means is likely to prove a fruitful approach to blocking or reversing epileptogenesis.

Neurotrophin Receptors

Seizures induce changes in the expression of neurotrophins, such as nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and neurotrophin 3 (NT3).[5,31] Neurotrophins increase synaptic efficacy and are thought to play a role in epileptogenesis.[104] The kindling process is slowed by intracerebroventricular infusion of antibodies to NGF.[107] Compounds acting on neurotrophin receptors (trkA, trkB, trkC) also may affect epilepsy or seizure expression. Conditional deletion of TrkB in the mouse forebrain severely impairs the kindling process.[38] Therapeutic approaches could involve pharmacologic agents acting on the neurotrophin receptors or on downstream events. Acute and chronic manipulations of the neurotrophin systems often have opposite effects on epileptogenesis due to regulatory mechanisms, so there is uncertainty about the correct strategy. It is also possible that genetically modified cell lines could be transplanted intracere-brally.[63]

Altering Gene Expression

Gene expression can be modified by growth factors, cytokines, and other factors that may be important in epileptogenesis; most importantly, neuronal activity itself modifies gene expression. Changes in cAMP and intracytoplasmic or nuclear [Ca^{2+}] act through cAMP response elements (CREs) and transcription factors such as CRE binding protein (CREB) whose effect is modified by phosphorylation. Seizure activity produces notable changes in [Ca^{2+}], and this is probably the factor leading to the expression of immediate early genes (such as those encoding the fos and jun families of proteins, which are important in transcriptional activation) in many brain regions shortly after seizure activity.

Established AEDs can alter gene expression. Valproate is a potent histone deacetylase inhibitor and through this mechanism has very diverse effects on gene expression.[44a] These have been well documented but their role in epileptogenesis or possible antiepileptogenesis has yet to be elucidated.

Manipulation of gene expression is likely to emerge as a major approach to suppressing or reversing epileptogenesis.

Single Versus Multiple Mechanisms

Mechanism-based approaches to the design of AEDs naturally tend to focus on a single mechanism of action, successfully so in the cases of vigabatrin and tiagabine. The serendipitous AEDs such as valproate, felbamate, and topiramate apparently have a multiplicity of mechanisms of action. There are many reasons why a multiplicity of action may be favorable. Obviously the spectrum of clinical activity may be enhanced. There also may be additive or synergistic effects of the different mechanisms. The therapeutic ratio may be improved, and the risk of developing tolerance may be diminished. A multiplicity of actions may be achieved in two principal ways. First, one pharmacophore may correspond to two target molecules. This may be the case in terms of several homologous targets, that is, different sodium channels (voltage dependent and persistent), different ion channels (such as voltage dependent sodium and calcium channels), or different glutamate receptors (inotropic and metabotropic). Examples of drugs combining these targets are already known and undoubtedly could be improved upon. Second, one molecule can contain more than one pharmacophore. Techniques of combinatorial chemistry that have

recently been brought to a high level can be used to exploit this possibility.

A whole range of such drugs could be designed to match either the range of clinical seizures experienced by a particular patient or to match the particular altered molecular function in the patient.

Summary and Conclusions

The future search for AEDs should concentrate on identifying drugs with novel mechanisms of action on acute or chronic ictogenesis. Further understanding of these processes is required before such a mechanism-based program can be fully effective. Screening tests are required that identify delayed or long-term effects on acute ictogenesis and effects on chronic epileptogenesis. Important potential targets for suppression of acute ictogenesis include potassium channels, presynaptic calcium channels, metabotropic receptors, and various proteins involved in presynaptic accumulation and release of neurotransmitters. More tentative targets include HCN channels and connexins. Selection of subtype-specific drugs (using recombinantly expressed channels or receptors) acting on sodium, potassium, and calcium channels; $GABA_A$/BZ receptors; AMPA; and NMDA receptors may allow better separation of antiepileptic effects from unwanted actions.

Chronic epileptogenesis involves a wide variety of changes in gene expression involving ion channels, receptors, and transporters. Drugs acting on protein kinases and on neurotrophic systems may be of particular importance. Improved understanding of the nature of chronic epileptogenesis will facilitate its prevention or reversal.

Chapter 139

Screening of New Compounds and the Role of the Pharmaceutical Industry

H. Steve White

Roger J. Porter

Harvey J. Kupferberg

Introduction

The search for new antiepileptic drugs (AEDs) requires the appropriate choice of a number of models for the identification of new therapeutic agents for the treatment of epileptic seizures. The animal models used in the search of new anticonvulsant drugs are varied and have been the subject of several recent reviews.[50,88,97,102,104,107,111,201]

Different approaches can be used in the discovery of new therapeutic agents for the treatment of seizure disorders. The model choice can be specific for a seizure type, such as complex partial,[44,104] absence,[24,163,194] and status epilepticus (SE).[94,196] It can be based on a mechanism of action, such as decreased neural excitability[33] or enhanced inhibition.[103] Alternatively, a seizure model in which the compound blocks the final expression of the experimental seizure can be used; for example, a "mechanism-independent" model such as the maximal electroshock seizure (MES).[179,181]

Several restrictions and conditions are inherent in the choice of model for identifying a new drug. It would be ideal and more efficient if the model were capable of screening large numbers of compounds without requiring large amounts of any one compound. Neither should the complexity and technical expertise required for the development and implementation of such a model be difficult.

Validation is a criticism often raised about new mechanistic seizure models. In the validation process, the new model must be evaluated against current, clinically effective therapeutic agents. The question then arises as to whether a model that is capable of identifying clinically effective compounds whose mechanisms are known will be able to identify unique compounds.

A second question that often arises is whether a given model reflects the pathophysiologic processes and symptomologies of the epilepsies. Currently, a number of model systems are highly predictive of efficacy against generalized tonic–clonic seizures (e.g., the MES test), generalized absence or spike-and-wave seizures (e.g., the genetically absence epileptic rat of Strasbourgh, the Lh/Lh mouse, γ-hydroxybutyrate induced spike-wave seizures), and partial seizures (e.g., the kindled rat).

No single approach can be used to identify an effective compound for the treatment of epileptic seizures. Furthermore, no ideal animal model would effectively identify a drug active against all forms of seizures, regardless of its mechanism of action. Therefore, new approaches must be undertaken for the discovery of new therapeutic agents.

In this era of molecular biology, when targets have become important in drug development, target validation using in vivo animal models is appropriate. As unique structural compounds are identified using basic screening procedures, they should be immediately evaluated in molecular target screening procedures. The reverse of this process should also occur.

When lead compounds are identified, additional information must be obtained before the development process begins. These include the establishment of a compound's pharmacologic and toxicologic profile and in vitro studies designed to ascertain proposed mechanisms of action. Other parameters such as absorption, distribution, excretion, metabolism, and drug–drug interactions must also be characterized.

Loscher et al. have published seven critical reviews dealing with the role of technical, biologic, and pharmacologic factors in the laboratory evaluation of anticonvulsant drugs. These seminal reviews should be read before undertaking the task of evaluating new chemical entities for their potential in the treatment of seizures. The reviews discuss in detail the influence of administration vehicles on seizure threshold[107]; the nuances of the various MES seizure models[97] and pentylenetetrazol (PTZ) seizure tests[102]; and the calculation and utility of protective indices[106]; the consequences of seasonal influences on amygdala kindling,[204] MES, PTZ,[99] and mouse models of generalized seizures.[100]

The objective of the initial part of this chapter is to discuss the historical background of the discovery and utilization of seizure models, then describe those models and methods that have direct applicability to the discovery of new anticonvulsant drugs and their mechanisms of action.

Historical Perspective

Prior to the discovery and development of phenytoin, anticonvulsant compounds such as phenobarbital and bromides were used for the treatment of seizures in patients without any preclinical experimental information. Although methods for producing seizures were known, Merritt and Putnam[130] first used a systematic approach in evaluating the potential of a series of compounds as antiseizure agents (see White for review and references[199]).

They studied the ability of a series of chemicals to raise convulsive threshold by using graded electrical stimulation in cats. They knew that phenobarbital was a clinically effective compound in treating seizures, whereas other barbiturates were comparatively ineffective or toxic (e.g., produced narcosis). A number of Parke Davis compounds were submitted for evaluation. Six were analogs of phenobarbital. A few were hydantoins, one of which was 5,5 diphenylhydantoin (diphenylhydantoin, phenytoin).

Several significant observations were made. They found that diphenylhydantoin, acetophenone, and several phenones and ketone derivatives had an anticonvulsant effect equivalent to that of phenobarbital, but without producing sedation.

P.1470

The majority of compounds evaluated by this procedure were inactive.

They also found that carbon dioxide raised seizure threshold when hypercapnia was observed. For example, it was impossible to produce convulsions with 40 milliamperes of current. When animals were allowed to breathe air for a few moments, the seizure threshold returned to normal. This result predicted the use of carbonic anhydrase inhibitors in treating seizures.

During the 1940s and 1950s, new compounds were synthesized, and structure-activity relationships (SARs) were investigated for anticonvulsant and hypnotic activity.[3,8] This approach, using methodology similar to that of Merritt and Putnam, gave rise to mesantoin, nirvanol, trimethadione, methylphenylsuccinimide, and phenacemide. Because these compounds are known to be chemically similar to phenyt-oin, their therapeutic potential was not unexpected. Vida summarized the anticonvulsant activity of a large number of compounds.[195]

During the mid 1940s to early 1950s, a number of papers appeared describing the properties of electrically induced seizures and the effect of chemical agents on them. Two basic mechanisms were proposed to explain how anticonvulsant drugs prevented seizures: by raising seizure threshold or by preventing seizure spread. Once the seizure threshold was exceeded by more than 20%, the pattern and duration of the seizure was relatively constant and independent of the intensity or duration of the stimulus.[187]

No matter whether a seizure was chemically or electrically induced, the drug effect on seizure pattern would be modified in an identical manner. Therefore, agents that inhibit seizure spread would attenuate the extensor tonic component of the seizure, independent of how the maximal seizure is produced. Toman and Goodman[186] summarized the “state-of-the-art” methodology for identifying new therapeutic agents. They concluded that a single test could adequately define the anticonvulsant properties of a drug.

Chen and Ensor[20] determined the anticonvulsant activity of nine known drugs by testing in both an electrical and chemical model. They then compared the results with the known clinical utility of these same drugs. The two methods ranked the potency of the drugs in a similar manner. This was done to see if similar qualitative and quantitative data could be obtained by using two methodologies. By 1951, phenytoin had opened a new era for the treatment of generalized tonic–clonic seizures.

The discovery of trimethadione and paramethadione for the "petit mal triad" soon followed. An animal model for evaluating therapeutic agents for the treatment of partial seizures was lacking. Toman et al.[185] described a "psychomotor" test in which mice are subjected to low-frequency stimulation to produce seizures resembling those seen in humans. A rectangular pulse of 6 Hz, 1 msec. pulse width, and a current of 32 mA is delivered for 3 seconds via electrodes placed on the cornea. The mice display an abnormal behavior for 25 seconds, which can best be described as "stunned." They remain motionless and do not respond to painful stimuli. These types of in vivo screening models are still used for the identification of new therapeutic agents for the treatment of seizures.

Animal Models for Drug Discovery

Genetic Models

Because of their seizure predisposition, genetic animal models of epileptic seizures have been used to identify and profile potential anticonvulsant compounds. These models are thought to mimic the clinical situation more closely than traditional electrically or chemically induced seizures in experimental animals.[1,105] The genetic models include the photosensitive baboon (*Papio papio*)[127,128]; several strains of audiogenic seizure mice, such as the DBA/2,[16] SJL/J,[54] Frings, and O'Grady[25]; genetically epileptic prone rats, GEPR-3 and GEPR-9[35,93]; Mongolian gerbil (*Meriones unguiculatus*)[101,113,116]; chickens[74]; tottering mice (tg/tg strain)[64]; and dogs.[112]

Audiogenetic Mice

Audiogenic seizure–susceptible mice exhibit wild running followed by generalized tonic seizures when exposed to high-intensity sound. The intensity of sound usually is in the range of 90 to 120 dB with frequencies between 11 and 16 kHz. Seizure susceptibility in some stains is enhanced if the mice are exposed to high-intensity sound following a priming stimulus.[25] Strain difference in seizure susceptibility occurs with age, usually reaching a maximum level between 2 and 4 weeks of life.[154] These seizure-prone mice have been used to identify a number of different types of central nervous system (CNS)-active agents.

The Frings mice maintain their susceptibility to sound stimulation over their entire adult life. Swinyard described similar activity in both Frings and O'Grady strains of mice for phenytoin, phenobarbital, and trimethadione.[180] Unfortunately, non-anticonvulsant drugs will also attenuate sound-induced seizures. Ataraxic agents, muscle relaxants, chlorpromazine, and reserpine will attenuate the sound-induced seizures of Frings mice in nontoxic doses.[140]

Several experimental compounds were evaluated for anticonvulsant activity using the Frings strain of audiogenic seizure–susceptible mice. MDL 27,266 was found to have similar values in the Frings and DBA/2 strains, with ED50s of 5.0 and 5.1 mg/kg, respectively.[200] Valrocemide (TV-1901), a valproic acid analog, was found to be more potent than valproic acid when administered intraperitoneally to Frings mice.[69]

The most commonly used strain of audiogenic seizure mice is the DBA/2. Chapman et al.[16] reviewed the literature for the use of DBA/2 mice in evaluating the pharmacologic activity of known anticonvulsant drugs. All of the commonly used anticonvulsant drugs, such as benzodiazepines, γ-aminobutyric acid (GABA) agonists, GABA-transaminase inhibitors, GABA-uptake inhibitors, competitive[33,136] and noncompetitive excitatory amino acid antagonists,[17,18,19] and calcium entry blockers,[40] were active in suppressing sound-induced seizures in DBA/2 mice.

Several currently marketed anticonvulsants have been profiled for anticonvulsant activity in the DBA/2 strain. Pregabalin's anticonvulsant activity was profiled in a number of animal models. Its anticonvulsant ED50 in DBA/2 mice was 2.7 mg/kg following oral administration.[193] Felbamate produced dose-dependent effects for suppression of sound-induced tonic, clonic, and wild-running phases using ED50s of 23.1, 48.4, and 114.6 mg/kg, respectively.[39] Retigabine was found to be active in many of the rodent models. The ED50 in the DBA/2 is 2.3 mg/kg following intraperitoneal administration.[147]

El Mouse

The El mouse is an electroencephalographically authentic animal model of epilepsy.[155,176,177] Seizures are induced by vestibular stimulation and become spontaneous after the mice experience several (10–15) induced seizures. The seizures appear to originate in the hippocampus or deep temporal lobe structures and are characterized by excessive salivation and automatism of the head and limbs. Paroxysmal electroencephalographic discharges are seen in the temporal lobe. King and LaMotte[87] published a comprehensive review of the El mouse as a model

of focal epilepsy. These seizures can be inhibited by phenytoin at 40 mg/kg twice daily for 3 days.[119]

Fueta et al. studied the antiepileptic action induced by a combination of vigabatrin and tiagabine in the El mouse.[52,53] They used brain slices from the El and the control ddY mouse and found that no synergistic effects took place. An α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) antagonist, YM928, in doses of 5 mg/kg or 10 mg/kg, administered intraperitoneally, significantly increased the number of stimulations required to elicit generalized seizures.[207] The novel anticonvulsant compound BW534U87, which is active in several electrically and chemically induced seizure models, is also active in preventing the focal seizures in the El mouse. The anticonvulsant activity is partially reversed with a selective adenosine A1 receptor antagonist.[166] Competitive *N*-methyl-D-aspartate (NMDA) antagonists have been shown to inhibit NMDA whole-cell currents in mouse spinal neurons as well as to block seizures in a dose-dependent manner in the El mouse.[34]

Several of the clinically effective anticonvulsant drugs, including ethosuximide, inhibited seizures induced by the intravenous administration of pentylenetetrazol.[174] The results were compared to those obtained by original sensory-induced seizures. The authors felt that PTZ-induced seizures were a more precise measure of anticonvulsant activity in the El mouse.

Tottering (tg/tg) and Quaking Mouse

The tottering mouse exhibits bilaterally synchronous spike-and-wave (6–7 Hz) discharges[132,133] that are sensitive to drugs used to treat absence seizures in humans.[64] The discharges are accompanied by movement arrest, fixed stare, twitching of the vibrissae, and myoclonic jerks of the head and jaw. Behaviorally, this genetic strain appears to exhibit both simple partial seizures with motor symptoms and absence seizures. Microscopically, there appears to be cellular loss and vesiculations of the cytoplasmic membranous structures in the cerebellum. The quaking mouse, like the tottering mouse, has an autosomal recessive genetic disorder that produces tonic–clonic seizures.

The homozygous mice exhibit tonic–clonic seizures when lifted by the tail and slowly rotated 180 degrees; approximately 85% of the control mice handled in this manner exhibit seizures. Drugs used to treat human absence seizures, such as ethosuximide, are ineffective in this seizure model, whereas drugs for the treatment of generalized tonic–clonic seizures and partial seizures are effective.[184]

The clinically effective anti-absence drugs diazepam, phenobarbital, and ethosuximide were effective against the absence-like seizures in the tottering mouse.[64] In contrast, phenytoin did not significantly reduce the incidence of the absence seizures in doses up to 60 mg/kg. The CNS-stimulant caffeine, in doses of 5 to 15 mg/kg, significantly decreased absence-like seizures 4 hours following intraperitoneal administration.[90]

The quaking mouse, like the tottering mouse, has an autosomal recessive genetic disorder that produces tonic–clonic seizures. The homozygous mice exhibit tonic–clonic seizures when lifted by the tail and slowly rotating them 180 degrees. Carbamazepine and phenytoin were effective in controlling the seizure, whereas ethosuximide and diazepam were ineffective. Valproate completely controlled the seizure when a dose of 400 mg/kg was administered.[184] Tonic–clonic convulsions in this genetic species were attenuated by both competitive and noncompetitive NMDA antagonists when administered by the intracerebroventricular route of administration.[131]

Unfortunately, most genetic models of spontaneous seizures are presently impractical as a means of identifying potential candidates in primary screens due to the limited availability of test animals and/or irregular seizure frequency.[110]

Audiogenetic Rats

Two separate and distinct colonies of genetically epilepsy-prone rats, GEPR-9 and GEPR-3, have been bred and are used to identify anticonvulsant drugs.[35] The two colonies differ in the convulsion intensity following a sound stimulus. The GEPR-9 rats exhibit a seizure pattern similar to the DBA/2 mice, characterized by a terminal complete tonic phase. The seizure pattern of the GEPR-3 consists of an initial running phase followed by clonic seizures. Changes in sound pressure and frequency are important factors to be considered when establishing this model in a laboratory.[183]

Several neurochemical deficits occur in the GEPR that may have human correlates. Both noradrenergic (NE) and serotonergic deficits appear to be important in the seizure disposition of the GEPR. Browning et al. found that a NE deficit greatly enhances the incidence of tonic convulsions and supports the hypothesis that an increase in excitatory neurotransmitters in the GEPR inferior colliculus may act to initiate audiogenic seizures, whereas the NE deficit may allow expression of the tonic components of the seizure seen in some GEPR.[12]

The GEPR-9 is extremely sensitive to electrically induced seizures.[13] The threshold current (mA) needed to produce tonic seizures in the GEPR-9 is one-fourth that of the GEPR-3 or normal rat. In fact, forelimb or facial clonus could not be elicited in the GEPR-9 at any current. A complete description of the ontogenetic development, neurochemistry, and seizure disposition of the GEPR has been summarized by Jobe et al.[71]

All the established AEDs attenuate the sound-induced seizures in the GEPR. In 1997, Consroe and Wolkin[26] compared the anticonvulsant profile of phenytoin, cannabidiol, delta 9 tetrahydrocannabinol, and cannabinol to clinically effective anticonvulsants in both the MES test and GEPR rats. They found that cannabidiol was relatively more potent than phenytoin. In general, phenytoin and carbamazepine, on a mg/kg basis, are more potent in blocking the tonic phase in the GEPR-9 than in attenuating the clonic seizure in the GEPR-3. Phenobarbital and ethosuximide are, however, equally potent in both strains of rats.[35]

Valproate is more potent in the GEPR-3 than the GEPR-9. Antidepressants such as imipramine and amitriptyline act both as anticonvulsants and proconvulsants in these models. This dichotomy can be explained by the fact that antidepressants and antiarrhythmics lower the seizure threshold while at the same time preventing seizure spread.

NMDA receptor antagonists significantly decreased AGS severity in the GEPR-9 rat. Systemic administration of the competitive NMDA antagonists 3-[(±)-2-carboxy-piperazin-4-yl]-propyl-1-phosphonate (CPP) and 2-amino-7-phosphonoheptanoic acid and the noncompetitive antagonist dizocilpine (MK-801) were effectively anticonvulsant in the GEPR-9 rat.[38]

The selective neuronal GABA uptake inhibitor NNC-771 has been found to protect against both the clonic and tonic seizure phases at doses of 0.23 mg/kg following intraperitoneal administration.[175] Bilateral injections of tiagabine, a GABA uptake inhibitor, into the inferior colliculus of GEPR-9 rats significantly reduced seizure severity.[48] These results suggest that GABA is an important inhibitor of acoustical transmission in this brain structure.

Epileptic Fowl

Seizure susceptibility in domestic fowl (*Gallus gallus*) is due to a homozygous autosomal recessive trait.[29] Spontaneous seizures occur at the time of hatching and continue to occur throughout the bird's life. Seizures can be induced by photic stimulation using an optimal frequency of 14 flashes per second.[30] Heterozygotes do not respond to the stimulus. The seizures are

P.1472

characterized by an upward and backward tonic extension of the head and neck, followed by loss of leg muscle control. A final phase consists of violent wing flapping with clonic leg movements. The interictal electroencephalogram (EEG) is characterized by high-voltage, slow-wave activity.

Seizure incidence and severity was evaluated following the administration of several of the clinically effective anticonvulsant drugs. Phenobarbital, primidone, phenytoin, and valproic acid reduced seizure susceptibility at plasma concentrations approximating those considered within the therapeutic range for controlling generalized and focal seizures in humans.[36,73,74,75,76,77] Ethosuximide was the only ineffective anticonvulsant in this model.[36]

Several experimental GABA mimetic compounds, GABA-selective transport inhibitors, and tetrahydrocannabinol were also active in attenuating the induced seizures.[73,153,206] Pedder et al.[137] demonstrated that both competitive (CPP and APH) and noncompetitive NMDA antagonists (MK-801) delayed the onset of seizures in a dose-dependent manner. An antiparasitic agent, ivermectin, attenuated photic stimulation-induced seizures in a dose-dependent manner.[31]

Hyperthermia can cause seizures in epileptic chicks but not in the adult epileptic chickens.[78] Phenobarbital and valproic acid attenuated the seizure activity, whereas phenytoin did not.[72]

Light-sensitive Epileptic Baboon

Killam et al.[86] found 60 of 100 baboons (*Papio papio*) exhibited paroxysmal responses to the first exposure of flashing light. Intermittent light stimulation (25 Hz) produces a characteristic EEG and motor paroxysmal response. In some animals, self-sustained epileptiform discharges appeared prior to the motor seizures.[85] Myoclonus of the eyelids, face and neck, trunk, and limbs characterized the motor seizures. The effect and duration of drugs can be evaluated in a dose-response relationship by scoring the severity of the seizure pattern. The administration of a subconvulsant dose of allylglycine (200 mg/kg intravenously) 2 to 9 hours prior to the photic stimulation produces a stable level of sustained generalized myoclonic responsiveness.[128]

A number of clinically effective and experimental anticonvulsants have been evaluated in this model of epilepsy. Benzodiazepines and phenobarbital are extremely effective in attenuating the light-induced epileptiform seizures.[85,128,138] GABAergic compounds produce mixed responses. Valproate partially attenuated seizures at high, clinically therapeutic plasma concentrations,[125] whereas muscimol and 4, 5, 6, 7 tetrahydroxyisoxazolo (4, 5, c) pyridine 3-ol (THIP) are proconvulsant.[124,138] Vigabatrin completely blocked the generalized myoclonus for several hours.[126] Phenytoin, carbamazepine, and ethosuximide are relatively ineffective in attenuating the myoclonic seizures.[127,172]

Other experimental compounds have been evaluated using this seizure model. These include beta-carboline abecarnil[192]; MDL 27266, an NMDA antagonist[200]; memantine, an NMDA channel-blocking antagonist[129]; and progabide, a GABA agonist.[15]

Electrically Induced Seizures

Maximal Seizure Pattern Test

Electrically induced seizures are perhaps the most frequently used model system for the identification of anticonvulsant activity. The type and intensity of the seizure is related to the intensity of the stimulus current and site of stimulation.[139] The electrical stimulus can be delivered via the cornea or ear clips. As the current is increased, the behavioral characteristics become more severe. The lowest effective current produces a “stunned response.” Higher currents produce “twitching of the vibrissae” and facial clonus. The behavioral responses continue to proceed to forelimb clonus and rearing. Finally, a current is reached that produces tonic flexion-extension of the fore- and hind-limbs.

The change in threshold current to produce tonic hind-limb extension in 50% (CC50) of the rodents can be used as a primary screen for anticonvulsant activity. Loscher et al.[97] demonstrated that ethosuximide was the only anticonvulsant that did not raise the threshold for tonic seizures. Phenytoin and carbamazepine tripled the current required to produce a tonic hind-limb seizure. Diazepam, valproic acid, and primidone were far less active in raising the CC50. It is therefore not surprising that these less potent drugs are relatively poor in preventing seizure spread in the supramaximal seizure pattern (MES) test.

It is also important to characterize a compound's effect on raising seizure threshold. In the early studies, a large number of animals were required to determine the CD50 for a given population. Loscher then described a direct cortical ramp-stimulation model to determine the changes in CD50 in rats following administration of known anticonvulsant drugs. This methodology allows for repeated determination of seizure threshold at short-time intervals in individual rats without inducing postictal threshold changes.[91] The changes in current needed to produce hind-limb extension using this method for carbamazepine, phenytoin, and valproate were similar to the earlier methods using a large population of animals. Thus, this approach offers distinct savings in animal costs and requires less compound.

When groups of mice are used to establish changes in seizure threshold, a “staircase” procedure can be used to define the population threshold.[49] The stimulus intensity of the next animal is determined by the response of the animal just tested. The stimulus intensity is increased to the next higher increment if the previous animal failed to exhibit a seizure or the next lower increment if the animal exhibits a seizure.[178] Using this information, the investigator can then calculate the current necessary to produce a seizure in 50% of the population; that is, the CC50.

The MES test is used to identify drugs that prevent seizure spread, and it is often employed as a primary screen for anticonvulsant activity. Phenytoin and carbamazepine are extremely active in this animal model. The electrical current for the supramaximal MES test in the CF1 mouse is 50 mA at 60 Hz for 0.2 seconds. This is delivered via corneal electrodes,[179,188] and is four to five times greater than the threshold current needed to produce a tonic hind-limb extension seizure.

The choice of mouse strain is extremely important in the MES test. When evaluating the strain, the CD97 is usually determined first, then the final current for the test can be estimated. For the supramaximal test, a current that is three to five times that of the CC97 is typically used. Because death doesn't usually occur in the CF1 male mouse following the tonic phase of the seizure,[189] this strain has been historically employed by the NINDS-sponsored ADD Program at the University of Utah.[202] In contrast, approximately 10% of young rats and a higher percentage of older rats may fail to display a tonic extension at a supramaximal stimulation (e.g., 150 mA, 0.2 sec.).

In most cases, electroshock stimulation is delivered through corneal electrodes, although other stimulation sites can be used. For example, transauricular stimulation in rats also produces a similar seizure pattern.[11] There are, however, differences in some seizure parameters. Transauricular stimulation is more effective in eliciting tonic convulsions, whereas facial and forelimb clonus is lost. The threshold for clonus is lower when transcorneal electrodes are used.

Direct electrical stimulation to various brain structures produces the identical behavioral responses seen following corneal stimulation. The studies of Esplin et al.[45,46] demonstrated that direct electrical stimulation of the spinal cord produces a seizure pattern similar to that seen following corneal stimulation. These observations suggest that the spinal cord serves as a conduction pathway for impulses generated from higher brain levels. Phenytoin had a minor effect on the tonic-extensor phase of the spinal cord–induced seizure. The anticonvulsant activity of phenytoin therefore must be due to its action on higher brain centers. Conversely, phenytoin, phenobarbital, and ethosuximide block the tonic hind-limb extension component of seizures induced by stimulation of the mesencephalic reticular formation of rats.[21]

Febrile Seizures

Febrile seizures are commonly observed in children; depending on their severity, the patient may be treated prophylactically with phenobarbital. Unfortunately, phenobarbital has been associated with negative effects on learning and behavior. Several animal models have been developed and validated for the purpose of identifying nonsedating anticonvulsants for the treatment of febrile seizures. Holtzman et al. developed a microwave-hyperthermia model that raises core temperature of 2- to 10-day-old rats and results in convulsions similar to febrile convulsions in human infants.[67] In 1983, Hjeresen et al., using similar microwave technology, used 13- to 17-day-old rats to produce seizures. This heating procedure impaired neither brain growth nor performance during behavioral testing. There appears to be a decrease in seizure susceptibility with age in the rat pups following microwave hyperthermia.[66]

Similar studies were conducted using chicks that display a genetic epileptic seizure phenotype. Epileptic seizures are produced by elevating their body temperature using microwave diathermy.[72] These hyperthermic seizures differ from those seen in photo-stimulated, epileptic-prone chickens. Hyperthermia does not produce seizures in adult epileptic chickens. Seizures in hyperthermia-induced epileptic chicks are attenuated by phenobarbital, whereas valproic acid and phenytoin have no effect.[72]

Hyperthermia can be produced in weanling rats (21 days old) by immersion in a 45°C water bath for a maximum of 4 minutes (four exposures over a 2-week period). The rat's seizures increase in severity and progress to a stage 5 generalized seizures.[135] This method was used to characterize the anticonvulsant activity of several drugs: clonazepam, MK801, valproic acid, remacemide, and phenobarbital. Remacemide and phenobarbital were inactive. Valproate actively decreased seizure severity and modestly attenuated seizure duration. It also reduced the number of animals experiencing seizures on test day one. Clonazepam effectively lowered seizure score and reduced the number of animals experiencing seizures during three of the four testing periods. MK801, at the dose used, caused behavioral side effects while reducing the maximum seizure grade.

Baram et al. were interested in the long-term outcome of febrile seizures in infants and young children.[2] They developed a methodology to produce hyperthermic-induced seizures using the infant rat. The seizures were induced by a regulated stream of mildly heated air over 1- to 11-day-old rats; the presence of seizures was confirmed by behavioral and EEG analysis. Stereotypical seizure activity was observed in 94% of the heat-treated rat pups, with 11% mortality. Depth recording from the amygdala and hippocampus clearly showed epileptic activity. Thus, this model allows for long-term studies of the mechanisms and outcome of febrile seizures.

In their initial studies, hyperthermic seizures—but not hyperthermia alone—resulted in numerous argyrophilic neurons in discrete regions of the limbic system. Within 24 hours of seizures, a significant proportion of neurons in the central nucleus of the amygdala and in the hippocampal CA3 and CA1 pyramidal cell layer were affected. However, by 4 weeks after the hyperthermic insult, no significant neuronal damage was evident in these regions.[191]

Chemically Induced Seizures

The use of chemicals to induce seizures began over a century ago and is still used in epilepsy research and drug discovery today.[37,173] Camphor, picrotoxin, and strychnine were used before the turn of the 20th century. The most commonly used chemoconvulsant, PTZ, was introduced in 1926.[65]

In addition to PTZ, other commonly used chemoconvulsants include bicuculline, picrotoxin, γ-hydroxybutyrate, NMDA, AMPA, kainate, and quisqualate. Other ictal- or seizure-producing compounds mentioned in the literature, but less frequently used in drug discovery, include pilocarpine, homocysteine/cobalt, flurothyl, 3-mercaptoproprionic acid, allylglycine, ß-carboline, penicillin, zinc, alumina, and tetanus toxin.[37]

Results obtained in these tests should be interpreted with some caution. For example, the finding that an experimental drug blocks the tonic seizures caused by theophylline does not prove that it works through a purinergic mechanism. Most compounds that prevent seizure spread, such as phenytoin and carbamazepine, are effective in blocking the tonic maximal seizure caused by theophylline, but do not attenuate the clonic seizure associated with theophylline.

Pentylenetetrazol

PTZ (Metrazol, leptazol) was one of the first and remains the most commonly used chemoconvulsants to identify anticonvulsant activity. Unfortunately, it cannot be used to differentiate drugs effective in “grand mal” or “petit mal” epilepsy when tonic seizures are used as the endpoint.[47]

Loscher et al.[102] systematically evaluated the role of technical, biologic, and pharmacologic factors that can influence PTX-induced seizures. PTZ, when infused intravenously, is an excellent convulsant for detecting changes in seizure threshold.[61,134] Some of the clinically effective anticonvulsants are effective in delaying the onset of clonic seizures. Santucci et al. measured the onset and characteristics of the EEG paroxysms initiated by a slow intravenous infusion of pentylenetet- razol in gallamine-immobilized, artificially ventilated rats.[152] Compounds with “anti-petit mal” activity are effective in this model, whereas drugs primarily effective against tonic extension seizures (e.g., phenytoin and carbamazepine) are not. Similar results were observed in anesthetized rats.[84] Pollack and Shen[141] used this method to quantify the anticonvulsant activity of valproate in rats.

When PTZ is administered subcutaneously in doses that only produce myoclonic jerks followed by clonic seizures, phenytoin, primidone, and carbamazepine are not able to completely attenuate the clonic seizure.

The strain of mouse must be carefully considered for this test. It is extremely difficult to obtain only clonic seizures in 97% of the randomly bred mice without producing generalized seizures characterized by wild running and then tonic extension. The CF1 mouse is different in this respect. A dose can be determined that produces clonic seizures in 97% of the mice without observing tonic limb extension. When PTZ is administered intravenously, it can be used as a primary screen to assess the effect of anticonvulsant drugs on seizure threshold.

Some experimental anticonvulsant compounds appear to be both anticonvulsant and proconvulsant when administered in higher doses. These compounds prevent seizure spread induced by the MES test in both mice and rats, but are ineffective

in blocking clonic seizures induced by chemoconvulsants. The timed intravenous PTZ test is used to evaluate the proconvulsant potential of new compounds. PTZ is infused into the tail vein of mice. The time to the appearance of the first focal seizure (first twitch) and the clonic seizure is measured. Proconvulsant compounds require less PTZ (mg/kg) to produce these endpoints. At high (e.g., behaviorally toxic) doses, phenytoin and carbamazepine decrease the amount of convulsant needed to produce these end-points even though they are both able to block the tonic hind-limb seizure induced by this chemical stimulant. Mexiletine (an antiarrhythmic) and lidocaine have been shown to inhibit seizure spread, but lower seizure threshold in this test.

Repeated administration of PTZ to mice can produce a kindling effect.[83] The kindling effect was directly proportional to the dose or the intensity of the kindling stimulus and a dosing interval of 3 days. Two anticonvulsants, ethosuximide and cannabidiol, blocked the development of kindling to the PTZ-induced minimal convulsions.

Flurothyl

Flurothyl (Indoklon), a fluorinated derivative of ethylic ether, produces seizures in both humans and animals following its inhalation or parenteral administration. Seizures are characterized by clonic movements of the fore limbs with loss of posture followed by tonic flexion and extension of the hind limbs. The entire episode lasts about 40 seconds in mice. Similar behavioral responses are seen in both normal[190] and seizure-prone rats.[51] Simon et al. evaluated the effects of 18 drugs used for the treatment of a variety of different seizure types in preventing the flurothyl initiated clonic–tonic seizures and death in mice.[157] All the drugs studied were effective in attenuating the tonic seizures. Compounds that prevent seizure spread, such as phenytoin and carbamazepine, were ineffective in preventing the clonic seizures.

Felbamate (300 mg/kg) prolonged the latencies to flurothyl-induced seizures.[22] A synthetic epalon, ganaxolone, when administered to postnatal (9, 15, 30, and 60 days old) Sprague–Dawley rats, preferentially attenuated the tonic–clonic seizures over clonic seizures.[95] The anticonvulsant activity of gabapentin was evaluated in immature rats that received kainic acid on postnatal day 35. Cilio et al. found that gabapentin raised flurothyl-induced seizure threshold in all age groups tested.[23]

Compounds that are not known as clinically effective anticonvulsants will attenuate flurothyl-induced seizures. Some imipramine-like and antiparkinson drugs block the tonic seizures at near toxic doses. Parenterally active synthetic analogs of the endogenous morphinomimetic pentapeptide Met5-enkephalin raise the seizure threshold of flurothyl- induced seizures.[28] A highly selective κ-opioid agonist, U50488, was shown to attenuate electrically induced seizures but did not raise the threshold of flurothyl-induced convulsions.[190]

Gamma-hydroxybutyric Acid and Generalized Absence Seizures

Gamma-hydroxybutyric acid (GHB) is a GABA metabolite that occurs naturally in the mammalian brain.[148] When it, or its pro-drug form γ-butrylactone, is administered to rats,[117] cats,[165,203] and monkeys,[159] the EEG displays slowing with occasional spikes and bursts of poly spiking interspersed with periods of electrical silence. The spike-and-wave characteristics of the EEG following GHB treatment are similar to that seen in absence seizures. Cortez and Snead[27] have recently presented an excellent review of this animal seizure model. Clinically effective anticonvulsant drugs for the treatment of generalized absence seizures have validated this model.

Ethosuximide, at plasma levels of 140 μg/mL, greatly redu-ced the incidence of spiking, whereas phenytoin worsened the condition.[160] In additional experiments with anticonvulsant drugs, Snead[161] demonstrated that intravenous clonazepam and ethosuximide abolished the intravenously administered GHB-induced changes; however, diazepam marginally improved the spike-and-wave response, and phenobarbital was without effect. The CNS stimulant dextroamphetamine and the specific opioid antagonists naloxone and naltrexone also attenuated or blocked the GHB-induced spike-and-wave discharges. These observations suggest that the GHB-induced EEG changes have either a dopaminergic or adrenergic component.[162,164] Seizures observed in the GHB model of absence seizures are analogous to those seen in the PTZ model and the genetic spontaneous spike-and-wave Wistar rat. These seizures can be blocked by T-type Ca^{2+} channel blockers, benzodiazepines, and $GABA_B$ drugs, and potentiated by phenobarbital, tiagabine, vigabatrin, and other nonselective GABA agonists.[163]

Focal Seizures: Kindling

A review of several acquired focal models of seizures and epilepsy has been published.[96] Many of these models are used to gain a greater understanding of how seizures originate and propagate over time. Various kinds of kindling models that produce acquired focal seizures have been used to identify potential therapeutic agents for the treatment of partial seizures. Recently, kindled seizure models have been used to identify drugs for the treatment of therapy-resistant epilepsy.[96]

Kindling is a model of epilepsy produced by repeated administration of an initially subconvulsive electrical stimulus. This results in an increase in seizure activity, culminating in a generalized seizure. The kindled phenomenon is possible in several species, usually cats, mice, and rats. The kindled model of epilepsy has been extensively reviewed by McNamara,[121,122,123] Loscher and Schmidt,[110] Racine,[145] and McIntyre.[120] The electrographic and behavioral components of kindled seizures are thought to be similar to human partial seizures, since the focal component of the kindled seizure can progress into a generalized seizure. In this model, quantification of a drug's effect on both the focal and generalized seizure is possible by using a graded response.[145]

Electrical stimulation of several limbic sites of the brain (e.g., entorhinal cortex, amygdala, and hippocampus) can produce kindling. The most common way to produce the kindled state is stimulation of a specific area of the amygdala via implanted electrodes. A fixed current is applied until an afterdischarge is produced at the site of stimulation. Repeated daily stimulation produces behavioral responses that can be classified or graded. In the early stages of kindling, animals develop focal clonic seizures that progress to rearing with loss of balance. At this point, the EEG has the characteristic of a generalized seizure.

The majority of studies evaluating drug effects in kindled rats use the model in which electrodes are implanted into the amygdala. The advantage to this model is the ability to observe changes in the afterdischarge duration as well as changes in behavioral response following drug administration. Data on the effects of clinically effective anticonvulsants in this model have been published over the last 30 years. Phenytoin and carbamazepine are not extremely effective in attenuating focal seizures, lowering the Racine scale from control grade 5 to grade 3 or 4. On the other hand, valproic acid is effective in blocking focal seizures. From the clinical standpoint, both phenytoin and carbamazepine appear to be more effective in treating a patient's partial seizures than does valproate. This

dichotomy in the relationship between effectiveness in the kindled rat seizure model and clinical response may be due to the differences in sensitivity to drugs within the rat population.

Several experimental drugs or drugs recently approved by the U.S. Food and Drug Administration (FDA) for the treatment of epileptic seizures in patients were studied in amygdala-kindled rats. Two NMDA receptor antagonists, CGX-1007 and CI-1041, were shown to attenuate the secondarily generalized seizure and not affect the focal kindled seizure.[7] The water-soluble AMPA receptor antagonist YM872 blocked fully kindled seizures in rats[62]; however, this effect may be at doses that produce ataxia and sedation. A broad-spectrum anticonvulsant analog of valproic acid, ABT-769, was shown to have similar activity to valproic acid in the amygdala-kindled rat.[55] Both compounds decrease afterdischarge duration and attenuate both the generalized and focal seizure component.

Loscher and Rundfeldt[108] studied the anticonvulsant activity of phenytoin in a large number of amygdala-kindled rats. They found that about 60% of the rats showed a variable response to phenytoin when they used focal seizure threshold as the end-point of the drug's anticonvulsant effect. The difference in response in phenytoin-treated kindled rats was restricted to kindled seizures. The threshold remained the same for generalized tonic electroconvulsions (determined via transauricular electrodes) in phenytoin responders and nonresponders of the kindled groups. The difference in response between groups was not due to differences in phenytoin's pharmacokinetic parameters.

Corneal stimulation is an alternative method to produce the kindled state. Corneal kindling can be done in both mice and rats. The major advantage of using mice as the experimental animal is that of cost. The efficacy of kindling depends on several stimulus parameters, including duration, intensity, and interval of the 60-Hz corneal electrode stimulation.[151] In general, mice are stimulated once daily for 2 seconds at 3 mA, whereas rats are stimulated twice daily for 4 seconds at 8 mA, as described by Walz et al.,[205] White et al.,[200] and Matagne.[118] Electrical stimulations are continued until a Racine stage 5 generalized seizure is obtained. Typically, ten consecutive stage 5 seizures (rearing and falling with clonus) are observed before drug testing is done.

Several experimental compounds were evaluated for their ability to prevent the generalized and focal seizures induced by corneal kindling. The neurosteroid ganaxolone was shown to be a potent anticonvulsant against fully kindled stage 5 seizures induced by corneal kindling in rats (ED50 of 4.5 mg/kg intraperitoneally), producing these effects at doses well below those that resulted in ataxia (TD50 of 14.2 mg/kg intraperitoneally).[14] An anticholinergic compound, F-721, was shown to both inhibit amygdala-kindled and corneal-kindled generalized seizures as well as decrease the afterdischarge duration by 83%.[182] A novel NMDA receptor antagonist that is selective for NR2B subunit, Cl-1041, blocked the fully expressed secondarily generalized seizure in a dose-dependent manner. Complete attenuation of the kindled seizure was only achieved at toxic doses.[7]

The use of corneally kindled mice also appears to be suitable as a primary screen for anticonvulsant activity.[118] Large numbers of mice can be rapidly kindled for drug screening studies. The pharmacodynamic characterization of responses from several drug studies gave reproducible results. The anticonvulsant activity in corneally kindled mice is similar to that observed in amygdala-kindled rats. Potschka and Loscher[144] compared the behavioral and pharmacologic differences in corneal kindling versus conventional kindling in mice. A clear progression of kindling development is seen in rats that is not seen in mice. Also, lethality in mice was a problem. Phenytoin nonresponders, seen frequently in kindled rats, were not observed in kindled mice.

Stimulation of other brain areas, such as hippocampus or cortex, also produce kindled seizures. Kamei et al.[79] compared the effects of several AEDs on seizures kindled in the neocortex, hippocampus, and amygdala of rats. They also studied the development of seizures (epileptogenesis) in these three brain areas. Amygdala-kindled rats developed generalized seizures more rapidly than did hippocampus- and neocortex-kindled rats. Although neocortex-kindled rats developed a kindled seizure similar to limbic-kindled seizures, more days of stimulation were required to produce the same effect.

Lothman et al.[114] described an alternate method for producing the fully kindled state in rats: the rapidly recurring hippocampal seizure (RRHS) model. The RRHS model stimulates the hippocampus of rats with 10-second trains of suprathreshold tetanic electrical stimuli every few minutes. Seizure intensity was quantified using the duration of afterdischarge and the accompanying behavioral responses. Severe limbic seizures were elicited on the first day following the initial repeated stimulation of the hippocampus. Seizures intensified on the second day and remained stable thereafter.

The RRHS model was used to screen and characterize several AEDs.[115] Behavioral seizures, electrographic seizures, afterdischarge thresholds, afterdischarge duration, and neurotoxicity were measured before and after intraperitoneal drug administration. Carbamazepine, phenobarbital, primidone, valproate, and diazepam suppressed the behavioral seizures in a dose-dependent manner. Phenytoin consistently had no effect on afterdischarge duration, and none of the drugs tested affected the afterdischarge threshold. Ethosuximide was totally without effect. The overall response patterns of the anticonvulsant drugs tested in the RRHS were similar to those seen in the amygdala-kindled rat model, although the mechanisms producing the phenomena may not be the same.

Levetiracetam, a newly clinically approved drug for the treatment of seizures, was evaluated in a model of rapid kindling with recurrent hippocampal seizures. Rats were given a dose of 54 mg/kg intraperitoneally and were stimulated 1 hour later. The seizure score fell from control stage 5 to an average of 1.67. The afterdischarge duration decreased from 57 to 21 seconds.[41]

Pharmacoresistant Animal Models

Introduction

Since 1993, several new AEDs have been brought to the world market for the management of partial epilepsy. With the exception of levetiracetam, the majority of these new AEDs were identified and developed as a result of their ability to block acute evoked seizures in rodent models of epilepsy. As discussed earlier, the mainstay of most AED discovery programs has been the MES test, the subcutaneous PTZ (scPTZ) test, and the kindled rat (also see the work by White et al.[201]). Unfortunately, despite their clinical predictiveness, there still remains a significant unmet need for the patient with "pharmacoresistant" epilepsy. To this end, the identification and characterization of one or more model systems that would predict efficacy in the pharmacoresistant patient population would be a valuable asset for any AED discovery program. Unfortunately, a model will only become clinically validated at the time that a drug is found to markedly reduce the incidence of therapy-resistant epilepsy in patients with epilepsy. In addition to being useful for therapy development, the ability to segregate animals on the basis of their responsiveness or lack of sensitivity to a given AED would be useful for attempting to understand the

molecular mechanisms underlying pharmacoresistance. In addition to understanding the mechanism of pharmacoresistance, an animal model of therapy resistance would be an asset for those studies designed to assess whether it is possible to reverse drug resistance, or potentially to predict which patient will remit and become pharmacoresistant. Given that most of these questions are extremely difficult to address directly in patients, it is important to continue the efforts to validate the established and newer models as they become available.

At present, a number of potentially interesting model systems of therapy resistance are available. The remainder of this section reviews the salient features of those models that have emerged in recent years that may ultimately prove valuable for both basic research and therapy discovery.

Defining Pharmacoresistance

In 2001 and 2002, two Workshops on Animal Models, jointly sponsored by the National Institutes of Health (NIH), National Institute of Neurological Disorders and Stroke (NINDS), and the American Epilepsy Society (AES), were convened to discuss the currently employed process whereby an investigational AED is evaluated.[170,171] These workshops evolved from a landmark White House–initiated conference, "Curing Epilepsy: Focus on the Future," which was sponsored by the NINDS in collaboration with the AES, Citizens United for Research in Epilepsy, Epilepsy Foundation, and the National Association of Epilepsy Centers. The participants of these workshops agreed that any proposed model of "pharmacoresistant" epilepsy should meet certain criteria. For example, "pharmacoresistance in animal models, based on human experience, can be minimally defined as persistent seizure activity that does not respond to monotherapy at tolerable doses with at least two current AEDs. An important need for the therapy-screening process is to find animal models that do not respond, or respond poorly to currently available AEDs" (see Stables, et al.[170]). Thus, the "demonstrated resistance" to two or more of the first-line AEDs employed in the treatment of partial epilepsy was considered pivotal. Furthermore, it was recommended that any model for therapy-resistant epilepsy should demonstrate parallels to human forms of pharmacoresistant epilepsy. Ideally, it would be hoped that any proposed model would lead to the identification of "a new therapy that will later be found to be effective in humans resistant to existing AEDs."

Models of Pharmacoresistant Epilepsy

In recent years, several in vivo model systems have been described that display a phenotype consistent with pharmacoresistant epilepsy (see Loscher[96] for review). These include the phenytoin-resistant kindled rat,[109,150] the lamotrigine-resistant kindled rat,[143,167,168,169] the 6-Hz psychomotor seizure model of partial epilepsy[4]; the post-SE models of temporal lobe epilepsy (TLE)[9,56,59,60,94]; and the methylazoxymethanol acetate (MAM) in utero model of nodular heterotopia.[158] See Loscher[96] for review and references. All these models are being utilized with increasing frequency in the search for novel AEDs, in an effort to differentiate them from the existing AEDs. The remainder of this section focuses on the above-mentioned in vivo models as they are currently being employed for therapy discovery. This is not to imply that other approaches utilizing in vitro systems are of any less value. For a discussion of this approach, the reader is referred to Dichter and Pollard[42] and Heinemann et al.[63] for review and references.

Antiepileptic Drug-resistant Kindled Rats

Phenytoin-resistant Kindled Rats

Over the last 20 years and more, the kindling model of partial epilepsy has been utilized with increasing frequency in the AED development process. The kindling model, unlike the MES and PTZ tests, is a model of focal epilepsy and one that displays a pharmacologic profile consistent with human partial epilepsy. Kindling refers to the process in which a progressive increase occurs in electrographic and behavioral seizure activity in response to repeated stimulation of a limbic brain region, such as the amygdala or hippocampus, with an initially subconvulsive current.[57] The kindling process is associated with a progressive increase in seizure severity and duration, a decrease in focal seizure threshold, and neuronal degeneration in limbic brain regions that resemble human TLE.

Löscher et al. have conducted extensive pharmacologic evaluations in the kindled rat model over the years and were among the first to demonstrate that kindled seizures were less sensitive to anticonvulsant treatment than were MES-induced generalized tonic extension seizures.[98,104] In subsequent investigations in the amygdala-kindled Wistar rat, Rundfeldt et al. found that the individual response of a fully kindled rat to a challenge dose of phenytoin differed markedly.[149] In their initial studies, they observed two population of rats: those that consistently responded to a challenge dose of phenytoin, and those that never responded to the same dose of phenytoin. This observation became the cornerstone of numerous studies designed to evaluate the effectiveness of “established” and “investigational” AEDs in phenytoin responders and nonresponders. Historical data collected over the years from more than 200 rats has demonstrated that approximately 16% of the animals display a consistent anticonvulsant response to a challenge dose of phenytoin; 23% display a variable response to the same challenge dose; and the remainder (61%) displays no response to phenytoin (see Löscher[96] for review and references). Based on this rather stable response, Löscher has suggested that these three groups of kindled rats model three different clinical populations: those patients who achieve complete seizure control; those who display a reduced seizure frequency in response to pharmacotherapy but never become seizure-free; and those who would be considered drug-refractory.

With the exception of levetiracetam, all the AEDs that have been tested in this model have been found to be less efficacious in the phenytoin nonresponder kindled rats. This observation is consistent with the clinical situation in which patients who are refractory to one AED are very likely to be refractory to other AEDs.[92,146] The finding that the efficacy of levetiracetam is maintained in the phenytoin-resistant rat would suggest that it might offer some potential advantage in the patient who has failed multiple AEDs. Unfortunately, not every patient who is refractory to one or more AEDs becomes seizure-free when treated with levetiracetam. As such, there still remains a significant unmet need for this patient population.

As with any chronic animal model, the phenytoin-resistant kindled rat model is very time- and labor-intensive. In addition to the surgical implantation of electrodes and the subsequent kindling protocol, there is the postkindling selection process wherein rats are repeatedly tested with a challenge dose of phenytoin to identify the responder and nonresponder population for the pharmacologic studies. One particular advantage of the phenytoin-resistant kindled rat is that it allows for comparative studies in both the responsive and nonresponsive population of rats from the same strain. In addition, the kindled rat, unlike the spontaneous seizure models (discussed later), does not require continuous video-EEG monitoring because the seizures are evoked.

P.1477

The Lamotrigine-resistant Kindled Rat Model

The lamotrigine-resistant kindled rat model of partial epilepsy was first described in 2000.[143] Unlike the phenytoin-resistant kindled rat, resistance to lamotrigine can be induced by treating rats with lamotrigine during the kindling acquisition phase. Thus, as shown by Postma et al.,[143] exposure to a low dose (5 mg/kg) of lamotrigine during kindling development leads to reduced efficacy of lamotrigine when administered to the fully kindled rat. A similar phenomenon was reported earlier for carbamazepine.[198] Based on these observations, Srivastava et al.[169] assessed whether this phenomenon would generalize to the PTZ kindling model. Indeed, when lamotrigine (5 mg/kg) was administered to Sprague-Dawley rats prior to each PTZ challenge dose during the kindling acquisition phase, fully kindled rats were found to be resistant to a subsequent challenge with a higher dose of lamotrigine. Perhaps more important is the observation that lamotrigine-refractory rats are also resistant to carbamazepine, phenytoin, and topiramate, but not to valproate or the investigational $KCNQ_2$ activator retigabine.[167,168,169]

Although less well characterized, the lamotrigine-resistant kindled rat may offer a practical advantage over the phenytoin-resistant rat in that it is not necessary to embark on an extensive prescreening protocol to identify those animals that are pharmacoresistant. In this regard, it might serve as an early model of drug-resistant epilepsy to identify novel AEDs for further evaluation in more extensive model systems, including the phenytoin-resistant kindled rat.

The Low-frequency (6 Hz) Electroshock Seizure Model

In many respects, the 6-Hz seizure model offers many of the same advantages of another acute electroshock seizure model: the MES test. As with the MES test, the 6-Hz seizure is an acute, electrically evoked seizure using standard corneal electroshock; it is a high throughput method, and requires minimal technical expertise. The only real difference is the frequency (6 Hz vs. 50 Hz) and duration (3 sec vs. 0.2 sec). As it turns out, these two stimulus parameters produce a seizure that is characterized by immobility, forelimb clonus, Straub tail, and facial automatisms that are thought to more closely model human limbic seizures.[4,5,10] When compared to either the MES or PTZ seizure, the 6-Hz seizure displays a pattern of neuronal activation, as measured by c-Fos staining, that is primarily localized to the amygdala and piriform cortex. At high current intensities (i.e., 44 mA), the dentate gyrus is recruited and displays prominent c-Fos staining.

When it was first introduced, the 6 Hz-model was thought to represent a useful model for identifying therapeutic agents for the treatment of “psychomotor seizures.” Unfortunately, at the time of its initial characterization, it failed to predict the clinical utility of two widely employed AEDs: phenytoin and thiantoin. Because it did not offer any particular advantage over the other models in place at the time, it was abandoned shortly after its introduction.[10]

Some 50 years later, Barton et al.,[10] at the University of Utah, resurrected the 6-Hz model as a potential screen for drugs effective against therapy-resistant epilepsy. Interestingly, the pharmacologic profile of the 6-Hz model is somewhat dependent on the intensity of the stimulation. For example, at a convulsive current (CC) sufficient to induce a prototypical seizure in 97% of the population tested (i.e., the CC_{97}), all AEDs evaluated (phenytoin, lamotrigine, ethosuximide, levetiracetam, and valproate) were effective in blocking the acute seizure. As the current intensity is increased to a level that is 1.5 times the CC_{97}, several AEDs lose their ability to protect against a 6-Hz seizure. At a current equivalent to two times the CC_{97}, only valproate and levetiracetam retained their ability to block 6-Hz seizures; albeit with a marked decrease in the potency of both drugs at two times the CC_{97}.[4] The finding that levetiracetam was found to be active at a specific stimulus intensity, whereas other anticonvulsants display little to no efficacy illustrates the use of the 6-Hz model as a screen for novel anticonvulsant compounds. This is a particularly important observation when one considers that levetiracetam was inactive in the acute seizure models, such as the MES and PTZ seizure tests.[58,89] Thus, the incorporation of a simple acute screen that would minimize the chances of “missing” a unique drug like levetiracetam should be an important consideration when setting up an anticonvulsant testing protocol to evaluate investigational AEDs. To this point, the 6-Hz seizure model has been incorporated into the testing protocol of the Anticonvulsant Drug Development Program at the University of Utah to examine those drugs that test negative in both the MES and PTZ seizure tests.

As a result of renewed interest in the 6-Hz model as a potential model of pharmacoresistant epilepsy, several new investigational drugs have been tested in this model.[5,6,68,69,70,80,81,82,96,156] Whether this approach will ultimately lead to the identification of a more efficacious AED for the treatment of refractory partial epilepsy remains to be determined. However, the finding that this model offers a means to differentiate the anticonvulsant profile of promising investigational AEDs is of interest in that it is a fast and simplistic model that can be used to quickly identify those drugs for further differentiation in more chronic, labor-intensive models, such as the kindled rat or post–status spontaneous seizure models (see later discussion).

In a manner similar to the earlier c-Fos studies, Duncan and Kohn[43] have shown that a 6-Hz seizure (32 mA, 3 sec duration) produces a robust increase in ^{14}C-2-deoxyglucose (2-DG) uptake in cerebral cortices, lateral amygdala, and caudate-putamen, but not the hippocampal areas. Interestingly, the investigational AED lacosamide (20 mg/kg, intraperitoneally), when administered 30 minutes prior to stimulation, completely antagonized the seizure-induced metabolic activation but did not affect basal 2-DG uptake.[43] These results demonstrate that lacosamide is able to block seizure-induced neural activation without suppressing normal brain metabolic activity.[43]

Post-status Epilepticus Models of Temporal Lobe Epilepsy

Post-SE models of refractory epilepsy are beginning to emerge as important tools in the differentiation of investigational AEDs. These models of pharmacoresistant epilepsy differ significantly from the AED-resistant kindled rat and the 6-Hz seizure model in that seizures are spontaneously evolving and not evoked. This adds another level of complexity to any pharmacologic evaluation. For example, issues of how to administer drug to an animal for a prolonged period of time become overshadowed by the challenge associated with detecting and evaluating efficacy using chronic video-EEG recording to quantitate seizure frequency and severity as outcome measures.

The development and characterization of this model system for pharmacologic testing has, in a large part, been due to a focused effort of the epilepsy community to identify clinically relevant models of pharmacoresistant epilepsy.[170] Because drug trials in rats with spontaneous seizures take on another level of complexity and are extremely laborious and time-consuming, there have only been a few pharmacologic studies conducted to date.[9,59,60] In many respects, the post-status models described thus far fulfill one very important characteristic of the ideal model system: They model spontaneous recurrent seizures (SRS) following a species-appropriate latent period.[170,171]

P.1478

In one of the first studies conducted using this model, Leite and Cavalheiro[94] found that high doses of phenobarbital (100 mg/kg), carbamazepine (120 mg/kg), phenytoin (100 mg/kg), and valproic acid (600 mg/kg), were highly effective in blocking SRS in the pilocarpine post-status model when administered over a 14-day period. In contrast, high-dose ethosuximide (400 mg/kg) was ineffective in this model. These investigators suggested that SRS following pilocarpine-induced SE could be a useful model for the identification of more efficacious drugs for difficult-to-treat complex partial seizures. In contrast to clinical experience, almost all the rats that received phenobarbital, phenytoin, carbamazepine, and valproate were protected against spontaneous seizures in their experiment. Whether this finding is the result of excessively high blood and brain levels of these AEDs is not known because levels were not determined in this study.

In an effort to control for some of the variables associated with chronic drug administration to rats, Glien et al.[56] has employed the use of implanted mini–osmotic pumps to deliver an AED (or vehicle) over a prolonged period of time. In one such study, Wistar rats were subjected to pilocarpine-induced SE, and SRSs were recorded in the months following status. At the point of study initiation, a group of eight rats with frequent SRSs were implanted subcutaneously with a saline-filled osmotic minipump for 2 weeks (predrug control period). They then were implanted subcutaneously with a levetiracetam-filled minipump for another 2 weeks (drug period). For the last 2 weeks of the study, rats were implanted subcutaneously with a saline-filled minipump (postdrug control period). For this study, the concentration of levetiracetam in the pump was sufficient to achieve blood levels consistent with those obtained in patients with TLE. Seizures were recorded by video monitoring for the 6-week duration of the study. The pre- and post-drug seizure frequency of the epileptic rats in this study was 21 and 25 seizures, respectively. During the levetiracetam arm of this study, the average seizure frequency was reduced to eight during the 2-week drug-treatment period. Interestingly, as with most randomized clinical studies, marked variability in the response rate was observed despite the fact that blood levels of levetiracetam were virtually identical in all rats. For example, three of eight rats were considered responders, achieving complete or almost complete seizure control, whereas three others were considered nonresponders; because of substantial predrug and postdrug control seizure frequency variability, two of the eight could not be included in either group. This study with levetiracetam shows that the testing of drugs in epileptic rats can yield interesting results that are likely to be more clinically relevant than results obtained from acute evoked-seizure models.

Results from another study evaluating the chronic effect of phenobarbital on SRSs in an electrical model of post-SE–induced epilepsy (i.e., sustained electrical stimulation of the basolateral amygdala of Sprague-Dawley rats) has demonstrated that it is possible to select drug responders and nonresponders from yet another model.[9] In this study with 11 rats, seizure frequency was monitored for 2 weeks before dosing with phenobarbital was initiated. The dose and dosing protocol for phenobarbital administration was based on pilot experiments designed to achieve blood levels within a therapeutic range of 10 to 40 µg/ml. This protocol was maintained for 2 weeks, then the seizure frequency was monitored for an additional 2 weeks in the absence of any drug treatment. Analysis of blood levels demonstrated that therapeutic levels were maintained in all rats for the duration of the active drug treatment period. Six of the eleven rats with SRSs became seizure-free in this experiment, one rat displayed a >90% reduction in seizure frequency, and three of the 11 rats showed an increase in seizure frequency during drug treatment; one of the 11 showed only a moderate (<50%) reduction in seizure frequency.[9]

In yet another example of how post-SE rats can be utilized for pharmacologic evaluation, Dudek et al. have employed a repeated-measures, cross-over treatment protocol to evaluate the efficacy of topiramate and the investigational AED RWJ 333369 in a post-kainate status model.[59,60] In these studies, RWJ 333369 was found to dose-dependently decrease the relative seizure frequency of SRSs at nontoxic doses. Furthermore, efficacy correlated very well with measured plasma concentrations.[59] When compared to results from an identical study conducted with topiramate, RWJ 333369 displayed a greater level of efficacy, and a greater percentage of rats displayed complete seizure freedom (seven out of eight rats vs. one out of eight rats, respectively). Collectively, these data support the concept that a repeated-measures, cross-over protocol is an effective method for testing AEDs in animals with post-status SRS. Furthermore, this approach may be useful for the development of adjunct therapies.

These examples demonstrate that it is possible to establish a model in which the pharmacology of the preclinical model mimics the human condition (e.g., the presence of responders and nonresponders). By testing new drugs in animals that are found to be nonresponsive to existing therapies, we may be able to better predict efficacy in a particular patient population and thereby enrich our chances of identifying the truly novel therapy. This approach, albeit costly and labor intensive, should be considered when attempting to differentiate a new drug from those that are either on the market or currently undergoing clinical trials.

The Methylazoxymethanol Acetate in utero Model of Nodular Heterotopia

Seizures associated with cortical dysplasia are often found to be resistant to the commonly employed AEDs.[32,208] Despite the fact that a number of animal models of cortical dysplasia are available, only one has been subjected to a systematic pharmacologic evaluation. In 2002, Smyth et al.[158] described the results of their study to investigate the effects of a limited number of AEDs in Sprague-Dawley rats exposed to methylazoxymethanol acetate (MAM) in utero. In utero exposure of the fetus to MAM causes nodular heterotopia with hyperexcitable dysplastic brain regions. In contrast to age-matched control rats, valproate did not increase the latency to kainate-induced seizures in those animals exposed in utero to MAM.[158] Furthermore, 4-aminopyridine–induced epileptiform bursting in acute hippocampal slices from MAM-exposed rats was resistant to treatment with phenobarbital, carbamazepine, valproate, ethosuximide, and lamotrigine. In contrast, 4-aminopyridine–induced bursting in slices from control rats was suppressed by these AEDs. The results from this limited study suggest that MAM-exposed rats have a reduced sensitivity to commonly prescribed AEDs, thereby mimicking the clinical response in patients with dysplasia-associated epilepsy. Given the unique nature of this model, there is a clear need for further evaluation of its validity to the human condition.

Summary

All these models are being utilized with increasing frequency in the search for novel AEDs in an effort to differentiate them from existing AEDs. It is too early to say whether any of these models, if implemented into the routine evaluation of investigational AEDs, will lead to the identification of the next-generation AED. The results from these various models have demonstrated that it is possible to “differentiate” compounds on the basis of their efficacy in one or more of these models.

P.1479

Furthermore, the use of these models has led to the development of novel drug-testing protocols in animals that more closely resemble human clinical protocols. Equally important is that each of these models provides a biologic system in which to evaluate the mechanisms underlying pharmacoresistant epilepsy and to test novel approaches designed to overcome or reverse therapy resistance, and to perhaps identify appropriate surrogate markers of pharmacoresistance. Through a greater understanding of these factors, one can envision the day when we will be able to identify the patient at risk for developing therapy-resistant epilepsy and institute a prophylactic therapy that prevents the emergence of pharmacoresistance.

Role of the Pharmaceutical Industry

Introduction: A Brief History of AED Discovery and Development

The pharmaceutical industry has played a pivotal role in the discovery and development of new AEDs (technically antiseizure drugs) since at least the 1930s, when Parke-Davis sent a series of compounds to Merritt and Putnam for screening using electroshock seizures in cats.[130] The discovery of phenytoin by these investigators was not only a remarkable discovery for patients, but documented, for the first time, that drugs could be evaluated in the laboratory for their efficacy. The event also probably represents the first successful industry–academia collaboration in AED discovery. In the next few years, a whole series of compounds followed, based on the hydantoin cyclic ureide structure—drugs such as Tridione and ethosuximide for absence seizures, as well as additional hydantoins and barbiturates. Ethosuximide was marketed in the United States in 1960, and marked the end of the exploitation of this particular molecular series. A long dry spell then occurred in the United States, with only diazepam marketed as an adjunctive therapy. Meanwhile, in Europe, both carbamazepine and valproate were moving onto the market. It was 1979 before valproate was available in the United States. Again, a void occurred in development until the early 1990s, when a veritable profusion of drugs appeared; for the first time, these were marketed early in the United States, as compared to other countries.

The Roles of the Industry in AED Discovery and Development

To consider the unique roles of the pharmaceutical industry in the process of getting effective new drugs to the patient, one must define the various processes needed to take a primitive but promising molecule and make it into a drug. This section covers each of the following six topics: (a) discovery, (b) chemical and pharmaceutical development, (c) drug safety, (d) drug metabolism, (e) drug regulatory processes, and (f) clinical development. Typically, each large drug company has departments (often of considerable size) in each of these somewhat oversimplified categories.[142] Each of the topics will conclude with discussions of potential collaboration between academia, government, and the industry.[197]

These six processes of drug discovery and development *are not entirely sequential*. This concept is worthy of considerable emphasis. Clearly, a drug must be discovered before it is tested in drug safety models or in humans. But pharmaceutical development begins very early and may eventually result in a follow-on drug after the first clinical launch. Likewise, drug metabolism begins early with animal studies and extends well into the clinical program—it may not end until late clinical phases utilizing studies such as population pharmacokinetics. Therefore, even though these categories are presented here in linear fashion, concurrent work by each group, especially after discovery, is the rule rather than the exception.

Discovery

The invention of a new molecule, either discovered in a disease model or rationally designed for a disease process, is the very first step in the process of making a new drug. The odds against such a molecule actually becoming a drug are exceedingly poor—perhaps one in 10,000 at this early stage (Fig. 1). Although high-throughput screening has been challenging rational chemical design, in fact both techniques are used in today's world of drug discovery. The next key ingredient, especially in large companies, is a cadre of medicinal chemists; these experts can take a promising molecule and make all kinds of improvements to it. Such improvements range from increased potency in the disease model all the way to simple but extremely important issues such as solubility and bioavailability. Patentability is also exceedingly important for drugs that are expected to be major financial contributors to a large company.

After the initial compounds are sorted out, a lead compound is usually put forth as the best candidate from all the various aspects. Consideration is always given to whether a new compound is potentially a better drug than one already available. For AEDs, a relatively new and sometimes disturbing consideration is whether the drug may also be effective in other indications, notably pain and/or bipolar disorder. These latter markets are often more lucrative—a drug that has promise only for epilepsy may fall out of the company's portfolio and thereby fail in the competition for the resources needed for further development.

At this stage, the potential for academic collaboration with industry is enormous. All sorts of possibilities can occur. An academic investigator who has discovered a promising molecule has many options available. These range from selling the molecule outright (or with royalty arrangements) to another small or large company, all the way to creating a new startup company (usually with venture capital support) to further the work on the molecule and make it (hopefully) more valuable in the marketplace. Universities have created business development offices just to handle such transactions, and the federal government has designed programs to assure that both the government and the federal inventor share in any eventual profits attained. Transfer usually includes not just one molecule, but, in addition, a whole series of patentable analogs. Clearly, the object of the latter is to protect the financial position of the deal.

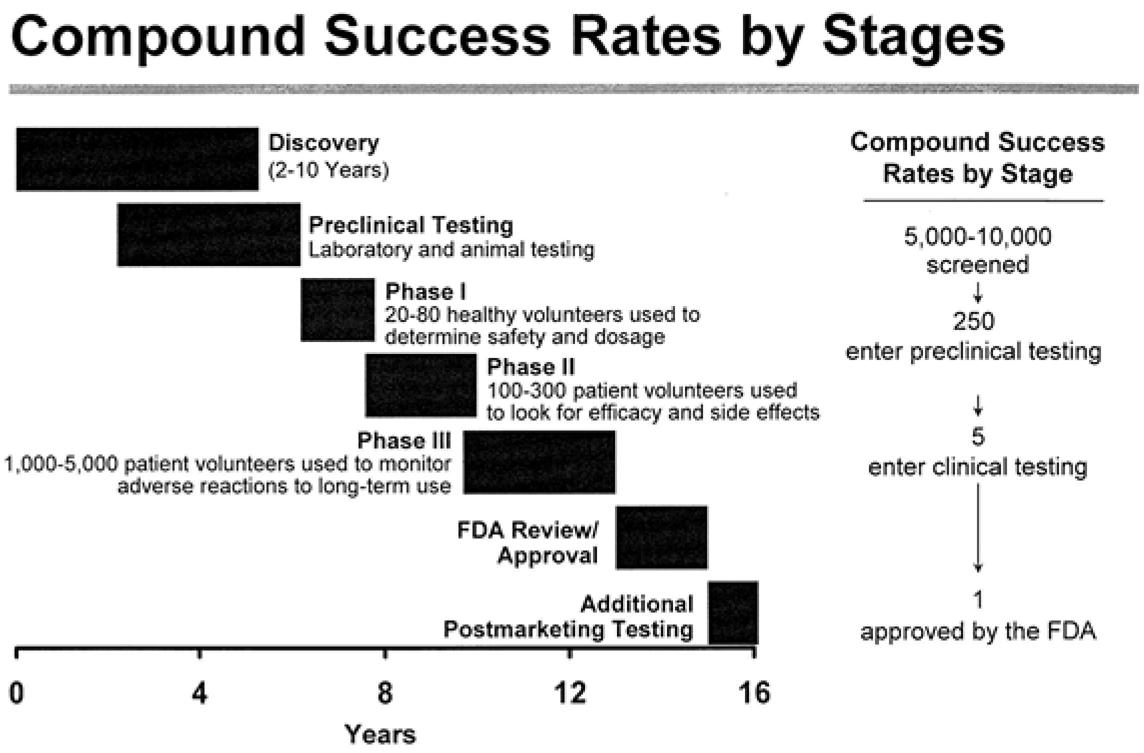

FIGURE 1. Compound success rate by stage. As can be seen, only 250 compounds of 5,000 to 10,000 screened enter preclinical testing, and only five of these enter the clinic. Only one of these five is approved for marketing. Although this figure emphasizes approval by the U.S. Food and Drug Administration, all large companies now emphasize worldwide registration, and most attempt, insofar as possible, simultaneous approvals worldwide. (From Pharmaceutical Research and Manufacturers of America. *1999 Industry profile.* Washington, DC: Pharmaceutical Research and Manufacturers of America, with permission.)

Pharmaceutical Development

When a scientist discovers a new drug, it is usually only available in small quantities through the original synthesis. But the further the drug is advanced in the development process, the more bulk compound is needed for further testing, not only by the original scientist, but by drug safety and metabolism study groups and, eventually, for clinical investigation. One of the early tasks, therefore, of the pharmaceutical department is to design more efficient syntheses to produce the drug in larger quantities. Eventually, the drug will have to be made under very careful, reproducible laboratory conditions with strict limits on impurities. Adherence to Good Manufacturing Practice (GMP) conditions is a huge (but exceedingly important) burden on drug manufacturers.

But having enough pure drug is only the beginning for this department, which is also responsible for the formulation of the drug, that is, the creation of a dosage form—such as a capsule or a pill—that is successful in the marketplace. A drug

taken orally, for example, must be bioavailable, meaning that the drug must reach the intended target in the body. Usually this means passing through the wall of the intestine, passing through the portal system of the liver, and reaching the systemic blood. Incredibly promising drugs can (and do) fail in pharmaceutics and are left behind. On the other hand, a wide and increasingly sophisticated variety of techniques are available to increase bioavailability for stubborn compounds.

Further discussion of pediatric formulations, parenteral formulations, extended-release formulations, and the like is beyond the scope of this chapter, but these formulations are also the responsibility of the pharmaceutical development department.

Except for highly specialized departments in academia and government, collaboration in this area is not very common. Making new formulations, for example, is not considered cutting-edge science by most academic investigators. Also, the process can be surprisingly expensive and labor-intensive. On occasion, one observes a new formulation which is made by an academic team, but the vast majority of this kind of work—which is highly regulated by the FDA—is left to the industry.

Drug Safety

When the FDA evaluates a drug, it must be "safe and effective for the intended use." Safety of the drug is as important as effectiveness, and safety testing is an integral part of the development of a new drug. Typically, a large pharmaceutical company has a drug safety department and a series of laboratories for a very wide range of testing, beginning with in vitro studies and, assuming that the drug continues to be safe, ending in animal testing. Although animal testing is mandatory, increasing sophistication of various non-animal studies has allowed an increasing number of studies to be performed without the use of live animals. Currently, every effort is made to limit the number of animals used to those that are absolutely necessary to support safe development in humans.[197] Further, only a limited number of studies (successfully performed, of course) are needed to begin human testing. A drug may fail in early human testing, in which case extensive animal testing will never be performed with that drug. The longest animal studies, typically the carcinogenicity studies, are not even started until the drug has been through a series of human studies, usually including a proof of concept for efficacy in humans.

A number of specific areas must be studied. These include both acute and chronic studies, and involve not only carcinogenicity as mentioned, but also, among others, reproductive and developmental toxicity, genotoxicity, cardiovascular toxicity, immunotoxicity, and neurotoxicity. The aim is rarely to find a compound that is completely safe, but one in which the adverse effects are minimal and manageable by the patient and the physician. Obviously there is a much greater tolerance for adverse effects in drugs for life-threatening diseases (such as cancer) than for more benign conditions (such as allergic rhinitis).

Some early in vitro tests can be carried out by academic laboratories, but drug safety testing is left to the industry for several reasons. First, although the testing is often very sophisticated, it is rarely exciting science, and academicians (and science funding agencies) have little interest in the process. Second, the process is highly regimented and controlled, requiring very detailed record keeping. The process must meet the standards of Good Laboratory Practices (GLP) and all studies must be available for inspection by the FDA or other regulatory agency. Failure to meet the proper standards may mean failure of approval of the drug, regardless of its therapeutic potential. Because of the rigor of the testing and its (usually) lack of scientific excitement, collaboration is uncommon.

Drug Metabolism

The drug metabolism department of a large pharmaceutical company becomes involved very early in the process of drug development, and usually stays involved up to the time of drug registration or beyond. The department is responsible for determining what happens to the drug in animals and in humans. The acronym ADME describes much of what the team does for oral medications—they study *a*bsorption, *d*istribution, *m*etabolism, and *e*xcretion.[197] The department is also responsible for the development and implementation of the assays for the drug (and its metabolites) in animal and human blood. The initial work in animals is used to predict what will happen in humans. If, for example, an active metabolite is suspected and discovered in animals, this may have an impact on how the drug will be studied in humans. Many other functions of this department impact the program—these include pharmacokinetics, analysis of dosage forms, drug distribution in the body, toxicokinetics, and the like.

Some departments of pharmaceutics in academia have developed sophisticated programs for determining certain drug ADME characteristics, and collaboration is possible. Again, if the academic laboratories wish to participate, GLP practices will be necessary for anything other than preliminary investigations. In many cases, the pharmaceutical companies will out-license some of the drug metabolism work to contract research organizations (CROs), some of which specialize in this kind of work and are very proficient at performing it. Large pharmaceutical companies prefer to do much of this work themselves (or closely supervise a CRO) for the simple reason that they do not wish to lose control over this critical part of drug development. This is especially true when one considers that drug metabolism departments are not nearly as expensive, say, as clinical departments.

Regulatory Affairs

The regulatory affairs department handles the proper paperwork flow, especially between the company and the responsible government agencies—such as the FDA. The area is not suitable for much collaboration, although its importance to the company can hardly be overemphasized. Regulatory affairs is so complex for large companies that subgroups develop expertise in certain areas or in certain parts of the world.

Clinical Research

After the discovery department has chosen the best compound from its series, the chemical and pharmaceutical sciences department has made and formulated enough pure compound, the drug safety department has done at least the early toxicologic studies, and the drug metabolism department has a sensitive assay in plasma, the regulatory affairs department can submit a document, usually with a clinical protocol created by the clinical research department, to the FDA or other health authorities to begin clinical investigations.[197]

Clinical research is classically divided into three phases (Fig. 1). Although it has become popular not to use this categorization in some companies, it is the most elementary way of thinking of drug development. Phase I trials are typically performed in young human volunteers to test the safety of the drug. Phase II trials are typically performed in a limited number of patients to see if the drug has efficacy for the disease in question—sometimes called *proof of principle*. Phase III trials serve to cement the proof of efficacy in a larger number of patients and to expose enough patients such that most (but not all, unfortunately) adverse effects can be well described. Overall, a typical program will expose 1,500 to 2,000 subjects in the clinical trial period over several years, although this number may vary widely depending on the disease under investigation.

A Phase I trial is a highly specialized program usually undertaken by the clinical pharmacology department within clinical research. The overall plan is to expose humans to a drug for the first time in a highly controlled setting, beginning with very small single doses and eventually giving larger doses for 10 to 14 days. Although this seems simple on the surface, proper safety measures will cause such a program to consume 8 to 12 months before enough data are available to move to Phase II. Collaboration with academia or government is not typical in most cases, because highly specialized inpatient units, either within the company or in a CRO, can perform these studies with maximum efficiency and safety. A prominent exception occurs in Phase I when the decision is made to use patients instead of volunteers. Under these circumstances, a combination of a source of patients allied with an inpatient facility is ideal, and either academia or government agencies (such as the NIH) can perform the studies in collaboration with the pharmaceutical company. Academic centers with specialized clinical research units are often ideal for such studies. Good Clinical Practices apply to all phases of clinical research.

Collaboration with patient caregivers is critical to Phase II trials. The collaboration is not always with academia, because some academic medical centers tend to be very bureaucratic and ponderously slow in making decisions and getting the research accomplished. Because speed of development is one of the most important financial factors for a company, other sources of patients, such as those gleaned from private practice, have been recruited.

In any case, the pharmaceutical company cannot perform Phase II trials without a source of patients, and therefore the company must collaborate with others. Using physicians in various institutions to collect a specialized population of patients is a natural trend, and negotiations are usually undertaken to the benefit of the physician, the company, and the patients; the latter will have an opportunity to try a new medicine that may be of considerable benefit to them. Phase II studies are intense. Safety of the first few patients to receive the drug is paramount. The optimal dose to be used in the patients is usually not well understood, and part of the Phase II effort is to attempt to narrow the range of doses that will be effective but produce few adverse effects. It should be noted that, aside from diseases exclusive to children, most studies are performed in adults before children are exposed. Women, on the contrary, are now entered early into the clinical trial process.

The collaboration in Phase II trials requires that the company and its partners adhere to Good Clinical Practices (GCP). This means, for example, adherence to a specific protocol (which may be jointly developed with the physician caregiver), very careful documentation of all data collection, and adherence to rules set forth for institutional review boards and for privacy. Phase II trials, especially if late in the program, are typically well-controlled for bias; this means protocols using randomization, control groups, blinding, and the like as part of the studies. Many good academic centers have teams who fully understand this process, are greatly experienced with these kinds of challenges, and produce excellent data as a result.

The collaborative needs of the industry during Phase III trials are similar to those in Phase II, except that the process is now on a large scale. The ideal drug dose may not be fully known, but a range is usually available from Phase II such that only a few dose groups must be studied. The adverse effects are better characterized, so that newly participating physicians know more of what to expect. Again, the studies are likely to be controlled, requiring local knowledge of how to perform complex studies and keep meticulous records. All aspects of GCP, of course, apply to Phase III.

After a drug is approved, companies very often continue studies in patients for a variety of reasons. Studies in children may be needed. A new dosage form may need to be investigated.

P.1482

Studies in other countries may be needed for country-specific approvals. These are just a few of the reasons for Phase IV studies, all of which require collaboration with physician caregivers who are willing to become physician investigators.

Summary and Conclusions

Drug discovery and development is a very complex, expensive, time-consuming process (Fig. 1). Pharmaceutical companies are very sophisticated in this process, but need collaboration, especially during discovery and clinical research. The collaborative opportunities for academia are many, and are especially reflected in the rapid growth of clinical trial participation by physician-investigators in these and other institutions.

Chapter 140

Clinical Trials of Antiepileptic Drugs in Adults and Children

Jacqueline A. French

Tracy A. Glauser

Bernd Schmidt

Introduction

The modern age of drug testing was ushered in in 1962 by the passage of the Kefauver-Harris amendments to the Federal Food, Drug, and Cosmetic Act.[25] This act required for the first time that a drug be proven effective prior to marketing and sale. In most countries, extensive efficacy and toxicity testing is required before a new antiepileptic drug is approved for general use, supervised in the United States by the Food and Drug Administration (FDA) (Chapter 142) and in Europe by the European Agency for the Evaluation of Medicinal Products (EMEA) (Chapter 143). This information is obtained by performing clinical trials. These trials are of great significance for two reasons. The first is that if trials fail to demonstrate efficacy to the satisfaction of registration boards, a potentially useful drug may not emerge on the market. The second is that at the time that a drug is approved for clinical use, all that is known about its efficacy and toxicity derives from information obtained through clinical trials. Improper trial design or inadequate analysis of results may lead to misinformation and misuse of the drug. It is of vital importance that these trials be performed in a logical and comprehensive manner. This chapter will explore aspects of antiepileptic drug trials, including design issues, different types of trials, ethical issues, special populations, and analysis of results.

Phases of Testing in Humans

After a drug has undergone extensive in vitro experiments and testing in animal models of seizures and epilepsies and there is preclinical evidence of efficacy and safety, an investigational new drug application will be obtained from regulatory agencies indicating that the drug is ready to be tested in humans. Before efficacy can be assessed, the drug must be evaluated in volunteers (phase I testing). Phase I testing is performed for evaluation of safety, pharmacokinetics, and human metabolism. Initially, single rising doses will be administered to healthy volunteers in order to determine the dose at which toxicity will emerge, and to make preliminary assessments of pharmacokinetics; these studies expose approximately 20 subjects. Single-dose studies will be followed by more chronic administration studies. Again, toxicity and pharmacokinetics are assessed, including determination of drug half-life, clearance, volume of distribution, time to maximum serum concentration, and presence or absence of nonlinear pharmacokinetics. Metabolites and means of elimination are identified.[13] An important determination from these studies is maximum tolerated dose. Phase I may also include studies of special populations who may be at particular risk from a given drug. For example, a drug with renal metabolism may be tested in patients with renal failure.

Obtaining quality information during phase I is critical for proceeding to phase II trials. The first testing of epilepsy patients will usually occur during phase II, which includes initial efficacy and safety testing in the population of interest, and usually also includes the first large multicenter safety and efficacy trials. The earliest trials are usually what is called “proof of principle.”[64,65] These trials are performed to get a first impression of whether the drug will be antiepileptic in humans. Based on this trial, a “go–no-go” decision may be made by the company testing the drug. In other words, the company will decide whether an investment in larger, more expensive testing is warranted. One example of a common proof-of-principle trial is a study in photosensitive epilepsy patients. Photosensitivity studies are ideal as an early trial, as they can usually be performed with a range of single doses. The fact that an investigational drug can be shown to reduce or eliminate the photoepileptiform response can be taken as an indication that it has passed the blood–brain barrier and may have an antiseizure effect, demonstrated on the surrogate marker of the photoparoxysmal response. Efficacy in this model is also often taken as an indication that the drug may have activity against a broad spectrum of seizure types.[11,64] Early trials may also include a maximum tolerated dose (MTD) study in epilepsy patients, as tolerated doses are known to differ significantly between normal volunteers and patients. Early trial results may also give a first indication of potential pharmacokinetic as well as pharmacodynamic interactions.[65] Several large phase II trials have failed because the dose has been poorly chosen.

Phase III testing includes continuation of safety and efficacy testing as well as trials for specific indications, or in special circumstances. Monotherapy studies and studies in patients with distinct epilepsy syndromes such as the Lennox-Gastaut syndrome might be included in phase III testing plans. When the drug is approved, trials frequently continue during phase IV or postmarketing studies with the aim to define the drug's optimal use in a general clinical practice population and to broaden the well-documented safety database. Other pivotal phase III trials for extended indications such as pediatric use, primary generalized seizure types, or a monotherapy indication may be pursued either before or after initial approval. Postmarketing surveillance is also done, looking for rare adverse events, pregnancy outcomes, and other information that might not be obtainable in preapproval data.

Efficacy Trials

As noted above, efficacy trials are usually performed as part of phases II and III. These pivotal trials are designed to definitively determine whether a drug has antiepileptic potential in humans. Trial design and implementation is driven by several

independent and potentially conflicting needs. These include the need of a pharmaceutical company to find out whether a compound is worth developing, in the least expensive way possible; the need of the company to demonstrate efficacy and safety to registering agencies (e.g., the FDA and EMEA); and, lastly, the need of physicians to know the potential utility of a new drug in the treatment of patients with epilepsy. It is frustrating to clinicians that the last need, which they may see as the most vital, may have the least influence on trial design. Unfortunately, if the first two needs aren't met, the drug may never come to market. Only after the drug is registered may there be the "luxury" of determining its clinical properties.

The fact that many efficacy trials are registration driven explains why trial design is very different in different countries. In Europe, active-control monotherapy trials are considered acceptable, and crossover designs have been more common in the past. Both these design elements are seen as problematic by the FDA, and are rarely or never used in the United States. As development programs have become global programs aiming at one dossier used for filings around the world, study designs are fairly standardized nowadays.

Trial Design

Need for Blinding and Control Groups

Efficacy trials must compare two treatment groups in a blinded fashion. It is not typical to use a population as its own control, comparing a baseline pretreatment epoch with an epoch after treatment has been initiated, because of placebo effect. In other words, patients who have an expectation that they may improve will demonstrate improvement with or without new treatment.

Physicians may have difficulty accepting the reality of the placebo effect in intractable epilepsy patients, who have been switched from treatment to treatment without benefit, yet time and again patients in the placebo arm of multicenter epilepsy studies will demonstrate a substantial seizure reduction. The degree of placebo effect will vary from study to study for unclear reasons. In recent studies, 0% to 36.5% of patients in the placebo arm of blinded trials showed a 50% or greater seizure reduction over a standard 3-month exposure period.[14] The degree of a placebo effect also varies between regions and individual centers within one large multicenter trial.

Active Versus Placebo Comparisons

For some purposes it is considered acceptable or even desirable to choose two active treatment arms as blinded comparison groups. Some of the best early examples of this type of trial were two VA cooperative studies,[46,47] which randomly assigned patients with newly diagnosed seizures to different antiepileptic drug therapies. This allowed direct comparison of these drugs in terms of both efficacy and safety. A large number of active control comparison trials have been performed in the last decade, comparing standard drugs such as carbamazepine and phenytoin to the newer drugs.[10,12,15,17,18,39,41,55,68] This type of trial may be extremely informative for clinical purposes. In Europe, they have contributed to the registration of a number of new antiepileptic drugs (AEDs) as monotherapy. In the United States, however, the FDA does not accept active controlled trials as proof of monotherapy efficacy.[43] These active-control trials, including the VA cooperative studies, were able to demonstrate equivalence between drugs. In order for the FDA to accept a trial as proof of efficacy, superiority of the new drug must be demonstrated.

Adjunctive Versus Monotherapy Trials

There are inherent disadvantages to adjunctive, or add-on, trials in which active treatments or placebo is added to the patient's baseline antiepileptic drugs. It is more difficult to prove efficacy in a patient who is already partially treated. Side effects may be magnified by combining drugs, and pharmacokinetic interactions may alter baseline or experimental drug levels. Despite these drawbacks, most efficacy trials use an adjunctive therapy design because of the ethical issues raised by monotherapy parallel trials involving placebo in patients with epilepsy. New trial designs were developed in the 1990s that attempted to circumvent ethical issues and permit monotherapy studies. The two most popular designs were described by Pledger and Kramer.[53] The first, which involves randomization to drug or placebo in inpatients who have had their background antiepileptic drugs withdrawn for presurgical evaluation, has been deemed too short to be used for registration purposes and not relevant for extrapolation to a general clinical population, and is now used primarily for a proof-of-principle trial.[13,28,63] A second design is performed in outpatients.[8,29,38,53,60,62] Patients are randomized to treatment with an experimental drug or placebo, after which baseline therapy is withdrawn over 2 to 8 weeks. A modified, or "ethical," placebo is utilized rather than a true placebo to reduce the likelihood of status epilepticus or secondary generalization. This can consist of a minimally effective dose of either the same investigational drug or of any other therapy presumed to be less effective than the test drug. A starting dose of valproic acid (15 mg/kg) has been employed in a number of trials for this purpose. Outcome is assessed in terms of "failures" and "completers." Failure is determined on the basis of escape criteria, such as doubling of seizure frequency, occurrence of generalized tonic–clonic seizures, or increase in seizure severity. If more patients receiving the experimental drug at a therapeutic dose in monotherapy can complete the trial, without fulfilling escape criteria, than patients receiving modified placebo in monotherapy, the treatment is considered effective in monotherapy. This trial design has been successfully used to obtain a monotherapy indication from the FDA for oxcarbazepine and lamotrigine (withdrawal to monotherapy in refractory patients). A drawback of this design is that antiseizure effects are evaluated in an AED withdrawal situation only.

Two other monotherapy designs have been employed to gain FDA monotherapy approval. These have been performed in patients with newly diagnosed epilepsy. One study compared oxcarbazepine to placebo in patients having frequent seizures (average 5.5 per month) at baseline.[59] The end-point was time to third seizure. Another study compared 50 mg of topiramate to 400 mg in newly diagnosed adolescents and adults with partial-onset seizures.[1] Outcome measures included time to first seizure as well as seizure-free rate at 6 months and 1 year. Although all these monotherapy trials led to registration of at least one AED as monotherapy, the trials continue to raise ethical as well as pragmatic issues. For this reason, efforts are under way to devise new methods to perform monotherapy trials.[30,34]

Parallel Versus Crossover Designs

In parallel trials, patients are randomly assigned to one of two treatment groups for a period of time. Their seizure frequency during the treatment period is compared to a pretreatment baseline. Seizure outcome is compared between the two groups. In a crossover design, patients are also randomly assigned to two treatment groups, but after a period of time each group is crossed over to the other treatment, usually after a washout period. Outcome as compared to baseline is determined for each treatment. There are some advantages to a crossover design. Far fewer patients are required to perform the trial, provided

that the subjects complete all required crossover periods, including the washouts. Also, if two active treatments are used, this trial design is more like clinical practice, in which patients are usually crossed from one treatment to another. Each patient will receive both treatments, allowing more direct comparison of efficacy and tolerability. The disadvantages of a crossover trial include a much longer duration, risk of patients dropping early, and, more importantly, a potential unblinding of the trial. This is of the utmost concern in a trial that compares placebo to active drug. Patients may be able to discern a difference in side effects when switching from placebo to drug, or vice versa. There may be carryover effects of a drug, which would impact the initial portion of the second treatment phase. For these reasons, the FDA and the EMEA do not favor such trials.

Patient Issues

Overall trial makeup is influenced as much by the population chosen for the trial as by the trial design. Trial populations may differ in terms of epilepsy syndrome, as well as disease severity.

Epilepsy Syndrome Selection

The majority of phase II and phase III AED trials are performed in patients with partial epilepsy, specifically with complex partial seizures. These patients comprise the majority of adults with uncontrolled seizures, and the pharmaceutical companies need an indication from registering bodies to treat partial seizures, for market share. With rare exceptions, a drug that is unable to treat such patients would not be profitable to develop. Recently, there has been discussion regarding bringing drugs forward for niche indications or for orphan diseases such as Lennox-Gastaut syndrome. Nonetheless, to date no new AEDs have been approved without a partial seizure indication.

When a partial seizure indication has been obtained, further studies may be performed to assess efficacy in other syndromes. Studies in different syndromes offer their own potential obstacles and may impact trial design. One example can be seen in the Lennox-Gastaut population. Initially, it was felt that seizures in these patients were easily recognizable, and that placebo effect would not be an issue in this severely impaired population. Therefore, open trials were undertaken in patients treated with cinromide, a drug that was in development. The results were very promising, demonstrating a >50% response. However, when the study was repeated with a placebo control, it was found that the entire treatment effect could be attributed to a placebo response.[23] It was felt that this reflected not only a bias in parental observation, but also a difficulty in differentiating between seizures and abnormal behaviors, common in this population. As a result, subsequent trials incorporated video-electroencephalographic (V-EEG) monitoring to train parents on differentiating seizures. In addition, the primary outcome variable was reduction in motor (tonic, atonic, and generalized tonic–clonic) seizures, which are the most recognizable. This led to a successful trial design, and ultimately to approval of three of the new AEDs (felbamate, lamotrigine, and topiramate) for use in the Lennox-Gastaut syndrome.[26,49,61] This and other examples of potential populations, study limitations, and ways of circumventing them are given in Table 1.

Seizure Severity

Another patient characteristic that may impact AED trials is disease severity. It cannot be taken for granted that a drug that has been proven to be highly effective in intractable, severely affected patients will also be the most ideal drug for new-onset patients. It is feasible that some drugs may work preferentially in refractory patients, due to specific pathophysiologic alterations that are found in these patients. One possible example of this relates to the antiepileptic drug vigabatrin. This drug exhibits retinal toxicity in selected populations and is not available in the United States, but is approved in Europe. In placebo-controlled add-on trials in refractory patients, this drug appeared to be more potent than almost any other available antiepileptic drug.[31] However, when tested in a head-to-head fashion against carbamazepine, it was not as effective.[16]

Once a drug has been proven safe, trials in new-onset patients are frequently performed. These trials have usually been performed as active-control comparisons, in which an investigational agent is compared to a standard agent, with the exception of oxcarbazepine, which was tested against placebo.[59] Both placebo control and active control may have drawbacks to confirm the efficacy of AEDs in newly diagnosed patients. Placebo-controlled trials are short by necessity, and only prove that a drug is better than "nothing." On the other hand, if the population for an active-control equivalence trial is chosen poorly, if the trial is not designed properly, or if the sample size is not sufficient to have the power to show a difference when one exists, then equivalence may be demonstrated between two drugs for which there actually exists a clinically meaningful difference in efficacy or safety.[34]

Women of Childbearing Age

Women of childbearing potential also bear further consideration. In earlier epilepsy trials, women were only included in studies if they were postmenopausal or had undergone surgical sterilization. Recently, there has been pressure to include more women in trials at an earlier point in development.[42] In order to do this, it is necessary to expose women of childbearing potential to drugs that do not have established efficacy and safety. Most protocols lay out strict guidelines for contraception that is considered acceptable during a trial based on potential hormonal interaction data. Occasionally, contraception will fail and a pregnancy will ensue. It is often the policy at present to discontinue the investigational drug immediately in such a situation. This may not always be the safest course for the mother or fetus, particularly if the individual had a very significant seizure reduction from that drug. Postmarketing pregnancy registries by sponsor companies and academic consortia have been set up to better investigate the comparative teratogenicity of AEDs.

Children

Clinical testing of antiepileptic drugs considers children separately because of the age-related changes in both brain and overall physiologic and biochemical status that occur during childhood along with the age dependency of certain seizure types and epileptic syndromes. Most studies on AEDs have considered "children" to be those younger than 12 years of age, and have included those aged 12 years and over in trials designed primarily for adults. The population of patients younger than 12 years is often subdivided into neonates (<1 month postnatal age); infants (1 month up to 2 years), and children (from 2 years up to 12 years). The children group can be further subdivided into preschool (2 to 5 years) and school age (5 to 12 years). This last division is not arbitrary; there are differences in the type of epilepsies likely to present before and after 5 years[57] and there are different methods and scales used to monitor behavioral and cognitive side effects between these two age groups.

Table 1 Epilepsy Syndromes and Potential Obstacles They Present

Epilepsy syndrome	Potential obstacle	Solution
Partial seizures	Simple partial seizures may be subjective and difficult to count	Count only observable simple partial or complex partial seizures
Primary generalized epilepsy (absence, myoclonic and tonic–clonic seizures)	Seizures usually well controlled on currently marketed medications Absence seizures may not be clinically apparent	Perform add-on study in refractory patients, using minor seizures such as myoclonus as end-point Perform inpatient monitoring, measuring spike-wave on EEG for

		absence
Lennox-Gastaut syndrome	Too many seizures to count accurately; in severely retarded subjects, abnormal behaviors may not be distinguishable from seizures	Use videotape to train parents to distinguish seizures from behaviors Use tonic–atonic seizure frequency as an independent outcome variable (less frequent and easily countable)
Neonatal seizures	Difficult to count clinically Difficult to do add-on, but placebo control raises ethical issues	Use video-EEG to count events Perform short placebo-controlled trials
Status epilepticus	Difficult to obtain informed consent Convulsive and nonconvulsive status have different prognoses	Obtain waiver of consent Carefully define clinical status syndromes, and randomize to different groups

EEG, electroencephalogram.

Trials targeted at resistant partial seizures in adults can be relevant to the same type of disorder in childhood. However, the spectrum of childhood treatment-resistant epilepsies is different than those in adulthood, and it should not be assumed that AEDs effective in adults will be appropriate for

P.1490

the resistant epilepsies special to childhood. In the infant, early myoclonic encephalopathy and early infantile epileptic encephalopathy[51] respond only rarely to established AEDs. West syndrome, severe myoclonic epilepsy in infants, myo-clonic astatic epilepsy, and Lennox-Gastaut syndrome, although responsive to some of the more recently introduced AEDs, remain difficult to treat in at least half of affected children. Epilepsies with cognitive symptomatology, such as acquired epileptic aphasia (Landau Kleffner syndrome) and epilepsy with continuous spikes and waves during slow sleep, are rare, with difficult-to-quantify clinical features making these patients challenging subjects for AED trials. Although these syndromes are relatively rare in adults, epilepsies with features of Lennox-Gastaut and West syndromes may persist beyond childhood. Children with these epilepsies deserve to have closely monitored trials designed to specifically address their needs.

The patterns of seizures and the designations of epileptic syndromes may evolve throughout childhood; these transformations are probably related to maturational features in the brain. For most circumstances, it is not known whether this, of necessity, means that the newly acquired state is likely to be more or less responsive to AEDs. However, the researcher must appreciate that alterations in seizure type during a trial can be due to evolution of the epilepsy, rather than the AED. For example, about one third of patients with an initial presentation of early infantile epileptic encephalopathy (EIEE, with suppression burst on the EEG) can progress to West syndrome (with hypsarrhythmia on EEG) and later appear to have Lennox-Gastaut syndrome (with diffuse slow spike-wave on EEG). Alternatively, some infants with initial EIEE later have focal spikes, having, in some cases, had hypsarrhythmia as an intervening stage.[50] Children with West syndrome often have resistant partial seizures later. Another transformation that would be problematic for the AED trialist occurs with severe myoclonic epilepsy in infants. Predominantly clonic, often lateralized, seizures occur in the first year of life, followed by myoclonic jerks and partial seizures during the second year, accompanied by the development on the EEG of generalized spike and polyspike waves, photosensitivity, and focal abnormalities.[24] Even in noncatastrophic epilepsies transformation can occur. For example, although childhood absence epilepsy is not accompanied by other seizure types in 60% of cases, generalized tonic–clonic seizures or progression to juvenile myoclonic epilepsy may occur in others.

The majority of inborn errors of metabolism of which seizures, particularly myoclonic seizures, are symptomatic present in childhood, particularly in infancy. Consideration of whether such an underlying condition could be present but unrecognized must always be an important feature of the assessment of suitability for AED trials. Alternatively, knowledge of the specific biochemical defect and the mode of action of the new AED might allow prediction of success or eliminate the likelihood of precipitation of adverse biochemical states. Maximal understanding of the biochemistry and pharmacology of new AEDs is essential before they are used for childhood seizures.

Drug Issues

In order to design and successfully implement a clinical trial with a given drug, a significant amount should be known about that drug's unique characteristics. Every trial design will not work for every drug, and innovative alterations may be necessary in a standard design, due to specific drug properties. Failure to fully explore drug–drug interactions early on can lead to problems in a phase II trial. For example, in an early phase II trial, felbamate was used as adjunctive therapy in patients taking carbamazepine as a baseline drug.[70] This trial failed to demonstrate efficacy against placebo, in part because felbamate caused a reduction in carbamazepine levels, possibly leading to seizure exacerbations. Felbamate is also known to increase phenytoin levels by 20%. When felbamate was tested in a Lennox-Gastaut protocol, all patients had to have phenyt-oin doses reduced by 20% prior to the baseline period.[26] If this had not been done, the increased phenytoin levels in the treated group could have lead to toxicity, and the study could have been unblinded. Similarly, since valproic acid doubles the half-life of lamotrigine, patients on valproic acid were excluded from blinded trials with that drug.[6,40,45,48] Pharmacodynamic

P.1491

interactions may also confound a trial. In the only adjunctive trial of oxcarbazepine in adults with partial seizures, the dropout rate in the high-dose group was >70% in the absence of pharmacokinetic interactions,[5] despite this dose having been very tolerable in a monotherapy trial.[9] It is felt that the high dropout rate was due to pharmacodynamic disturbances when oxcarbazepine was added to other AEDs, coupled with a relatively rapid titration. Knowledge about the tolerability of rapidly titrating an AED may be important for other reasons. Inpatient monotherapy trials require rapid titration of study drug, as the treatment period is usually 2 weeks or less. Drugs that need a slow titration would not be suitable for this type of trial.

Selecting the appropriate dose range is essential for running a successful trial. In most circumstances, a dose approaching the maximally tolerated dose should be selected. If too high a dose is chosen, there will be excessive patient dropouts from toxicity. If, on the other hand, too low a dose is selected, efficacy may not be demonstrated. Overall perceptions about a drug may be predicated on the dose chosen for phase II studies. For example, initial adjunctive studies with topiramate (see Chapter 159) were performed at or near the maximally tolerated dose. This produced the appearance of a very potent drug, with a high side effect profile. In contrast, trials with lamotri-gine (Chapter 150) and gabapentin (Chapter 149) were performed at lower doses, resulting in an appearance of only moderate potency but good tolerability. If different doses had been selected, the results may have looked quite different.

The pharmacokinetic differences between children and adults cannot be ignored during drug evaluation. Most drugs administered orally are absorbed by passive diffusion in the small intestine. Multiple age-related factors affect the rate and extent of oral medication absorption, including gastric pH (reaches adult values by 2 to 3 years), gastric acid secretion (adult values by 3 months), gastric emptying (adult values by 6 to 8 months), and intestinal motility (variable in neonates, unknown when it reaches adult values). Oral absorption of phenobarbital and phenytoin are reduced in neonates compared to older children. Similar problems exist with intramuscular absorption in neonates; at this age the rectal route is probably the most reliable, provided a suitable formulation can be obtained. In contrast, in infants and children, drugs given orally or intramuscularly are absorbed more rapidly than in adults.

Age-dependent distribution factors (e.g., changing body composition, variable degree of protein/tissue binding) combine with physiochemical properties of the drug to determine a drug's distribution characteristics.

Body composition changes markedly from newborn to adult. For example, a newborn's brain mass and skeletal muscle mass is 12% and 25% of its total body weight compared to 2% and 40% in adults, respectively. Acidic drugs are less well bound to plasma proteins in neonates and infants than in older children. Weak bases are also less well bound in neonates, but binding may be increased in infants and children.

In the absence of exposure to enzyme-inducing drugs in utero, metabolic degradation of AEDs is very slow during the first 2 weeks. A rapid increase in metabolic rate occurs for the next 2 years, after which the rate gradually declines to adult levels. Renal excretion of drugs is very slow in the neonate, but is comparable to that of the adult by age 6 to 8 months. The highest relative capacities to excrete AED are found in infants aged 1 to 13 months.

Some drug-specific pharmacokinetic phenomena, such as whether a drug undergoes linear or nonlinear metabolism, is constant across all ages. Information obtained in adults on this type of AED property is relevant to all ages. Compared to adults, children tend to receive more short courses of other types of drugs (e.g., antibiotics); it is important that interactions, and particularly effects on pharmacokinetics of a trial AED, are explored and recognized. Febrile illnesses, which may affect drug elimination, are common in young children. Should fever occur during an AED trial, its presence should be noted, both as a possible adverse reaction and as a potential influence on pharmacokinetic parameters.

Analysis of Results: Standard Measures

The standard measure used in analysis of AED trials is seizure frequency. Typically, different seizure types are counted separately. For example, for a trial evaluating patients with partial seizures, simple partial, complex partial, and secondarily generalized seizures would be analyzed separately.

Choosing an Outcome Variable

In every trial, a primary outcome variable must be chosen in advance. This is to prevent an ineffective drug from appearing effective because there was a chance reduction in seizure frequency for one seizure type out of many. Typically, reduction in complex partial seizures is chosen as the primary outcome variable. It is much more difficult to demonstrate reduction in simple partial seizures, because they are more variable and subjective, and in secondly generalized seizures, because only a fraction of enrolled patients will have this seizure type.

Handling Seizure Data

There are intrinsic problems inherent in analyzing seizure data. One can get a good understanding from an example given by Gordon Pledger.[54] Two patients are enrolled in a trial. One has a baseline seizure rate of 50 per month, the other 100 per month. Both patients have a reduction of 50 per month. Whereas one has a 50% reduction in seizure frequency, the other has a 100% reduction. Has the drug been equally effective in both patients? In another example, how do two patients compare when one who has gone from three to two seizures per month, and the other has gone from 30 to two per month? Seizure data are nonparametric. One way of handling this problem is to normalize the data prior to applying a statistical treatment. Another is to use an analysis that is suitable for nonparametric data. Since there are so many ways to handle the data, a statistical treatment must be chosen in advance. Unfortunately, not all of the statistical treatments are intuitively comprehensible to a clinician who is trying to review the data. For example, the multicenter gabapentin trials were analyzed using response ratio.[35,36] This consists of the difference between the treatment and baseline seizure rates divided by the sum of the two rates; for clinicians, this ratio has no obvious clinical meaning. The other problem with the vast array of methods of analysis is that results from different trials are not easily compared.

Intent to Treat

All drug study outcomes are evaluated by "intent to treat" analysis. This means that all randomized patients are entered in the analysis, even if they drop out early on. Using the last-observation-carried-forward (LOCF) approach, the last obtained seizure frequency count will be used as outcome, even if the patients did not complete the exposure required by the protocol. The impact of dropouts on a trial may vary based on the chosen outcome variable as well as the trial design. Dropouts are often "censored" from the results at the time of dropout. This is why in a trial of oxcarbazepine in which over half the patients dropped out of the 2,400-mg arm, the

P.1492

50% responder rate could still be 50%.[5] On the other hand, in some circumstances, dropouts will reduce the likelihood of a significant outcome. For this reason, investigators must make a determined effort to enroll only patients who are likely to complete the trial.

Other Analysis Problems

Many patients with epilepsy have seizures in clusters. This can cause problems in analysis in situations when seizures are so frequent during a cluster that they seem to blend together. It may be impossible for an observer to separate or count the seizures. This problem is particularly troublesome in Lennox-Gastaut trials. Enrolling patients who do not have epilepsy at all would cause serious problems in data analysis. To prevent this, some trials require electrographic evidence of epilepsy in the form of an interictal abnormality, although this is becoming less frequent due to the problems it causes in recruitment. The presence of such an abnormality may also be helpful in correctly classifying patients.

Noncompliance is another serious potential problem. A drug cannot be effective if the subject is not ingesting it. Because of intent-to-treat analysis, even patients in whom there is evidence of noncompliance will be included in analysis. Patients with known noncompliance must be excluded as subjects, and compliance must be monitored during the trial by pill counting or other means.

Nonstandard Outcome Measures

Seizure frequency may be a crude measure of antiepileptic drug effect. Unquestionably, patients may receive substantial benefit from a drug without any change in seizure frequency. Recently there has been renewed interest in exploring novel outcome measures.

One such outcome measure is seizure severity. After receiving a new drug, a patient might experience a significant reduction in falling and injury with seizures, or postictal period may shorten, without any reduction in seizure frequency. Several seizure severity scales have been developed to objectively assess changes in seizure severity.[2,3,4,19,20] The scales may incorporate information obtained by questionnaire from both patients and observers. One such scale has been used successfully to evaluate outcome in a trial of lamotrigine.[67] At the present time these data are considered purely elective and cannot be used in isolation for drug approval.

Quality-of-life scales are another way of assessing outcome from clinical trials. These scales attempt to combine efficacy, tolerability, and safety in an overall measure. Information is again obtained from questionnaires filled out by patients and significant others. The most frequently used scale is the QOLIE (quality of life in epilepsy). More information about these scales can be obtained in Chapter 100. Although these scales are certainly valuable, they have been criticized because they cannot distinguish the various factors that may go into "feeling better." For example, if a drug had antidepressant properties, patients' quality-of-life scores might improve substantially, and yet the drug may have no antiepileptic effect whatsoever.

Another method that has been used to assess overall outcome is time on the drug. If patients or their physicians are dissatisfied with either efficacy or tolerability of a drug, they are likely to implement a change to another agent. In an early VA cooperative study, four antiepileptic drugs were compared in new-onset patients.[47] Although there was no significant difference in efficacy, patients discontinued phenobarbital and pri-midone earlier than phenytoin and carbamazepine, due to side effects. Many of the newer AEDs have also demonstrated longer time on a drug when compared to older AEDs in active-control equivalence trials, and this has always directly related to better tolerability.[10,12,17,18,21,39,58,68] However, in some of these trials, some efficacy outcome measures, such as time to first seizure, have gone in the opposite direction to tolerability outcomes, making interpretation of time-on-drug outcomes difficult.[32] Complicating matters, interpretation of drug tolerability outcomes may be confounded by titration rates, selection of doses, and use of suboptimal formulations such as immediate-release carbamazepine (used in earlier trials vs. controlled-released carbamazepine formulations used in most recent studies).

Safety Trials

Safety of an investigational AED can be assessed in several ways. Phase II trials are designed to assess both safety and efficacy. In addition, some trials may be performed solely for safety evaluation. These are usually part of phase III.

Safety Testing during Phase II Efficacy Trials

Large multicenter placebo-controlled trials provide the first information about drug safety and toxicity. Even in a placebo-controlled trial, toxicity directly related to an investigational drug is difficult to determine. Most of these trials are add-on. Pharmacodynamic interactions with baseline AEDs will tend to amplify apparent toxicity from the new drug. In a study by Schmidt, toxicity developed in 90% of patients who were converted from monotherapy to polytherapy with standard agents.[66] Monotherapy studies almost always demonstrate lower adverse event profiles than adjunctive studies with the same drug. It is very important to compare side effects in the placebo and drug-treated groups. Also, since this list of side effects usually includes 20 to 30 items, by chance some may have a statistically higher occurrence in the treatment group. Several trials must be performed before a clear picture of toxicity develops.

Many development plans include studies comparing multiple doses. If such information is not available, it may be very difficult to determine which side effects are dose related and which are idiosyncratic, although investigators who have participated in the study may have a sense of this from their clinical experience.

Placebo-controlled studies usually have a 3-month treatment duration and are performed in 60 to 120 patients per dose arm studied. These trials cannot assess long-term toxicity, nor will they be likely to uncover rare idiosyncratic toxicities, such as blood dyscrasias and liver failure. For this reason, studies are necessary using more chronic treatment in a large number of subjects. Part of this information will derive from subjects who choose to remain on a drug after a placebo-controlled trial is completed. To obtain broader information, a drug development plan will frequently include a safety trial, in which a large number of patients are treated for 1 to 2 years. These trials are difficult to interpret, because there is no control group. Certain adverse events, such as sudden death and psychosis, are more common in patients with epilepsy than in the population at large. The true incidence may not be known, particularly for the intractable population that are candidates for investigational drug trials. In recent years, several adverse events have been uncovered either in long-term open label studies or even when the drug has been used after approval. Significant examples include visual field defects associated with vigabatrin, glaucoma associated with topiramate, hypohidrosis associated

with both topiramate and zonisamide, and renal calculi associated with topiramate and zonisamide.[27,44,56,71]

Safety Issues in Children

The pediatric epilepsy population presents special safety concerns including potential effects of the investigational AED on brain growth and development, cognitive development, and physical development. Normal development of the brain and, in particular, of the neocortex has been reviewed by Evrard et al.[31] The chemical factors underlying the various anatomic and physiologic stages of brain maturation remain ill understood. The neuroepithelium is derived from the dorsal midline ectoderm. Segmentation is induced by the notochord. Neuronal and glial elements are generated by the neuronal tube. During the first half of gestation, after neurulation, there is neuronal multiplication, followed by neuronal migration and, later, regional development of the cerebral vesicles. Toward term, growth and arborization of the neurons is followed by the development of synapses, myelination, and gliogenesis. In early childhood, considerable plasticity of development is present, with remodeling of synaptic connections and loss of those apparently redundant. At this stage, persistence of transmission through unwanted pathways, such as may occur in seizures, is clearly undesirable, yet it is equally important that an AED not inhibit normal synaptogenesis.

Neuronal migration and its disorders are now recognized to be of major importance in the pathogenesis of epilepsy.[52] Anatomic events are well described: Neuroblasts in the periventricular germinal matrix migrate to the neocortex in close attachment to specific glial cells with which they interact in a dynamic manner through cell adhesion molecules, but the underlying biochemical events remain speculative. Thus, the brain of the young child is undergoing considerable anatomic and physiologic change. This is particularly so in preterm and term neonates, and to a marginally lesser extent in the infant. By the nature of their activities, AEDs are developed for their abilities to reduce neuronal excitation. Such damping of cerebral activity might, in theory, lead to failure of development of appropriate synaptic connections, to poor perpetuation of their connections, or to early or excessive loss of synapses. It is expected that major effects on the immature brain would be identified in preclinical trials in animal models. Nevertheless, awareness of potential problems in relation to brain growth and neurologic and cognitive development is important in AED trials, especially when previously untried agents are prescribed for immature infants who, by virtue of the presence of seizures, already have abnormal brain function. Serial assessments of head circumference and neurodevelopmental status are essential in pediatric AED trials.

Some established AEDs are associated with unacceptable weight gain in childhood. It is important to closely monitor new AEDs for this effect. Established AEDs can cause alterations in blood levels of hormones, but these do not appear to be of clinical importance for height growth.[69] Nevertheless, effects on height and timing of puberty need to be considered when using a trial AED.

During childhood, the liver, kidneys, and other organs are growing and theoretically could be more vulnerable to adverse effects of AEDs; their growth also may indicate a greater capacity for recovery. To date, in the absence of specific inborn errors of metabolism, nonneurologic organs are no more likely to suffer damage in childhood than in adulthood.

It is important to ensure that every pediatric subject in a drug trial has been thoroughly evaluated (prior to study entry) for an underlying metabolic or other chronic medical disorder that could worsen as a result of participation. The greatest risks lie with the severely handicapped and the very young (whose seizures may be the first signs of an underlying disorder). In general, a child with epilepsy who is otherwise healthy (e.g., normal growth and development, no history of chronic medical problems) is unlikely to have a significant underlying metabolic disorder. However, caution for all neonates, infants, and young children is appropriate both prior to entry into the trial and as they progress through the study.

Prior to commencing a trial AED, tests of renal and hepatic function, a full blood count, an electrocardiograph, and microscopy of the urine are essential. Certain biochemical tests, such as alkaline phosphatase, have different normal values in children, and these must be acknowledged. Only in exceptional circumstances is it acceptable to use a trial drug when the biochemical status is other than completely normal.

Ethical Issues

Many antiepileptic drug trials involve investigational drugs. Particularly in early stages of testing, the risks of treatment with these agents may not be known. Even in later stages of testing, in trials involving standard drugs, a rigid protocol may impose inconveniences and risks to subjects, when compared with standard clinical care. Yet, these trials are vital in the process of drug development and approval. Any patient who enrolls in an antiepileptic drug trial must be made aware of the potential risks and benefits of participation, by means of informed consent. In this respect the Helsinki-Charter and its amendments look after the patient's best interest, and its implementation is locally supervised by institutional review boards (IRBs).

It is always difficult to determine what risks are appropriate for patients to be subjected to. Most patients enter trials with investigational drugs because they have failed all standard drugs and continue to have seizures that impair their quality of life. They may also be influenced by the promise of free medical care or free drugs, which are offered by pharmaceutical companies. Because of this, it is frequently the most severely afflicted patients who are enrolled in trials. This may affect trial outcome, as these patients may be the most difficult to treat. Whereas it may be more beneficial for drug development to enroll less severely affected patients, physicians may be constrained by the ethics of doing so. Each physician must make his or her own decisions on who they feel comfortable enrolling. The further a drug is in development, the more comfortable a physician may feel in enrolling patients who have less intractable epilepsy.

In most AED trials, the patient's treating physician is an investigator in the study. This raises potential conflict of interest. The physician is usually paid commensurate with the number of patients enrolled. There may be circumstances in which two trials are running concurrently, one of which is more lucrative than the other. That same physician is the one who will explain options for treatment. A physician in this situation must guard against painting an overly rosy picture of an investigational drug. This is more true now than ever, as more new drugs are approved and drug study subjects become more difficult to find.

Ethical Issues in Children

The multiple ethical issues involved in research involving children are examined in detail by Grodin and Glantz.[38] Some ethical issues that deserve particular mention include the need for parental written consent and, if possible, child consent or assent; the importance of considering the patient's epilepsy

syndrome on trial suitability; the investigator's large responsibility to properly classify the patient's seizure type and epilepsy syndrome; and lastly, where possible, the need to take action to reduce patient pain during the trial.

Persons below the age of 18 (or, in some societies, 16) are considered not to be competent to make their own decisions about treatment. For most children, the parent or legal guardian is considered an allowable surrogate in the matter of consent to medical treatment. This presumption is made on the basis that such a surrogate will have the child's best interests at heart. In addition, since parents are inevitably involved in the consequences of treatment choices, they have a right to stand by their own values in relation to the child's upbringing, and they are entitled to promote circumstances in which the family may function as an intimate unit.[38] The child's consent to such parental involvement must be assumed, but this makes it particularly incumbent on the investigator to ensure that parental comprehension of the risk–benefit ratio is maximized. Written information and written consent are essential. Clearly, in children able to understand the implications of a drug trial, information should be given to the individual involved and that individual's written consent or assent obtained.

For many children with epilepsy, a specific syndrome can be identified. Where this is possible, a reasonably accurate prognosis can be given. The threshold for using a trial AED should be higher for those epilepsies that are likely to remit than where severe, frequent seizures are expected to persist despite optimal use of established AEDs. Thus, only if it is believed that side effects would be fewer should a trial drug be used early in its investigation for childhood absence epilepsy or benign partial epilepsy with centrotemporal spikes. On the other hand, it is justifiable to consider the early use of trial therapy in situations such as the Lennox Gastaut syndrome and seizures secondary to inoperable structural lesions.

The clinician investigator's prime aim always must be the child's well-being.[38] The clinician investigator carries a heavy responsibility to ensure that his or her knowledge of epilepsies is sufficiently sophisticated to allow proper categorization of childhood seizures and identification of syndromes. Otherwise, children may unnecessarily be exposed to a drug that is not expected to help them.

All monitoring procedures should be conducted with as little discomfort as possible. For example, the use of anesthetic cream can minimize the pain associated with venipuncture. Neurophysiologic measurements, if indicated, should be taken, if at all possible, without the use of needle electrodes.

Applicability of Trial Data to Clinical Practice

The goal of regulatory authorities is to obtain rigorous scientific evidence that a new AED is safe and effective. The goal of clinicians is to obtain the kind of clinically relevant information about a new AED that will lead to appropriate selection of treatment for their patients, including information about how to use a drug to its maximal advantage, and data that can determine accurate risk assessment. Several areas where these two may differ have already been discussed above. For example, regulatory trials are usually short in duration, and may not supply sufficient information regarding long-term side effects of medication. This may impact the ability of the clinician to make an accurate risk–benefit assessment. Antiepileptic drugs may not necessarily undergo rigorous testing in certain epilepsy syndromes, particularly in children, that are of great interest to clinicians. Therefore, clinicians may be left to extrapolate data from the trials that have been done. Also, many randomized controlled trials of drugs in development are performed in patients with the most severe epilepsy. It is unclear whether the results can or should be generalized to the remainder of patients with epilepsy, who, by and large, do not have intractable disease. It may also be difficult to determine whether the patient with less severe epilepsy will be willing to remain on a medication with some side effects, which may seem less concerning to the patients with severe refractory epilepsy.

Efficacy Versus Effectiveness

The concept of efficacy versus effectiveness becomes even more important in an age when evidence-based medicine has become a guiding principle in clinical care. The concept of evidence-based medicine is that if clinical trial data are available, that data should be used to make treatment decisions. However, it is important to remember that clinical trials usually focus on *efficacy* rather than *effectiveness*. Efficacy can be defined as the ability to reach an end-point in the context of a clinical trial. Effectiveness is defined as the value of an antiepileptic drug in the environment of use or, in other words, its ability to benefit patients in clinical practice. Although efficacy and effectiveness are linked, they are not always the same. For example, in clinical practice, duration of titration may be guided by patient response. If the patient begins to complain of side effects, titration rates can be slowed or concomitant antiepileptic drugs can be reduced. This is usually not possible in the setting of a clinical trial, where trial methodology has to be predetermined. This may lead to an appearance of poor tolerability in a trial compared to clinical practice. Further, in a clinical trial all patients are titrated to a predetermined dose, often irrespective of tolerability. This too may impact trial outcome. Trial doses and titration rates must often be selected before ideal conditions of use have been determined. Many examples of this can be seen. As already noted above, a 2,400-mg dose was included as one arm in an adjunctive oxcarbazepine trial. This led to dropout of over 50% of patients.[5] In a trial of topiramate as monotherapy in newly diagnosed patients with partial seizures, patients were randomized to either 50 mg or 400 mg. The low dose led to failure due to seizure recurrence, whereas the high dose led to a high dropout rate. The conclusion was that 400 mg was an effective dose. While this may be true, the trial could not assess whether this was the optimal dose, since only two doses were tested. More tolerable doses such as 100 and 200 mg were not included in the trial.[1] Conversely, the highest dose of gabapentin tested in randomized placebo-controlled trials was 1,800 mg.[33] Since no higher doses were included in this study, it is impossible to determine whether 1,800 mg was the highest optimal dose. Many such examples could be given. Clearly, in essence clinical trials may represent a "proof of principle" that a specific treatment is effective in a specific condition. However, trials may not definitively outline optimal use. There is clear need for more pragmatic trials that will provide more guidance.

Summary and Conclusions

The pathway to antiepileptic drug approval is relatively clear-cut. Trial methodology is well established for add-on efficacy and tolerability studies in patients with treatment-resistent partial seizures. These studies lead to market approval in the U.S. and Europe, but leave many important clinical questions unanswered. In addition, trial designs for monotherapy studies, studies in children, and in syndromes outside of partial epilepsy are not well characterized, and progress is needed. Also, there is a need for better early (proof of principle) studies that will identify potentially successful versus unsuccessful drugs at an earlier stage.

Chapter 141

Pharmacogenetics and Pharmacogenomics

Nicole Walley

Sanjay M. Sisodiya

David B. Goldstein

Introduction

Although pharmacologic treatment successfully controls seizures for a majority of patients with epilepsy, current treatment options are far from satisfactory for many patients. Recent progress emerging from the genome project and related activities suggests that it may finally be possible to systematically search for genetic differences among patients that influence how they respond to treatment. Here we review the potential of pharmacogenetics to improve the treatment of epilepsy and address some of the barriers to progress.

Limitations of Current Epilepsy Treatment

Perhaps the most important weakness of current treatment options is that they fail to control seizures for a substantial minority of patients. Nearly one-third of patients do not achieve adequate seizure control upon treatment with any of the currently available antiepileptic drugs (AEDs).[63] Furthermore, those who fail even one drug trial have a poor prognosis: Only 11% of patients who withdraw from their first AED due to inefficacy will ever go on to achieve seizure freedom.[17,40,41] The end result is a significant number of patients who are forced to (a) live with recurrent seizures or (b) resort to invasive surgery, which is not available to all refractory patients, is not guaranteed to eradicate seizures, and can have devastating consequences in some cases.

Although nine new AEDs have been approved during the last 15 years, these have made only a modest impact on the proportion of patients who respond well to treatment. There are currently more than 15 pharmacologic agents now available for clinical use, but approximately 30% of epilepsy patients remain refractory to treatment.[5,63] The chances of achieving seizure freedom with new AEDs has not been significantly improved, although levetiracetam (Keppra) is reported to reduce seizures in 40% of refractory patients, with 6% to 13% achieving seizure freedom.[8,39,68]

The other key limitation is that AEDs can cause both serious and life-threatening adverse reactions, as well as less serious reactions that may nonetheless have important effects on patient quality of life. It has been estimated that 17% of emergency room visits due to adverse drug reactions (ADRs),[58] and 10% of ADRs leading to hospitalization[87] are caused by AEDs. ADRs were cited as the cause of discontinuation in nearly 40% of decisions to terminate treatment with a particular medication[40] and, although patients exposed to high doses of AEDs are more likely to develop ADRs, side effects are not necessarily dose related and also can occur during the course of efficacious drug trials.

The newer AEDs, although offering little improvement for refractory cases, do tend to be tolerated better by patients. Withdrawal rates due to adverse reactions are significantly lower for the newer AEDs.[41] However, older ADRs have not been eradicated and some new ADRs have been introduced, such as the behavioral and cognitive ADRs associated with levetiracetam and topiramate respectively. Tolerability remains a major limitation in epilepsy treatment.

In addition to these key aspects, there are secondary challenges in the use of AEDs, notably the trial-and-error process usually required to identify appropriate doses or drug combinations for individuals. Patients require dramatically different doses to control seizures (Fig. 1), however efficacious dose is impossible to predict. Current routine, nonemergency methods of dosing stipulate, “start low, go slow.” A patient is slowly titrated upward until he becomes seizure-free or he experiences dose-related ADRs; at this point, use of a new drug is often considered. This can take months for those who require uncharacteristically high doses of a medication, or years for those who fail one or more trials and must repeat the process—during which time patients continue to suffer seizures.

Pharmacogenetics as a Probe into Biological Processes

In our view, the improvement of seizure control and the minimization of side effects are the primary motivations for pharmacogenetics studies in epilepsy, and projects should be prioritized on this basis. It is also worth noting, however, that pharmacogenetics may open a window into biologic process that are poorly understood in humans and otherwise not amenable to study.

Levetiracetam and Human Behavior

The approval of levetiracetam has brought seizure relief to some previously refractory patients. It is generally well tolerated, but has been known to cause behavioral abnormalities. Behavioral ADRs have been cited as the most common reason for withdrawal from levetiracetam treatment, and between 5.9% and 30.7% of patients report experiencing behavioral changes.[35,86] Levetiracetam-induced behavioral abnormalities can manifest as irritability, aggression, depression, or psychosis. The identification of gene variants relevant to these ADRs therefore could identify pathways relevant to human behavior, and perhaps more specifically relevant to neuropsychiatric conditions such as schizophreniform psychosis.

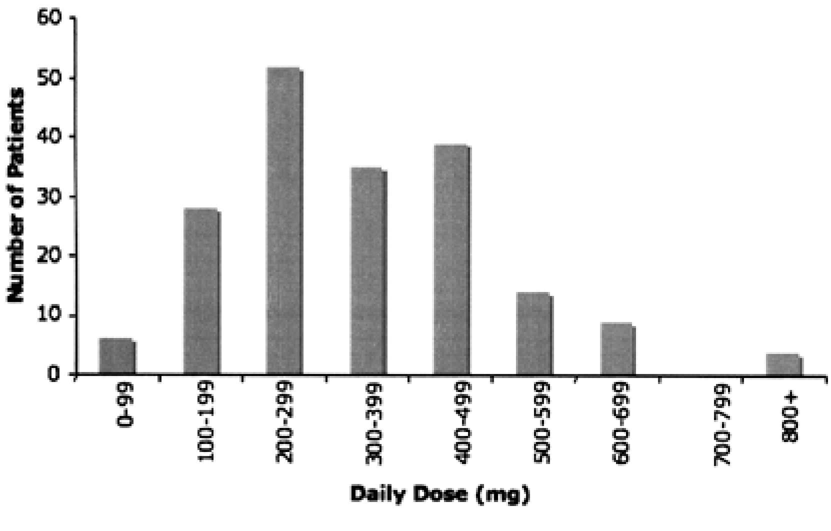

FIGURE 1. Distribution of maintenance dose of lamotrigine. Maintenance dose among patients from the same clinic is highly variable. All patients were treated with Lamo-trigine at the National Hospital for Neurology and Neurosurgery, Queen Square, London. Additional (maximum) dose distributions can be found in Tate et al.[76]

Topiramate and Human Cognition

Topiramate is a new AED commonly used as adjunctive and monotherapy. The most common reason for discontinuation of topiramate therapy is cognitive side effects, which can manifest as mental slowing, language difficulties, and confusion.

Nearly one-half of patients exposed to topiramate report cognitive ADRs (unpublished data), and 27% of patients who discontinue topiramate treatment cite cognitive adverse events as the cause of cessation.[77] Although topiramate is most commonly used as add-on therapy, and the incidence of ADRs is increased with polytherapy, healthy volunteers challenged with topiramate alone also experience cognitive difficulties, as determined by neuropsychological tests.[47,49] Although many AEDs have negative cognitive side effects, topiramate's profile is distinctive. For example, verbal fluency is more affected by topiramate than by other AEDs[24] and appears to affect only a subset of susceptible patients.[51] If genetic differences that mediate to-piramate sensitivity exist among people, their identification may inform clinicians about the underlying brain systems involved in verbal fluency tasks.

Epilepsy Pharmacogenetics: What is Needed?

Genetic Methods

It is possible (although still not certain) that systematic pharmacogenetic research can identify gene variants that will considerably improve the use of AEDs. Here we describe the key elements of contemporary pharmacogenetics research.

Candidate Gene Approach

Until recently, it was not feasible to consider in a single study more than a handful of genes; even then, the genetic information considered for each gene was very limited. Very recently, however, it became feasible to carry out large-scale candidate gene studies in which the genetic variation in hundreds of genes is systematically analyzed. Moreover, whereas whole-genome association studies remain costly, reasonable coverage of most polymorphisms in the full human genome is available in standardized sets of polymorphisms, such as those supplied by Illumina.

In pharmacogenetics, a particularly strong case can be made for candidate gene approaches because the likely modes drug action are usually known or suspected, at least partially. Therefore drug targets make obvious candidate genes and clearly deserve careful evaluation. Consistent with this notion, recent work on the targets of warfarin and phenytoin/carbamazepine identified polymorphisms associated with dosing.[14,76] Moreover, nearly 80% of genetic variants identified by pharmacogenetics reside in the three major categories for pharmacogenetic candidates: Drug targets, drug metabolizing enzymes, and drug transporters (although this reflects in part the bias of where researchers have chosen to look; for a review of this subject see the work by Goldstein, Tate, and Sisodiya[28] and their unpublished update.

For epilepsy pharmacogenetics, a set of high-priority candidate genes are readily identified on the basis of both pharmacokinetics and major modes of action.

Pharmacokinetic candidates

- Drug-metabolizing enzymes (DMEs). The most studied genes to date in pharmacogenetics are those encoding DMEs. For most AEDs, the key enzymes that metabolize the parent compound and active (or toxic) metabolites are well known (Table 1), and many of them have well described functional variants. It is already clear that these variants have some impact on patient response to AEDs: For example, CYP2C9 variation affects phenytoin dosing (see discussion in next section). It does not appear likely, however, that DME variation will prove of substantial clinical relevance in epilepsy.
- Transporters. Drug transporters may influence AEDs at a variety of points. They can influence uptake in the gut, the amount of metabolism in the liver and, perhaps most important, the properties of the blood–brain barrier. In the latter case, the effect of transporters may either be general or affected by seizures. As a class of proteins, however, drug transporters are not well studied. It is not clearly known what transporters move which drugs at therapeutically relevant concentrations, and few examples of functional variation have been characterized, making it unclear what role transporters play in pharmacogenetics.

- However, drug transporters are known to be overexpressed in resection tissue from refractory epilepsy patients.[7,18,72,78] The apparent upregulation of transporter expression at the seizure focus indicates a potential causative role for transporters in refractory epilepsy.

Table 1 Drug-Metabolizing Enzymes of Commonly Used AEDs

AED	Major DMEs	Minor DMEs
Carbamazepine	CYP3A4 epoxide hydrolase	CYP2C8 GST
Ethosuximide	CYP3A4	CYP2B
	CYP3A5	CYP2C isoenzymes CYP2E
	100% Renal clearance	
Gabapentin		
	Renal clearance	
Levetiracetam		
Lamotrigine	UGT1A4	
	Renal clearance	
Pregabalin		
Phenytoin	CYP2C9	CYP2C19
Topiramate	Renal clearance	CYPs (specific enzymes unknown)
Valproate	B-oxidization	CYP2C9 CYP2A6

Table 2 Known and Suspected Mechanisms of Action of Commonly

Used AEDs

Drug	Major drug target	Other suspected actions
CBZ	Sodium (Na) channel α-subunit	Inhibition of voltage-gated calcium (Ca^{2+}) channels and potentiation of potassium (K^+) channels Antagonism of adenosine receptors Inhibition of glutamate release Increase of extracellular serotonin and dopamine transmission Decrease of basal and stimulated cAMP levels[3]
ETX	T-type calcium channels	Inhibition of Na^+/K^+ ATPase[27]
GBP	Ca channel α2δ-subunits 1 and 2	Inhibition of GABA transaminase[43] and GABA reuptake[21] Decreased free content of glutamine/glutamate and reduced glutamate release[19,50]
LEV	Synaptic vesicle protein 2A	N-type Ca^{2+} channels[46] Inhibition of intracellular Ca^{2+} release[4]
LTG	Na channel α-subunit	Suppressed presynaptic Ca^{2+} influx[10] Vesicular release, independent of Na^+ and Ca^{2+} currents[13] Enhanced/inhibited hyperpolarizing K current[32] Downregulation of cortical 5-HT1A receptors[82]
PGB	Ca channel α2δ-subunit	
PHY	Na channel α-subunit	Inhibition of Ca^{2+} channels[66,80] Inhibition of Ca^{2+} calmodulin-mediated protein phosphorylations[15,16]
TPM	Voltage-gated Na channels L-type Ca channels AMPA/Kainate receptors $GABA_A$ receptor Carbonic anhydrase	
VPA	Glutamic acid decarboxylase GABA transaminase Succinic semialdehyde dehydrogenase Voltage-gated Na channels	

CBZ, carbamazepine; ETX, ethosuximide; GBP, gabapentin; LEV, levetiracetam; LTG, lamotrigine; PGB, pregabalin; PHY, phenytoin; TPM, topiramate; VPA, valproate.

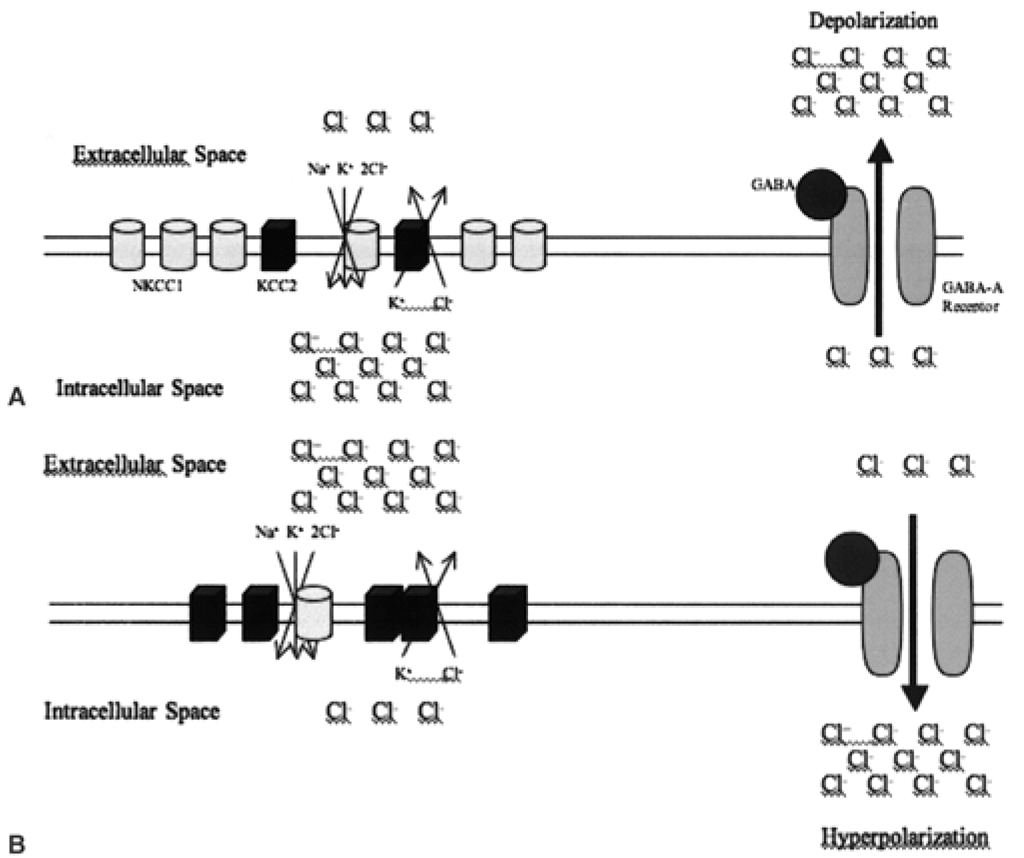

FIGURE 2. Chloride transporter expression and GABAergic neurotransmission. **A:** In fetal neurons, NKCC1 is the predominantly expressed chloride transporter, resulting in a high intracellular concentration of Cl^- ions and depolarization upon GABAergic opening of chloride channels. In fetal tissue, GABA is excitatory. **B:** In mature neurons, KCC2 is the predominant chloride transporter, resulting in a high extracellular concentration of Cl^- and hyperpolarization upon GABAergic opening of chloride channels. In adult tissue, GABA is inhibitory.

Pharmacodynamic candidates

- Drug targets. The major modes of action for most AEDs are known, although in some cases the most important among several candidate modes of action remains unclear (Table 2). The major modes of action fall into one of three broad categories: Modulation of voltage-gated ion channel function, enhancement of γ-aminobutyric acid (GABA)-mediated inhibition, and attenuation of excitatory (glutamate-mediated) transmission.[42] In addition to

P.1499

P.1500

the precise target itself, it should also be appreciated that molecules downstream of the drug targets upon which an AED acts may contain variation that influences response. Thus, pharmacogenetic studies of GABA-acting drugs should appropriately consider chloride ion homeostasis broadly and consider relevant genes. The importance of this perspective is clearly illustrated by chloride ion transporters.

- Chloride ion homeostasis is primarily regulated by a balance of oppositely acting chloride transporters: NKCC1 (also known as SLC12A2), which transports chloride ions into the neuron and KCC2 (also known as SCL12A5), which extrudes chloride ions from the neuron. In adult neurons, KCC2 is the dominantly expressed transporter, resulting in a high extracellular concentration of chloride ions. In fetal neurons, the balance is reversed, such that NKCC1 is dominantly expressed, and there is a high intracellular chloride ion concentration.[54,61] The change in expression results in GABA having an inhibitory effect in mature neurons and an excitatory effect in fetal neurons (Fig. 2). This is known to have pharmacologic implications, because GABA-acting drugs can exacerbate seizure activity in infantile seizures.[25] In addition, expression levels of these chloride channels are altered in seizure-affected brain tissue.[52,67] From a pharmacogenetic standpoint, genetic alteration of chloride transporter protein expression or function most certainly has the potential to affect patient response to GABA-acting drugs.

Direct and Indirect Genetic Methods

Association studies to identify gene variants that influence a particular phenotype can be divided into direct and indirect approaches. In the direct approach, all variants that are good candidates for being functional are identified and checked for association with response. In the indirect approach, a set of genetic markers is identified that is sufficient to represent common variation in the region of interest through haplotype tagging, relying on linkage disequilibrium (LD) among polymorphisms.

To date, pharmacogenetics has followed essentially a direct approach. Many of the important DMEs have been resequenced, and all variants that looked to be potentially functional have been studied. In this way, it is possible, for example, to carry out an association study for phenytoin simply by relating the two low-activity variants of its major metabolizing enzyme, CYP2C9, and patient response.

Beyond DMEs, however, knowledge of functional variation in genes is very limited. One could resequence exons, but this could still miss important regulatory variation. These reasons argue for a tagging-based approach.

Tagging, however, will never perfectly capture all genetic variation and, in particular, it is known that variants with low minor allele frequency may not be well represented.[1,88] For this reason, we strongly favor a hybrid approach that combines elements of direct and indirect association. This model utilizes bioinformatic criteria to identify variants that are more likely to cause functional consequences than a randomly chosen polymorphism (putatively functional single-nucleotide polymorphisms [SNPs]). In our own work we have used the following criteria:

- SNPs that cause amino acid changes are predicted to cause functional differences (i.e., mRNA stability) or lie within splice junctions[36]
- SNPs in promoter regions[79]
- SNPs that occur in regions that are known to be highly conserved across species[9,70]

Today tagging SNPs (tSNPs) are usually selected on the basis of the genotype data provided by the HapMap project. This project has genotyped over 1 million polymorphisms in 269 DNA samples from four ethnic backgrounds (central

European, Han Chinese, Japanese, and Yoruban Africans).[2] Critically, the project preferentially typed variants that are more likely to be functional. For this reason, the majority of SNPs selected on the basis of the above criteria have been typed in HapMap. It is therefore considerably more efficient to take into account the possible functional variants that are to be typed when selecting tSNPs. As an example, we applied this hybrid approach to 450 candidate genes for response to AEDs (Fig. 3). We found that, on average, 10 SNPs are required to tag a gene. It is estimated that humans have 10 million polymorphisms,[12] and there are currently over 9 million SNPs dbSNP (with some redundancy).[48] Thus, it is possible to screen most polymorphisms within a set of candidate genes.

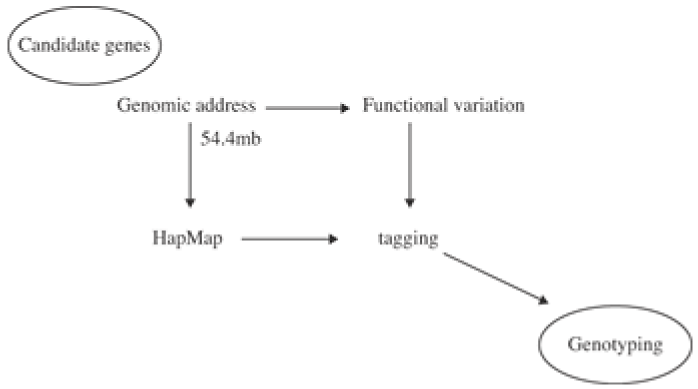

FIGURE 3. Scheme of tag selection using hybrid tagging approach. Using the genomic sequence of all candidate genes, putatively functional variants are identified according to (a) potential coding/splicing function, (b) location in promoter region, and (c) location in regions of high evolutionary conservation. In addition, the genes are tagged using available HapMap data and force, including as tags HapMap SNPs that appear in the functional set. A final set of tags is produced that is predicted to represent all common variants up to a specified threshold.

High Throughput Genotyping

The comprehensive approach just described results in an average of about 10 tSNPs per gene. This means that approximately 5,000 SNPs for 500 genes would be reasonable to cover the most attractive candidate genes in epilepsy pharmacogenetics, a number that was previously cost-prohibitive. The genotyping costs for a high-throughput platform such as Illumina are now about US$0.03 to US$0.04 per sample per genotype, meaning that sample sizes in the thousands can now be analyzed in the context of project grant support.

Analyses

Several issues must be addressed when undertaking large-scale case-control studies. Of particular importance is population stratification, which has been known to cause false-positive associations, especially when allele frequencies differ across populations. Study groups, therefore, must be assessed for ethnicity using ancestry-informative markers. Results and replication attempts can also be confounded by genetic heterogeneity, where a different gene/allele contributes to disease based on population/ethnic differences. Most important, though, is power. To maintain power, especially when testing many genes/polymorphisms for the same phenotype, large numbers of cases and ethnically matched controls must be used.

In addition to these classical pitfalls of genetic association studies, there are novel challenges that currently have no solution. Particular to pharmacogenetics is the unmonitored exploration of complex phenotypic space. There are many ways to consider response phenotypes and, as discussed earlier, no consensus exists on how it should be done.

Also, phenotype depends on a number of factors, none of which relies solely on one gene or allele. Common disease and response phenotypes occur as a result of interactions between genes and environment, and genes and other genes. Analyses can match cases and controls to try to control for as much of the phenotypic variation as possible, however gene–gene interactions cannot be controlled for and neither does there exist a way to identify them.

Clinical Cohorts

In both disease genetics studies and treatment response studies, many of the key challenges are not on the genetic side, but rather on the clinical side. It is very difficult and time-consuming to build well-phenotyped clinical cohorts, and it is often not clear how phenotypes should be defined. These challenges are acute in epilepsy, where clinical diagnosis is inexact, and response phenotypes are often arbitrary.

Retrospective and Prospective Cohorts

Retrospective cohorts are valuable resources because they are immediately accessible; however, they also come with several limitations: Phenotypic data from retrospective cohorts are collected from a clinical perspective and can overlook certain points of interest for genetic studies (for example, serum levels are not always recorded in routine clinical practice but are important when studying dose from a pharmacogenetic standpoint). Additionally, retrieving response information from patient records can be difficult and time-consuming, and the phenotypes necessary for pharmacogenetic study must be tailored to the available clinical data, which can compromise its validity and accuracy.

Prospective cohorts can solve many of these problems. Phenotypic data are ascertained by the clinician with the specific aims of the genetic study in mind to ensure that the appropriate phenotypes are specific and consistent. Patient recruitment can also be tailored to the aims of the study. However, prospective cohorts take time to build, and doing so is a costly endeavor. For these reasons, few pharmacogenetic studies in epilepsy utilize prospective cohorts, and therefore these studies reflect the limitations that retrospective cohorts necessarily entail.

Drug Response Phenotypes

Efficacy phenotypes.

“Refractory,” as it is currently used is a qualitative clinical term applied to patients who have failed a specified number of syndrome-appropriate drug trials. However, this definition implies nothing about the biologic cause of drug failure, and does not necessarily specify the trialed drugs. However, patients who fail only sodium (Na) channel–acting drugs are not biologically equivalent to patients who fail all drugs regardless of drug mechanism. Furthermore, it can only be said that a patient is resistant to Drug A if Drug A has failed. Therefore, simply classifying a patient as “refractory” is an inadequate phenotype. Instead, refractory patients should be subgrouped according to the drug(s) or drug class(es) to which they are resistant.

“Responder” likewise is not an objectively measured phenotype. The responder phenotype can be confused with spontaneous seizure remission, and patients with infrequent seizures prior to drug treatment are frequently too hastily qualified as responders. Additionally, a patient who achieves seizure freedom after failing the first two AEDs is not necessarily biologically equivalent to a patient who responds to the first drug trial.

Many factors must be considered. For example, a patient who becomes seizure-free from a starting point of one seizure per year clearly has a different response phenotype from a patient who becomes seizure-free from a starting point of hundreds of seizures per year. In epilepsy pharmacogenetics, currently no guidelines exist that specify how to take into account seizure frequency before and after initiation of treatment, and over what time frame, to arrive at a biologically (and clinically) meaningful definition of response.

Adverse events phenotypes.

Serious adverse events are probably of most interest for pharmacogenetic study. However, these are rare and are unlikely to be captured in sufficient numbers for study by assembled cohorts. Additionally, many mild adverse events can go unreported. For example, many patients, while exposed to topiramate, never complain of any cognitive side effects. It has been observed, however, that upon withdrawal of the drug, patients experience measurable cognitive improvement, indicating that these adverse events are easily overlooked and often underestimated.[38]

Also, adverse events can be difficult to quantify. The behavioral effects of levetiracetam, for example, can be reported as irritability or feelings of aggression, effects that cannot be measured, thus making phenotype classification heavily reliant upon the description of the patient.

Dosing phenotypes.

During the course of treatment, patients are exposed to many doses during the titration period, and dose remains subject to change throughout the course of treatment. There is currently no way to integrate a patient's dosing history into a single maintenance dose. Moreover, at a biologic level, clearly a number of different definable phenotypes relate to the dosing decisions made by a clinician. For example, the maintenance dose on polytherapy may be influenced by drug–drug interactions or the induction of relevant DMEs by concomitant medications in addition to any pharmacodynamic variants, whereas under monotherapy, variants relevant to drug interactions and enzyme induction may be less important.

Similarly, increases in dose may be constrained in some patients by tolerability, whereas other patients do not increase dose due to the achievement of effective seizure control.

These points alone make clear that dose, however defined, is likely to be a "heterogeneous trait," to use the analogous terminology from the study of common disease. This sort of heterogeneity has made dose a surprisingly controversial phenotype in the epilepsy community, especially given the clear example from other therapeutic areas (e.g., warfarin).

We should therefore make clear that, from the perspective of both complex trait genetics and pharmacogenetics, dosing is quite a standard choice as a phenotype. Many things will influence it, and there are various subphenotypes masquerading underneath any specific "dosing" phenotype (e.g., maximum dose, maintenance dose defined one way or another, etc.). But two clear and related motivations exist for investigating dose as a phenotype in pharmacogenetic studies. First, although genetics will never explain all the variation among patients in what dose clinician ultimately settle on, in may well explain some of that variation. It is therefore possible that gene variants that predict dose requirements will eventually have clinical utility. How do you find such variants? You use dose as a phenotype, of course, in a complex trait study of the genetic determinants of dose. Second, dose as a phenotype may be an effective phenotype for identifying gene variants that influence how patients respond to AEDs, which may be variants that are well worth knowing about, regardless of whether they offer clinically useful predictions. The SCN1A intronic polymorphism was identified in exactly this way[76] and, if it turns out to be a real functional polymorphism that affects splicing, as appears very likely, it illustrates the value of dose as a phenotype.

Pharmacogenetic Studies to Date

Past pharmacogenetic associations in epilepsy have been limited by the technical issues discussed earlier and therefore have focused mainly on pharmacokinetics and have been limited to one or a few candidate genes.

CYP2C9 and Phenytoin Dosing

CYP2C9 is the major metabolizing enzyme for phenytoin and has two common variants, CYP2C9*2 and CYP2C9*3, with reduced enzymatic activity[59,74] making it an obvious candidate for dosing studies. The *3 allele was first associated to the phenytoin poor-metabolizer phenotype in a study of 12 individuals,[37] and several independent studies have since confirmed that CYP2C9 allelic variants are associated with a maximum tolerated dose of phenytoin.[45,76,81] An additional study found that slow-metabolizing alleles are a risk factor for phenytoin-induced cutaneous ADRs (cADRs; rash).[44] These findings are among the first in epilepsy pharmacogenetics; however, they fail to account for the majority of dose variation in patients, thus suggesting that an additional, more important factor is responsible for dose. Indeed, more recent studies have found a pharmacodynamic factor that is more important than CYP2C9 in determining phenytoin dose.[76]

ABCB1 and Drug Transport

ABCB1 (also known as multidrug resistance protein 1 [MDR1], P-glycoprotein) has been shown to have a weak affinity for AEDs.[56,57,64] It shows overexpression in resected human epileptiform brain tissue,[18,72,78] and has characterized functional variation: A synonymous substitution in exon 26 that causes decreased transporter expression[29,30] due to its effects on mRNA stability.[84] This suggests that it may play an important role in drug-resistant epilepsy due to increased reduced concentrations of AEDs at their target site, the brain.

Pharmacogenetic studies have shown this variant[69] and haplotypes containing this variant[33,89] to be associated with drug-resistant epilepsy. It should be emphasized, though, that the only true attempt to replicate the initial study found no association.[75]

Recently, the transport of AEDs at clinically relevant concentrations by ABCB1 has come into question,[7,85] suggesting that these associations are false positives or that the exon 26 variant is in high linkage disequilibrium with an as yet unidentified causal variant.[73]

Although these pharmacokinetic pharmacogenetic associations have proved (a) to be without clinical application or (b) to be potentially false, more recent work in pharmacogenetics have identified pharmacodynamic variants that appear to be replicable and to have great potential for future clinical applicability.

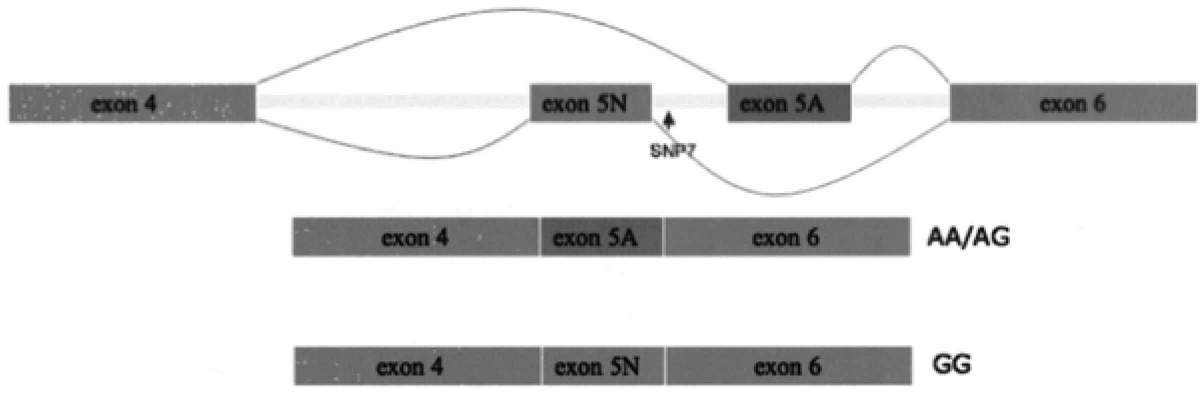

FIGURE 4. SCN1A splicing. The proportion of the two splice variants is genotype-dependent. The major allele (**A**) disrupts a splicing sequence for exon 5N, whereas the GG genotype restores the site and allows for efficient splicing of the exon. Patients with the GG genotype have higher proportions of the 5N exon in resected brain tissue. This genotype also associates with lower maximum doses of phenytoin and carbamazepine, perhaps attributable to higher proportions of a more drug-sensitive exon being expressed in Na channels. Differential sensitivity of the 5A and 5N exons has yet to be assessed.

HLA and SJS/TEN in Carbamazepine-exposed Patients

Many different classes of drugs are known to cause severe cutaneous adverse reactions manifesting in the form of Stevens-Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN). These conditions are rare but are acutely life threatening, with a mortality rate as high as 40%[62]; they have been recorded as idiosyncratic reactions upon exposure to

P.1503

the aromatic AEDs, mainly carbamazepine, lamotrigine, and phenytoin.

cADRs have been hypothesized to result from the inability to metabolize drug compounds or certain active metabolites, however no genetic defects altering the structure of AED DMEs have been associated with cADRs. Instead, immune reactions are likely to be responsible for severe cADRs, and evidence suggests that major histocompatibility complex (MHC)-dependent presentation of a drug or its metabolites activates T cells and causes a severe immune response and cell death.[53,65] Furthermore, carbamazepine and/or its metabolites may be capable of binding peptides that are presented to the MHC and are recognized by T cells, which elicits the severe reaction,[31,55] thus suggesting that HLA is a strong candidate region for these severe cADRs.

It was recently reported that the *1502 allele of the MHC B gene (HLA-B) is strongly associated with carbamazepine-induced SJS/TEN.[11] In this small study, this allele was present in 100% of SJS cases, but only 3%

of carbamazepine-exposed controls.

An expansion of this study to include larger numbers of patients confirmed these findings. Of 60 SJS/TEN cases, 59 patients had the *1502 allele. The remaining patient had an additional HLA-B minor allele, HLA-B*1558, present at low frequency in the study population and absent from carbamazepine-exposed tolerant controls.[34]

The strong association of the HLA-B*1502 variant suggests a potential for the clinical applicability of the SJS/TEN marker, although replication and prospective evaluation must precede large-scale clinical application.[34]

SCN1A and Dosing

As previously mentioned, different patients require highly variable doses of the drugs phenytoin and carbamazepine to control seizures. Tate et al.[76] used a candidate gene approach to identify gene variants that might affect the dose of phenytoin and carbamazepine, namely CYP2C9, ABCB1, and SCN1A. SCN1A is the major target of both phenytoin and carbamazepine,[20,42,71] and also harbors rare mutations that are responsible for some Mendelian forms of epilepsy.[22,23,60,83] CYP2C9 and ABCB1 both have known functional variation (see earlier sections), but no functional variants were known to exist in the SCN1A gene, so a haplotype tagging strategy was employed to represent common variation. A significant association was found with one of the tagging SNPs and the maximum dose of both drugs.

The Function of "Tag 7"

Upon association of genotype at Tag 7 with a maximum dose of phenytoin and carbamazepine, the SNP was assessed for functional implications that might explain how it affects dose. This SNP, SCN1A IVS5–91 G>A (rs3812718), lies in a donor splice site of an alternatively spliced exon. This alternative exon, 5N, is the predominant form of exon 5 in fetal Na channels, whereas 5A predominates in the adult form of Na channels. The major allele disrupts the splice sequence for 5N, whereas the minor allele (G) restores an intact splicing sequence (Fig. 4). The hypothesis, then, is that the polymorphism affects dosing requirements by changing the relative amounts of 5A and 5N forms of the α-subunit, and these forms are differentially sensitive to AEDs, although this is unconfirmed.

5N and 5A in the Epileptic Brain

To further investigate this hypothesis, Tate et al.[76] compared the relative proportions of 5A and 5N in resected tissue from patients who had undergone surgery for refractory temporal lobe epilepsy. Results showed that, among epilepsy patients, those with the GG genotype have a significantly higher proportion of 5N in temporal lobe tissue than do the wild-type (AA) and heterozygous (AG) genotypes. Surprisingly, there were no significant differences between genotype and proportion of 5N in the seizure focus: The hippocampus. This is possibly due to a high level of neuronal loss in the hippocampus; also, the lack of correlation between the G >A polymorphism and 5N proportions may reflect the relative paucity of neurons compared with other cell types. Future investigations will necessarily assess the proportions of 5N in individually identified neurons from the seizure focus.

In addition, comparisons of patient resection tissue with control brain tissue from a PD brain bank revealed that, regardless of genotype, the proportion of the 5N form of the α-subunit is significantly higher in patients than in controls. This is true for multiple Na channel subunits, including those encoded by the genes *SCN1A* and *SCN8A* (Fig. 5). The upregulation of the fetal form of the α-subunit in multiple Na channel genes is likewise seen in animal models following seizure induction,[6,26] indicating that 5N upregulation is the result, rather than the cause, of seizure activity.

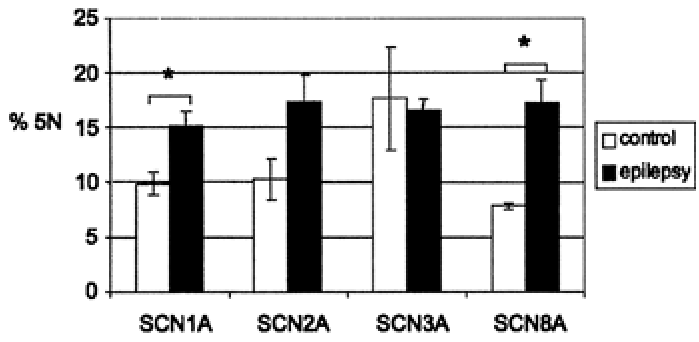

FIGURE 5. Upregulation of 5N in multiple Na channel genes. The proportion of 5N transcripts is significantly upregulated in two of four Na channel genes in resected seizure tissue when compared with postmortem control tissue.

Implications of 5N in Epilepsy

Prior to this pharmacogenetic work in SCN1A, the upregulation of the fetal form of the α-subunit had never been observed in human epileptic brain tissue. Although the exact cause and effect of this phenomenon remain unknown, the observation that patients with the GG genotype (and consequently higher proportions of 5N) require lower doses of AEDs, and that 5N-containing forms of the α-subunit are upregulated in these patients' brains suggests that this form of the exon may be somehow protective. The molecular characterization of a cause and effect relationship between seizures and 5N upregulation could will provide insight into the pathophysiology of epilepsy and perhaps suggest new molecular targets for the development of new AEDs.

Summary and Conclusions

The potential of epilepsy pharmacogenetics may be well illustrated by the examples of carbamazepine, phenytoin, and warfarin dosing. In these studies, one of the most obvious possible places to look for gene variants that influence response, the target of the gene, was very carefully studied. In both cases, intronic polymorphisms were discovered that associate with dosing decisions. If these are true associations, they suggest the possibility that pharmacodynamic variants that influence response to treatment might be common.

As studies that are sufficiently large to identify multiple effects are finally getting under way, the next several years will prove hugely informative. In our view, it is likely that, for certain genetic diagnostics, it may be necessary to consider multiple polymorphisms. Thus, although neither the SCN1A or CYP2C9 variants appear to explain enough variation in dosing decisions to be clinically important (although the role of SCN1A remains to be carefully studied in control settings), it may be the case that a number of such polymorphisms in combination will provide better dosing predictions.

It seems to us unlikely that treatment will be impacted over that time frame, but we should at least have an idea of how important genetic variation is in patient response. If many new variants are identified, it will warrant the establishment of translational research facilities that are sufficient to work out how to apply the genetic findings to improve care.

Chapter 142

The Role of the Food and Drug Administration

Russell Katz

The views expressed in this article are those of the author and do not reflect an official position of the Food and Drug Administration.

Introduction

Legal authority for the regulation of drug and biologic products moving in interstate commerce in the United States and for granting approval to market drug and biologic products rests with the Food and Drug Administration (FDA), an agency of the Public Health Service in the Department of Health and Human Services. Practically speaking, this means that an investigator who wishes to administer an unapproved drug product to a human being must do so under an Investigational New Drug (IND) application that has been submitted to the FDA. Although any qualified individual may submit such an application (and a large number of such applications are submitted by individual investigators), this chapter is largely concerned with issues of drug development faced by commercial sponsors intending to bring a drug product to market. The relevant laws and regulations governing research with investigational drugs, as well as standards for marketing of new drugs, have been described in detail elsewhere.[1,2,3]

Although many of the issues encountered in the development and evaluation of antiepileptic drugs also pertain to drugs of other classes, epilepsy does present a number of relatively unique problems for the regulatory agency, as well as for the sponsor. These problems range from the general, such as the choice of the appropriate clinical trial designs, to the specific, including such fundamental aspects of trial conduct as the appropriate collection of the basic data on which an adequate interpretation of the study depends. Most of these issues and problems have arisen in the context of the three most recent New Drug Applications (NDAs) acted on by the FDA.

Clinical Trials

Add-on Trials

The most fundamental question that needs to be addressed is the appropriate design for the adequate and well-controlled clinical investigations required by law in determining the effectiveness of a treatment. By far the most commonly employed clinical trial design currently being utilized by sponsors is the so-called add-on design, in which patients not adequately controlled by optimal therapy with currently available treatments are randomized to have the investigational therapy added on to their current treatment regimen, or to have placebo added on to their current treatment regimen. This trial design has great appeal for two reasons: First, ethical concerns regarding the use of placebo do not arise, because those patients who receive placebo continue to receive their standard treatment. Second, the trial is designed to demonstrate the superiority of the investigational treatment over the placebo treatment; in other words, the trial is designed to demonstrate a difference between treatments. Studies designed to demonstrate an equivalence between treatments (e.g., a study comparing the effects of an investigational antiepileptic drug with a standard antiepileptic drug) ordinarily cannot be interpreted unambiguously.[4,5]

The standard add-on trial is not without problems, some of them structural, and therefore not fixable, and some related to study conduct, which can be handled. In the first place, this type of study can be relied on to offer conclusions about the new treatment only in combination with other antiepileptic drugs; that is, it is incapable, by design, of addressing the question of whether the treatment in question is effective when given alone, as monotherapy. It is possible that a therapy, because of pharmacodynamic interactions, is effective only in the presence of other antiepileptic drugs, but not by itself. Some consider a demonstration of effectiveness only in add-on trials to be an inadequate basis for the approval of a proposed new treatment for epilepsy; however, as of this writing, it is clear that the FDA is willing to permit marketing solely on the basis of data from add-on trials.

Add-on trials pose other difficulties. Beyond any potential pharmacodynamic interactions, most investigational antiepileptic drugs have pharmacokinetic interactions, often complex, with standard antiepileptic drugs. Unless the plasma levels of the (unbound) standard treatments are tightly controlled in a clinical trial, any apparent effect (beneficial or negative) of the new treatment may simply be the result of an alteration in the plasma level of one or more of the concomitant antiepileptic drugs. Unfortunately, sponsors ordinarily do not adequately characterize or quantify the possible kinetic interactions between their treatment and individual standard antiepileptic drugs, let alone the highly complex interactions that may occur when a new treatment is added to a regimen consisting of several concomitant antiepileptic drugs, before these same combinations are used in definitive clinical trials. Then, once the trials begin, plasma levels of the standard antiepileptic drugs are often not monitored with sufficient frequency or rigor to provide assurance that they are indeed constant. Given these conditions, it is often impossible to address this crucial question with adequate data.

Although the add-on design does permit internally consistent conclusions about the effectiveness of the treatment (albeit only in combination with other treatments), it is often misinterpreted. The demonstration of the superiority of the new treatment does not imply, as some suggest, that the new treatment is superior to the standard treatments used as concomitant therapy. In reality, add-on trials permit only the conclusion that the new treatment, when added on to standard treatments, is superior to placebo when added on to standard treatments. This is an important distinction. Even if patients achieve better control with the add-on treatment than they had with the standard before the study, this trial design cannot be

interpreted as demonstrating superiority over any of the drugs in the regimen, or to any of the standard drugs with which the patients may have previously failed therapy. For superiority to be proved, the new treatment would need to be compared directly with a standard treatment (either in a monotherapy or add-on setting) and be shown to be superior to it. It is generally acknowledged that the demonstration of such a difference would ordinarily require studies including so many patients as to make them essentially impossible from a practical point of view.

An additional problem with add-on studies relates to the use of specific concomitant antiepileptic drugs and the ability of the study to support adequate directions for use in approved labeling. Specifically, if sufficient numbers of patients are not receiving a particular standard antiepileptic drug, it may not be possible to draw adequate conclusions about the effectiveness of the new treatment in combination with that particular standard.

Novel Trial Design

Although trials of antiepileptic drugs have often used a crossover design (especially in Europe), the FDA's experience with this design has been disappointing, and most trials that have resulted in NDA approvals have employed the more acceptable parallel design.

Recently, trials with other novel designs, including monotherapy trials, trials utilizing outcome measures not directly related to seizure frequency, and trials with fixed plasma level designs, have been performed; these have been discussed by others.[6,7,8]

Because seizures occur (more or less) frequently and unpredictably, seizure counts, the primary data for these studies, must be recorded by the patient or a responsible caregiver. This is ordinarily accomplished with the use of a detailed diary, in which the number of events, type and time of seizures, and other details are recorded. A particular problem arises, however, when these events occur in rapid succession, or a single event is sufficiently prolonged, so that accurate mensuration is impossible. These events, often idiosyncratically identified as seizure clusters or seizure flurries (or even status epilepticus), pose a thorny problem in the interpretation of a trial that depends on accurate counting of events. Lack of prospective definition of these episodes makes accurate assessment almost impossible, and arbitrary assignment of a particular number of seizures to such an episode, as has been done, is unsatisfactory. A satisfactory method of dealing with these episodes (which appear to occur not infrequently in the setting of large controlled trials) has not yet been established, and this continues to be an unsolved problem in the analysis of clinical trials.

Evaluation of Clinical Data

An issue of great importance in the evaluation of antiepileptic drugs concerns the specific data necessary to support a specific indication. Specifically, in the three most recent cases (felbamate, gabapentin, and lamotrigine), the Advisory Committee (a group of outside experts empaneled to assist the FDA) recommended that these drugs not be granted a general claim as antiepileptic drugs, but rather recommended that they be indicated as adjunctive therapy (or monotherapy if the data supported it) for the treatment of specific seizure types, usually refractory partial seizures. In addition, the Committee made a clear distinction between partial seizures with and without generalization. Specifically, for a sponsor to be granted a claim for the treatment of partial seizures with generalization, an *independent*, statistically significant decrease in secondarily generalized seizures in the treatment group compared with the control group is required. Should sponsors wish to gain a claim for this specific seizure type, they are advised to enroll sufficient numbers of patients with this seizure type to be able to demonstrate a genuine drug effect on this type of seizure.

Drugs for Status Epilepticus

Essentially all antiepileptic drugs currently under development in this country are proposed as treatments for patients with chronic epilepsy. However, there is some interest in developing treatments for status epilepticus. Status epilepticus poses a particularly difficult problem for the sponsor interested in developing a treatment for this serious condition, as well as for the regulatory agency. Because status epilepticus is considered a potentially life-threatening emergency, sponsors and investigators are naturally reluctant to treat these patients with a presumably inactive control (i.e., placebo). However, as has been seen, studies designed to demonstrate equivalence between two active treatments cannot ordinarily be interpreted, because to do so requires a precise and accurate knowledge of the natural history of the untreated condition. In the case of status epilepticus, this natural history (e.g., how long a particular event will last) is not precisely known. Therefore, it poses a great challenge to design a trial with the capacity to demonstrate a difference between an acceptable control and an investigational treatment. The FDA has explored this issue and has promoted the view that because no standard treatment regimen for status is universally accepted, investigators should be willing to enter into a trial in which varying treatment modalities and regimens could be compared. When acute serious conditions like status are treated, early rescue with standard treatments can be incorporated into the design. For example, two doses of a treatment can be compared, with a rescue treatment given after an appropriate (brief) period of observation. The rate of administered rescue therapy between the two treatment groups could be an important outcome measure. Conducting these studies, however, is always more difficult when an attempt is made to rigorously study a drug that is already approved for another indication but is considered standard treatment for status.

Issues Concerning Children

A particularly problematic area in the development of antiepileptic drugs involves children. Traditionally, drug studies in children have been performed relatively late in the development of a particular treatment, with children usually being enrolled only when there is reasonably good evidence of the safety and effectiveness of the treatment in adults. A recent workshop on the development of drugs to treat children with epilepsy sponsored by the Epilepsy Branch of the National Institutes of Health recommended, however, that such studies be undertaken much earlier in the process, reflecting the community's view that much more should be known about the effects of new drugs in children at the time of their approval, especially as all new drugs to treat patients with epilepsy are used in children, regardless of the populations studied before approval.

A problem still remains, however, in the (most common) case in which a drug is approved for adults with a particular seizure type and a sponsor desires approval for the same seizure type in children. The question then arises regarding what sort of additional evidence of effectiveness, if any, is required. In the case of the three antiepileptic drugs previously mentioned,

the Advisory Committee explicitly insisted that additional controlled trials be performed in children with partial seizures to support a pediatric claim, despite the fact that controlled trials had demonstrated the effectiveness of these drugs in partial seizures in adults. This vote reflected the Committee's view that events (partial seizures) that appeared the same in children and adults need not necessarily result from the same pathogenetic mechanisms in these two populations, and that it could not be assumed that the treatment applied would necessarily have identical effects in both populations. (It should be noted that at the previously mentioned National Institutes of Health workshop, participants voted overwhelmingly to recommend that if a drug is shown to be effective against a particular seizure type in adults, it should be considered effective against the same seizure type in children.)

Summary and Conclusions

This chapter has attempted to discuss just a few of the complex regulatory and scientific issues that need to be considered by the pharmaceutical industry and the FDA during the process of bringing safe and effective antiepileptic drugs to the marketplace as expeditiously as possible.

Chapter 143

The Role of European Regulatory Agencies

Michel Baulac

Eric Abadie

Introduction

Since 1989, eleven new antiepileptic drugs (AEDs) have been approved in the EU countries for epileptic disorders as indication. The regulatory work also included the evaluation of new dosages and routes of administration, as well as new indications when a drug initially approved for a given seizure type or epileptic condition was subsequently approved for additional seizure types or populations. In parallel, the EU pharmaceutical legislative framework was progressively implemented. The European Agency for the Evaluation of Medicinal Products (EMEA) was established in 1995 to coordinate and harmonize the processing of EU licence applications. The Committee for Human Medicinal Products (CHMP) is the advisory committee to the EMEA for medicines for human use, and comprises two delegates from each EU member state.

The national competent authorities or drug agencies from the member states are the scientific pillars of the EMEA. The EMEA's guidance and recommendations are conveyed through an ensemble of guidelines. The EMEA position concerning AEDs is included in a specific scientific note for guidance, but it also derives from the experience acquired through the scientific advice provided and the EU procedures that involved recent applications for registration of new AEDs.

Overview of the Licensing Process in EU Countries

There are three routes by which a drug may be granted a product licence in the European Union. The centralized procedure, by which the company is authorized to release the drug in the market in any EU country, and the mutual recognition procedure, and a decentralized procedure. Some details of these procedures are shown in FIGURE 1. The national procedures, which involve the regulatory agencies in each individual member state, are critical in the mutual recognition system. The latter procedures also continue to be used when a drug initially approved through a national procedure, mostly before 1995, is subsequently considered for extension of its indications within the same country.

Once a product receives a marketing authorization from the EMEA, the company can approach individual governments to have it introduced in the relevant national markets. However, a company may decide not to launch in a particular country for commercial reasons. It is at this stage that other factors come into play, including the evaluation of the drug's added value by the national health systems and pricing negotiations, which can significantly delay the actual marketing process.

The AEDs recently marketed in EU countries have followed different routes. Vigabatrin, lamotrigine, gabapentin, felbamate, and topiramate were marketed through national procedures, which were initiated before 1995. Every variation or extension of their indications continues to be dealt with by the individual national regulatory bodies, which explains some variability across EU countries regarding the wording of the indication, the dosage recommendations, or the age range, especially in the pediatric indications. Tiagabine, in 1996, was the first AED whose license application followed an EU procedure—the mutual recognition procedure. The EU approval of oxcarbazepine was also obtained through mutual recognition in 2000, given the fact that some EU countries had already individually approved this drug in the early 1990s. Levetiracetam

(2000), pregabalin (2004), and zonisamide (2005) gained their EU approval through the centralized procedure. In addition, rufinamide was approved in 2006 for the adjunctive treatment of the Lennox-Gastaut syndrome seizures through Orphan Drug application.

EMEA Guidance and Recommendations

Within the framework of the pharmaceutical legislation, EMEA guidelines do not have legal force in that the definitive legal requirements are those outlined in the relevant EU legislative framework as well as appropriate national rules. However, guidelines are to be considered as a harmonized EU position and, when followed by relevant parties such as the applicants, companies, and regulators, will facilitate assessment, approval, and control of medicinal products in the European Union. Nevertheless, alternative approaches may be taken, provided that these are appropriately justified.

Scientific guidelines (or notes for guidance), including those related to quality, efficacy, and safety, are based on the most up-to-date scientific knowledge. A guideline is normally developed in accordance with the following steps:[15] (a) selection of topic and inclusion in the relevant work program(s); (b) appointment of a rapporteur and (if necessary) a corapporteur; (c) development of a concept paper and release for consultation; (d) preparation of the initial draft guideline; (e) release for consultation of the draft guideline and collection of comments; and (f) preparation of the final version, adoption for publication, and implementation.

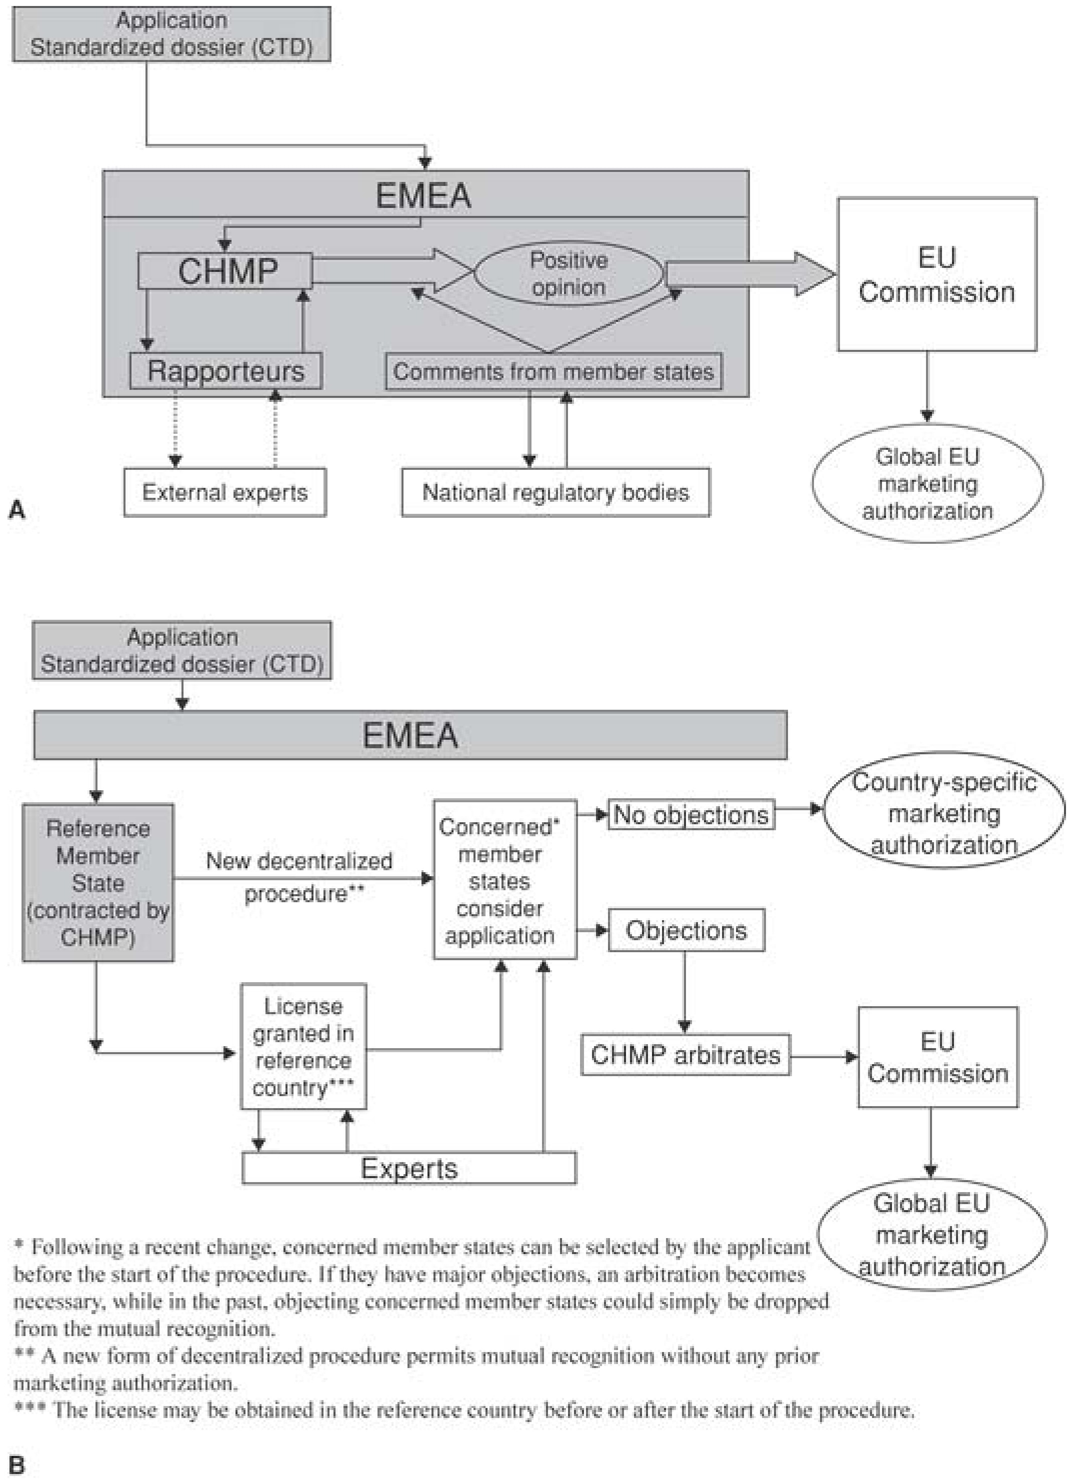

FIGURE 1. A: The centralized procedure for the EU approval of medicinal products for human use. The pharmaceutical company files an application including the Common Technical Document (CTD) to the European Agency for the Evaluation of Medicinal Products (EMEA), which is then passed to the Committee for Human Medicinal Products (CHMP). Two CHMP members, known as the “rapporteur” and “corapporteur,” are selected to consider the application, and they can involve the external experts of their choice. Their assessments form the basis for the final approval by the CHMP. Following assessment, the CHMP gives an “opinion” on the application, which, in turn, is considered by the EU Commission, which is the licensing authority. The CHMP works according to a strict timetable laid down

in EU law. An "opinion" (positive or negative) has to be issued within 210 days (average 180) of receipt of the application. In the case of a positive opinion, the recommendation by the CHMP is transformed into a decision by the EU Commission. **B:** The EU decentralized system, or mutual recognition procedure, for the EU approval of medicinal products for human use: Under this system, the CHMP does not take part in the decision-making process unless there is disagreement between member states. The company asks one member state, which must have already approved the product, to act as Reference Member State. Then, the other member states for which licensing is requested ("Concerned Member States") have 90 days to "mutually recognize" the marketing authorization already granted in the Reference Member State. When other countries raise major objections, the matter is referred to the CHMP for arbitration. Selection of the member states that are "concerned" by the indication reduces disagreements. A new decentralized procedure is now applicable, bypassing the step of a preexisting marketing authorization in the Reference Member State.

The need for a new guideline may be made evident by frequently encountered problems with established products or by questions brought forward within the framework of scientific advice. A need for a guideline may also arise due to the development of new technologies, new practices, or new therapeutic areas. Inputs for developing or revising guidelines may also be received from interested parties (e.g., industry, health professional groups, scientific societies, patients' associations, etc.). Guidelines can also be initiated and drafted by the International Conference on Harmonization (ICH).

The rapporteur for the development of a guideline is a member of the CHMP Efficacy Working Party who works on the

P.1512

P.1513

draft with experts of his or her choice. After release for consultation, comments are expected from EU/EEA/EFTA countries, other regulatory authorities (e.g., the U.S. Food and Drug Administration, Health Canada), industry associations, scientific and academic societies, patients' groups, and health care professionals. Unless otherwise indicated, guidelines come into operation 6 months after their adoption. The current EMEA guideline on AEDs[11] was drafted from April 1998 to September 1999, commented on from October 1999 to April 2000, and adopted in November 2000, and it came into operation in May 2001.

Specific EMEA Guidance on Antiepileptic Drugs

The specific EMEA position concerning the development of AEDs is described in the current note for guidance,[11] but it also derives from the experience acquired through scientific advice and EU procedures that involved AEDs. Key aspects are reviewed in the sections below.

Global Development Plan for a New Drug

The clinical development of a new AED follows a stepwise approach. The preclinical data, including data on pharmacologic actions, toxicology, pharmacokinetics, and interaction profile, should be known before starting studies in humans. Initial human safety and pharmacokinetic data are usually obtained in healthy volunteers. For ethical reasons, the patient population selected for the initial clinical trials is usually represented by subjects with epilepsy who have continuing seizures in spite of several attempts to control the disorder with appropriate AEDs, used in combination and at optimized dosages. Therefore, the first application usually concerns the add-on indication in refractory partial seizures in adults, based on results of randomized, parallel-group, double-blind, adjunctive-therapy, placebo-controlled trials. A sufficient number of adolescents (over 12 years of age) should be recruited in the confirmatory studies. It is useful at this stage to submit a global development plan, showing which extensions are envisioned. In particular, the preclinical profile or some clinical exploratory studies (e.g., a double-blind cross-over study after an open enrichment phase) may suggest that the test drug has a potential for usefulness in other seizure types (e.g., seizure types associated with generalized epilepsies) or other syndromes. Once evidence for a beneficial effect has emerged from studies in adults, it is recommended to implement pediatric studies as planned in the clinical development plan and before registration of the product in adults (see guidelines on investigation of medicinal products in the pediatric population[6]). It may also be useful for the applicant to define at an early stage plans regarding the monotherapy indication, and which patient populations will be investigated for this purpose. A policy regarding elderly patients is also of importance. The development of parenteral formulations is encouraged. Besides bioequivalence and safety data, the demonstration of efficacy in status epilepticus may be an important objective with such formulations, although very little regulatory experience has been acquired in this particular domain.

Approach by Seizure Type and Epileptic Syndrome

Patients included in the clinical trials should be classified according to the International Classification of Seizures and, when possible, the International Classification of Epilepsies and Epileptic Syndromes. It is recommended to evaluate the whole spectrum of effectiveness of the test drug, not only according to the type of seizures (e.g., partial vs. generalized seizures), but also to the type of seizures associated with a specific epileptic syndrome. It is acknowledged that patients with partial epilepsies usually represent the initial target, since they are the most prevalent and a substantial percentage of them are not well controlled. Efficacy, however, should be evaluated for all the seizure types present in this condition, including simple, complex partial, and secondarily generalized tonic–clonic (GTC) seizures. A pooled analysis across several studies, optimally prespecified, may permit assessment of efficacy in the less frequent seizure types.

The other syndromes should be explored separately, which is the case for idiopathic generalized epilepsies and symptomatic/cryptogenic generalized epilepsies, including some syndromes specific for infancy and childhood (e.g., West syndrome or infantile spasms, Lennox-Gastaut syndrome, Doose syndrome, Dravet syndrome). Addressing these syndromes will require evaluating the efficacy of an agent separately on the different seizure types present in the given condition (e.g., spasms, GTC seizures, absences, and myoclonic, tonic, or atonic seizures). The impact upon the other clinical features of the disease, such as cognitive outcome, should also be addressed. The global antiepileptic efficacy of an agent in a specific epileptic syndrome can only be claimed when efficacy has been shown for all seizure types associated with that syndrome.

In newly diagnosed patients, who often have a low number of seizures, it may be difficult to identify the seizure type or the syndromic context at the time of inclusion. Some apparently primarily GTC seizures may in fact be secondary to unrecognized partial seizures, particularly in patients with nocturnal seizures. Other GTC seizures may occur in an unrecognized context of idiopathic generalized epilepsy, in the absence of typical electroencephalographic (EEG) traits or other seizure types. The choice of including or excluding undetermined GTC seizures should be made in relation to the expected efficacy spectrum of the test drug, and of the comparator in case of active control trials. Some of these undetermined seizures may be classified later on in the trial, and it might be important to see whether response for these reclassified seizures or syndromes are compatible with the efficacy spectrum of the test product and of the comparator.

Development of Antiepileptic Drugs in Children

Pediatric studies should be conducted as early as the development of the test product allows, in order to avoid an excessive delay in obtaining a marketing authorization for children compared to the marketing authorization for adults. The pediatric needs in epilepsy were assessed by the CHMP Pediatric Expert Group,[2] which identified the general need for studies of AEDs in refractory epilepsies. Existing data are generally insufficient in two particular domains: (a) pharmacokinetic, efficacy, and safety data of the newer AEDs in refractory epilepsies in young children, particularly under the age of 3 to 4 years, and (b) long-term safety including effects on cognitive function and brain maturation.

A recurrent regulatory issue is the need for evidence of efficacy in children when demonstration of efficacy has been already obtained in adults. To authorize an indication in refractory partial epilepsy, for instance, is it necessary to replicate a randomized controlled trial in children when efficacy in partial epilepsy has already been demonstrated in adults, or would pharmacokinetic and safety data be sufficient? The current CHMP position is that demonstration of efficacy in children

P.1514

remains necessary in most of the cases, because there are examples of negative add-on studies in children contrasting with positive results obtained in similar epileptic conditions in adults. Specific seizure types seen in only childhood (e.g., infantile spasms) or specific seizure types within an epileptic syndrome seen in childhood (e.g., Doose syndrome, Lennox-Gastaut syndrome, and continuous spike wave in sleep syndromes) need specific investigations. These syndromes may qualify for classification as orphan disorders and benefit from incentives for orphan indications.

From the safety viewpoint, approximately 100 children treated with the study drug should be followed for at least 1 year. Moreover, short-term and long-term studies should be designed to detect possible impact on learning, intelligence, growth, endocrine functions, and puberty. Some of these studies may require continuation in the postmarketing period.

Development of Antiepileptic Drugs in the Elderly

The prevalence of newly diagnosed epilepsy increases substantially after 65 years of age. Elderly patients who may have suffered from epilepsy for years or may have developed epilepsy recently should be considered differently. Efficacy and safety of AEDs in newly diagnosed elderly patients may be different from those seen in younger adults for the following reasons: (a) different epilepsy etiologies; (b) age-related differences in pharmacokinetics; (c) an increased risk of adverse effects associated with standard dosages, especially with respect to impact on cognitive functions, vigilance, and the cardiovascular system; and (d) pharmacokinetic and/or pharmacodynamic interactions with other drugs frequently used in the elderly. Based on this background, it is important to determine whether the pharmacokinetic behavior of the drug is different in elderly subjects as compared to younger adults. Moreover, a reasonable number of geriatric patients should be included in the phase III database. The clinical impact of the test product, especially on cognitive function and on alertness, should be evaluated. Potential drug interactions of the test drug should also be assessed, especially with other products frequently used in this age group. Depending on the data, specific efficacy and safety trials in this population may be needed.

The Add-on Indication

The add-on indication may be granted on the basis of positive results in the pivotal add-on trials. These trials should utilize a multicenter, double-blind, placebo-controlled, randomized, parallel-group design. Several studies with a similar design are generally needed to confirm efficacy and safety in a sufficient number of patients, and to explore the dose range. Head-to-head comparative add-on studies with new AEDs would also be of interest.

Since efficacy end-points are usually based on changes in seizure frequency, seizures must be recognizable by either patients or relatives, and a policy should be defined when seizures occur in clusters. The spontaneous fluctuations of the epileptic disorder must be taken into account; for example, patients whose baseline seizure frequency differs substantially from their usual seizure frequency should not be included, in order to minimize the regression to the mean phenomenon.

Great attention should be paid to the exploration of the dose range, and any maximal predefined dose should be justified. The dose range should be explored with several dose arms in order to establish the minimum clinically effective dose, as well as the maximum effective or maximum tolerated doses, and to characterize the dose-response relationship. A too-short titration period may lead to high dropout rates for adverse reactions early in the trial, and may prevent adequate exploration of the upper part of the dose range. The maximum tolerated dose should be defined with consideration of the percentage of patients who withdrew due to adverse events. An excessive withdrawal rate may compromise the effectiveness of this maximum dose.

The maintenance treatment period in add-on trials should be at least 12 weeks in order to establish that efficacy is not short lasting. Determination of the plasma levels of the test product may be useful in correlating plasma concentration values to efficacy and occurrence of adverse events. The interaction potential should be taken into account in both directions (e.g., interaction of the concomitant treatment vs. the test product and of the test product vs. preexisting AED treatment). The therapeutic dosages may be different in the presence of enzyme inhibitors or inducers. If the test product inhibits the metabolism of a concomitant AED, and thus increases its plasma concentration, proof of efficacy of the test product will require that the plasma concentrations of the concomitant drug(s) have been maintained within certain limits.

At the end of the maintenance period, further assessments should be performed to generate three orders of information: (a) data on the long-term effects of the test product, both in terms of safety and absence of tolerance, with 1-year duration of assessment being considered the minimum; (b) data on the consequences of the withdrawal of the test product, particularly with respect to potential rebound phenomena; and (c) data on conversion to monotherapy with the test product.[5]

The assessment of efficacy is essentially based on the change in seizure frequency during the double-blind treatment period. One valuable primary variable is the percentage change in seizure frequency, or some parameterization of it. The other variable dichotomizes the data into responders/nonresponders, where responders are patients who obtained at least a certain percentage of seizure frequency reduction versus baseline (a 50% reduction is generally the cutoff used, but a more ambitious cutoff such as a 75% reduction might also be used). It is recommended to provide information for both these variables, irrespective of whichever is defined as the primary one. Other variables such as seizure severity, number of days with or without seizures, and scales measuring quality of life have been less frequently employed. Efficacy variables should allow full investigation of the distribution of changes in seizure frequency during treatment. In particular, potential exacerbation of seizures should be assessed.

The percentage of seizure-free patients is considered an important outcome parameter, even if these percentages are usually very low in refractory populations. A clinically meaningful assessment of seizure freedom should be done over the entire double-blind treatment period, 3 months for instance.[8] Careful explanation of how responder rates (including seizure-free rates) are calculated is also necessary for a meaningful interpretation of the results: For example, seizure-free rates may refer to completers who were seizure free during the entire treatment period, or may be calculated by using the last-observation-carried-forward analysis and therefore include patients who discontinued the trial prematurely.

Some difficulties have been encountered when interpreting add-on studies, for example, when the parallel groups turn out to be dissimilar in terms of baseline seizure frequency, when a given seizure type was underrepresented, or when unexpectedly high placebo responses were observed. In some instances, a particular dose arm that was assessed with insufficient statistical power in an individual trial may turn out to be very important for the demonstration of the dose-response relationship, or for the determination of the therapeutic dose range. When

several studies are available, meta-analyses have been used in such circumstances to obtain some supportive information.

Assessment of long-term efficacy, which in follow-up studies is made difficult by the open-label design and by changes in concomitant AEDs, should take into account the progressive enrichment of the population remaining in the study.

The Monotherapy Indication

There is consensus among clinicians and regulators that when an AED has been approved for adjunctive therapy, the extension of the indication to monotherapy should be based on specific regulatory trials conducted in monotherapy settings. Obtaining a monotherapy license for new AEDs has become increasingly difficult, mainly due to methodologic difficulties with these trials, different viewpoints from the scientific and regulatory communities, and well-founded ethical concerns regarding the use of suboptimally treated control groups in some trial designs.

Presurgical designs generate information that generally can only be considered as proof of concept or as supportive data. Withdrawal or conversion to monotherapy studies[5] usually consists of an initial period of add-on treatment followed by gradual withdrawal of the concomitant AED(s), leading to a maintenance phase in which the test drug is administered alone in the regimen. The control group is usually given a low, suboptimal (pseudoplacebo) dose of the test drug or of another AED, which raises serious ethical concerns despite use of escape criteria designed to minimize the risks associated with possible seizure deterioration. The primary efficacy variable in this paradigm is retention time in the trial after withdrawal of concomitant AED treatment. Retention is often very short and does not allow assessment of long-term seizure control, which should be the clinical objective in patients under monotherapy treatment. The dose(s) tested, moreover, may be different from those needed in less severe patients. This design, however, presents definite advantages, because it has demonstrated assay sensitivity in differentiating test drugs from pseudoplacebo, thereby providing unequivocal proof of efficacy in a monotherapy setting. The suggestion was recently made that if the data from the pseudoplacebo arms in all the studies conducted to date were pooled, perhaps through a meta-analysis, the pooled data set could be used as historical control data, thereby eliminating the need for a concurrent placebo or pseudoplacebo arm in future studies.[9] This proposal could be evaluated by the CHMP and its Efficacy Working Party; however, according to the current CHMP guideline and recent regulatory procedures, withdrawal to monotherapy data can only be considered as supportive in the monotherapy dossier. When provided within the context of an adjunctive therapy application, positive data obtained in a withdrawal to monotherapy study may also be regarded as useful safety information about the risk incurred by patients who might discontinue by themselves concomitant medication after addition of the new drug. The overall understanding, in any case, is that trials performed in patients with chronic refractory epilepsy cannot be directly extrapolated to other populations, particularly recently diagnosed patients, because of differences in disease characteristics and drug responsiveness. One possible way of circumventing this problem is to conduct dose-controlled studies in which a low dose of the test product is compared with a high dose of the same product in patients with newly diagnosed epilepsy. Although these studies have been employed for the demonstration of the efficacy of a new AED in monotherapy, the use of low (suboptimal) doses remains an ethical concern, even when escape criteria are incorporated to protect the patient against the risks of an ineffective treatment. Moreover, these trials may not allow a sufficiently long duration of double-blind assessment, and the high and the low dosages selected may not be clinically optimal, resulting in inadequate evaluation of the risk–benefit balance of the test product.

Trials conducted in newly or recently diagnosed patients are more representative of the population of patients treated with monotherapy. The use of placebo or pseudoplacebo as a control treatment is generally considered unethical in this population. Double-blind active control trials are therefore required to assess response to monotherapy in these patients; follow-up duration should permit assessment of long-term efficacy and tolerability, with seizure freedom being the primary objective in this group of patients. Accordingly, the recommendation is that the study should assess as a primary efficacy variable the proportion of patients remaining seizure free for at least 6 months (excluding the dose-escalating period). The trial should also have a minimum of 1-year duration in order to assess safety and maintenance of efficacy. Retention time on treatment, which is a combined measure of efficacy and tolerability, should also be determined because it enables assessment of the global effectiveness of the drug. Any exit criteria used to assess lack of efficacy (e.g., second or nth seizure) should be justified.

Existing active-control trials, which were designed to demonstrate superiority of a test product over an established comparator (usually carbamazepine), have failed to do so.[13] Therefore, demonstration of noninferiority is regarded as a more realistic working hypothesis for these trial designs; the clinical objective would then be the demonstration of a similar risk–benefit balance of the test product as compared to an acknowledged, optimally used standard AED. Optimal use of the comparator implies that the comparator should have an adequate spectrum of efficacy against the seizure types exhibited by the population considered for the study and that its dosage should be titrated properly and adjusted flexibly, allowing for dosage decreases in case of tolerability problems, and dosage escalations (up to a predefined maximum) in case of seizure recurrence.

Noninferiority trials, to be valid, must meet several requirements.[14] There must be evidence, either direct or indirect, that the comparator is showing its usual level of efficacy. The trial should be strictly comparable to earlier similar trials with the same comparator, and these similarly designed trials should have been consistently able to identify a difference in efficacy between the comparator and a less active treatment, which defines assay sensitivity. Such historical evidence of sensitivity to drug effects is weak for AED trials in newly diagnosed patients, although a few trials demonstrated superiority of an active control over the test product. For these reasons, active-control trials in newly diagnosed patients have been criticized on the ground that they involve a risk of not distinguishing between equivalent effectiveness and equivalent ineffectiveness.

Demonstration of noninferiority is also based on predefinition of a noninferiority margin, which represents the lowest efficacy limit that may be considered as a clinically acceptable difference versus the comparator. This margin should be determined based on statistical reasoning, clinical judgment, and past experience with placebo-controlled trials. In order to demonstrate efficacy, this margin cannot be greater than the smallest effect size that the active control would be reliably expected to have compared with placebo.[14] The notion that an established treatment, carbamazepine, for example, consistently shows superiority to placebo, and by which margin, may be regarded as insufficiently documented in newly diagnosed epilepsy.[3]

While acknowledging these difficulties, the CHMP is open to adopt a pragmatic attitude and to discuss designs of noninferiority active-control trials during scientific advice. A noninferiority margin can be determined from historical studies with the same comparator, taking into account the variability in

efficacy results. The noninferiority margin should be expressed as an absolute value as well as a relative value. The EMEA note for guidance does not indicate any specific noninferiority margin for seizure freedom or retention rates, in order to keep the possibility of adapting to the state of the knowledge and to the specificities of individual trials.

Particular attention should be given to the characteristics of the newly diagnosed patients. In particular, the number of prerandomization seizures is a factor that may influence the outcome. This was suggested by studies where patients with less than three seizures during the last 3 months prior to initiation of treatment had better efficacy outcomes than those with more than three seizures.[1,10] Any selection of the population concerning the number of prerandomization seizures should be justified. For the same reasons, designs that select patients who had a single seizure, and in whom using a placebo control would not be unethical, may not be representative enough of the general population with newly diagnosed epilepsy.

Most of the newer AEDs that are licensed for monotherapy use in EU countries, including lamotrigine, gabapentin, and topiramate, have been approved for this indication through national procedures in individual member states. The only EU procedure, the mutual recognition procedure, was conducted for oxcarbazepine in 2000, before implementation of the current guideline. The oxcarbazepine monotherapy dossier included four active-control studies in newly diagnosed patients[13] using phenytoin, sodium valproate, or an immediate-release form of carbamazepine as comparators, including a total of 780 patients. These studies did not permit identification of any differences between oxcarbazepine and the comparators in terms of efficacy, but they were not designed to demonstrate noninferiority. In addition, supportive efficacy data for oxcarbazepine were obtained in refractory patients with withdrawal to monotherapy trial designs.

Safety

The EMEA guideline includes general principles regarding the identification of adverse effects, whether they belong to the systemic, neurologic, or psychiatric domain. The safety database may include information gained in other therapeutic indications for which the drug is developed (e.g., neuropathic pain or migraine). Special efforts should be made to assess potential adverse effects that are characteristic of the class of the product being investigated, depending on its pharmacodynamic properties, mechanism(s) of action, and the receptor sites involved. For example, AEDs sharing the property of inhibiting carbonic anhydrase have some common adverse effects.[4]

Possible exacerbation of seizures should also be investigated. There is an increased awareness that AEDs can sometimes aggravate epileptic disorders, and this possibility should be taken into account in the design of clinical trials. Aggravation may consist of increased seizure frequency, often for specific seizure types (e.g., absence or myoclonic seizures), or appearance of new seizure types. Efforts should be made to identify the mechanisms involved (e.g., inappropriate choice of the drug for the patient's seizure types or syndrome, modifications of concomitant therapy per protocol requirements or due to drug interactions, spontaneous fluctuation of the condition, AED intoxication with or without overdosage, and paradoxic reactions whereby an AED appears to exacerbate a type of seizure against which it is usually effective). For instance, episodes of nonconvulsive status epilepticus, sometimes associated with signs of toxic encephalopathy, have been reported in refractory patients with partial epilepsy receiving adjunctive treatment with tiagabine.[12]

The Article 31 of directive 2001/83 of the European Commission permits the referral to the CHMP of any safety concern affecting the interests of the EU population. This procedure was followed for vigabatrin after the discovery of the risk for visual field constriction, and led to changes in the indication and warnings in the summary of the product characteristics.

Incentive Programs for Rare Diseases and Orphan Medicinal Products

Several epileptic diseases or syndromes meet the criteria for rare disease designation by the EMEA. Examples include severe myoclonic epilepsy in infancy, Lennox-Gastaut syndrome, West syndrome, and progressive myoclonic epilepsies. A dedicated committee (Committee for Orphan Medicinal Products [COMP]) reviews applications for these designated conditions and recommends their approvals. Incentives are available to foster the development of new therapies for rare diseases. Rufinamide was approved through this legislation for the adjunctive treatment of the Lennox-Gastaut syndrome seizures. Stiripentol has also been registered for the adjunctive treatment of seizures in the Dravet Syndrome (Severe Myoclonic Epilepsy in Infancy). There is a requirement, however, for additional data showing the efficacy of stiripentol associated with maximum doses of clobazam and valproate.

Collaboration with Other Organizations

In a move designed to improve the coordination of regulatory approval procedures, the U.S. Food and Drug Administration and the EMEA have started a pilot program, allowing companies to seek parallel scientific advice from both agencies simultaneously for the testing of their products. With respect to collaboration with other countries, including non-EU European countries, the revised EU pharmaceutical legislation has introduced a new provision that allows the CHMP to give opinions, in cooperation with the World Health Organization (WHO), on products that are intended for use outside the European Union. At present, these recent programs are intended for breakthrough medicines for life-threatening diseases, but they might open the door for larger-scale regulatory collaboration in other domains, including AED development and approval.

Summary and Conclusions

The EMEA coordinates and harmonizes the processing of EU license applications. The CHMP is the advisory committee to the EMEA for human medicinal products and comprises two delegates from each EU member state. The scientific expertise relies on the individual national drug agencies from the member states. The EMEA guidance and recommendations are conveyed through an ensemble of guidelines. The specific EMEA position concerning the development and approval of AEDs is described in a specific scientific guideline, but it also takes into account the experience acquired subsequently through the scientific advice and EU procedures that involved recent AEDs.

Chapter 144

Adrenocorticotropic Hormone and Steroids

Richard A. Hrachovy

James D. Frost Jr.

Introduction

Since the 1950s, adrenocorticotropic hormone (ACTH) and corticosteroids have been used to treat a variety of seizure types and epileptic syndromes. In most instances, these agents have been utilized after trials of standard antiepileptic drugs proved them to be ineffective. However, with the exception of infantile spasms, the therapeutic benefit of ACTH and corticosteroids in the treatment of disorders, such as Lennox-Gastaut syndrome, Landau-Kleffner syndrome, Rasmussen syndrome, and others, remains to be substantiated. In this chapter, the role of ACTH and prednisone in the treatment of various epileptic disorders is reviewed, and possible mechanisms by which the agents exert their antiepileptic effects are discussed.

Structure and Chemistry

Adrenocorticotropic Hormone

ACTH is a polypeptide containing 39 amino acids, the first 24 of which are required for full biologic activity. The sequence of these 24 amino acids is the same in humans and many animals, and for commercial use, ACTH is extracted from the pituitary glands of certain mammals.[109] Synthetic preparations are also available commercially (typically $ACTH_{1-24}$), and both forms have been used in the treatment of seizure disorders.

Prednisone

Prednisone is a synthetic glucocorticoid with significant anti-inflammatory and immunosuppressant effects, and only minimal mineralocorticoid properties. It is a white, odorless, crystalline powder that is formulated with several inactive ingredients for commercial use.[109] The structural formula of prednisone is shown in FIGURE 1.

Basic Mechanisms of Action

The mechanisms by which ACTH and corticosteroids produce their antiepileptic effects are not known. Certain observations during the hormonal treatment of patients with infantile spasms, to the effect that only short (less than 2 weeks) courses of therapy are required in most patients to produce permanent control of seizures, suggest that the mechanism by which ACTH and corticosteroids produce seizure control, at least in the case of infantile spasms, is unlike that of traditional antiepileptic agents. One basic question has yet to be answered: Is the effect of ACTH simply related to its ability to stimulate the release of steroids from the adrenal cortex, or does ACTH work directly on the brain to produce its antiepileptic effect? Certain evidence suggests that the latter case may be true. There are several reports that ACTH may be effective in treating patients with infantile spasms whose adrenal function is suppressed.[20,29,167] Also, the fact that some patients with infantile spasms who fail to respond to corticosteroids respond to ACTH and vice versa, lends support to this hypothesis.[60,64] Unfortunately, the treatment of infantile spasms with ACTH fragments, which are devoid of adrenocortical stimulatory effects, has been unsuccessful.[127,166]

Some of the potential mechanisms by which ACTH and corticosteroids may produce their antiepileptic effects are summarized below.

- *ACTH and corticosteroids regulate brain growth and metabolism.* Glucocorticoids and ACTH have been reported to accelerate the growth of neuroblasts in culture.[129,135] ACTH accelerates myelination[125] and stimulates RNA and DNA synthesis,[3] and both ACTH and steroids induce various enzymes of the central nervous system (CNS). For example, corticosteroids stimulate the sodium-potassium exchanger (or Na^+/K^+ATPase) in the developing cerebral cortex of the kitten.[68] Recent studies using highly sensitive gene expression profiling techniques (including DNA microarrays) have, for example, identified over 200 corticosteroid-responsive genes in the rat hippocampus alone, and these have included genes known to be involved in cell adhesion, growth promotion, axogenesis, synaptogenesis, and signal transduction.[165] Animal studies have demonstrated that corticosteroids upregulate basic fibroblast growth factor (bFGF)-2 gene expression in various brain regions. This neuropeptide has been shown to have widespread neurotrophic effects (on neurons, astrocytes, and oligodendrocytes) that regulate differentiation and function of the CNS, and it also appears to have neuroprotective activity that may facilitate recovery from injury.[114] In a human study, ACTH treatment of patients with infantile spasms was associated with increased levels of ß-nerve growth factor (NGF) in patients who had a good response to therapy,[141] suggesting that steroid modulation of NGF gene activity may be one factor underlying the efficacy of hormonal therapy. ACTH therapy for infantile spasms has also been shown to result in significant increases of serum and cerebrospinal fluid (CSF) lactate and pyruvate levels, with the most pronounced changes observed in patients who responded favorably to therapy,[113] suggesting that ACTH-induced alteration of pyruvate metabolism may contribute to its therapeutic effect. Because of these diverse effects of ACTH and corticosteroid therapy on CNS development and metabolic function, hormonal modulation of such physiologic events at a critical stage of brain maturation is one of the most commonly proposed hypotheses concerning the mechanism of action of these agents in infantile spasms.[135]

P.1520

- *ACTH and corticosteroids have direct anticonvulsant effects.* In animal models, ACTH has both pro- and anticonvulsant effects. In young rats, ACTH has been shown to have a proconvulsant effect, reducing the threshold for minimal clonic electroshock seizures. However, in adult rats, ACTH increases the threshold for electroshock seizures, and moderate to high doses of ACTH delay seizure kindling.[129] Corticosteroids have been shown to reduce hippocampal excitability in vitro.[163]

- *ACTH and corticosteroids modulate various neurotransmitter systems.* ACTH and related peptides have been reported to increase or decrease γ-aminobutyric acid (GABA) and dopamine D_2 receptor sites, reduce serotonin 5-HT_2 sites in cortex, and increase ß-adrenergic receptor binding in cortex.[27,130] The reported effects of ACTH on the metabolism of neurotransmitters have been variable. In developing animals, ACTH treatment did not alter whole-brain levels of 5-hydroxytoptamine, 5-hydroxyindolacetic acid, dopamine, dihydroxyphenylacetic acid, homovanillic acid, or glutamic acid decarboxylase,[72] whereas in adult rats, the effects of ACTH treatment on the levels of dopamine, norepinephrine, acetylcholine, serotonin, and GABA have ranged from no effect to increased turnover to increased synthesis.[130] Corticosteroids have been shown to increase the activity of GABA[79] and to block 5-hydroxytryptophan–induced myoclonus in animals.[81]

Dysfunction of certain neurotransmitter systems, most commonly the serotonergic and adrenergic, has been suggested as the pathophysiologic mechanism underlying infantile spasms.[56] However, investigations of the levels of CSF metabolites of these and other neurotransmitters in patients with infantile spasms have been inconclusive, as have studies of the effects of hormonal therapy on neurotransmitter metabolite levels.[56,130] Also, attempts at treating patients with infantile spasms using antiserotonergic and antiadrenergic drugs have not been highly successful.[58,59]

Thus, although ACTH and corticosteroids are known to modulate various neurotransmitter systems, the significance of these neuromodulatory influences in relation to the antiepileptic effects of these agents remains unknown.

- *ACTH and corticosteroids suppress the immune system.* It has been a longstanding hypothesis that an immunologic defect might be the mechanism underlying infantile spasms.[56] Several immunologic abnormalities have been reported in patients with infantile spasms, including antibodies to brain tissue in sera,[115,133] increased numbers of activated B cells and subsets of T cells in sera,[66] and an increased frequency of the human leukocyte antigen (HLA).[54,65,159] However, a definite link between the immune system and infantile spasms has not been established.
- *A dysfunction of the hypothalamic-pituitary-adrenal axis exists*. Several studies have identified reduced CSF levels of ACTH[6,7,28,117,118] and cortisol[6] in infantile spasms patients. Considering the known effectiveness of ACTH and corticosteroids in this disorder, these findings suggest a possible role for the hypothalamo-pituitary-adrenal axis in the pathogenesis of infantile spasms. Baram and her colleagues[4,7,10] have hypothesized that the basic abnormality underlying infantile spasms is stress-induced production of corticotropin-releasing hormone (CRH) early in life. The presence of elevated CRH levels produces permanent excitatory changes in brainstem circuits, which become the region from which spasms originate. The efficacy of ACTH and corticosteroids is thought to be related to their ability to downregulate CRH synthesis. However, although CRH has been shown to produce seizures in developing animals, the seizures and interictal electroencephalogram (EEG) features of these animals are not typical of those associated with infantile spasms.[7] Furthermore, elevated CSF levels of CRH have not been found in infantile spasms patients,[7] and treatment of infantile spasms patients with α-helical CRH, a competitive antagonist of CRH, has not proven beneficial.[5] Therefore, the applicability of this model to infantile spasms is doubtful.

Pharmacologic Fundamentals

Adrenocorticotropic Hormone

Although ACTH is available as a lyophilized white amorphous solid that may be reconstituted with sterile water for injection, repository ACTH injection (ACTH in a solution with partially hydrolyzed gelatin) is usually used in the treatment of patients with seizures. Following intramuscular administration of repository ACTH, the drug is absorbed during a period of 8 to 16 hours. In healthy adults, subcutaneous administration of 80 U of repository ACTH produced peak plasma concentrations of 17-hydroxycorticosteroids in 3 to 12 hours, and baseline concentrations were attained in 10 to 25 hours.[109] In most normal adults, maximal adrenal stimulation is attained after infusing 1 to 6 U of ACTH intravenously during a period of 8 hours. More cortisol is secreted with a fixed dose of ACTH if the drug is slowly given intravenously or if ACTH is given intramuscularly as the repository injection.[109] The study of Hrachovy et al.[63] on the effects of ACTH on serum cortisol levels in patients with infantile spasms showed no difference in maximal serum cortisol levels attained between patients receiving 20 U/day of repository ACTH and those receiving 30 or 40 U/day.

In the blood, ACTH is transported with Cohn protein fractions II and III. The precise distribution of the drug is not known, but it is rapidly removed from the plasma by many tissues.[109] Although the precise metabolic fate of ACTH is not known, circulating ACTH may be enzymatically cleaved at the 16-17 lysine–arginine bond by the plasmin-plasminogen system.[109] The half-life of ACTH in plasma is about 15 minutes.[50]

Prednisone

Prednisone is well absorbed following oral administration, and peak serum concentrations are seen 1 to 2 hours following oral administration.[22] Prednisone is 70% protein-bound,[14] and prednisolone, the primary metabolite of prednisone, is nonlinearly bound to transcortin and albumin.[33] The volume of distribution of prednisone is approximately 1 L/kg.[42] After oral dosing with either prednisone or prednisolone, the plasma concentration-time profiles are superimposable. A first-pass exposure to liver enzymes after oral administration of prednisone facilitates the establishment of an equilibrium between prednisone and prednisolone before they reach the systemic circulation.[33] The serum half-life of prednisone following a single oral dose of the drug is 2.6 to 3 hours.[22,31] The biologic half-life (duration of action) is between 12 to 36 hours.[50]

Adverse Effects

Dose-Related Effects

Although the side effects of hormonal therapy in epileptic patients have not been studied systematically, complications of treatment depend on the size of the dose and duration of treatment. Most of the data concerning side effects of ACTH and corticosteroid therapy in epileptic patients have been collected from patients with infantile spasms.

Hypertension

Hypertension develops in 4% to 33% of patients with infan-tile spasms who are treated with ACTH or corticoster-oids.[36,61,64,137] Evidence suggests that hypertension occurs more commonly in patients treated with higher doses.[61,137] Hypertension, if it develops following initiation of hormonal therapy, can be treated by reduction of dose, salt restriction, or use of antihypertensive medications.

Immunosuppression

A variety of infections have been reported to occur in patients treated with ACTH and corticosteroids, including pneumonia, septicemia, urinary tract infections, gastroenteritis, ear infections, candidiasis, and encephalitis.[17,21,43,61,91,96,99,137,139,146] Pneumonia is one of the most commonly occurring infections and may result in death. Thus, the preexistence or development of a respiratory tract or other infection is sufficient reason to delay or discontinue hormonal therapy.

Electrolyte Abnormalities

Hypokalemia may occur rarely in patients with infantile spasms receiving hormonal therapy.[43,61,95,99,139,140] This side effect is usually seen in patients receiving higher doses and longer durations of hormonal treatment.[61,99] Electrolyte disturbances have also been reported to occur more commonly in patients receiving synthetic ACTH.[19]

Hypertrophic Cardiomyopathy

Echocardiographic studies have shown that evidence of myocardial hypertrophy develops in 72% to 90% of patients with infantile spasms who are treated with ACTH.[2,9,88,95,132,136,158] These echocardiographic changes are reversible within months after discontinuation of ACTH therapy. It has been suggested that this myocardial change may be secondary to arterial hypertension, hyperinsulinism, and a direct effect of ACTH on myocardial cells or thickening of the myocardium, which is due to increased interstitial edema caused by increased sodium and water content.[88,95]

Brain Abnormalities

Studies using computed tomography (CT) and magnetic reson-ance imaging (MRI) have revealed that brain “shrinkage” may develop in patients with infantile spasms who are treated with ACTH and corticosteroids.[12,39,46,51,53,71,84,86,94,101,102,105,122,145,148,172] This phenomenon reportedly reverses on discontinuance of therapy; however, in several studies[39,71,106,122] the shrinkage was not reversible in 12% to 44% of patients. A variety of explanations have been suggested for these CT changes occurring during hormonal therapy including communicating hydrocephalus, loss of water, inhibition of brain growth, and alterations in the blood–brain barrier.[36,39] Intracranial hemorrhage, probably secondary to arterial hypertension, has been rarely reported in patients with infantile spasms treated with hormonal therapy.[137] Subdural effusion or subdural hematoma also occurs rarely.[46,70,71,122,145]

Eye Abnormalities

Long-term steroid therapy may be associated with the development of posterior capsular cataracts. This side effect was not observed by Hrachovy et al.[60,61,62,63,64] in patients with infantile spasms treated with ACTH or prednisone; some of these patients were given formal ophthalmologic examinations, including slit lamp examinations before, during, and following hormonal therapy. Elevated intraocular pressure was reported in a small number of patients with infantile spasms treated with high-dose corticosteroid therapy.[35] The elevated intraocular pressure was controlled with antiglaucoma medication.

Gastrointestinal Disturbances

Gastrointestinal ulceration and hemorrhages may occur in patients receiving ACTH and corticosteroids.[116] This problem has been reported rarely in patients treated with hormonal therapy.[25,38,116]

Genitourinary Disturbances

Nephrocalcinosis has been reported in small numbers of patients with infantile spasms receiving ACTH and cortico-steroids. This adverse effect has been found at autopsy[140] and using imaging studies.[131]

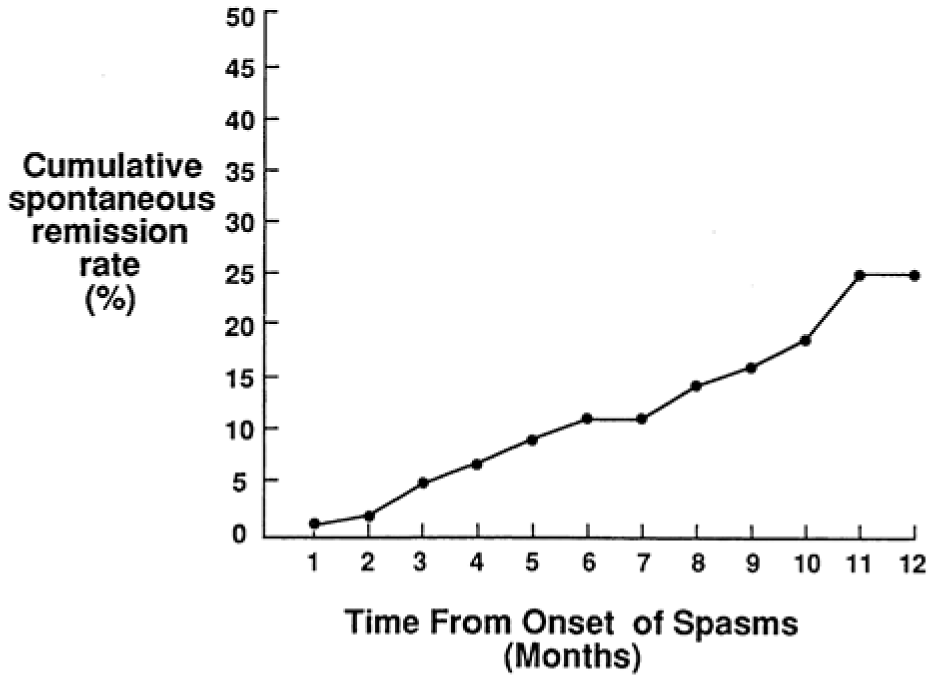

FIGURE 2. Spontaneous remission rate during the first year after onset of infantile spasms in patients who did not receive hormonal therapy (*n* = 44). From Hrachovy RA, Glaze DG, Frost JD Jr. A retrospective study of spontaneous remission and long-term outcome in patients with infantile spasms. *Epilepsia.* 1991;32:212–214, with permission.

Osteoporosis

On rare occasions, osteoporosis has been reported to occur in patients with infantile spasms treated with ACTH and corticosteroids.[99,137,140] This rare side effect would be expected to occur only in those patients receiving long-term hormonal therapy.

Weight Gain and Cushingoid Features

Many patients receiving ACTH or corticosteroids exhibit weight gain of variable degree and Cushingoid features. These changes are most pronounced in patients receiving higher doses.[16,18,21,25,61,95,96,99,137,153,154]

Irritability and Behavioral Changes

Irritability and other behavioral changes (e.g., sleep disturbance) have been reported to develop in 33% to 85% of patients with infantile spasms treated with ACTH or corticosteroids.[16,18,25,45,61,99,137,153,154,164]

Skin Disturbances

Hirsutism and acne may develop in patients treated with ACTH and corticosteroids.[99,137,154] These effects rapidly disappear following discontinuation of therapy.

Drug Interactions

Drugs that induce hepatic enzymes, such as phenobarbital or phenytoin, may increase the clearance of corticosteroids. Therefore, increases in corticosteroid dose may be required to achieve the desired response. However, it is not known if the concurrent use of drugs such as phenytoin or phenobarbital diminishes the "anticonvulsant" effect of prednisone in seizure disorders.

Clinical Indications and Contraindications

ACTH and corticosteroids are indicated as first-line therapy of infantile spasms. Their therapeutic role in Lennox-Gastaut syndrome, Landau-Kleffner syndrome, Rasmussen syndrome, and other myoclonic seizures is undetermined.

With the exception of known hypersensitivity to the drugs, the only other definite contraindication to the use of ACTH and corticosteroids in epileptic patients is systemic infection.

How to Use the Drug

Dosage Formulations and Strengths

Adrenocorticotropic Hormone

Repository ACTH injection (the most commonly used form of ACTH in epileptic patients) is available in strengths of 40 U/mL (U.S. Pharmacopeia) or 80 U/mL (USP). One USP unit of ACTH is equivalent to 1 milligram of the international standard.

Prednisone

Prednisone is available in tablet form in strengths of 1, 2.5, 5, 10, 20, and 50 mg.

Treatment Regimens for Specific Disorders

The studies reporting the effectiveness of ACTH and cortico-steroids in the treatment of seizures and epileptic syndromes have been plagued with many methodologic problems, making it difficult to evaluate and substantiate the therapeutic benefit of these hormones in the treatment of such disorders. Some of these methodologic shortcomings are reviewed, after which the treatment of specific disorders with ACTH and prednisone is discussed.

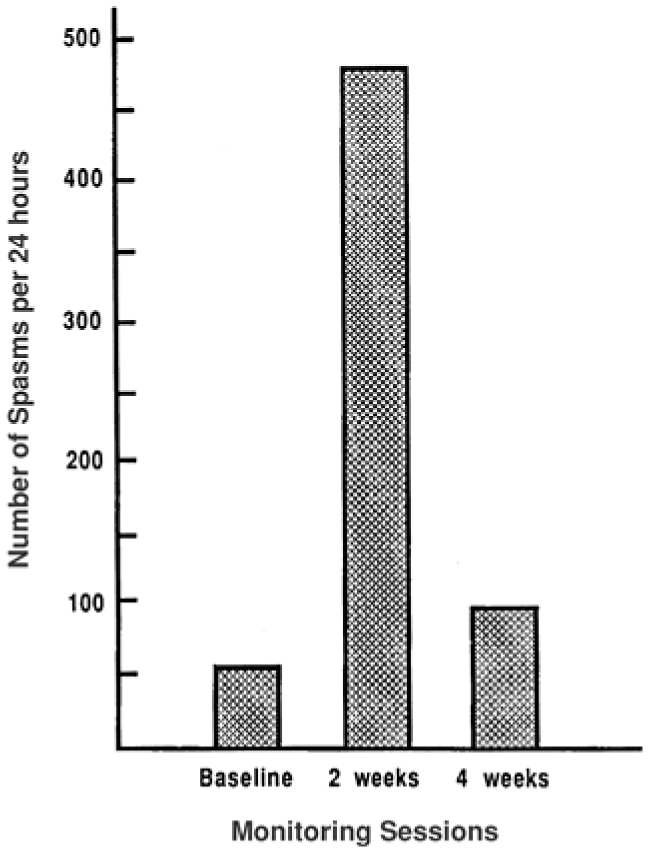

FIGURE 3. Variation in spasm frequency in a patient monitored at 2-week intervals.

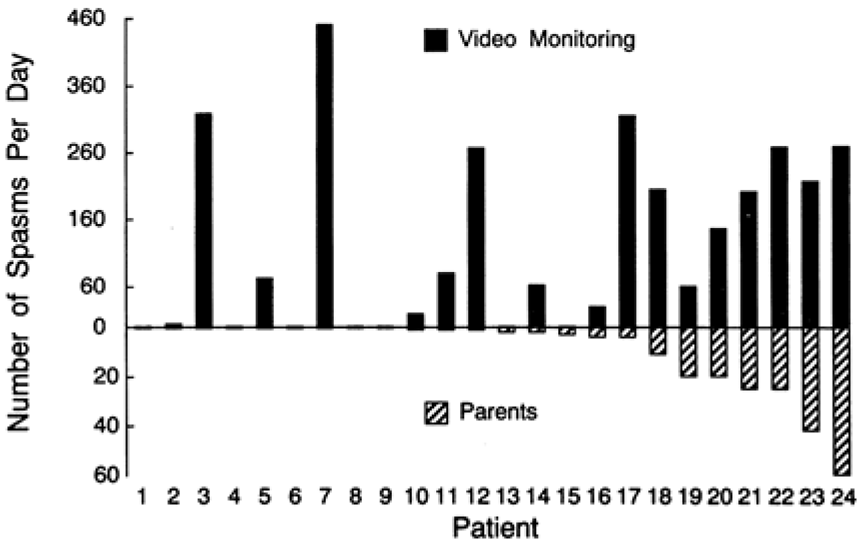

FIGURE 4. Spasm frequency after institution of ACTH or prednisone therapy: comparison of parents' estimates with 24-hour polygraphic/video monitoring.

- The natural history of many disorders that have been treated with ACTH and corticosteroids is poorly understood. For example, patients with infantile spasms or with the Landau-Kleffner syndrome may experience spontaneous remissions at various times following onset of the disorders. A retrospective study of infantile spasms[67] revealed a relatively linear rate of spontaneous remission, with 25% of patients experiencing spontaneous cessation of spasms within 12 months of onset (Fig. 2). Furthermore, in such disorders as infantile spasms,

Lennox-Gastaut syndrome, Landau-Kleffner syndrome, and various myoclonic epilepsies, seizure frequency varies tremendously over weeks and months. The variability of seizure frequency over time for a patient with infantile spasms[55] is demonstrated in FIGURE 3. Obviously, it is not possible to control for these two factors totally in any study of anticonvulsant efficacy in the disorders mentioned; however, they must always be considered in interpreting the results of any study reporting the effectiveness of ACTH, corticosteroids, or other agents in the treatment of these disorders.

- Very few well-controlled, blinded studies have evaluated the anticonvulsant efficacy of ACTH and corticosteroids, and these have been restricted to the disorder of infantile spasms (see the following paragraphs). Most studies either have been retrospective or have consisted of anecdotal reports.[36]
- The doses of ACTH and corticosteroids given, and the duration of treatment, have varied markedly. For example, doses of ACTH used to treat infantile spasms have ranged from <1 U/day to 180 U/day, and treatment duration has ranged from 1 week to more than 12 months.[36,92] Similar variations in doses of ACTH and corticosteroids and duration of treatment exist in studies of other seizure disorders.
- The study population is not always clearly defined. For example, some studies do not clearly separate patients with Lennox-Gastaut syndrome from those with other myoclonic epilepsies or infantile spasms.[1,36,92,154]
- Some investigators have treated epileptic patients with either ACTH or corticosteroids alone, whereas others have used both drugs in tandem, usually ACTH followed by corticosteroids.[36,77,80,92,96,99,119]
- The methods for determining response to ACTH and corticosteroid therapy have usually not been objective, or the means of determining response has not been stated.[36] Most studies reporting the effectiveness of ACTH and corticosteroids in various seizure disorders have relied primarily on the subjective observations of parents or other caretakers to determine therapeutic benefit. It has been documented by means of video electroencephalographic (V-EEG) monitoring that parents of infants with infantile spasms usually grossly underestimate the number of spasms their child is experiencing[55,57] (Fig. 4). Parents of children experiencing absence, myoclonic, atonic, and tonic seizures have similar difficulties in accurately determining seizure frequency.
- Appropriate criteria for determining response to therapy are not standardized and are often unspecified. For example, in the disorder of infantile spasms, some investigators have used total cessation of spasms as the definition of therapeutic response,[60,61,62,63,64] whereas others have used various graded-response paradigms.[36,92] Objective criteria for determining response in other disorders (e.g., Lennox-Gastaut syndrome) also remain to be established. Should response in the Lennox-Gastaut syndrome be defined in terms of seizure frequency only, or should drug effects on interictal epileptiform activity also be included? Until such objective criteria are established, the role of hormonal therapy, as well of as that of other agents used to treat these disorders, will remain controversial.

Infantile Spasms

Since the report in 1958 by Sorel and Dusaucy-Bauloye[157] that treatment of infantile spasms with ACTH results in the cessation of spasms and disappearance of the hypsarrhythmic EEG pattern, many reports have appeared concerning the treatment of this disorder using ACTH and corticosteroids. An in-depth review of this topic can be found in a recently published book by Frost and Hrachovy.[36] The therapeutic response to these agents can be divided into two categories—acute effects and long-term effects.

Acute effects.

During the past five decades, three basic opinions concerning the acute effects of ACTH and corticosteroids on spasm frequency and the hypsarrhythmic EEG pattern have evolved. Some individuals consider ACTH and corticosteroids to be equipotential, whereas others consider ACTH to be superior.[8,80,90,92,99,100,153,154,155,167] Still others believe that higher doses and longer durations of ACTH therapy[8,15,18,44,80,87,94,96,99,152,153,154] are superior to lower doses and shorter durations of therapy.[43,47,49,69,73,74,85,89,104,112,120,121,134,145,160,161,167,170,172] The most dramatic results have appeared in the reports by Snead et al.[153,154] and Kivity et al.,[80] in which 92% to 100% of patients treated with high-dose ACTH experienced cessation of spasms and disappearance of the hypsarrhythmic pattern. These results obtained with high-dose ACTH therapy far surpassed any previously reported. Unfortunately, most previous studies have suffered from many of the methodologic problems listed earlier, most importantly the lack of controlled, blinded trials and the lack of an objective means of assessing response.

Starting in the late 1970s, a series of controlled trials of ACTH and corticosteroids in the treatment of infantile spasms was performed by Hrachovy et al. in small numbers of patients. Serial, long-term polygraphic/video monitoring studies were utilized to determine objectively the acute response to therapy. In all studies, response was defined as cessation of spasms and disappearance of the hypsarrhythmic EEG pattern. The initial studies were aimed at comparing the relative efficacies of low-dose ACTH (20 to 30 U/day for 2 to 6 weeks) and prednisone (2 mg/kg/day for 2 to 6 weeks).[60,62,63,64] The results of these studies are as follows: (a) There was no significant difference in response to low-dose ACTH and prednisone; (b) patients who failed to respond to ACTH could respond to prednisone and vice versa; (c) approximately 60% of patients responded to low-dose ACTH, prednisone therapy, or both; (d) response to hormonal therapy usually occurred within 1 to 2 weeks of initiation of therapy in most patients, an observation reported by others;[36] (e) once a response was documented, hormonal therapy could be immediately discontinued, and the response maintained; (f) if a relapse occurred, a second course of ACTH or prednisone therapy was usually effective; (g) treatment lag and etiology were not useful predictors of response to hormonal therapy—patients with long treatment lags responded just as well as those with short ones, and symptomatic patients responded just as well as cryptogenic patients; (h) disappearance of the hypsarrhythmic EEG pattern could occur after ACTH or prednisone therapy, even though spasms continued; and (i) the side-effect profiles of low-dose ACTH and prednisone were similar.

Following completion of the studies of low-dose ACTH and prednisone therapy, a single-blind study of high-dose ACTH versus low-dose ACTH therapy in patients with infantile spasms was performed.[61] Patients receiving high-dose ACTH therapy were treated as follows: 150 U/m^2/day for 3 weeks, then 80 U/m^2/day for 2 weeks, then 80 U/m^2 every other day for 3 weeks, then 50 U/m^2/day for 1 week, with the dose tapered to none during a final 3-week period. Patients assigned to low-dose ACTH therapy received 20 to 30 U/day for 2 to 6 weeks. The results of this study were as follows: (a) No significant difference in response rates was noted between patients assigned to high-dose or low-dose ACTH therapy— 58% of patients treated with low-dose ACTH responded, versus 50% of those treated with high-dose ACTH; (b) no significant difference was noted in the number of normal EEG findings in patients who responded to high-dose versus low-dose ACTH therapy; (c) no significant difference was noted in the relapse rate between the two groups; and (d) the side effects seen in both treatment groups were similar, with the exception of hypertension, which occurred more frequently in the high-dose group.

In 1996, Baram et al.[8] reported the results of a controlled, blinded trial of high-dose ACTH (beginning dose 150 u/m^2/day) versus prednisone (2 mg/kg/day) utilizing V-EEG monitoring to determine response objectively. Of the patients treated with high-dose ACTH, 13 of 15 (87%) responded in comparison to 4 of 14 (29%) patients treated with prednisone.

Unfortunately, not only are the results of these controlled studies conflicting, but the numbers of patients in these studies are too small to reach meaningful conclusions. Thus, although ACTH and corticosteroids have been used to treat patients with infantile spasms for half a century, there remain major disagreements and conflicting views about the use of these agents. In 2004, committees of the American Academy of Neurology and the Child Neurology Society[103] published a practice parameter for the medical treatment of infantile spasms. These committees rigorously reviewed the scientific merit of the various agents used in the treatment of infantile spasms. As concerns the treatment of infantile spasms with ACTH and corticosteroids, the committee concluded that ACTH is probably effective in the short-term treatment of infantile spasms, but there was insufficient evidence to suggest an optimal dosage or duration of treatment with ACTH. Also, the committee determined that insufficient evidence existed that corticosteroids are effective in the treatment of infantile spasms.

The reported relapse rates for low-dose ACTH have ranged from 21% to 100%;[43,47,61,74,104,112,156,170] those for high-dose ACTH have ranged from 13% to 59%;[8,18,61,87,153,154] and those for prednisone have ranged from 9% to 100%.[21,74,82,126,154] However, the relapse rate in most studies is in the range of 25% to 33%.[36]

Many investigators have reported that treatment lag is not a useful predictor of acute response to therapy.[32,52,61,62,63,64,87,124,167,173] However, several authors[69,90,99,119,143,147,160] have observed better response rates in patients with short treatment lags (usually less than 1 month). Also, some investigators have reported that symptomatic patients responded as well as cryptogenic patients.[32,52,62,63,64,87,120,124,167,173] On the other hand, some authors have reported a better response in cryptogenic patients.[69,96,99,119,138,143,147,160]

Long-term effects.

The results of studies assessing long-term outcome in patients with infantile spasms following ACTH and corticosteroid therapy are just as varied as those regarding the acute effects of hormonal therapy. About 9% to 13% of patients with infantile spasms treated with lower doses and shorter durations of hormonal therapy have been reported to have normal development.[75,76,90,108,124,168,169] However, some investigators have found no difference in long-term outcomes in treated versus untreated patients.[34,36,75,90,92] Others have reported better outcomes in patients given higher doses and longer durations of ACTH therapy.[80,99,151] These studies are plagued by many of the problems described earlier. Primarily, most studies concerned with long-term outcome have been retrospective. Furthermore, the classification of patients (cryptogenic vs. symptomatic) has been highly variable from study to study, and many studies have not used such diagnostic tests as CT or MRI to aid in classifying a patient as symptomatic or cryptogenic.[36] A major problem inherent to all studies of

this disorder is the inability to predict long-term outcome accurately in most patients with infantile spasms at time of onset. Without such knowledge, it is extremely difficult to assess the effects of hormonal therapy.

Very few prospective studies evaluating long-term outcome in infantile spasms have been performed. One such study by Glaze et al.[40] that included patients treated with low-dose ACTH (20 to 30 U/day for 2 to 6 weeks) or prednisone (2 mg/kg/day for 2 to 6 weeks) revealed the following: (a) Only 5% of patients had a normal outcome; (b) severe or very severe impairment was observed in 67% of the patients; (c) no significant difference was noted between responders and nonresponders with respect to long-term outcome; (d) no significant difference was noted in long-term outcome between responders to ACTH and responders to prednisone; (e) no significant difference was noted in long-term outcome between patients treated within 5 weeks after onset of spasms and those treated more than 5 weeks after onset—early treatment of cryptogenic patients did not ensure a normal long-term outcome even if the patients responded to therapy; (f) cryptogenic patients had significantly better outcomes (40% were normal) than did symptomatic patients (5% were normal)—this is one consistent finding among all studies of long-term outcome in this disorder; (g) factors could not be identified that would allow prediction of which patients would have good outcomes and which would not, even in the cryptogenic group; and (h) other seizure types developed in roughly half the patients. However, no other seizures developed in cryptogenic patients who responded to hormonal therapy. In a subsequent prospective study in a small number of patients that compared high-dose ACTH (150 U/m^2/day) with lower doses of ACTH (20–30 U/day), there was no significant difference in developmental outcome between the two groups at an average follow-up period of 10 years.[13]

Considering the lack of controlled, prospective studies examining the effect of ACTH and corticosteroids on long-term outcome, it is not surprising that the committees of the American Academy of Neurology and the Child Neurology (see earlier) concluded in 2004 that the data were insufficient to make any recommendations regarding the use of ACTH or corticosteroids to improve long-term outcome in infantile spasms patients. Also, they concluded that the data were insufficient to indicate that early initiation of treatment with these agents would improve long-term outcome. Similar conclusions were reached by Frost and Hrachovy[36] in their review of the subject.

Recommended treatment regimen for infantile spasms.

A variety of therapeutic agents have been reported to be effective in the treatment of infantile spasms. If an agent is effective, the response usually occurs within the first few weeks of initiation of treatment. Thus, the key factor in treating these patients is to avoid unnecessarily prolonged treatment with ineffective agents. If one modality does not produce a response in a short time, it is withdrawn and a new trial is initiated using a new agent.[36] If hormonal therapy is chosen, either ACTH or corticosteroids may be used. If ACTH is used, a lower dose is recommended, because the current evidence does not indicate that higher doses of the drug produce better response rates, and adverse effects are more common with higher doses (see earlier discussion). Before institution of hormonal therapy, clinical evaluation (including CT, MRI, or both) should be performed, and a baseline EEG, including a sleep tracing, should be obtained. If ACTH is chosen, the initial dose is 20 U/day. After 2 weeks of ACTH therapy at 20 U/day, the EEG is repeated. If the patient shows a response (defined as total cessation of spasms and disappearance of the hypsarrhythmic pattern), ACTH is tapered and discontinued during a 1-week period. If the patient has not responded after 2 weeks of ACTH therapy, the dose is increased to 30 U/day, and treatment is continued at this dose for an additional 4 weeks, after which it is tapered and discontinued during a 1-week period. The EEG is repeated at this point. Patients who have responded to ACTH are followed in a routine clinical manner. If a relapse occurs later, a course of ACTH is repeated at the dose at which the initial response occurred. If a patient does not respond to ACTH and has not been treated with prednisone, prednisone can be given after ACTH has been discontinued for 1 week. If prednisone is administered, it should be given at a dose of 2 mg/kg/day. The follow-up is similar to that of patients receiving ACTH. If a patient shows a response after 2 weeks of therapy, prednisone is tapered and discontinued during a 1-week period, and the patient is followed routinely. If the patient has not responded after 2 weeks of prednisone therapy, the drug is continued at a dose of 2 mg/kg/day for an additional 4 weeks, after which it is tapered during a 1-week period and discontinued. Patients who have responded to prednisone are followed in a routine manner. If a relapse occurs, a course of prednisone is repeated. If the patient does not respond to prednisone and has not been treated with ACTH, ACTH is begun after prednisone therapy has been discontinued for 1 week.

Throughout the entire course of ACTH or prednisone therapy, the patient's blood pressure should be monitored closely, and serum electrolytes should be checked weekly. The patient also should be observed closely for signs of infection.

Synthetic ACTH and ACTH fragments.

Different formulations of ACTH are used throughout the world to treat infantile spasms patients. In the United States and some other countries, most physicians use natural ACTH, which is injected intramuscularly in gel (repository) form. In Japan and many other countries, synthetic preparations (typically $ACTH_{1-24}$) are used. There appears to be no difference in the therapeutic efficacy between the naturally occurring ACTH preparation and the various synthetic ACTH compounds.[36] Treatment of infantile spasms using certain fragments, $ACTH_{4-10}$ and $ACTH_{4-9}$, which are devoid of stimulating effects on the adrenal cortex, has been unsuccessful.[127,166]

Lennox-Gastaut Syndrome

ACTH and corticosteroids have been reported to be effective in a significant number of patients with the Lennox-Gastaut syndrome.[1,24,90,93,123,142,149,171] Doses of ACTH of up to 100 U/day and prednisone of up to 4 mg/kg/day were used in these studies. Duration of treatment has ranged from 10 days to many months. Although response rates of 40% to 60% have been reported, it is not clear which seizure types seen in Lennox-Gastaut patients are most responsive to ACTH or corticosteroid therapy, or how the EEG is affected by hormonal therapy. Also, it has been reported that the effects of hormonal therapy are transient and that relapses are common.[1] The marked variability in seizure frequency over time and the difficulty in assessing seizure frequency in patients with Lennox-Gastaut syndrome, as well as the lack of objective criteria for evaluating response, make the determination of antiepileptic efficacy in such patients extremely difficult.

Finally, if ACTH and corticosteroids are beneficial in stopping seizures and improving the EEG patterns of patients with Lennox-Gastaut syndrome, it is difficult to explain why the EEG and clinical features of Lennox-Gastaut syndrome develop in some patients with infantile spasms while they are being treated with ACTH or corticosteroids (R. A. Hrachovy, unpublished observations).

At present, the role of ACTH and corticosteroids in the treatment of Lennox-Gastaut syndrome remains uncertain. Current evidence indicates that hormonal therapy does not significantly alter the course of these patients.

Landau-Kleffner Syndrome

A handful of studies concerning the treatment of Landau-Kleffner syndrome with ACTH and corticosteroids have been published.[11,78,97,98,107,110,123,144,150,162] The reported efficacy is highly variable, ranging from no effect to reduction of seizure frequency and improvement in neuropsychologic function and language. The information on dosage in these studies is limited. In those studies in which the doses of prednisone were indicated, the initial daily dose ranged from 25 to 60 mg/day. The doses of ACTH used have not been provided.

Early treatment, initially high doses of steroids, and long duration of therapy (many months) have been identified as important factors leading to response and decreased rates of relapse.[97,107] However, the relatively few number of patients treated, the lack of controlled trials, and the markedly fluctuating course of patients with Landau-Kleffner syndrome make it difficult to determine if the clinical and EEG improvements reported are in fact attributable to steroid therapy. Further studies are needed to determine if ACTH and corticosteroids are effective in treating this disorder, and what treatment regimen is most effective.

Rasmussen Syndrome

Initial anecdotal reports of hormonal therapy in patients with Rasmussen syndrome were negative.[41,128] However, recent studies have been more encouraging. Dulac et al.[26] reported that all seven patients with epilepsia partialis continua secondary to Rasmussen syndrome initially responded after 1 to 18 months of high-dose corticosteroid therapy, consisting of 3 to 18 boluses of methylprednisolone (400 mg/m^2) during the first year and oral prednisone for 2 to 26 months. Only one of the seven patients achieved a “stable response” during the 2-year follow-up. The remainder had transient exacerbations of decreasing intensity (five patients); the final patient with epilepsia partialis continua showed increasing deficit. Hart et al.[48] reported that 10 of 17 patients (59%) with Rasmussen syndrome who were treated with steroids showed some reduction (25%–75%) in seizure frequency in the “short term.” Doses of prednisone used varied across patients. ACTH was used in one patient, but the dose was not provided. Some of the patients treated with steroids also received immunoglobulins. Only two patients showed prolonged benefit after steroid withdrawal. These authors attributed the somewhat better results reported by Dulac et al.[26] to the differences in the steroid regimen used. They also suggested that in “optimal doses,” steroids may modify the endpoint of the disease, and that the quality of life at that point may be superior to that after hemispherectomy.

At present, the real benefit (short-term and long-term) of steroid therapy for Rasmussen syndrome has not been established. The difficulties in performing blinded studies of therapy in this disorder are summarized by Hart et al.[48] Because the incidence of Rasmussen syndrome is very low, these authors recommend the establishment of a central registry and the use of standardized protocols in the assessment of the medical treatment of this disorder. The general recommendation for the treatment of Rasmussen syndrome by these investigators is an initial course of intravenous immunoglobulins. If no improvement is seen after 1 month of immunoglobulin therapy, a combination of intravenous methylprednisolone given at variable intervals during 3 years and oral prednisone for 1 to 2 years should be tried.

Specific recommendations concerning the treatment of Rasmussen syndrome with hormonal therapy cannot be made until further studies are completed.

Other Disorders

Isolated reports document the use of ACTH and cortico-steroids as being beneficial in patients with various other types of seizures, including absence,[37,83,111,154] generalized tonic-clonic,[23,83] myoclonic,[37,154] partial,[154] and status epile-pticus.[30,111] The information provided in these reports is insufficient to recommend the treatment of these seizure types with ACTH or corticosteroids.

Discontinuing the Drug

The information concerning when and how to discontinue ACTH and corticosteroids in the treatment of infantile spasms was presented earlier. Response criteria and optional duration of treatment for Lennox-Gastaut syndrome, Rasmussen syndrome, and Landau-Kleffner syndrome have not been established.

Summary and Conclusions

In summary, although ACTH and corticosteroids have been shown to be effective in the treatment of infantile spasms, their role in the treatment of other seizure disorders has yet to be determined. Side effects associated with hormonal therapy can range from mild and transitory to fatal; consequently, patients must be closely monitored. The mechanism by which ACTH and corticosteroids exert their antiepileptic effect remains to be elucidated.

Chapter 145

Benzodiazepines

Dieter Schmidt

Alan J. Wilensky

Introduction

The benzodiazepines represent a clinically relevant class of compounds that possess a broad range of properties, including anticonvulsant efficacy. In 1965, diazepam was the first benzodiazepine used to treat status epilepticus (SE) in humans and, since then, several other benzodiazepines have entered the market.[29] Currently, benzodiazepines such as diazepam or lorazepam are drugs of first choice for emergency treatment of acute seizures, series of seizures, and initial treatment of SE.[56] More recently, buccal midazolam has been evaluated for emergency use in acute seizures, mainly in children.[44] In addition, a number of other benzodiazepines such as clobazam, clonazepam, clorazepate, and nitrazepam are in clinical use in various parts of the world, mostly as add-on medication for refractory epilepsy. However, sedation and hypersalivation at doses that are comparable to those that protect against seizures, and, importantly, loss of efficacy during prolonged treatment, have limited their usefulness. Earlier reviews are available.[29,57] This chapter outlines the chemistry, pharmacology (including clinical pharmacokinetics), efficacy, adverse effects, and clinical use of several benzodiazepines—clorazepate, clobazam, clonazepam, diazepam, lorazepam, midazolam, and nitrazepam—used in the treatment of epilepsy.

Chemical Structure, Formulations and Methods for Determination in Body Fluids

The term *benzodiazepine* refers to that central portion of the chemical structure comprising a benzene ring attached to a seven-membered diazepine ring (Fig. 1A). The majority of clinically important benzodiazepines contain a third ring (5-aryl substituent) and have nitrogen substitutions at the 1 and 4 positions of the diazepine ring (Fig. 1B); these are generally referred to as 1,4-benzodiazepines. Altering the positions of the two nitrogen atoms in the heterocyclic ring can confer similar anticonvulsant properties. An example is clobazam, a 1,5-benzodiazepine.[2,29] Both midazolam, a short-acting benzodiazepine, and flumazenil, an equally short-lived benzodiazepine competitive antagonist, have imidazole rings attached at position 1 of the diazepine ring, in contrast to other anticonvulsant benzodiazepines, which have hydrogen or an alkyl group in that position.[2]

Formulations

In many countries—with the notable exception of the United States—clobazam is available for oral administration as tablets but not available for intravenous or intramuscular injection. Clonazepam can be administered as tablets and drops and as an intravenous formulation. Clorazepate can be prescribed as tablets and slow-release capsules and, in some countries, as an intravenous and intramuscular formulation. Diazepam is administered by oral, intravenous, intramuscular, and rectal routes and is available as oral solution, tablets, a sustained-release capsule, a rectal suppository, a rectal solution, a rectal gel, and a parenteral formulation. Intramuscular injection of diazepam produces variable serum levels and is not a recommended route of administration.[57] Lorazepam is widely available as oral and sublingual tablets and as an intravenous and intramuscular formulation. Midazolam is in use as a tablet, syrup, and a parenteral formulation for buccal, oral, intranasal, and rectal routes. Nitrazepam is administered by oral, rectal, and intravenous and intramuscular routes.[2]

Methods for Determination of Benzodiazepines in Body Fluids

Assay methods are available for the determination of serum levels of various benzodiazepines, including gas and liquid chromatographic procedures.[2,29] However, as will be pointed out, their usefulness for guiding the treatment of epilepsy is limited, mainly because the dosage is usually titrated against immediate therapeutic effects, and the correlation of serum concentration to effect during chronic treatment is hampered by the development of tolerance to therapeutic and adverse effects of benzodiazepines.

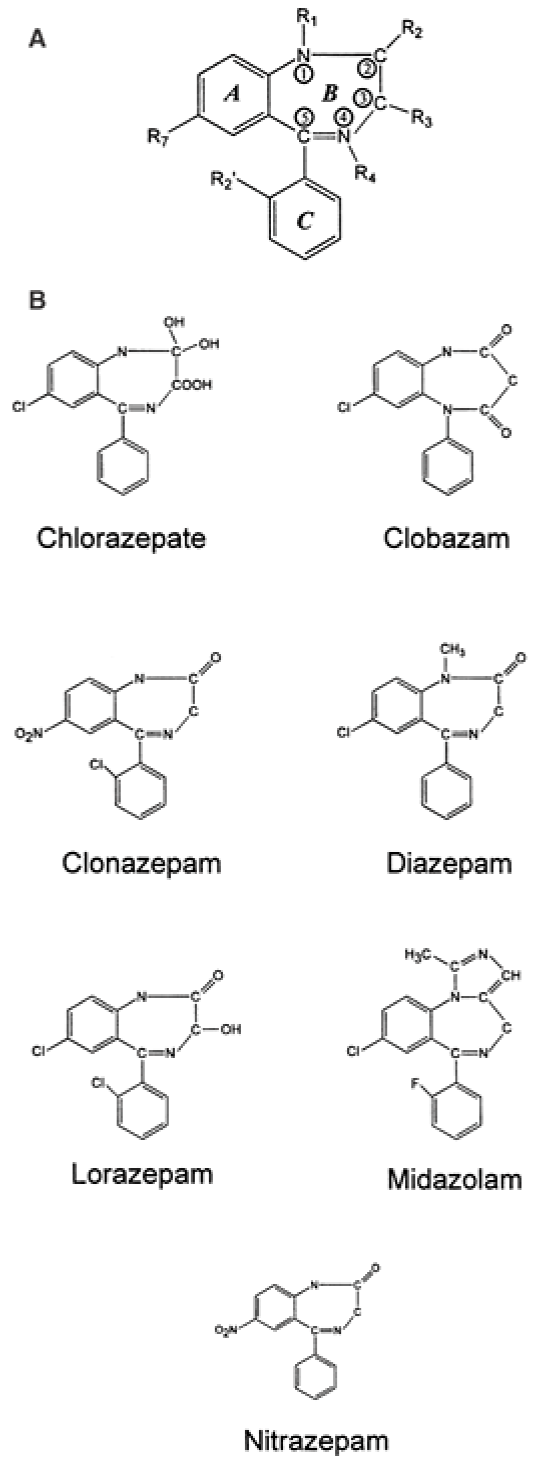

FIGURE 1. A: The generic chemical structure of benzodiazepines. **B:** The chemical structure of common anticonvulsant benzodiazepines. Note that clobazam is a 1,5-benzodiazepine.

Pharmacology

Activity in Experimental Models of Seizures/Epilepsy

Benzodiazepines effectively block seizures induced by pentylenetetrazol, a potent noncompetitive antagonist at γ-aminobutyric acid $(GABA)_A$ receptors. Activity in this animal seizure model has been considered very predictive of drugs with potential clinical utility against myoclonic and absence seizures.[39] Benzodiazepines also block seizures induced by maximal electroshock model, which is used to screen possible antiepileptic drugs (AEDs) for the treatment of partial seizures with or without secondary generalization. In addition, the benzodiazepines have been shown to be effective in models of partial seizures induced by cortical lesions induced by a variety of agents, including alumina cream, cobalt, penicillin, and strychnine.[39] Finally, loss of efficacy during prolonged treatment with benzodiazepines has been shown in a number of experimental models of partial epilepsy, including amygdala kindling.[37]

Mechanisms of Action

The primary target of benzodiazepines is a postsynaptic receptor for the neutral amino acid GABA, the major inhibitory neurotransmitter in the central nervous system (CNS). GABA is released from presynaptic neurons and binds to at least two classes of receptors, $GABA_A$ and $GABA_B$ receptors, which are found on almost all cortical neurons.[40] It is well established that benzodiazepines have primary actions as anticonvulsants by interacting with $GABA_A$ receptors at the benzodiazepine binding site and allosterically modifying the GABA receptor currents to enhance inhibition.[40] Binding to the benzodiazepine recognition site results in enhancement of $GABA_A$ receptor current by increasing the frequency of the $GABA_A$ receptor opening without significantly affecting the mean open time or conductance of the channel.[40] This is in contrast to barbiturates, which increase the mean open time and burst duration of $GABA_A$ receptor channel openings without affecting frequency of channel opening.[40,51] It is important to recognize that benzodiazepines, unlike barbiturates, cannot directly activate the $GABA_A$ receptor in the absence of GABA, the endogenous ligand, even at very high concentrations.[40] However, advances in understanding the molecular biology of GABA receptors demonstrate that the GABA receptor is made up of many different subunits (α, β, γ, δ, ρ) with different subtypes in many combinations; it is undergoing continual characterization.[40] $GABA_A$ receptors containing the α_1 subunit are an important target for protection of seizures by benzodiazepines.[51] The effects of benzodiazepines on tonic $GABA_A$ receptor currents, which originate from GABA acting on extrasynaptic receptors, may be important for their action.[51] The antiabsence activity of benzodiazepines probably results from their ability to interfere with hypersynchronous activity in the thalamocortical circuitry that is believed to underlie the 3-Hz spike-and-wave activity that is characteristic of generalized absence seizures.[51] More specifically, benzodiazepines are thought to reduce the inhibitory output of the reticular neurons by effects on benzodiazepine-sensitive α_3-containing $GABA_A$ receptors and therefore prevent absence seizure activity.[51]

It is of clinical interest that the multiple GABA receptor isoforms described here have a differential sensitivity to benzodiazepine receptor ligands that may have different clinical actions. In the future, it may be possible to develop benzodiazepine receptor ligands that have selective anticonvulsant actions without undesirable side effects. One such side effect is the development of tolerance to effect during prolonged treatment. Although the exact mechanism of tolerance is not clear, it has been suggested to include a reduction in the allosteric interactions between the $GABA_A$ receptors at the benzodiazepine recognition site and changes in the subunit pattern.[49] Because tolerance to adverse effects such as sedation sets in within days, whereas tolerance to efficacy takes weeks to months to fully develop, the mechanisms for tolerance to side effects and efficacy may differ. However, some of the clinical effects of benzodiazepines in experimental animals cannot be explained simply by their potentiation of GABA-activated currents,[29] and benzodiazepines may act on targets other than the $GABA_A$ receptor. Through unknown mechanisms, benzodiazepines may produce elevations of GABA levels in the cerebrospinal fluid.[38] At high concentrations, especially those that may be achieved in the treatment of SE, benzodiazepines may have significant effects on inhibiting currents carried by voltage-gated sodium and, to a lesser extent, calcium channels.[40]

Table 1 Clinical pharmacokinetics of benzodiazepines

AED	T_{max} (h)	V (L/Kg)	Fraction bound (%)	Half-life (h)	Clearance (m/min/kg)
Clobazam	1.3-1.7	0.87-1.83	82–90	16.6–48.6, DMC 36–46	0.36-0.63
Clonazepam	1–4	2.1±0.6	86	17–56	94-125
Clorazepate	PO: 0.5-2, IM: 2.7–11	0.7-2.2	96-98	40–130	0.18-0.27
Diazepam	PO: 30–90 min, IM: 30-60 min Rectal gel: 10-30 min	0.95-2.0	96-99 DMD 97	28-54	15-35
Lorazepam	PO: 2.4 ±0.3 SL: 2.3±0.7 IM: 1.2 ±0.3	0.85–1.5	93.2±1.8	7–26	0.91–1.76
Midazolam	PO: 0.5–0.97 IM: 0.24–0.51	0.7-1.7	96	1.36–4	6.4-11.1
Nitrazepam	1.35–2.47	2.5-2.9	85–88	21–40	1.51–1.91

(DMC, desmethylclobazam; DMD, desmethyldiazepam; IM, intramuscular; PO, oral, SL, sublingual; T_{max} time of peak concentration; V, volume of distribution; mean ± standard deviation. Modified from Anderson GD, Miller JW. Benzodiazepines. Chemistry, Biotransformation and Pharmacokinetics. In: Levy R, Mattson R, Meldrum B, Perucca E, eds. *Antiepileptic Drugs*, 5th ed. Philadelphia: Lippincott Williams & Wilkins;2002:187-205, with permission.)

Clinical Pharmacokinetics

Absorption

In general, the benzodiazepines are absorbed rapidly, with peak concentrations after oral use ranging from 0.5 to 4 hours. The absorption of orally administered benzodiazepines is 80% or more.[2]

Although clorazepate is soluble and well absorbed orally, the acidic gastric environment is bypassed during intravenous administration, resulting in less production of the active metabolite desmethyldiazepam. Thus, intravenous administration is not useful in the treatment of SE.[2]

Within tens of seconds after intravenous administration, the anticonvulsant effect of diazepam can be seen on an

P.1533

electroencephalogram (EEG) as suppression of epileptiform discharges in humans.[57] On a cautionary note, intravenous diazepam solution may precipitate when mixed with saline solution, and it may also adsorb to polyvinyl tubing.[29,56] If left diluted in an intravenous fluid bag for 24 hours, diazepam is reported to lose 95% of its intrinsic activity;[29] thus, fresh solutions should be made within 6 hours of use. Rectal delivery of diazepam results in higher and earlier peak blood concentrations compared with either oral or intramuscular routes.

Lorazepam can be administered orally, sublingually, and intravenously. It is rapidly distributed into the brain, and peak levels are attained within 5 minutes.[2] Human studies demonstrate sedative effects and EEG sleep spindles within 0.5 to 4 minutes of infusion of doses ranging between 2 and 5 mg.[29] The ability to administer lorazepam sublingually is attractive when intravenous access is not readily available.[24] Sublingual use of lorazepam is easier to administer, maintains privacy, and is seen as more dignified than rectal application of diazepam. Some physicians recommend it instead of rectal diazepam for prevention of seizure recurrence. Sublingual lorazepam was successful in controlling serial seizures in ten children.[69]

Plasma Protein Binding and Distribution

The various benzodiazepines are fairly highly protein-bound, although it is the free (unbound) benzodiazepine that is active (Table 1). The benzodiazepines as a group are lipophilic and have a high volume of distribution. In obese patients, the volume of distribution is larger.[29] Some studies show a larger volume of distribution of benzodiazepines in female patients compared with that in male patients, which is thought to be a reflection of the proportion of adipose tissue.[29] Brain levels of diazepam are nearly double that of serum concentrations, and appear to be highest in brainstem and white matter compared with gray matter.[29] Protein binding is reduced in neonates and patients with hepatic disease. The mean apparent volume of distribution is approximately 1.1 L/kg (range, 0.8 to 2.6 L/kg), and is generally higher in young children.[29] Renal or hepatic disease results in a decreased plasma clearance of desmethyldiazepam. Diazepam distributes rapidly throughout lipid tissues and quickly crosses the blood–brain barrier (BBB).[29] Within minutes, however, brain concentrations decline swiftly as diazepam is redistributed to other fatty tissues, resulting in a short distribution half-life ($t\alpha$, approximately 1 hour).[29,57] After a single bolus injection, the concentration of free (active) diazepam in the brain may fall below therapeutic levels within half an hour.[57]

Metabolism

All the anticonvulsant benzodiazepines, except for lorazepam and clonazepam, are metabolized by hepatic microsomal enzymes to pharmacologically active demethylated and hydroxylated compounds[26,29] (Fig. 2). These metabolites are subsequently glucuronidated to inactive, more water-soluble compounds that are readily excreted in the urine. The active metabolites are often very important; for example, clorazepate is essentially a prodrug for its active metabolite, desmethyldiazepam. Clobazam has up to 14 metabolites, but the main active metabolite is desmethylclobazam, also called norclobazam. Desmethylclobazam has comparable affinity for the brain benzodiazepine receptor and also has antiepileptic activity.[57] After long-term administration, at steady state the serum concentration of desmethylclobazam in most studies is eight to 20 times higher than that of clobazam.[29] Clobazam and its metabolite desmethylclobazam both have anticonvulsant properties, but desmethylclobazam is only one-fifth as potent as the parent compound.[29] Because the ratio of plasma levels of the metabolite desmethylclobazam to those of the parent drug is about 10:1, and because the metabolite also has a longer half-life, the anticonvulsant property may be more attributable to desmethylclobazam than to clobazam.

Clonazepam undergoes nitroreduction to 7-aminoclona-zepam, followed by acetylation to 7-acetamidoclonazepam, but neither metabolite appears to have clinically important pharmacologic activity.[25] A major metabolic pathway for clonazepam involves acetylation. Rapid acetylators are more likely than slow acetylators to require higher doses.

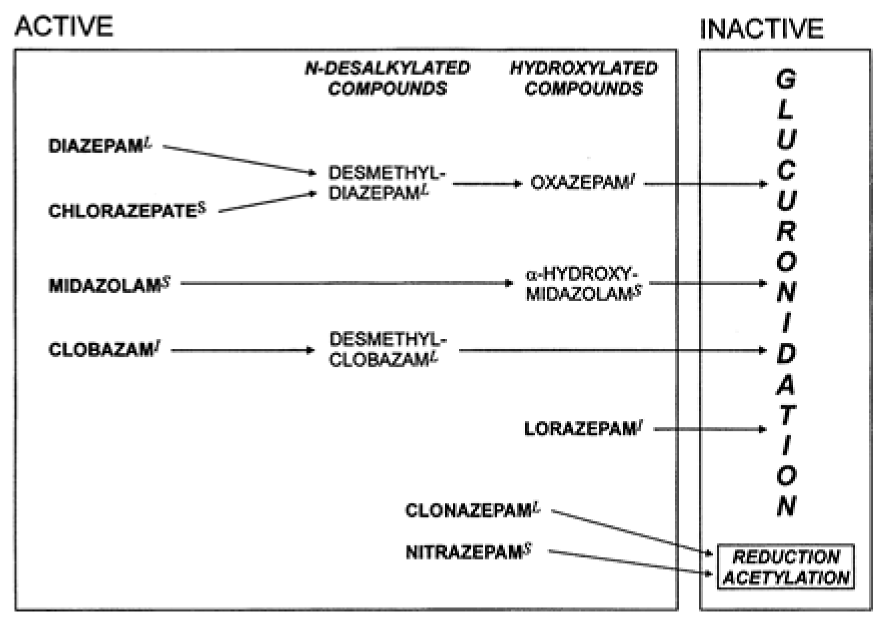

FIGURE 2. The metabolism and biotransformation of anticonvulsant benzodiazepines.

Clorazepate is a prodrug and exerts its effects through its active metabolite, desmethyldiazepam. Clorazepate undergoes complete transformation (100%) to desmethyldiazepam.[29] Desmethyldiazepam is also the main metabolite of diazepam

P.1534

(see section on diazepam for a description of its characteristics). Clorazepate has intrinsic anticonvulsant activity, but this is small compared with that of desmethyldiazepam. Clorazepate is decarboxylated to desmethyldiazepam mainly in the stomach and bloodstream. The decarboxylation rate of clorazepate to desmethyldiazepam in the stomach is pH-dependent, with a lower pH resulting in a faster rate of conversion. There is a relatively instantaneous breakdown of clorazepate to desmethyldiazepam at a pH of 4 (90% at 10 minutes and 97% at 1 hour).[29] Desmethyldiazepam rapidly crosses the BBB. Desmethyldiazepam is hydroxylated to oxazepam, which is conjugated fairly rapidly and excreted; thus, desmethyldiazepam has no active metabolites.

Diazepam is biotransformed by hepatic microsomal enzymes in two principal steps: initial demethylation to desmethyldiazepam, followed by hydroxylation to oxazepam (see Fig. 2). Oxazepam is then conjugated to glucuronide, producing an inactive metabolite that is largely excreted in the urine.

Desmethyldiazepam, which is also an active metabolite of clorazepate (see section on clorazepate), has one-third the anticonvulsant potency of its parent compound, diazepam.[21] Biotransformation is also age-dependent, with limited demethylation and hydroxylation beginning as early as the 13th week of gestation, and enzymatic capacity increases steadily to maturity during the first few years of life.

Lorazepam is rapidly converted by hepatic metabolism to a glucuronide through conjugation at the 3-hydroxyl portion of the seven-membered diazepine ring.[28] More than 75% of the drug is converted to the glucuronide and excreted in the urine. The glucuronide is an inactive metabolite and does not have any toxic or antiepileptic effects. Two minor metabolites have no significant toxic or antiepileptic activity.[28] Hepatic failure results in the accumulation and reduced clearance of the parent drug, lorazepam, resulting in prolongation of the elimination half-life of lorazepam by 50%.[28] Renal failure does not affect clearance of the parent drug; however, it causes accumulation and reduced clearance of the glucuronide metabolite, but no additional toxicity.[28,29]

Midazolam metabolism occurs by oxidation of the imidazole ring, mostly to 1-hydroxymidazolam, which has about 10% of the biologic activity of midazolam and an elimination half-life of 1 hour.[2]

The major metabolic pathway of nitrazepam involves hepatic nitroreduction, with 7-aminonitrazepam and 7-acetami-nonitrazepam being the principal metabolites. The metabolites are inactive and are excreted renally. Only about 1% of the unchanged nitrazepam shows up in the urine.[29] Glucuronidation is less affected by aging or hepatic disease than demethylation or hydroxylation. Thus, lorazepam and midazolam would be preferable among benzodiazepines for elderly patients or individuals with cirrhosis. Nevertheless, caution must always be exercised in prescribing drugs to older patients, who have a generally diminished volume of distribution and decreased metabolism.[22]

Elimination

Clonazepam and clobazam and its metabolite desmethylclobazam are slowly eliminated, with a half-life of 20 to 56 hours (see Table 1). Because of its long half-life, alternate-day administration of clonazepam or clobazam is possible and has been suggested to reduce tolerance without sacrificing seizure control. Because of the long half-life of desmethyldiazepam, clorazepate can be given once a day, but divided doses decrease the likelihood of toxicity and allow for more stable steady-state levels than once-a-day dosing.[66] Clearance of unbound desmethyldiazepam was reduced in renal failure, although the free fraction was increased and the elimination half-life ($t\beta$) was shortened compared with those of healthy controls, highlighting the complex nature of drug pharmacokinetics in certain disease states.[29] Severe liver disease seems to prolong the half-life of desmethyldiazepam.

The $t\beta$ of diazepam ranges from 1 to 2 days in healthy volunteers and is age-dependent—shorter in infants and children, and prolonged in premature infants and the elderly.[57] Desmethyldiazepam has a much longer $t\beta$ than diazepam, because its formation depends on the continued redistribution of diazepam from peripheral to central compartments, and back again to the periphery. Thus, the $t\beta$ for desmethyldiazepam is longer with administration of diazepam than of clorazepate, a prodrug completely converted to desmethyldiazepam. This results in a greater accumulation of desmethyldiazepam than diazepam in both plasma and cerebrospinal fluid during long-term treatment.[29]

For clinical use, the duration of effect of various benzodiazepines is an important variable. The “long-acting” agents, such as clobazam, clorazepate, and lorazepam, have half-lives longer than 24 hours and produce active metabolites;

P.1535

the “intermediate-acting” benzodiazepines, such as nitrazepam and clonazepam, have half-lives shorter than 24 hours and do not produce active metabolites; there are also “short-acting” agents, such as midazolam.[26] Two factors must be taken into consideration regarding duration of effect: distribution half-life ($t\alpha$) and $t\beta$. During acute administration, as in the treatment of SE, the rates of absorption and distribution are important, whereas during long-term therapy, in which distribution is complete, the $t\beta$ is more critical, because it largely determines steady-state serum levels of a drug. This principle is best illustrated by the clinical use of diazepam and lorazepam. Oral diazepam has a short $t\alpha$ (approximately 1 hour) but a long $t\beta$ (approximately 40 hours); furthermore, the major active metabolite, desmethyldiazepam, prolongs the $t\beta$ to 100 hours or more. The net result after a single dose, because of rapid distribution, is a short duration of action. After repeated doses, diazepam and its metabolites potentially accumulate in the body. Oral lorazepam, on the other hand, has a longer $t\alpha$ (1.5 hours) than diazepam but a shorter $t\beta$ (14 hours), and it produces no active metabolites.[23] Thus, compared with diazepam, a single dose of lorazepam leads to a longer lasting clinical effect, and repeated doses of lorazepam are less likely to produce very high levels throughout the body.

Relationship Between Plasma Concentration and Effects (Including Value of Therapeutic Drug Monitoring)

Levels of each benzodiazepine can be obtained, but therapeutic levels for most drugs are not clearly defined, because wide ranges are possible, and these have not been well defined according to seizure type and age. The development of tachyphylaxis during acute administration of repeated doses and the onset of tolerance during prolonged treatment result in a relatively poor correlation between plasma levels and efficacy and side effects, limiting the usefulness of therapeutic drug monitoring. Furthermore, the means to obtain benzodiazepine levels rapidly is not always readily available.

Efficacy

Emergency Treatment

Clonazepam is still used widely in the treatment of various forms of SE (Table 2). Its indications are the same as for diazepam, and its effectiveness is similar.[60] It can be given intravenously or as oral and rectal solution. A few drops of the solution are swallowed as a last resort by some patients anxious to control incipient seizures at home or when out of the house. *Diazepam* was the first benzodiazepine used to treat generalized convulsive SE, and for many years it has been the initial drug of choice in arresting SE.[29,57] Diazepam is most widely used in the treatment of SE, both convulsive and nonconvulsive. Early reports soon after the introduction of diazepam into clinical use provided spectacular results in a large majority of patients with severe epilepsy.[29,57] However, the reported efficacy of diazepam in arresting different forms of SE varies widely across many studies (75%–93%). Diazepam appears to be more effective against partial seizures (simple or complex) than generalized seizures.[29,57] In contrast, SE arising in the context of certain childhood encephalopathic epilepsies responds less favorably to diazepam.[60] The presence of structural brain lesions, an increased susceptibility to seizures, or both in children may account in part for this age-related difference.[60] Although a single intravenous bolus of 10 to 20 mg (in adults), given at a rate of 2 to 5 mg/min, can stop various types of SE in more than 80% of patients within 5 to 10 minutes, the relapse rate is high (>50%) among initial responders.[57,60] This finding, not unexpected given the pharmacokinetics of diazepam, led to the development of protocols for continuous intravenous infusion, with recommended target serum levels of between 200 and 800 ng/L.[17] The rapid development of tolerance, lack of consistent efficacy, uncertainty of long-term complications, and requirement for intensive monitoring render this approach less than desirable.[60] At present, with safer alternatives available, continuous intravenous infusion of diazepam as a treatment for SE has largely fallen out of favor.

The short duration of effect of diazepam prompted studies of the combined use of diazepam and phenytoin (15 to 20 mg/kg), which has a slower onset but a longer-lasting effect, to maintain seizure control and prevent relapse of SE.[60] Of note, diazepam and phenytoin cannot be infused through the same intravenous line, because crystallization may occur, although this may not happen with fosphenytoin, a water-soluble prodrug of phenytoin.[29] Intravenous diazepam, rather than magnesium sulfate, may be the preferred anticonvulsant agent to treat initial preeclamptic seizures.[19] Rectal administration of diazepam gel (0.5–1.0 mg/kg; maximum, 20 mg) has been shown to be effective and safe in stopping serial seizures, both in children and adults. Between 55% and 71% of patients remained seizure-free for 12 hours after administration of rectal gel, which was statistically significantly different from 23% to 29% reported for placebo.[12,13,18] Sedation is the most common side effect, occurring in approximately one-quarter of patients, and the risk of respiratory depression is lower than with intravenous use of diazepam.[48] One further advantage of rectal diazepam is that treatment can be administered by caretakers in a nonmedical setting. Rectal diazepam has also been studied as prophylaxis of febrile seizures (FS), with conflicting reports of its efficacy.[57]

Table 2 Clinical use of benzodiazepines

Drug	Clinical use	Main advantages	Main disadvantages
Clobazam	Second-line adjunctive therapy for refractory partial and generalized seizures, intermittent therapy, nonconvulsive SE	Highly effective, may be better tolerated than other benzodiazepines; rapid onset of action	Tolerance in 30%-50%, withdrawal problems
Clonazepam	Second-line adjunctive therapy in partial and generalized seizures (especially absence and myoclonic seizures), Lennox-Gastaut syndrome, and the premonitory stage and early status epilepticus, second-line for established status	Useful second-line adjunctive drug	Strong sedation, hypersalivation in some patients, tolerance
Diazepam	First-line treatment for the premonitory and early stage of SE (intravenous, bolus or rectal solution). Second-line for established status (intravenous infusion), nonconvulsive SE. Prophylaxis of FS. Home treatment of acute repetitive seizures (rectal solution or gel)	Highly effective, rapid onset of action, several methods of administration	Sedation, tolerance, withdrawal problems
Lorazepam	First-line treatment for the early stage of SE (intravenous bolus)	Longer duration of action than diazepam, can be repeated often, rate of injection not critical	Sedation, frequent and rapid development of tolerance and tachyphylaxis
Midazolam	Second-line treatment for the early stage of SE (IM, intravenous bolus, rectal solution)	Effective, rapid onset of action, can be given intramuscularly	Collapse of respiratory pathways, sedation
Nitrazepam	Second- to third-line adjunctive therapy in partial and generalized seizures (especially myoclonic	Last resort for severe childhood epilepsies	Severe sedation and muscular hypotonia in some patients

seizures, infantile spasms)

(Modified from Schmidt D. Benzodiazepines: Diazepam. In: Levy RH, Mattson RH, Meldrum BS, eds. *Antiepileptic Drugs,* 4th ed. New York: Raven Press;1995:705-724.) Preference may vary, and the list of clinical use is not exhaustive (see text).

Clinical studies of *lorazepam* in SE since the mid-1970s have long confirmed that its anticonvulsant effect is rapid and prolonged. The Epilepsy Foundation of America Working Group on SE, which summarized the data comparing the four major drugs used to stop SE, reported an average range of 6 to 10 minutes to stop status with lorazepam.[20] In 1983, Leppik et al.[36] compared lorazepam with diazepam and found that the median time for lorazepam to stop clinical SE was 3 minutes (range, 0–15 minutes). As initial treatment, 4 mg of lorazepam was effective in 78% of patients, versus 58% with 10 mg of diazepam. The difference in efficacy, however, between the two drugs was not statistically significant. More patients required a second dose of diazepam, but not a second dose of lorazepam. Appleton et al.[3] studied 102 children and found that lorazepam was superior to diazepam in children with acute convulsions of SE. A single dose of lorazepam was effective in terminating seizures in 76% of cases, versus 51% for diazepam. The recurrence rate of seizures or status was significantly lower in the lorazepam group.[3] In a comparison of 2 mg intravenous lorazepam, 5 mg intravenous diazepam, and placebo for the out-of-hospital treatment of SE, both drugs were safe and more effective than placebo when administered by paramedics in adults with prolonged or repetitive generalized convulsive seizures.[1] An identical second injection was given if needed. SE had been terminated in more patients treated with lorazepam (59%) or diazepam (42%) than patients given placebo (21%). The odds ratio for termination of SE at arrival was 1.9 (95%; confidence interval, 0.8 to 4.4) in the lorazepam group as compared to the diazepam group. The rates of respiratory or circulatory complications after the study treatment had been administered were 10.6% for the lorazepam group, 10.3% for the diazepam group, and 22.5% for the placebo group. The authors concluded that lorazepam was likely to be a better therapy than diazepam for paramedic treatment of out-of-hospital SE in adults. The lower recurrence

P.1536

rate of SE with lorazepam versus diazepam is thought to be the consequence of its longer tα within the brain, and the more extensive redistribution of diazepam within lipid stores.[15,60] The effective duration of diazepam is only 15 to 30 minutes, versus 12 to 24 hours for lorazepam.[20] Thus, despite the slower penetration of lorazepam across the blood–brain barrier (BBB) compared with diazepam (6–10 minutes vs. 3–6 minutes), lorazepam may be preferable for its longer duration of action.[29]

The effectiveness of intravenous lorazepam versus intravenous phenytoin has also been studied. Treiman et al.[63] reported the results of a randomized open study of lorazepam versus phenytoin, and found that lorazepam stopped status significantly faster than phenytoin. Further, lorazepam was effective as a single initial agent in 79% of patients, whereas phenytoin was effective in only 56%. There was a slightly higher recurrence rate in patients treated with lorazepam than in those treated with phenytoin, which has led Treiman et al. to recommend adjunctive treatment with phenytoin within 24 hours of starting lorazepam treatment.[63] How rapidly a drug controls status may be as critical as its efficacy in stopping status. The time required to stop status is a major determinant in the morbidity and mortality of status.[60] Therefore, the rapidity with which lorazepam stops status gives it a profound theoretical and clinical advantage over phenytoin (see Table 3 for recommended dosages).

The use of high-dose lorazepam has been reported in a limited number of patients with refractory SE. Labar et al.[32] reported that in nine patients with refractory SE, lorazepam in doses of up to 0.3 to 9 mg/h as a continuous infusion was used effectively without causing significant arterial hypotension.[32] They speculate that lorazepam may be an alternative to high-dose barbiturates, which can cause significant hypotension. Lorazepam in a dose of 0.1 mg/kg has been suggested as the drug of first choice for terminating SE.[42]

Table 3 Dosing recommendations

Drug	Dosing recommendations
Clobazam	Oral: Children: 0.87 mg/kg (SD, ±0.6), Adults: 30.8 mg (SD, ±16.7), Mostly: 10–20 mg/day
Clonazepam	Oral: Starting dose: 0.25 mg, increase to 0.5, up to 4.0 mg. Children: 1–3 mg/day; IV: 1 mg bolus injection over 1 min in adults, and 250–500 μg in children. IM injection of as low as 0.02 mg/kg in children[44]
Clorazepate	Starting dose of 0.3 mg/kg/day increasing no faster than once a week to avoid sedative effects. Chronic dose between 0.4 and 3 mg/kg/day. Because of more rapid metabolism, children are dosed at the higher end of this range and average adult doses are 0.5–1 mg/kg/day.
Diazepam	IV: Out of hospital: single IV bolus of 10–20 mg (in adults), given at a rate of 2–5 mg/min, 0.25–0.5 mg/kg in children at a rate of 1–5 mg/min. ICU: 20 mg, 2 mg/kg/day infusion. Children: 0.2–0.3 mg/kg/day, maximum: 20 mg. Rectal: diazepam gel: 0.5–1.0 mg/kg; maximum 20 mg in adults and children.[24], [25], [26], [27] Adults: 10–20 mg; children: age 2–5: 0.5 mg/kg; age 6–10: 0.3 mg/kg; 12 years and older: 0.2 mg/kg (given over 2–5 min).
Lorazepam	IV bolus of 0.07–0.1 mg/kg, usually 4 mg, in adults, repeated after 10 minutes if necessary; in children a bolus of 0.1 mg/kg is recommended. The rate of injection not more than 1 mg/min. IV infusion with a loading dose of 0.2 mg/kg and an infusion rate of 0.08 to 0.39 mg/kg per hour.[60] Sublingual: 0.05 mg/kg-0.15 mg/kg in children.[13]
Midazolam	IV bolus of 0.1–0.3 mg/kg, at a rate not exceeding 2 mg/min, which can also be repeated once. Continuous IV infusion: loading dose of 0.2 mg/kg and an infusion rate of 0.08–0.39 mg/kg/hour; IM: 5–10 mg adults, 0.15–0.3 mg/kg children, can be repeated once. Buccal: instillation of 10 mg can be given by catheter and syringe in children and adults. Intranasal: 0.2–0.3 mg/kg in a 5 mg/mL ampoule dripped directly into the nostrils, over 3 min in children, over 5 min in adults.
Nitrazepam	Oral: adults: <0.5 mg/kg/day; children: up to 1 mg/kg/day. Usually 1.25–10 mg/day.

(Modified from references 12, 13, 16, 18, 29, 31, 44, 57, 67, and 69, with permission.)

Sublingual lorazepam was successful in controlling serial seizures in ten children.[69] The effective dose is from about 0.05 mg/kg to 0.15 mg/kg.[69] Side effects were minimal and consisted of drowsiness, unsteadiness, nausea, and hyperactivity.

P.1537

Sublingual lorazepam appears to be an easy and effective way to treat serial seizures at home.[69]

Midazolam, as an intravenous bolus, intramuscular, intranasal or rectal solution, has been used as an alternative to diazepam or lorazepam during management of prolonged seizures, of early SE, and the premonitory stage of SE. It is more water soluble than diazepam and is rapidly and completely absorbed after intramuscular, nasal, and buccal administration.[29] Treatment of refractory generalized SE with continuous infusion of midazolam has been described in clinical observations of adults and children.[45,46] However, loss of initial efficacy was reported in many patients with refractory nonconvulsive SE receiving prolonged intravenous infusion of midazolam.[14] Midazolam, when administered as an intravenous bolus and subsequent continuous infusion, has controlled EEG-confirmed neonatal seizures with no response to phenobarbital.[11] In a small study of patients with refractory SE, midazolam, administered with an intravenous bolus and followed by an infusion, and intravenous propofol did not differ in clinical and EEG seizure control.[50] As pointed out above, midazolam solution is rapidly absorbed after buccal and nasal instillation. Buccal midazolam was at least as effective as rectal diazepam in the acute treatment of prolonged seizures lasting more than 5 minutes.[59] The authors suggested that buccal administration is more socially acceptable and convenient, particularly for treatment of long seizures that occur outside the hospital setting.[59] Midazolam nasal spray appears to be as effective as diazepam rectal solution in the acute treatment of seizure exacerbations.[65] Furthermore, most patients and caregivers preferred the nasal spray because of the ease of administration and social acceptability, including protection of privacy.[42,65] Intranasal midazolam has been shown to be useful in a small study of first-aid treatment of acute seizures in pediatric community settings.[27] Intranasal midazolam was compared with intravenous diazepam in children with SE in a hospital setting.[41] Although intranasal midazolam was safe and as effective as diazepam, seizure control was more rapidly achieved with diazepam.[41] In a small randomized study of children with FS, intranasal midazolam controlled seizures later than diazepam administered intravenously.[35] However, for obvious ethical reasons, no placebo control group was available; thus spontaneous remission of FS may have occurred in both arms of treatment, at least in some patients. Intranasal midazolam can be used when intravenous administration is inconvenient or not possible.

Chronic Treatment

Clobazam has been shown in a large Canadian randomized controlled trial to be an effective anticonvulsant for monotherapy of previously untreated children with partial-onset seizures, with a similar efficacy compared to phenytoin or carbamazepine. Phenytoin and carbamazepine induced more biologic side effects, such as rash, whereas clobazam induced slightly more behavioral side effects.[7,10] Tolerance to effect, according to the authors' definition, developed in 7.5% of patients receiving clobazam, 4.2% with carbamazepine, and 6.7% with phenytoin.[10] As shown in randomized trials, clobazam is also efficacious when used as add-on treatment for refractory partial epilepsy in children and adults,[30,58] and intermittent clobazam therapy may be useful for treatment of FS.[52] The Canadian Clobazam Cooperative Group performed the largest single study, comprising 877 epileptic patients,

P.1538

both children and adults, with all types of seizures—atypical absence, myoclonic seizures, Lennox-Gastaut syndrome, and generalized tonic–clonic seizures.[9] More than half the patients became seizure-free or had a greater than 50% reduction in seizure frequency.[9]

Clonazepam add-on treatment has shown efficacy in a number of small randomized trials performed during the 1970s and 1980s against many types of seizures, including both partial and generalized seizures in all age groups, both as add-on treatment[29] or as monotherapy for previously untreated patients with absence seizures or partial seizures.[29] Clonazepam is an efficacious AED for adjunctive therapy of generalized absence and myoclonic seizures and also for partial seizures. However, due to sedation, tolerance, problems during withdrawal, and hypersalivation, it is increasingly used as a second- or third-line adjunctive drug only when better-tolerated adjunctive AEDs have not been helpful. It has been evaluated in single-arm studies in partial and generalized epilepsy, and the effects have generally been modest. It has been used in benign rolandic epilepsy and also in epilepsia partialis continua. In the generalized epilepsies, its effectiveness is similar to that of ethosuximide for absence seizures,[55] and it can be useful in myoclonic seizures, such as in juvenile myoclonic epilepsy and Lennox-Gastaut syndrome.[54] When given as a single intramuscular injection of as low as 0.02 mg/kg body weight in children, clonazepam reduced epileptiform activity in the EEG and reduced partial and generalized seizures.[16] This interesting finding suggests that lower than previously considered dosages of clonazepam may be effective. Clonazepam is also useful for bridge therapy while AEDs are changed or withdrawn.[53]

Sharing the fate of oral diazepam, *clorazepate*, a prodrug that is converted to the active AED desmethyldiazepam, is only rarely used for the treatment of epilepsy.[29] Early clinical studies of clorazepate therapy in epilepsy from the 1980s suggested that it may be useful as add-on treatment for absence, atonic, myoclonic, and partial seizures.[29]

Oral *diazepam* is rarely used, and not recommended for chronic treatment of epilepsy, as reviewed by Schmidt.[57] Controlled trials during the 1970s showed that diazepam is less effective than phenytoin or phenobarbital for treatment of generalized tonic-clonic seizures and about as effective as pheneturide, a now obsolete agent, in control of partial seizures.[57] A single 20-mg dose of oral diazepam significantly reduced the incidence of serial seizures at plasma concentrations of 273 ± 190 (SD) ng/m.[57] Oral intermittent diazepam given for prophylaxis of recurrent FS showed no difference to placebo (reviewed in Schmidt[57]). After excluding many protocol violators, however, analyzing children actually receiving diazepam showed an 82% and statistically significant reduction in the risk of FS with diazepam.[57] The poor efficacy of long-term oral diazepam treatment in epilepsy may be related to the development of tolerance and the difficulty to maintain effective serum concentrations.

Midazolam has not been evaluated in trials of chronic oral treatment for epilepsy.

Nitrazepam is largely confined to second- or third-line treatment of severe childhood epilepsies, mainly West syndrome (see Table 1). Although quite effective, it is rarely used because of severe, and in some patients intolerable, drowsiness, ataxia, hypersecretion, and hypersalivation (due to nitrazepam-induced hypotonia of muscles used for swallowing saliva), and aspiration pneumonia in some patients.[5] Nitrazepam has largely been superseded in the treatment of infantile spasms (West syndrome) by vigabatrin, valproate, steroids, or adrenocorticotropic hormone (ACTH). Furthermore, intravenous nitrazepam has precipitated tonic SE in a patient with Lennox-Gastaut syndrome.[62]

Adverse Effects

Dose-Related, Nonidiosyncratic Adverse Effects

Benzodiazepines are relatively safe drugs despite potential adverse effects. Very large doses, whether taken accidentally or intentionally, are rarely fatal unless other sedative drugs or ethanol are taken concomitantly. Mechanistically, this is supported by pharmacologic studies demonstrating that benzodiazepines cannot directly activate the γ-aminobutyric acid $(GABA)_A$ receptor, even at very high concentrations, without the presence of the endogenous ligand GABA or other allosteric modulators capable of direct activation, such as barbiturates.[61]

The principal clinical concern when administering benzodiazepines acutely, as in SE, is respiratory and cardiovascular depression, as well as sialorrhea and inability to handle oral secretions.[29] These side effects may worsen with concomitant administration of other CNS depressants, such as phenobarbital. The combination of a benzodiazepine and phenobarbital should be used cautiously because of the potential for respiratory depression, hypotension, and sedation. Status protocols usually require intubation when these agents are used together.

In rare instances, intravenous administration of benzodiazepines may induce generalized tonic SE in patients with the Lennox-Gastaut syndrome.[8] Intravenous injections of diazepam can cause thrombophlebitis, but this may be primarily a consequence of precipitation following rapid injection, or it may result from the concurrent administration of diazepam and phenytoin through the same intravenous line, causing crystallization.

During long-term therapy, it is well known that benzodiazepines cause dose-related CNS depression, hypotonia, ataxia, incoordination, dizziness, dysarthria, nystagmus, blurred vision, diplopia, and behavioral abnormalities such as hyperactivity, restlessness, short attention span, irritability, disruptiveness, and aggressiveness.[29] Benzodiazepines can also cause drooling and incoordination of swallowing.[68]

Clobazam, a 1,5-benzodiazepine, is thought to have fewer side effects than other benzodiazepines at equipotent doses.[29] Interestingly, levels of the metabolite desmethylclobazam but not of clobazam correlated with side effects.[29]

Increased frequency of seizures and the emergence of different types of seizures have been suggested to follow clonazepam therapy.[4,55] However, natural fluctuation of seizure frequency may have been responsible, at least in part, for the observed increase of seizure frequency.

Diazepam may precipitate generalized tonic or tonic–clonic seizures and may cause conversion of absence status to tonic SE.[57]

Prolonged sedation due to accumulation of conjugated metabolites of midazolam has been described in nonepileptic patients with renal failure.[6] This may explain why in some patients with renal failure sedation persists while serum concentrations of midazolam and its unconjugated metabolite have fallen to ineffective levels.[6]

Idiosyncratic Reactions

Idiosyncratic reactions of the skin or other organ systems (for example, aplastic anemia) have not been reported. For this reason, patients with severe hypersensitivity reactions to several AEDs who need further treatment, but cannot tolerate

P.1539

continued exposure to those drugs, will benefit from switching treatment to benzodiazepines.

Second Generation Effects (Including Teratogenicity and Other Effects on the Offspring)

It is not clear that benzodiazepines alone have significant teratogenic potential; many of the women from the reported cases were treated for psychiatric disease, epilepsy, and diabetes, and some were on polypharmacy with other known teratogens. Nevertheless, benzodiazepines may possibly augment the teratogenic potential of other drugs,[34] and there may be neurobehavioral problems in some children stemming from long-term benzodiazepine use during pregnancy.[43] Perhaps the best described teratogenic abnormality after exposure to agents such as diazepam and chlordiazepoxide during the first trimester of pregnancy is facial clefts and, to a lesser extent, cardiac or musculoskeletal malformations.[33] There is one letter reporting severe congenital malformation in a mother exposed to clorazepate in the first trimester of pregnancy.[47] All the anticonvulsant benzodiazepines are excreted into breast milk, but the levels are low and generally do not pose a significant hazard to the newborn.[29]

Tolerance to Therapeutic and Adverse Effects

Tolerance with partial or complete loss of efficacy during prolonged treatment limits the usefulness of benzodiazepines as AEDs. On average, tolerance to effect usually develops within the first several months in as many as one in three to one in two epilepsy patients treated with either clobazam or clonazepam for epilepsy.[29,56] Cross-tolerance to benzodiazepines may occur with long-term administration, rendering use of alternative benzodiazepines less effective.[29] Tolerance to sedative effects occurs more rapidly, usually within the first weeks of treatment. Potential explanations for how tolerance develops have been discussed in the section on mechanism of action. Tolerance usually forces clinicians either to withdraw a drug, risk further sedation, or exceed labeled dose ranges with increasing doses. Dose increments overcome tolerance in some patients, at least for a while. Because tolerance is reversible when the drug is discontinued, intermittent treatment and drug holidays have been suggested for patients who have developed tolerance.[9] However, the available anecdotal evidence suggests that such maneuvers are useful in only a minority of patients.[9]

Benzodiazepines can also produce physical drug dependence, not to be confused with drug tolerance or addiction, which can lead to withdrawal symptoms.[29] Tremulousness, agitation, insomnia, autonomic symptoms (tachycardia), depression, disorientation, and seizures (including status), can occur after abrupt cessation of benzodiazepines in patients with epilepsy.[29] Withdrawal symptoms are more frequently seen in patients receiving short-acting, high-potency benzodiazepines than in those receiving long-acting compounds such as clobazam or clonazepam.[29]

Tachyphylaxis, or reduced efficacy with repeated doses, has been reported for lorazepam[67] and for rectal diazepam.[48] Tachyphylaxis may also be a function of the duration of status, and the fact that recurrent episodes of status may represent subclinical status, which is more refractory to medical treatment. The longer the duration of status, the less effective benzodiazepines are in controlling it.[64] This may possibly be a consequence of the upregulation of GABA receptors and a relative increase in GABA levels after prolonged status.[64]

Drug Interactions

The benzodiazepines appear to be relatively inert in terms of drug interactions. They do not have enzyme-inducing effects.[22,23] In epileptic patients treated with enzyme inducers such as carbamazepine, phenytoin, and phenobarbital, the clearance of desmethyldiazepam is much larger than in normal controls.[67] Many cytochrome P450 enzyme-inducing drugs can decrease serum concentrations of diazepam and its metabolites. Alternatively, microsomal enzyme inhibitors, such as valproate, isoniazid, cimetidine, and diltiazem, can elevate serum diazepam levels.[29] The benzodiazepines are generally highly protein-bound, but they do not significantly affect and are not affected by the protein binding of other drugs, although there are exceptions. Protein binding of diazepam appears to be displaced by valproate, which results in increased free levels of diazepam.[29] When benzodiazepines are used with other AEDs that have readily measurable and reliable levels, measuring drug levels may be helpful in patient management. Antacids affect the absorption of clorazepate and desmethyldiazepam; they slow absorption and lower levels of desmethyldiazepam, although there was no significant difference of absorption as measured by the area under the plasma level-time curves.[29]

Role in Epilepsy Treatment

Indications

The benzodiazepines lorazepam and diazepam, along with intravenous phenytoin and phenobarbital, play a major role in the treatment of SE. Lorazepam is considered the drug of first choice for terminating SE.[42] Their intravenous route of administration, combined with their quick onset of action, makes them suitable as the initial treatment of status. Continuous intravenous infusion of lorazepam or midazolam for seizure control may become more commonplace in the intensive care setting.[31,46] Refractory SE has also been treated with midazolam; in patients with normal renal and hepatic function, midazolam has a much shorter half-life than lorazepam, and it can be easily administered by continuous intravenous infusion.[31] The rectal use of diazepam gel is an important effective and safe on-site treatment to stop series or clusters of seizures.

In contrast, results of the use of oral benzodiazepines in the long-term treatment of epilepsy have been less spectacular. Nevertheless, these drugs have an important role, because they appear to have some efficacy in many types of seizures and epilepsy syndromes. Benzodiazepines are usually administered on a long-term basis as adjunctive drugs. For example, benzodiazepines are often the first- or second-choice drug for myoclonic seizures along with valproic acid. Their long-term use is limited by tolerance, but intermittent administration, such as the use of diazepam to prevent serial or cluster seizures in adults and children, may bypass tolerance, at least in some patients.[29]

Dosing Recommendations

Dosing recommendations including titration issues, differences for adults and children, and the impact of comedication are summarized in Table 3.

Precautions

Benzodiazepines should be used with caution in renally and hepatically impaired patients because impaired renal excretion and hepatic metabolism may lead to excess accumulation. In addition, parenteral benzodiazepines should be used with caution in patients with compromised respiratory function, and in patients on comedication with sedating agents such as phenobarbital. In the elderly, in whom benzodiazepine clearance is reduced, the dosage should be decreased to minimize ataxia and sedation.

Contraindications

Benzodiazepines are contraindicated in uncommon cases with a known hypersensitivity to benzodiazepines.

Summary and Conclusions

Benzodiazepines play an important and varied role in the treatment of epilepsy. Diazepam and lorazepam are the most frequently used drugs in the initial treatment of SE. Lorazepam is the intravenous drug of first choice for terminating SE. Additionally, midazolam and lorazepam are being used increasingly as continuous intravenous drips in cases of refractory SE. Buccal and intranasal midazolam and rectal diazepam are useful in treating clusters of seizures or prolonged seizures at home, thus reducing the need for emergency room visits.

Benzodiazepines, although extremely potent anticonvulsant drugs, are most effective when used as acute or emergency treatment; they have disadvantages that limit their use as chronic therapy, the most notable of these being tolerance and sedation. Nonetheless, benzodiazepines have a wide spectrum of activity and have a useful niche as adjunctive medications in selected patients with both partial and primary generalized seizures. They are especially suitable for intermittent use in patients who have clusters of seizures, because this may circumvent the problem of tolerance, at least in some patients. Because this class of drugs can be administered effectively by many different routes, they are extremely versatile and useful agents in a variety of clinical settings.

Chapter 146

Carbamazepine

Evan J. Fertig

Richard H. Mattson

Introduction

Carbamazepine (5*H*-dibenz[*b,f*]azepin-5-carboxamide) is one of the most widely prescribed antiepileptic drugs for the treatment of partial and generalized tonic–clonic seizures in the United States and Europe. Since 1993, nine new antiepileptic medications have been approved by the U.S. Food and Drug Administration [felbatol (Felbamate), gabapentin (Neurontin), lamotrigine (Lamictal), topiramate (Topamax), tiagabine (Gabitril), oxcarbazepine (Trileptal), levetiracetam (Keppra), zonisamide (Zonegran), and pregabalin (Lyrica). In general, these "second-generation" antiepileptic medications have better pharmacokinetic and tolerability profiles than the "first-generation" antiepileptic medications such as carbamazepine.[41] Lacking, however, is any demonstration of superior efficacy. In addition, the newer agents can be significantly more expensive, and there is no clear evidence that they are more cost effective.[136] Likely because of its wide availability, relative inexpensiveness, and proven clinical efficacy, carbamazepine continues to be widely used for epilepsy.

Chemical Structure, Formulation, and Monitoring

Chemical Structure and Synthesis

The development of carbamazepine, like that of many anti-epileptic drugs, came about indirectly. According to the reports of Galbraith[43] and Schmutz,[118] C. J. Geigy, Ltd., sought to develop a psychoactive drug in the 1950s following the introduction of the neuroleptic chlorpromazine by Rhone Poulenc. Researchers at Geigy who were seeking to develop a similarly acting tricyclic drug substituted a CH–CH for the sulfur in the chlorpromazine molecule. This change produced imipramine (Tofranil), which, unlike chlorpromazine, demonstrated antidepressant properties when tested in psychiatric patients (Fig. 1). In further efforts to find a neuroleptic, studies were made of other tricyclic carbamoyl compounds of an imino-stilbene that had been synthesized earlier in the Geigy labs by Morel.[43,118] Structural changes in the molecule included the substitution at the 5 position of carboxamide for the basic side chain present in imipramine. One of these compounds (G26301) revealed even more potent anticonvulsant activity, especially in the maximal electroshock test. Early studies in animals and clinical trials confirmed its value as an antiepileptic drug. In 1957, Shindler and Lattner[43,118] replaced the CH_2–CH_2 with a CH=CH bridge (Fig. 1) to produce carbamazepine.

Formulations

Carbamazepine is available in scored 100- and 200-mg tablets; the former are chewable and particularly useful in treating children. A suspension is also available for patients who have problems swallowing tablets or require treatment though nasogastric tubing. This liquid formulation yields peak levels about 2 hours after ingestion; peak levels are lower and occur later with the tablets.[20,91,108] A slow-release formulation is available in Europe, and two for twice-daily administration are available in the United States.[6,46,126,128] Use of the slow-release formulation allows avoidance of the peak and trough levels sometimes encountered when the standard tablets are used. This is important, particularly when carbamazepine is coadministered with enzyme-inducing drugs, such as phenobarbital and phenytoin.[6,58,70,126,128] A recent prospective, open-label study demonstrated improved tolerability of the extended-release formulation as compared to the immediate-release formulation.[38]

Unfortunately, a parenteral formulation is not available because of the poor lipid solubility of carbamazepine. A soluble preparation based on a complexation of carbamazepine in cyclodextrins appears to be promising, but it has not been fully developed.[37]

Methods for Determination in Body Fluids

Immunoassay is the most common technique used for the determination of carbamazepine concentration in the blood. In general, this technique does not measure the metabolites of carbamazepine, some of which are biologically relevant.[92] Liquid chromatographic assays have the advantage of allowing quantification of carbamazepine and its principal metabolite, carbamazepine-10,11-epoxide. Determination of free carbamazepine concentration has no additional advantage over determination of total plasma concentration.[92] Carbamazepine levels in saliva have been shown to correlate predictably with plasma levels, but this technique has not been accepted into common clinical practice.[19,27,68]

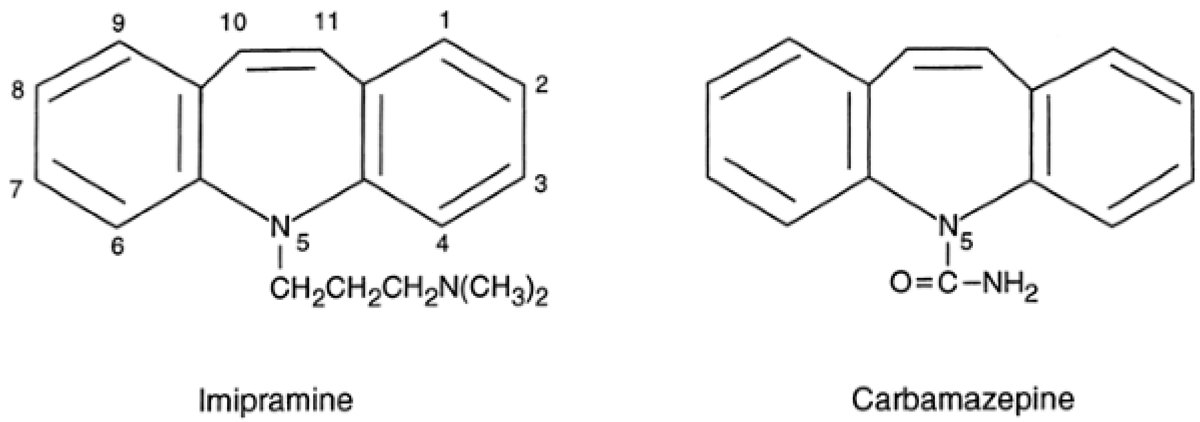

FIGURE 1. Structural formulas of imipramine and carbamazepine.

Pharmacology

Activity in Experimental Models of Seizures/Epilepsy

The original detailed pharmacologic studies of Theobald and Kuntz[127] in animal models revealed potent efficacy against seizures induced by maximal electroshock, with much less effect in preventing experimental seizures induced by pentylenetetrazol. Studies in hippocampal slice preparations revealed a reduction of burst firing in a calcium-free environment, implying a direct membrane, rather than a neurotransmitter-mediated action.[55,71,85] These actions closely paralleled those of phenytoin. The promise of this new drug led to further development. Predictions of efficacy against epileptic seizures were borne out in early clinical trials of adults and children.[8,10,106] Blom[8] also reported that carbamazepine was effective in the treatment of trigeminal neuralgia. These early trials noted that,

P.1544

unlike older available antiepileptic drugs, carbamazepine often conferred a positive “psychotropic” effect as well.[32] This was attributed, at least in part, to its structural similarity to the antidepressant imipramine.

Many open and controlled trials during the last four decades have established carbamazepine as a drug of first choice, based on its potent efficacy and overall good tolerability for the treatment of partial and tonic–clonic seizures.[7,70] Europeans acquired considerable experience with the drug as a treatment for epilepsy in the 1960s. The use of carbamazepine to treat trigeminal neuralgia was approved by the U.S. Food and Drug

Administration in 1968, but approval for its use in the treatment of epilepsy was delayed until 1974 because of reports of aplastic anemia. Although the initial reports of studies in children were favorable,[106] carbamazepine was not approved for treatment of children in the United States for more than another 20 years.

Mechanism of Action

Confirmation of the neural membrane effect came from the very important studies by McLean and MacDonald,[85] which indicated an effect at the sodium channel. They found that carbamazepine, like phenytoin, markedly reduced sustained high-frequency repetitive neuronal firing at clinically relevant concentrations. The effect was voltage and use dependent. This combination of characteristics led these and other investigators to conclude that the drug acted at the sodium channel in the "inactive state."[71] This mechanism explained why seizures with high-frequency discharge would be suppressed, whereas normal neuronal firing at lower rates would be unaffected by the drug, an observation quite in keeping with clinical effects at the usual dose.

Many other possible mechanisms have been investigated, including a synaptic action on excitatory amino acid receptors, but the evidence is not persuasive that carbamazepine is active at these sites at clinically relevant concentrations. Similarly, effects on γ-aminobutyric acid (GABA), adenosine, acetylcholine, and monoamine systems have been postulated, but without convincing evidence. On the other hand, it can be inferred that carbamazepine must have other effects on the central nervous system in addition to its action on the sodium channel because the drug has somewhat different adverse effects than phenytoin and, unlike phenytoin, possesses efficacy in the treatment of endogenous depression[70] and seizures associated with alcohol withdrawal.[39]

Clinical Pharmacokinetics

Absorption

Carbamazepine is a member of the family of iminostilbenes—tricyclic structures that are extremely insoluble in water. The partition coefficient of carbamazepine is 58 in the octanol/aqueous system.[37] Absorption is relatively complete in human studies, although some evidence indicates that infrequent large doses are less bioavailable than are more frequently administered smaller quantities.[6,91,108] Samples of both generic carbamazepine and Tegretol brand have clinically relevant decreased bioavailability when kept in a humid environment.[4] The drug should be stored in a closed container in a cool, dark, dry place.[20] The bioavailability can vary considerably from lot to lot of both different generic formulations as well as the innovator product (Tegretol).[88,91] Because of this variable absorption, patients should continue to use the same product rather than change between different generic preparations or the brand name Tegretol.

Absorption also may change perioperatively, perhaps because slowed gastrointestinal activity during bed rest at the time of surgery for epilepsy or other conditions may be associated with a transient drop in blood levels and loss of seizure control, which is then followed by toxic peak levels caused by a large reabsorption occurring after activity is resumed.[124] Perioperative metabolic changes with decreased clearance also probably account for delayed transient increases in blood concentrations postoperatively. Hiremath et al. found that postoperative carbamazepine blood levels directly correlated with preoperative carbamazepine blood levels, total intraoperative fentanyl dose, and body weight. A preoperative carbamazepine level >9 was a significant risk factor for the development of symptoms of clinical toxicity following surgery.[53] Carbamazepine dose reduction in the immediate postoperative period should be considered for some patients. Monitoring carbamazepine blood levels is also useful at this time.[74]

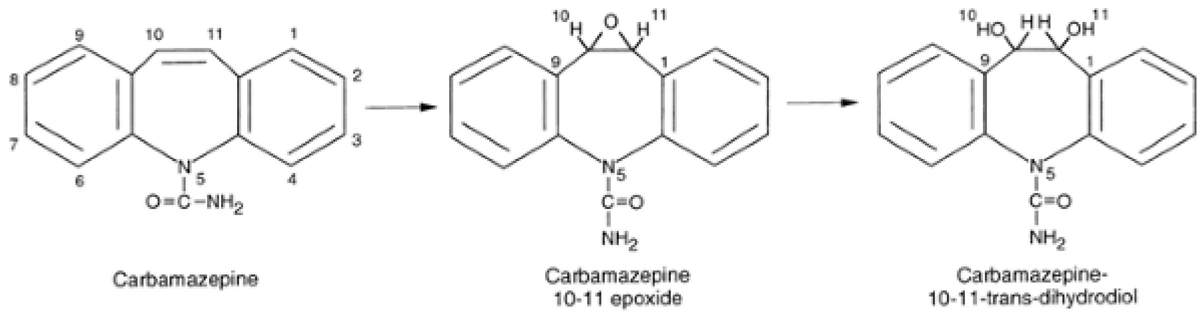

FIGURE 2. Biotransformation of carbamazepine.

Plasma Protein Binding and Distribution

Carbamazepine is approximately 75% protein bound, primarily to albumin. A smaller quantity is bound to α-acid glycoprotein. The free fraction may change in medical conditions that lower serum level of albumin, such as renal and hepatic disease, which may also alter the binding properties of α-acid

P.1545

glycoprotein. Certain highly bound compounds, such as valproate, may displace carbamazepine and increase its free fraction. Carbamazepine is extensively distributed to body tissue and has a volume of distribution of approximately 1.5 mL/kg.[91] Following an initial dose, concentrations are highest in tissues with increased blood flow, such as cerebral cortex. During long-term administration using divided doses, brain concentration is more evenly distributed. Using intracerebral extracellular microdialysis in patients with epilepsy, Scheyer et al. determined that brain concentrations closely parallel concentrations of free carbamazepine in blood in both time and quantity.[116] Entry of the metabolite carbamazepine-10,11-epoxide is more gradual, but concentrations also parallel free blood levels. The less rapid entry of the epoxide most likely reflects its lower lipid solubility.

Metabolism and Elimination

Clearance is almost entirely by hepatic metabolism. Carbamazepine is primarily oxidized by the cytochrome P450 system (CYP 3A4 isoform) to carbamazepine-10,11-epoxide. The intermediate metabolite is further hydrolyzed by microsomal epoxide hydrolase to carbamazepine-10,11-*trans*-dihydrodiol (Fig. 2).[5,37,63,66,91] The diol and the conjugated product are eliminated by the kidneys.[63,91]

Carbamazepine clearance can be quite variable for several reasons. On initial administration in a single dose to volunteers, the half-life of carbamazepine is 24 to 36 hours or longer, but autoinduction during continuous administration as monotherapy approximately doubles the clearance.[37,89,115] Autoinduction leads to a new steady state within a few weeks and to a half-life of about 12 to 15 hours in adults.[5,36,63,66,89,114,115] Carbamazepine clearance can also be influenced by its interaction with other drugs (see later discussion).

Role of Therapeutic Drug Monitoring

The boundaries of carbamazepine's therapeutic range vary by institution, but in general it is considered to be from 4 to 12 μg/mL. Dosing, however, should be titrated according to clinical response. Some patients with carbamazepine levels in the “therapeutic range” may have symptoms of toxicity because of elevated levels of carbamazepine-10,11-epoxide.[92]

The pharmacokinetic complexities of carbamazepine, especially when it is coadministered with other drugs, require awareness of factors that may inhibit or enhance its clearance as well as its pharmacologically active intermediate metabolite carbamazepine-10,11-epoxide.[63,66] When an inducing or inhibiting drug is coadministered, the physician must be alert to clinical changes, and periodic monitoring of blood levels of carbamazepine is helpful. Induction may occur within a week and deinduction within a matter of days.[114] If carbamazepine treatment is initiated in patients receiving oral contraceptives, antipsychotics, antiviral therapy for HIV, statins, warfarin, or cyclosporine, clearance of these drugs can be increased, with loss of efficacy and serious consequences.[29,66,84,97] Inhibition of carbamazepine clearance by drugs such as erythromycin or propoxyphene may lead to increased levels and neurotoxic adverse effects within a few days. If the carbamazepine dose is lowered to compensate for the changes, reinstitution of higher doses will be needed when the interacting drug is discontinued. Levels of carbamazepine-10,11-epoxide may increase to a clinically relevant range in patients receiving carbamazepine and valproate, especially if phenobarbital or phenytoin is coadministered.[63,66,74] It may be advisable to use a consistent formulation, whether generic carbamazepine or Tegretol, to minimize effects due to variable bioavailability. Periodic blood level monitoring is advisable when clinical problems arise or changes are made in coadministered drugs. All of these changes in pharmacokinetics need to be anticipated to ensure optimal control and minimal adverse effects. Measurement of complete blood cell counts and serum liver chemistries, as well as other laboratory monitoring and history and examination, especially during the first weeks and months of therapy, may help to detect medical problems.[34,74,99]

Efficacy

Screening tests in animals had indicated high potency in the maximal electroshock model, which commonly predicts efficacy for partial and tonic–clonic seizures. Relative lack of efficacy in the pentylenetetrazol model suggested that usefulness in generalized seizures of absence or myoclonic type would be limited. In keeping with these studies, early clinical reports[8,10,106] indicated efficacy both as add-on and monotherapy in open trials. Many other open, uncontrolled trials were reported during the next decade both in adults[95] and children,[45] confirming efficacy for partial and generalized tonic–clonic seizures.

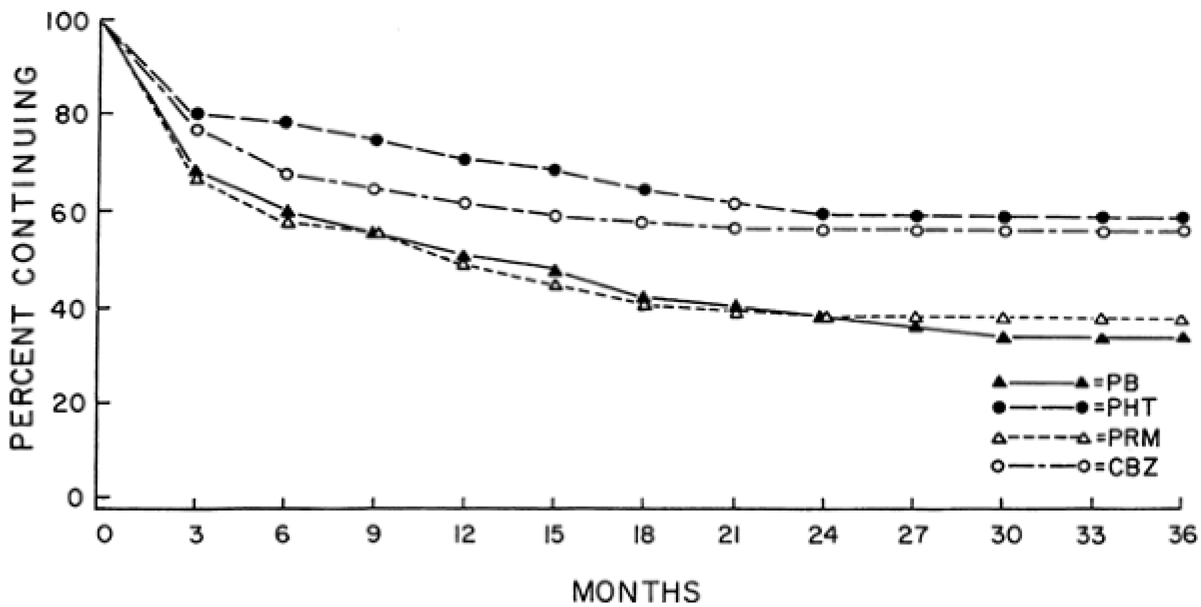

FIGURE 3. Retention (successful treatment) of 622 patients with partial seizures randomized to carbamazepine (CBZ)[80], phenobarbital (PB), phenytoin (PHT), or primidone (PRM). p <.05 CBZ/PHT versus PB/PRM.

Use in Adults

Carbamazepine has been most widely studied for use in adults, and it has been compared to both the older and newer antiepileptic medications. In the 1970s, double-blind, controlled trials of carbamazepine as add-on therapy[17,64,110,120,130] provided evidence that it was comparable in efficacy to phe-nytoin, primidone, or phenobarbital. Kosteljanetz et al.[64] confirmed these results using carbamazepine and phenytoin as monotherapy; no differences were found, but the study lasted only 10 weeks and numbers were small. Ramsay et al.[105] also

found carbamazepine and phenytoin to be comparably effective for partial and tonic–clonic seizures in a double-blind, randomized parallel study of monotherapy in 70 patients followed for 6 months. Many subsequent studies have confirmed these results. The largest long-term double-blind, active control comparative studies of monotherapy were conducted by the Veterans Administration (VA) Cooperative Study Groups No. 118 and No. 264. In an initial trial, 622 adult patients with partial and secondarily generalized tonic–clonic seizures were randomized to treatment, and carbamazepine was found to be equally as effective as phenobarbital, phenytoin, or primidone in controlling secondarily generalized tonic–clonic seizures in adults (Fig. 3).[80] Although the results for many outcome measures of efficacy in the treatment of predominantly partial seizures (seizure frequency, rate, score, and time to first seizure)[22] were equal, carbamazepine proved to be more effective than the barbiturates in providing complete control of all partial seizures, both simple and complex, at every follow-up visit for a mean duration of 3 years. This difference was statistically significant ($p < .05$) at the 12-month visit for patients with complex partial seizures (Table 1).

No difference in efficacy was observed between carbamazepine and phenytoin. In this study, phenytoin was not shown to be significantly more effective than the barbiturates. The only trial showing a difference in efficacy between carbamazepine and phenytoin was reported by Callaghan et al.[15] They reported that generalized seizures were controlled completely in 73% of 37 patients treated with phenytoin and in 39% of 28 patients given carbamazepine ($p < .01$). The reason for the superior efficacy for phenytoin is unclear. Because all other trials have found equivalence between the two drugs, their finding may be a chance outcome. A meta-analysis was performed comparing the efficacy of carbamazepine and phenytoin monotherapy for children and adults with partial onset or generalized onset tonic–clonic seizures.[131] Individual patient data were only available for analysis from 3 of the 10 studies that met their inclusion criteria for the meta-analysis,[30,50,80] but nearly 60% of the individual patient data were from VA Cooperative Study Group No. 118. Not surprisingly, the meta-analysis results were congruent with this VA study: No difference was determined for efficacy between carbamazepine and phenytoin (measured in terms of 6- and 12-month seizure remission, time to first seizure) nor in time to withdrawal of treatment.

A meta-analysis was performed by the same group to examine the efficacy of carbamazepine versus phenobarbital,[132] and again, of the four trials included in the analysis,[30,50,80,102] the bulk of individual patient data were from the VA Cooperative Study Group No. 118. For all seizure types, time to 12-month remission and first seizure favored carbamazepine, but the results were not statistically significant because the confidence interval crossed 1. Time to withdrawal of therapy clearly favored carbamazepine, however, and was statistically significant. In subset analysis of individuals with partial seizures, phenobarbital was superior for time to first seizure. This was not a robust finding because both agents were equivalent for time to 12-month remission.

Table 2 Measures of the efficacy of carbamazepine versus valproate at 12 months in patients with complex partial seizures

	Carbamazepine (no. patients)	Valproate (no. patients)	*p* Value
Seizure-rating score[a]	4.0 (71)	4.2 (75)	.79
Complex partial (n^+ 206) seizure count[a]	2.7 (60)	7.6 (65)	.05
Monthly seizure rate	0.9 (96)	2.2 (105)	.01
Seizure control (% of patients)[a]	34 (62)	29 (65)	.57
Seizure-rating score[b]	2.0 (57)	6.2 (61)	.04

[a]Seizures occurring in the first month were excluded.
[b]The higher the score, the worse is the seizure control.

Carbamazepine is comparable in efficacy to valproate for treatment of both generalized and partial seizur-es.[15,31,50,57,69,104,109] Many trials, however, have been limited by nonblinded design, short follow-up, or relatively small numbers of patients.[76,79,122] In a second VA Cooperative Study, 480 adult patients were randomized to carbamazepine or valproate. Efficacy measures again included seizure count, seizure rate, seizure score, time to first seizure, and percentage of patients who remained seizure free. Although statistically significant differences were not detected for those with *predominantly* tonic–clonic seizures, the trend favored carbamazepine. In fact, a later retrospective analysis of patients with *only* tonic–clonic seizures revealed carbamazepine to be significantly ($p < .05$) more effective than valproate in providing complete control at 12-month follow-up.[79] For treatment of *predominantly* complex partial seizures, carbamazepine was significantly more effective than valproate in four of the five outcome measures but not for 100% seizure control (Table 2).[82]

In contrast to these reported differences in efficacy, several large long-term studies conducted in the United Kingdom and a more recent trial comparing topiramate, carbamazepine, and valproate monotherapy did not find that carbamazepine had superior efficacy. The study by Heller et al. of adults used as primary measure the percentage adult of patients entering long-term remission, a point not assessed in the VA studies.[50] In the "Epiteg" trial, Richens et al.[109] found that the percentage of patients entering long-term remission was similar for carbamazepine and valproate. Carbamazepine, however, had a more successful outcome in regard to time to first seizure at 1 year of follow-up. Richens et al. concluded that the apparently better outcome for carbamazepine was attributable to suboptimal dosing of valproate early in the study, and that higher doses later in the course of the treatment resulted in comparable remission rates. Another factor that might explain the different outcomes between the VA studies and those from the United Kingdom include different outcome measures.[22] Only time to first seizure and complete seizure control were used in all studies. In addition, the populations were different. Patients in the UK studies had new-onset epilepsy, whereas approximately half of the patients in the VA trials had been previously treated. Patients with a history of previous treatment or undergoing long-term treatment represent a more difficult population for achieving control,[83] and modest differences in efficacy may become apparent only with inclusion of more difficult cases of epilepsy. Finally, and of equal importance, differences may have been found in the VA studies because the very large number of patients in the complex partial seizure group (more than twice the number in any other study) provided the power to detect statistically significant differences. A meta-analysis comparing carbamazepine versus valproate was performed that included individual patient data from the four original studies cited earlier[30,50,82,109] and an additional small pediatric study.[133] Only one study was double-blinded.[82] There were no overall differences in time to withdrawal of treatment, time to first seizure, or time to 12-month remission of seizures, but in subgroup analysis of patients with partial-onset seizures, carbamazepine was superior to valproate for time to first seizure and time to 12-month remission of seizures. Valproate was not, as one would expect, superior to carbamazepine for generalized-onset tonic–clonic seizures; however, the subgroup with this seizure type was small. There were also concerns that patients with partial-onset seizures may have been misclassified as generalized-onset seizures because the age of onset for this group was suspiciously late for this syndrome. In addition, outcomes for only generalized-onset tonic–clonic seizures were examined, but one would expect a greater effect of valproate for absence or myoclonic seizures. A more recent double-blind comparison of topiramate, carbamazepine, and valproate monotherapy in newly diagnosed epilepsy found no differences in efficacy in the subset with partial epilepsy.[104]

Table 3 Carbamazepine versus oxcarbazepine monotherapy for newly diagnosed, previously untreated epilepsy

	Carbamazepine	Oxcarbazepine	*p* Value
Mean final daily dose (mg)	684 (300–1400)	1040 (300–1800)	
Mean serum concentration (μmol/L)	29.6 (±9.0)	57.0 (±20.0)[a]	

>50% Seizure reduction (% of patients)[b]	81.4	80.2	n.s.

Brodie et al.[12] compared carbamazepine with lamotrigine in a population of patients with new-onset epilepsy and failed to reveal differences in seizure control. Because this was a more treatment-responsive (new-onset) patient population and because the number of patients with complex partial seizures was not large, small differences in efficacy may have escaped detection. A randomized, open-label, multicenter trial of la-motrigine versus carbamazepine for patients with partial and/or generalized seizures also did not find a statistically significant difference in efficacy, but there was a trend that the higher dose of lamotrigine (200 mg) was more effective than carbamazepine (600 mg).[107] Time to withdrawal was used as a composite measure of safety and efficacy, and there was no difference of this measure between the two groups. However, more patients on carbamazepine withdrew due to adverse events.[107] A more recent open-label multicenter trial compared lamotrigine and carbamazepine for patients aged 2 years or older with newly diagnosed partial epilepsy. As with the two earlier trials, no statistically significant difference in efficacy was found, but overall lamotrigine was better tolerated.[93] A meta-analysis compared carbamazepine and lamotrigine as monotherapy for partial onset or generalized onset tonic–clonic seizures in adults and children. Individual patient data from 1,384 patients were collected from five studies[11,12,93,107] (one of which[12] consisted of two studies with similar protocols). As would be expected from the trials analyzed, lamotrigine was significantly better than carbamazepine in regard to time to treatment withdrawal. Carbamazepine was superior to lamotrigine in regard to the efficacy measures of time to first seizure postrandomization (hazard ratio [HR] 1.14; 95% confidence interval [CI] 0.92–1.43) and seizure freedom at 6 months (HR 0.92; 95% CI 0.81–1.04), but as unity was crossed, these results were not statistically significant. Longer-term outcomes could not be determined by this meta-analysis.[44]

A controlled comparative trial of carbamazepine with oxcarbazepine also revealed equivalent efficacy.[25] No significant difference was seen for seizure freedom during the 48-week maintenance phase or the number of individuals having at least 50% seizure frequency reduction. Although the incidence of side effects was equivalent, more individuals in the carbamazepine arm were forced to exit the trial due to “severe side effects.” Allergic side effects were the most common reason for withdrawal of trial medication (Table 3). Additional randomized, controlled studies comparing carbamazepine and oxcarbazepine have not been performed.

An initial unblinded trial in Finland reported by Kalvainen et al.[60] indicated that carbamazepine was somewhat more successful in control of partial seizures than vigabatrin, although the latter had fewer important adverse effects. A larger multicenter, randomized, double-blind study in 459 patients with newly diagnosed, previously untreated partial epilepsy confirmed that carbamazepine was superior to vigabatrin in both time to first seizure after the first 6 weeks of randomization and seizure freedom at 1 year (58% vs. 38%). No difference, however, was seen in the primary outcome of withdrawal due to lack of efficacy or adverse events (Table 4).[18]

A multicenter, randomized, double-blind study of patients with newly diagnosed, previously untreated epilepsy indicated that carbamazepine had superior efficacy to the investigational agent remacemide for all outcome measures (time to first seizure after dose titration and time to second, third, and fourth seizure after randomization).[13]

Table 5 Carbamazepine versus lamotrigine in elderly patients with newly diagnosed epilepsy

	Carbamazepine	Lamotrigine	*p* Value
Median daily dose (mg)	400 (200–800)	100 (75–300)	
Median serum concentration (mg/mL)	6.9	2.3	
Seizure freedom (% of patients)[a]	21	39	.027
Maintained treatment (% of patients)	42.6	71	<.001

Use in Children

Results of efficacy studies in children very closely parallel those reported for adult populations.[34,45,70,98,106,125,133,137] Partial seizures associated with benign rolandic or symptomatic epilepsy as well as secondarily generalized tonic–clonic seizures all respond well to carbamazepine therapy.[9,34,45,70] A randomized, double-blind comparative study of two fixed doses of to-piramate and carbamazepine or valproate was performed in children ages 6 years and older. No difference was seen for time

to exit, time to first seizure, or seizure freedom at 6 months. Carbamazepine had equivalent efficacy to topiramate for the partial seizure subset.[135] A Canadian double-blind comparative study of clobazam for treated or previously untreated children with partial or generalized onset seizures found no overall difference in retention at 12 months. Efficacy data were not presented for the partial seizure subset alone.[16] A small open-label comparative trial of carbamazepine and vigabatrin in children found no difference in efficacy but suggested that the latter was better tolerated.[137]

Use in the Elderly

Two double-blind, randomized monotherapy trials compared carbamazepine to lamotrigine or lamotrigine and gabapentin in the elderly with newly diagnosed epilepsy.[11,112] Because of the late age of onset of epilepsy, the majority of individuals in these trials can be assumed to have partial epilepsy. The UK Lamotrigine Elderly Study Group found no difference in time to first seizure between carbamazepine and lamotrigine, but significantly more patients on lamotrigine versus carbamazepine were seizure free during the last 16 weeks of treatment (Table 5).[11] This finding may be a reflection of the short duration of the trial. The duration of follow-up extended to 1 year in the more recent VA Cooperative Study 428. No difference among carbamazepine, gabapentin, and lamotrigine was seen for the efficacy outcome measures of time to first seizure, seizure freedom at 12 months, and seizure free retention at 12 months. Withdrawal of therapy due to adverse events was higher for carbamazepine than for the other drugs in both studies (Table 6). Overall, these studies suggest that carbamazepine and lamotri-gine have equivalent efficacy in the elderly with new-onset untreated epilepsy, but that lamotrigine should be considered for initial monotherapy given its better tolerability profile in this age group. Both studies used the immediate-release formulation of carbamazepine, and it is unknown whether the extended-release formulation of carbamazepine would have fared better in regard to tolerability in these studies. The study also used an "intent to treat" analysis in seizure control such that withdrawals due to adverse effects were also considered seizure control failures. Analysis of results from evaluable data prior to withdrawal indicated a trend to best control by carbamazepine followed by lamotrigine and least efficacy for gabapentin.

Limits of Use

In contrast to partial and generalized tonic–clonic seizures, absence, myoclonic, and atonic seizures do not improve with carbamazepine therapy and may even be aggravated in some patients.[47,48,101,119,123] Carbamazepine, like most standard antiepileptic drugs, has not proved very useful in the management of symptomatic generalized epilepsy syndromes such as Lennox-Gastaut syndrome or West syndrome. Carbamazepine's insolubility and consequent lack of a parenteral formulation make it less useful in treating neonates and infants.

Table 7 Incidence and prevalence of adverse effects with use of carbamazepine

Effect	Percentage of patients[a] (*n* = 231)	Percentage at 12-month visit[b] (*n* = 130)

Sedation	42	8
Weight gain	32	9
(Large weight gain)[c]	8	3
Nystagmus	30	6

Adverse Effects

Carbamazepine is a well-tolerated antiepileptic drug, and for this reason it has won a place as a drug of choice for the treatment of partial and secondarily generalized tonic–clonic seizures, especially within the European medical community.[70] The reported frequency of adverse effects is variable, in part because of methods of assessment. Active questioning and direct examination of patients will elicit more presumed drug-related effects than passive self-report.[78,80,82] In the VA Multicenter Studies, adverse effects were measured at every visit. Both patients and families were specifically asked about, and patients were examined for, each possible adverse effect. If the complaint (e.g., tiredness) could only be attributed to the drug, it was recorded as a drug-related adverse effect. Consequently, this method errs on the side of overrecording adverse effects. Table 7 shows the adverse effects recorded in 236 patients randomized to carbamazepine in the comparative trial with valproate.[82] The problems are quite similar to those encountered with other standard antiepileptic drugs. Tremor and weight gain were significantly less common than with

valproate. In the initial VA Cooperative Study No. 118, patients taking carbamazepine had less impotence than those taking barbiturates and fewer cosmetic adverse effects than those taking phenytoin.[80] It is interesting that a retrospective analysis disclosed that carbamazepine-treated patients had significantly greater weight gain than those on phenobarbital, phenytoin, or primidone (unpublished data). Of importance is the low prevalence of adverse effects at the 12-month visit, confirming excellent long-term tolerability. The types and frequencies of adverse effects in 155 patients randomized to carbamazepine in the first VA Cooperative Study were very similar.[80]

Dose-related, Nonidiosyncratic Reactions

The systemic adverse effect that most commonly occurs during initiation of therapy is nausea or gastrointestinal discomfort, which abates in most patients as pharmacodynamic tolerance develops and autoinduction lowers blood and brain concentrations (Table 7).

Neurotoxic adverse effects are primarily dose related and reversible. During initiation of therapy, dizziness, diplopia or blurred vision, sedation, and headache are most comm-on.[17,34,52,54,80,81,82,105,110] Slow, gradual increase in dose at startup minimizes these effects. With long-term administration, these symptoms usually subside, unless maximal dose is given because of difficulty in obtaining seizure control (Table 7). When coadministered with an enzyme-inducing drug, such as phenobarbital or phenytoin, peak levels of carbamazepine commonly occur several hours after intake and persist for approximately 1 hour.[37,58] Shorter intervals between doses or use of a sustained-release formulation may minimize this pattern.[70] Following accidental or purposeful carbamazepine overdose, dizziness, incoordination, ataxia, mydriasis, ophthalmoplegia, dyskinesia, stupor, coma, and respiratory arrest can occur. Although overdose is potentially life threatening, the prognosis is favorable with optimal medical support.[134] As might be expected because of the close chemical relation to tricyclic antidepressants, cardiac arrhythmias can occur.[54,82,134] Occasionally, movement disorders are seen, including dystonia, choreoathetosis, and tics.[54,134] These may be associated with overdose but also appear to be idiosyncratic and occur in patients with usually well-tolerated blood concentrations.[54] Although most reports of adverse effects have been in blinded, controlled studies conducted on adults, extensive clinical experience also indicates carbamazepine has an adverse effect profile in children.[34,52,54,98,125]

Adverse neuropsychological effects of carbamazepine are generally minimal, especially when compared with those of the barbiturates. Studies by Trimble[129] as well as initial reports from Troupin et al.[130] indicated that carbamazepine produced fewer cognitive effects than phenobarbital or phenytoin. In a later reanalysis, Dodrill and Troupin[33] concluded that the differences between carbamazepine and phenytoin in their original study were attributable to unusually high doses and blood levels of phenytoin, which affected speed and coordination of motor tasks. In the first VA Cooperative Study No. 118, extensive testing was carried out on repeated visits using a battery of neuropsychological tests. There were no statistically significant differences among carbamazepine, phenobarbital, phenytoin, or primidone during long-term administration when doses and blood levels of drugs were within the target range. In the analysis of data from this study, however, Smith et al. reported that patients taking carbamazepine most often had the lowest (most favorable) score on most tests in the battery.[121] In the second VA Multicenter Cooperative Study No. 264, carbamazepine and valproate were compared using a battery of behavioral tests before treatment and again after 6 months of therapy. No worsening of test performance was found for patients on either drug, nor were differences found between the two drugs.[103] No improvement (practice effect) was observed, however, in contrast to results in a control group. Similarly, in a study comparing carbamazepine with vigabatrin in nonblinded long-term monotherapy trials, Kalvainen et al.[60] found that patients taking vigabatrin as well as a control group improved in neuropsychological test performance on repeated administration, whereas those treated with carbamazepine failed to show this presumed practice effect. Meador et al.[86,87] compared carbamazepine, phenytoin, and phenobarbital in patients and normal controls. They found no significant differences between carbamazepine and phenytoin but did observe some greater compromises in subjects given phenobarbital. The lack of significant cognitive adverse effects was confirmed in children taking carbamazepine by Aldenkamp et al.[1] Withdrawal of carbamazepine and other antiepileptic drugs had little effect on cognitive tests. In a review of available trials, they also concluded that there were no differences in cognitive test results between patients taking carbamazepine or phenytoin but pointed out that no study was fully adequate.[2] Overall, the evidence suggests that in the usual doses of 10 to 15 mg/kg and with blood concentrations of 4 to 12 mg/mL, carbamazepine is well tolerated and causes minimal adverse effects on cognition, affect, and behavior.

Idiosyncratic Reactions

Serious systemic effects are uncommon. Approximately 10% of patients experience a hypersensitivity rash during the first weeks or months of treatment.[12,18,57,80,82,109] This effect was observed in the two double-blinded monotherapy multicenter studies in adult epilepsy patients conducted by the VA.[80,82] Rash occurred in 9% of 155 patients randomized to carbamazepine in the first study and in 11% of 240 in the second trial. These figures agree very closely with those

recorded in the “Epiteg” trial in the United Kingdom[109] and in a double-blind study comparing carbamazepine and lamo-trigine.[12] The frequency of rash does not differ significantly from that observed with administration of other standard antiepileptic drugs, with the exception of valproate.[80] Fewer than 1% of patients taking valproate had a sensitivity rash.[82] In approximately half of the patients experiencing a hypersensitivity reaction, lowering the dose or temporarily stopping the drug results in disappearance and may allow continuation or reinstitution of carbamazepine therapy, especially if the reaction is mild. More severe reactions may include uncomfortable pruritus and, infrequently, fever, malaise, and generalized aches and pains. Involvement of mucous membranes and other systemic manifestations indicate a serious medical problem, such as Stevens-Johnson syndrome or Lyell syndrome, requiring prompt and total discontinuation of the drug. Other interventions, including antihistamines, steroids, and hospitalization,[40,54] may be required. Fatal eosinophilic myocarditis has also been reported as a manifestation of hypersensitivity.[113]

The other major life-threatening complication associated with carbamazepine use is aplastic anemia or agranulocytosis. This adverse effect delayed approval of carbamazepine in the United States by the Food and Drug Administration for some years. Long-term surveillance of serious idiosyncratic toxicity suggests an incidence of aplastic anemia of approximately 1 case in 200,000 exposures to carbamazepine.[20,98,99] It is unclear why the risk seemed to be considerably higher during the original trials. The initial cases were reported in patients being treated for trigeminal neuralgia, suggesting that elderly patients are at greater risk. It is unlikely that regular monitoring of the complete blood cell count and platelet count allows early detection and discontinuation of drug before the toxic burden becomes irreversible.[34,99] In view of the rarity of aplastic anemia, it can be readily calculated that routine monitoring to identify rare cases costs millions of dollars. Confounding the issue of monitoring for aplastic anemia is the leukopenia that occurs frequently during initiation of drug therapy.[25,99] Indeed, in the original VA Multicenter Antiepileptic Drug Trial, 30% of patients had leukocyte counts <5,000 cells/mm^3 during the first 6 months of follow-up.[80] Although this was more common with carbamazepine than with phe-nytoin, phenobarbital, or primidone, the differences did not reach statistical significance. More important, neutropenia of a clinically significant degree (<1,000 cells/mm^3) was observed in only one blood sample from one patient treated with carbamazepine. The cell count fell to 896 cells/mm^3; on repeated determination (without changing drug dose), the value had risen and remained at <1,000 cells/mm^3, so long-term treatment was continued. Although leukopenia is rarely clinically significant, a gradually decreasing white blood cell count engenders fear of the rare but potentially catastrophic aplastic anemia and at times may lead to discontinuing of carbamazepine unnecessarily.[34,70]

Other serious adverse effects include hepatitis, which is usually seen in association with a generalized hypersensitivity reaction,[3,40,121] and systemic lupus erythematosus.[3,54] Cardiac conduction disturbances have also been reported[62,82] and may require discontinuing therapy, especially in elderly patients with cardiac disease. A more common systemic effect with long-term carbamazepine administration is hyponatremia. Conflicting evidence concerning the mechanism suggests both a direct renal tubular effect and inappropriate release of antidiuretic hormone.[59] The hyponatremia is usually not clinically significant, but if it is coupled with hemodilution or insufficient salt intake, encephalopathy and worsening of seizures may result.[82,100] Hyponatremia may be more frequent and severe in patients treated with oxcarbazepine than with carbamazepine, especially the elderly.[35] The mild anticholinergic properties of carbamazepine infrequently aggravate glaucoma or urinary retention.

Second-generation Effects

Teratogenic effects have been reported in offspring of mothers taking any of the standard antiepileptic drugs.[28] (For detailed review, see Chapter 108.) Initially, carbamazepine was thought to be safer than phenobarbital, phenytoin, or valproate, but later reports[28,54,67] suggested an increased risk for major malformations, including spina bifida.[111] Although carbamazepine use was associated with an increased frequency of spina bifida relative to phenobarbital and phenytoin, the number of cases was very small.[111] The risk for malformations was especially high when carbamazepine was coadministered with phenobarbital or valproate. Lindhout et al.[67] suspected that this effect was perhaps secondary to increased concentrations of carbamazepine-10,11-epoxide or other epoxide intermediates. In the more recent U.K. Epilepsy and Pregnancy Register, 3,607 pregnant women with epilepsy were followed prospectively. The malformation rate was significantly lower for carbamazepine monotherapy (2.2%; 95% CI 1.4%–3.4%) than valproate monotherapy (6.2%; 95% CI 4.6%–8.2%). The malformation rate was also slightly lower for carbamazepine than for lamotrigine monotherapy (3.2%; 95% CI 2.1%–4.9%) or even women who took no antiepileptic medication during pregnancy (3.5%; 95% CI 1.8%–6.8%). Polytherapy increased the risk of malformation, especially when the regimen included valproate.[90] Overall, the evidence does not suggest that any standard antiepileptic drug is preferable to the others in pregnancy, and selection should be based on epilepsy syndrome, seizure control, and tolerability.[28] Ideally, monotherapy with the lowest effective dose should be used (see Chapters 108 and 198).

Drug Interactions

An increase in clearance is characteristically seen when carbamazepine is coadministered with other enzyme-inducing drugs, such as phenobarbital, phenytoin, and oxcarbazepine.[5,66,96] This results in a half-life as short as 6 hours, and frequent dosing may be required to avoid clinically undesirable peak and trough effects.[56] Conversely, biotransformation can be inhibited by coadministration of a number of drugs, including the macrolide antibiotics (erythromycin and others), cimetidine, calcium channel blockers (verapamil and others), danazol (a synthetic estrogen), dextropropoxyphene, and several imidazoles.[20,24,66,97] Some of these are generally given for short periods, but if they are administered on a long-term basis, determination of carbamazepine blood levels is indicated and changes in dose may be required. The epoxide hydrolase can also be inhibited, most notably by valproate, an antiepileptic drug commonly used together with carbamazepine when monotherapy is adequate to control seizures. The coadministration of an enzyme-inducing compound, such as felbamate, phenobarbital, or phenytoin, with carbamazepine induces its conversion to the 10,11-epoxide.[63,96] If the patient is also treated with valproate, inhibition of the epoxide hydrolase can lead to clinically meaningful concentrations of the pharmacodynamically active metabolite.[5,36,63,66,74,77]

Interactions are frequent when carbamazepine is given in combination with other drugs, and these can significantly increase or decrease the clearance of carbamazepine and its active intermediate metabolite carbamazepine-10,11-epoxide, as indicated earlier. In addition to the effect of other compounds on carbamazepine clearance, the inducing properties of carbamazepine can increase the clearance of other antiepileptic

P.1552

drugs, including ethosuximide, felbamate, lamotrigine, oxcarbazepine and its active metabolite tiagabine, topiramate, and valproic acid,[96] and produce a competitive inhibitory effect on phenytoin. This sometimes results in modest elevations in phenytoin serum concentrations.[14,66] The inductive effects on valproate clearance appear to be somewhat less than on phenytoin.[77] Carbamazepine increases the clearance of sex hormones given as oral contraceptives, occasionally resulting in unplanned pregnancies.[66,84] Carbamazepine can also increase the clearance of other important drugs metabolized by the CYP3A4 pathway, including antiarrhythmics, antiviral therapies for HIV, antineoplastics, statins, and oral anticoagulants such as warfarin.[97] Both the autoinductive and deinductive effects begin within days, and deinduction occurs rapidly.[66,77,114]

Changes in protein binding are usually too modest to have clinical significance,[66] although valproate may physically displace carbamazepine and increase its potential for causing peak dose-related adverse effects, especially when seizure control is difficult and high doses are used.[73,74,77]

Role in Epilepsy Treatment

Indications

Carbamazepine and other major established drugs, such as phenytoin, are equally effective in the treatment of many seizure types, but the response to treatment may differ among individual patients. Many comparative crossover studies of carbamazepine and phenytoin have shown that carbamazepine may be effective and tolerable when phenytoin fails and vice versa.[15,49,64,130] The newer antiepileptic medications have not been shown to have superior efficacy as monotherapy for new-onset epilepsy to the older agents like carbamazepine or phenytoin.[65] However, when selecting an antiepileptic medication for monotherapy, efficacy is only one of the variables that should be taken into account. Consideration should also be given to other comorbidities such as migraine, psychiatric disease, or obesity. Other factors to be considered are hormonal milieu and risk of endocrine-related conditions such as osteoporosis; risk of teratogenicity; and metabolism of concurrently prescribed medications. Factors external to the patient's health status such as the medication's availability, cost, and coverage by third-party payers should also be considered.[41,42] Compliance is also more likely with a simpler dosing schedule, and when carbamazepine is selected, if possible, an extended-release formulation should be used. When poor control of seizures requires coadministration of two or more antiepileptic drugs, carbamazepine is effective. Indeed, in the original controlled clinical trials, carbamazepine was added on to other established antiepileptic drugs.[17,64,120,130] Because comparative trials have not been performed, there is no evidence to suggest that the newer antiepileptic drugs are more effective for refractory epilepsy than carbamazepine or phenytoin.

In summary, even when the newer antiepileptic medications are taken into account, the preponderance of evidence indicates that carbamazepine is unsurpassed in efficacy for the treatment of partial and secondarily generalized seizures and by some measures is more effective than traditional antiepileptic medications such as barbiturates or valproate as well as gabapentin and vigabatrin among new antiepileptic drugs in the treatment of partial seizures.[10,18,80,82,112] In a recent survey of expert opinion, carbamazepine and oxcarbazepine were rated as the initial treatment of choice for symptomatic localization-related epilepsy, and in contrast to a prior survey, phenytoin was no longer rated as a first-line therapy.[61]

Dosing Recommendations

In cases of new-onset epilepsy, the treatment should be initiated gradually because carbamazepine often produces dizziness, gastrointestinal upset, sedation, and visual disturbances if full daily maintenance doses are used. For most outpatients, carbamazepine is best started with an initial test dose of 100 mg, followed by further increments as tolerated. Should no adverse effects appear with 100 mg on the first day, administration twice daily can be attempted and repeated for another day, followed by an increase to three 100-mg doses approximately equally divided throughout the day. In most patients, an increase to 200 mg twice daily is appropriate and possible during the first week. This slow and gradual escalation minimizes side effects. The relatively low doses still provide adequate blood levels because of the initially slow clearance.[37,114,115] Autoinduction steadily reduces blood levels relative to the dose and, together with pharmacodynamic tolerance, allows dose increases to 200 mg three times daily by the end of the first or during the second week. The presence of uncomfortable dose-related side effects during initiation of therapy (see earlier discussion) should lead to withholding the subsequent dose until symptoms have cleared. If subsequent reintroduction of the previous dose continues to produce side effects, the dose should be lowered. For most adults (60–80 kg in weight), doses of 600 to 800 mg (10 mg/kg) are reasonable first targets for long-term therapy.[82] If seizures are not controlled, one dose should be increased gradually in 100- or 200-mg increments until control is obtained or unacceptable adverse effects appear. In the latter case, a slight reduction is indicated until the symptoms abate or decrease to a tolerable level. If at this point control is unacceptable, it may be necessary to coadminister carbamazepine with another antiepileptic drug or substitute it with another. Clinical response dictates dose, but monitoring of antiepileptic drug levels during initiation of therapy helps to achieve a target concentration that can reasonably be expected to provide control. This is valuable in view of carbamazepine autoinduction.

This recommended dosing regimen depends to some degree on the severity of the epilepsy and how difficult it is to achieve control. For patients with new-onset epilepsy associated with tonic–clonic seizures, modest doses given twice daily may be quite satisfactory.[82] This regimen facilitates compliance and provides relatively smooth blood concentrations.[23] On the other hand, when carbamazepine is coadministered with phenytoin or phenobarbital, its clearance is significantly enhanced and the half-life may decrease to 6 to 8 hours.[37,66] To optimize absorption and minimize peak and trough effects, especially when the dose needs to be close to maximally tolerated quantities, more frequent daily administration is recommended to maximize control without producing peak toxic effects.[58,70] Use of sustained-release formulations of carbamazepine given twice daily minimizes the fluctuations and should prove optimal for these patients.[88,128]

Clinical use in children is similar to that in adults. Doses need to be reduced according to size. On the other hand, clearance in preadolescent children is increased, and they may require a 50% increase in dose to achieve blood concentrations comparable with those of adults.[34,37]

Precautions

Among women using oral contraceptive pills, caution is advisable because of the increased risk for contraceptive failure resulting from the increased clearance of female sex hormo-nes.[54,66,84] In fertile women, especially if they are planning pre-gnancy, some concern arises about the risk for congenital

malformations, including especially spina bifida.[67,111] All standard antiepileptic drugs carry some teratogenic risk, however, although the association with spina bifida and neural tube closure appears to be greatest for valproate. In general, when these antiepileptic drugs, including carbamazepine, are used at the lowest effective dose as monotherapy, teratogenic risks are relatively low, and drug selection is based more appropriately on the best agent for treatment of the mother's specific epilepsy and seizure type.[28] Carbamazepine is present in breast milk, but its effect on infants has not been studied. Use of carbamazepine in elderly patients is somewhat more complicated. These patients often take multiple other drugs, and carbamazepine may induce metabolism of compounds such as warfarin (Coumadin) and cyclosporine.[29] Interactions may have potentially serious consequences.[66,77] Carbamazepine-associated hyponatremia and cardiac dysrhythmias, as well as the absence of a parenteral formulation, also make carbamazepine a less-than-optimal drug for this population.[75,76] As in all cases of drug selection, however, a decision should be reached based on a review of the needs and risks of each individual patient rather than on the basis of age alone.[76] Precautions should also be taken in patients with history of adverse hematologic reaction or hypersensitivity to other medications (especially anticonvulsants), glaucoma, liver or kidney dysfunction, or history of atypical absence seizures.[20]

Contraindications

Carbamazepine is contraindicated for patients who have had prior hypersensitivity reactions to carbamazepine or tricyclic compounds. Concomitant monoamine oxidase inhibitor and carbamazepine therapy can result in seizure exacerbation and hyperpyrexia.[20] It is recommended that monoamine oxidase inhibitors be discontinued at least 14 days prior to initiating therapy with carbamazepine. Carbamazepine should also not be used in patients with prior bone marrow depression.[20]

Summary and Conclusions

Carbamazepine is one of the most frequently prescribed first-line drugs for the treatment of partial and generalized tonic–clonic seizures; it is effective in both adults and children. In contrast, carbamazepine is ineffective against absence, myoclonic, and atonic seizures, and it may even aggravate them. Carbamazepine is as potent as phenytoin but has fewer cosmetic side effects. Compared to valproate, tremor and weight gain are much less common. Most patients do not experience significant cognitive adverse effects. About 10% of patients develop a hypersensitivity rash during the first weeks of treatment, but if the reaction is mild, reducing the dose or temporarily stopping the drug may allow carbamazepine therapy to continue. Aplastic anemia, originally a feared idiosyncratic reaction, is rare: There is about 1 case in 200,000 exposures. Routine blood tests are not useful in preventing irreversible aplastic anemia. In contrast, benign leukopenia occurs in up to 30% of patients taking carbamazepine, but this does not appear to increase the risk of aplastic anemia. Elderly patients are especially vulnerable to the consequences of hyponatremia and effects on cardiac conduction.

Treatment should be initiated at a low dose (e.g., 100 mg/d) and then increased gradually in the absence of side effects. Clearance is initially slow, but autoinduction shortens the drug's half-life substantially and steadily reduces blood levels relative to dose within the first 3 to 4 weeks of therapy. For most adults, long-term treatment requires at least 10 mg/kg daily. Children clear carbamazepine more rapidly and thus may require doses up to 50% higher than adults to achieve comparable blood levels.

Chapter 147

Ethosuximide

Edward B. Bromfield

Introduction

Among several succinimides synthesized as modifications of the hydantoin-barbiturate heterocyclic ring, only one, ethosuximide, is still in widespread use; another, methsuximide, has a broader spectrum of action but is used less often (see Chapter 163). Ethosuximide has been available since 1958, and remains a first-line drug for the treatment of absence and related seizures.

Chemical Structure, Formulations, and Methods for Determination in Body Fluids

The similarity of ethosuximide, 2-ethyl-2-methylsuccinimide (Fig. 1), to other traditional antiepileptic drugs (AEDs) with a five- or six-membered heterocyclic ring structure is apparent, with a nitrogen atom located between two carbonyl groups. Unlike most, however, it is highly water-soluble. It has one asymmetric carbon and is used in its racemic form.[22] It is a crystalline powder or a waxy solid, sold as a liquid-filled capsule (250 mg) or as syrup (250 mg/5 mL). High-performance liquid chromatography can be used to measure plasma levels.[28]

Pharmacology

Activity in Experimental Models of Seizures/Epilepsy

Ethosuximide's efficacy against absence seizures is consistent with its potency in several chemical convulsant models, particularly pentylenetetrazol, as opposed to the maximal electroshock model.[14] It is also successful in other models believed to mimic absence seizures, including systemic penicillin, intravenous γ-hydroxybutyrate, intraventricular leucine-enkephalin, and spontaneous seizures in selected genetically epilepsy-prone rodents (Strasbourg), and as well experimental seizures induced by fluorothyl, enflurane, barbiturate withdrawal, and cortical estrogen or cobalt.[14,19,21,25] On the other hand, ethosuximide is relatively ineffective against seizures induced by bicuculline, strychnine, aminophylline, kainic acid, and *N*-methyl-D-aspartate, as well as cortical aluminum or amygdaloid kindling.[14,21,25]

Activity in Other ModelszHH

Low-threshold, “transient” (T-type) calcium (Ca) channels on thalamic neurons seem to play a critical role in the thalamocortical interactions that underlie the 3-Hz spike-and-wave pattern characteristic of absence seizures.[14,19] Ethosuximide blocks the low-threshold Ca current mediated by these channels in a voltage-dependent manner, such that the degree of current blockade increases at more hyperpolarized conditions.[8,14,25] That this mechanism is adequate to decrease abnormal thalamocortical excitability without affecting normal, tonic thalamic cell activity has been demonstrated in a computer simulation.[17] Dimethadione, another specific antiabsence drug, also blocks these currents at therapeutically relevant concentrations, whereas carbamazepine and phenytoin do not,[8,19] and valproate does so to a much lesser degree.[19] Ethosuximide also has other potentially important ionic effects, such as partial blockade of noninactivating sodium (Na) currents and Ca-dependent potassium (K) channels.[14,16]

Mechanisms of Action

Although the main effect of Ca-current blockade appears to be a decrease in thalamocortical excitation, ethosuximide may also interfere with rhythmic inhibitory activity,[11,14] which appears to be important in generating absence seizures.[2] Effects on neurotransmitter synthesis, metabolism, or action do not seem to underlie these effects, but the effects on T-type Ca channels discussed earlier could be responsible.[8,14]

Clinical Pharmacokinetics

Absorption

Absorption after oral administration is essentially complete, and peaks 3 to 5 hours after ingestion of the capsule;[22] absorption occurs slightly more quickly in acute than in long-term administration, and with the syrup as opposed to the capsule formulation. No significant first-pass metabolism occurs.

Plasma Protein Binding and Distribution

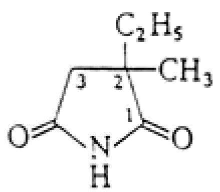
Because of ethosuximide's high water solubility, its volume of distribution is high, estimated at 0.7 L/kg.[22] Concentrations in adipose tissue are about one-third of those in plasma.[22] Ethosuximide rapidly crosses the blood–brain barrier, and equilibration between plasma and cerebrospinal fluid occurs in 20 to 30 minutes; this is three to four times as rapid as for valproate, phenobarbital, phenytoin, or carbamazepine.[22] Concentration is uniform within the brain. Because ethosuximide is not significantly protein-bound, cerebrospinal, salivary, and lacrimal concentrations are similar to those of plasma. Breast milk has only slightly lower concentrations, with a milk-to-plasma ratio of 0.8 to 0.9.[15,22]

Metabolism and Excretion

During long-term administration, approximately 20% of the dose is excreted renally unchanged, with the remainder

P.1558

hepatically metabolized to inactive compounds via the cytochrome P450/mixed-function oxidase system, principally CYP3A.[1,22] These reactions include mainly hydroxylation of the ethyl side chain in either the 1- or 2- position (see Fig. 1), with metabolites conjugated predominantly with glucuronic acid and then excreted in the urine. Elimination of ethosuximide follows first-order kinetics.[22] In adults, serum half-life is approximately 40 to 60 hours, with substantial variation between individuals; in children and newborns, half-life is slightly shorter, 30 to 40 hours.[15,22] Levels during pregnancy may fall, but not as much as those of some other drugs.[15,22] Although autoinduction of metabolism has been demonstrated in rats, this process probably does not occur in humans.[22]



ETHOSUXIMIDE

FIGURE 1. Chemical structure of ethosuximide.

There is little data on ethosuximide concentrations in hepatic or renal disease, but increases would be expected. Ethosuximide is dialyzable, with an estimate of a 50% decrease in levels over a 6-hour dialysis session.[22]

Relationship Between Plasma Concentrations and Effects

Given ethosuximide's relatively long half-life, it takes 7 to 12 days of administration to reach steady-state plasma levels, and little variation is noted between peaks and troughs, even with once-daily administration,[22] although it is usually administered twice a day. Average daily doses are 15 to 40 mg/kg to achieve the usual therapeutic range of 40 to 100 μg/mL. Although the dose-level relationship is generally linear within the usual dose range, there is evidence of saturation kinetics in some patients.[22] Among 33 patients with complete control of absence seizures, 91% had levels of at least 40 μg/mL.[29]

Efficacy

Ethosuximide remains a drug of first choice for typical absence seizures, and there is evidence of efficacy against atypical absence and myoclonic seizures, particularly epileptic negative myoclonus. In several series of patients with typical absence seizures, with or without concomitant tonic–clonic seizures, approximately half the patients experienced complete or nearly complete (>90%) control of absences, and 95% had at least a 50% decrease.[4,29] This proportion is similar to that obtained with valproate.[26,29] Absence status epilepticus, or "spike-wave stupor" (Chapter 60), in its purest form occurs in either patients with childhood- or adolescent-onset idiopathic generalized epilepsy, and often responds to ethosuximide for long-term prevention of recurrence, although benzodiazepines and other shorter-acting drugs are usually used for acute treatment.[10] Based on anecdotal evidence, adjunctive use of ethosuximide has also been proposed for myoclonic seizures, as in juvenile myoclonic epilepsy and Lennox-Gastaut syndrome, and perhaps photosensitive epilepsy.[29]

Epileptic negative myoclonus is the only focal seizure type for which ethosuximide is typically effective. Although rare, it can occur in a variety of idiopathic and cryptogenic epileptic syndromes, and is characterized by interruption of ongoing electromyographic (EMG) activity contralateral to a lateralized electroencephalographic (EEG) spike-and-wave discharge[29] (see Chapter 50).

Adverse Effects

Dose-related Effects

Dose-related adverse effects involve mainly the gastrointestinal and nervous systems. In early studies, published mainly during the 1960s, 26% to 46% of patients experienced adverse effects.[12] Gastrointestinal effects include nausea, abdominal discomfort, vomiting, anorexia, and diarrhea. These usually appear early and may resolve spontaneously or with dose reduction. Administering the same total daily dose but in more frequent, smaller doses, especially with food, can also be effective; this is the main reason for the standard twice-a-day schedule, given that the half-life is sufficiently long to allow q.d. use otherwise. The other main dose-related effects involve the nervous system, including especially drowsiness, as well as dizziness and fatigue.[9,12,21] Insomnia, hiccups, and ataxia may also occur. Headache and behavioral disturbances, including nervousness, irritability, depression, hallucinations, psychosis, and cognitive impairment, may have idiosyncratic as well as dose-related components. It is notable, however, that improvements in cognitive performance with the use of ethosuximide have also been reported in individuals both with and without epilepsy.[4,9,12]

Idiosyncratic Reactions

Among the idiosyncratic adverse effects of ethosuximide are serious skin rash, including erythema multiforme and Stevens-Johnson syndrome, as well as connective tissue syndromes resembling systemic lupus erythematosus or scleroderma.[9,12] Antinuclear antibodies usually accompany the lupus-like syndrome, but may be asymptomatic.[9] As in other drug-induced lupus-like conditions, renal involvement is extremely rare. Bone marrow toxicity, including granulocytopenia, thrombocytopenia, or pancytopenia, has rarely been noted,[9,12] with eight cases reported over the first 36 years of use, but six of these eight were on other AEDs.[12] As with other drugs, clinical screening by patient education and direct questioning about symptoms is more important than "routine" blood counts.[12,20] The latter may, however, reveal a dose-related, reversible granulocytopenia.[9] There are extremely rare reports of hepatic failure and autoimmune thyroiditis.[9]

Rare instances of dramatic behavioral and psychiatric impairments, including psychosis and impaired consciousness, may be not the direct result of the drug, but rather of its therapeutic effects on the abnormal EEG pattern and associated seizures, a phenomenon known as "forced normalization."[9,31] This has been reported in children with typical absence seizures and no history of psychiatric illness.[12]

Extrapyramidal movement disorders have also been reported, perhaps as a cumulative effect related to dose and duration of use. These include acute dystonic reactions that are responsive to antihistamines, similar to those seen with neuroleptics, as well as bradykinesia, parkinsonism, dyskinesias, and akathisia.[9,12]

Second-Generation Effects

Because ethosuximide is most commonly used in children, and rarely if ever used alone in adults, little information exists about teratogenic effects.[9,29] Rodent studies suggest that these effects are less than with other common AEDs,[9,12] perhaps because no epoxide metabolite has been identified. However, because ethosuximide is not significantly protein-bound, the fetus is exposed to higher levels than with the more highly bound AEDs.[12,15,29] Ethosuximide, as mentioned, is present in breast milk, and adverse behavioral effects on the nursing infant have been reported by some but not all observers.[15,29] Breast-feeding infants have approximately 30% to 50% of the serum ethosuximide concentrations of their mothers.[15]

Drug Interactions

The hepatic metabolism of ethosuximide underlies its pharmacokinetic interactions with other AEDs. Although there is a suggestion that ethosuximide may inhibit P450 enzyme metabolism, this effect is inconsistent and probably minor.[22] Furthermore, the lack of protein binding precludes interactions via displacement from binding sites. There is a potentially important effect of enzyme-inducing drugs on the metabolism of ethosuximide. Concurrent administration of phenytoin, carbamazepine, or phenobarbital may result in falls in ethosuximide serum levels on the order of 15% to 25%, with clearance of a single dose increasing by about 65%.[22] Valproic acid, commonly combined with ethosuximide, inhibits some P450 isoforms and may elevate ethosuximide levels slightly,[9,18,22] although there are rare reports of decreases in ethosuximide after the addition of valproate, as well as of no change.[22] With regard to drugs other than those prescribed for epilepsy, enzyme inducers such as rifampin increase clearance, and inhibitors such as isoniazid may inhibit its metabolism.[22]

Role in epilepsy treatment

Indications

Ethosuximide is a first-line drug for typical absence seizures in the syndrome of childhood absence epilepsy, and it can be used as monotherapy if generalized tonic–clonic seizures are not present. Although valproic acid is equally effective,[7,26] hepatotoxicity is a concern, especially in younger children, arguably making ethosuximide the drug of choice. In older children, in whom new-onset generalized tonic–clonic seizures are more common—approximately 40% above age 7[29]—valproate monotherapy may be preferable. If generalized tonic–clonic seizures have already occurred, ethosuximide must be combined with another drug effective against these, or monotherapy with valproate or one of the newer broad-spectrum drugs, such as lamotrigine, topiramate, zonisamide, and levetiracetam, must be instituted. Of these, only lamotrigine has received significant study, but reviews have found insufficient data to compare its effectiveness with that of the older drugs.[23] In the minority of patients whose absence seizures are not well controlled on either ethosuximide or valproate, the alternative drug or a combination of the two may be efficacious;[7,29] Bourgeois[3] has found in an experimental model that the therapeutic effects of this combination are additive, whereas toxic effects are less than additive, resulting in a favorable therapeutic ratio. Ethosuximide may also be combined with benzodiazepines or acetazolamide, as well as with the newer drugs mentioned earlier, in cases of refractory absence.

Ethosuximide is also useful in the control and prevention of absence status epilepticus,[13,24,29] particularly when this is associated with a known history of primary generalized epilepsy, as noted earlier. When absence status presents de novo in adults, it can represent "secondary bilateral synchrony" from an occult focus[30] and, in this instance, it would not be expected to respond to ethosuximide, although clinical data are sparse. In combination with clonazepam, ethosuximide has also been somewhat effective in the childhood syndrome of continuous spike-and-waves during slow-wave sleep.[32]

Atypical absence seizures, as seen in symptomatic generalized epilepsies, may respond to ethosuximide alone,[29] but because of the high incidence of additional seizure types, other drugs, particularly valproate, are almost always required. Evidence for the effectiveness of ethosuximide in other primarily generalized seizures, such as myoclonic, tonic, or atonic seizures, is limited, but it may have an adjunctive role.[27,29] On the other hand, ethosuximide is clearly indicated for the rare partial seizure type of epileptic negative myoclonus.[29]

Dosing Recommendations

Ethosuximide is manufactured in two forms, a 250-mg capsule and a syrup containing 250 mg/5 mL. Although its long half-life could allow once-daily dosing, most patients do better with two or three doses, particularly after meals, to minimize gastrointestinal side effects.[29] In younger children, a full target dose of 15 to 20 mg/kg can be given, with steady state reached in 1 to 2 weeks. In older children and adults, Sherwin[29] recommends starting at 250 mg/d and increasing the daily dose by 250 mg every 3 to 4 days until a daily dose of 15 to 20 mg/kg is reached, dose-related side effects occur, or seizures are controlled. In the elderly, whose metabolism may be slower and whose sensitivity to side effects greater, increments of 125 to 250 mg/d can be added at weekly intervals, aiming for a slightly lower target range of 10 to 20 mg/kg/d. Depending on clinical response, daily doses as high as 40 mg/kg/d in children, or 2,000 mg/d or 30 mg/kg in adults, can be used.[29] As mentioned, the usual therapeutic range is 40 to 100 μg/mL (300 to 700 μmol/L),[5,29] although levels up to 150 μg/mL may be needed, particularly in cases of absence status. In growing children, intermittent dose increases will be needed to maintain levels. Because patients may be unaware of having these seizures, and because even clinically inapparent generalized spike-and-wave complexes may impair function,[6] routine or prolonged EEG studies may provide useful information about drug efficacy.[26]

Precautions

During titration, patients should be monitored for adverse effects, especially those affecting the gastrointestinal or central nervous systems (CNS). Regarding a possible risk of marrow suppression, intermittent measurement of complete blood counts is reasonable, although it is not clear that any regular interval is indicated.[20] Counseling regarding symptoms of granulocytopenia or thrombocytopenia, such as fever, sore throat, and bleeding, is more important.

As with any AED, ethosuximide should be discontinued and another appropriate drug substituted if unacceptable side effects occur at doses that do not control seizures. If seizures are controlled, consideration for drug withdrawal is appropriate after 2 years without seizures, particularly if EEG with hyperventilation shows no spike-and-wave activity. It is

P.1560

prudent also to repeat the EEG approximately 1 month after the drug has been withdrawn.[29] Because of its long half-life and the usually minor clinical impact of the absence seizures for which ethosuximide is given, abrupt discontinuation is probably safe, but gradual reduction during several weeks is preferable unless the drug is being withdrawn because of severe adverse effects.

Contraindications

The only absolute contraindication to ethosuximide is a severe prior allergic reaction to the drug or to other succinimides. Relative contraindications are a history of psychiatric illness, blood dyscrasias, or systemic lupus erythematosus. It must be used with caution in patients with renal or hepatic disease. Ethosuximide is not indicated for patients with partial or generalized tonic–clonic seizures unless absence seizures are also present.

Summary and Conclusions

Ethosuximide is a first-choice drug for the treatment of typical absence and related seizures. Mechanistically, it reduces rhythmic activity in the thalamocortical system, possibly by blockade of the low-threshold, voltage-dependent Ca current mediated by T-type Ca channels on thalamic neurons. Although generally well tolerated, it has the potential for dose-related adverse gastrointestinal and CNS effects, and can have idiosyncratic neuropsychiatric, dermatologic, and, rarely, bone marrow effects. There is a fairly well established therapeutic range of plasma levels, which can be achieved with once daily or more frequent dosing. Even in an era of newer, broad-spectrum drugs, ethosuximide will likely retain its place as a selective antiabsence drug.

Chapter 148
Felbamate

William H. Theodore

Introduction

Felbamate (2-phenyl-1, 3-propanediol dicarbamate) (FBM), structurally unrelated to any other antiepileptic drug (AED) in current clinical use, is particularly interesting because its pharmacologic activity in animal models suggests a spectrum broader than that of most other AEDs, indicating the potential for clinical efficacy in patients with generalized as well as localization-related epilepsies.[68] Moreover, it is one of the few nonsedating agents available. Unfortunately, it is associated with a high risk for hematologic and hepatic toxicity.

Chemical structure

FBM is related structurally to the antianxiety drug meprobamate (Fig. 1A). Its molecular weight is 238.24, and the factor to convert from micrograms (μg) per milliliter to micromoles (mmol) per liter is 4.2. It is relatively insoluble in water or ethanol, but it penetrates the central nervous system readily.[11,59]

FluoroFBM (FFBM, 2-phenyl-2-fluoro-1, 3 propanediol dicarbamate), currently in preclinical development, is an analog designed to have clinical efficacy similar to FBM without the serious adverse effects of the latter.[4] FFBM has a fluorine substituted for hydrogen in the 2-position of the propanediol moiety (Fig. 1B). This substitution appears to prevent the production of the reactive toxic metabolite of FBM, atropaldehyde (ATPAL, or 2-phenylpropenal). If FFBM does prove to have similar efficacy and dose-related toxicity, but no severe systemic side effects, it may become an extremely useful AED; there are still only a few without cognitive side effects.

Methods for Determination in Body Fluids

High-performance liquid chromatography (HPLC) with spectrophotometric detection is the standard method for FBM measurement; multiple AEDs can be measured simultaneously.[9] Gas-liquid chromatography and HPLC provide comparable results.[23] Capillary electrophoresis has been proposed as a more rapid alternative.[72] Interlaboratory variation does not depend on the method used; it may be greater for AEDs like FBM that are measured less frequently, and laboratory participation in an external quality control program is essential.[89]

Pharmacology

Activity in Experimental Models of Seizures/Epilepsy

FBM is active in maximal electroshock, pentylenetetrazole, bicuculline, and picrotoxin seizure models in experimental animals, suggesting a broad spectrum of activity.[58] Its protective index (TD_{50}/ED_{50}) in the rat maximal electroshock model is 63 (compared with 100 for phenytoin), and in the pentylenetetrazole model it is 12 (vs. 1.6 for valproic acid).[59] No pharmacodynamic evidence of tolerance to FBM was found in 15-day studies in rats and mice.[76] FBM increased the threshold for focal seizures and reduced seizure severity, duration, and afterdischarge duration at doses that produce no adverse behavioral effects in amygdala-kindled rats.[92] FBM is not protective against bupropion-induced seizures.[84] FBM in doses of 100 to 500 mmol had no effect on soman-induced burst frequency, but decreased duration.[26]

Both FBM and its congener fluoroFBM are effective in the perforant path stimulation model of status epilepticus, even in late stages, and may have some antiepileptogenic effects.[49,50] Some studies have suggested pharmacodynamic synergism between lamotrigine and FBM in activity against maximal electroshock, 4-aminopyridine, and pentylenetetrazole-induced seizures.[12,48] Interestingly, lamotrigine but not levetiracetam showed additive toxicity to FBM in mice.[46,47]

Mechanisms of Action

In cultured hippocampal neurons, FBM has an unusual pattern of activity, blocking currents evoked by *N*-methyl-D-aspartate (NMDA) but facilitating γ-aminobutyric acid (GABA)ergic responses.[64,82,90] The pattern of interaction with $GABA_A$ receptors suggests relatively weak, barbiturate-like, modulatory (rather than direct agonist) activity.[64] Strychnine (0.25–0.5 mg/kg) and picrotoxin (3 mg/kg) impaired the protective activity of FBM against maximal electroshock (MES), suggesting that GABAergic inhibition and strychnine-insensitive glycine receptor–mediated events may contribute to anticonvulsant activity.[75]

Proposed mechanisms and sites for the NMDA receptor interaction include competitive antagonism at the glycine site, open channel blocking or, most likely, noncompetitive allosteric channel effect.[51] FBM does not appear to affect inhibitory glycine receptor currents in hippocampal neurons.[35] These features may explain both the AED spectrum of FBM and its stimulant-like side effects at clinical doses. FBM has neuroprotectant effects that could be mediated by NMDA receptor interaction.[52] Several pharmacologic features of FBM may account for its clinical properties. At therapeutic concentrations (50–300 mmol) FBM may bind to resting NMDA channels in the absence of glutamatergic ligands and decrease subsequent NMDA currents by stabilization of desensitized channels, thus inhibiting seizure discharges but having less effect on normal activity.[44] NMDA subunit specificity, with selectivity for NR1a/NR2B subunits, could have a similar effect.[27,40]

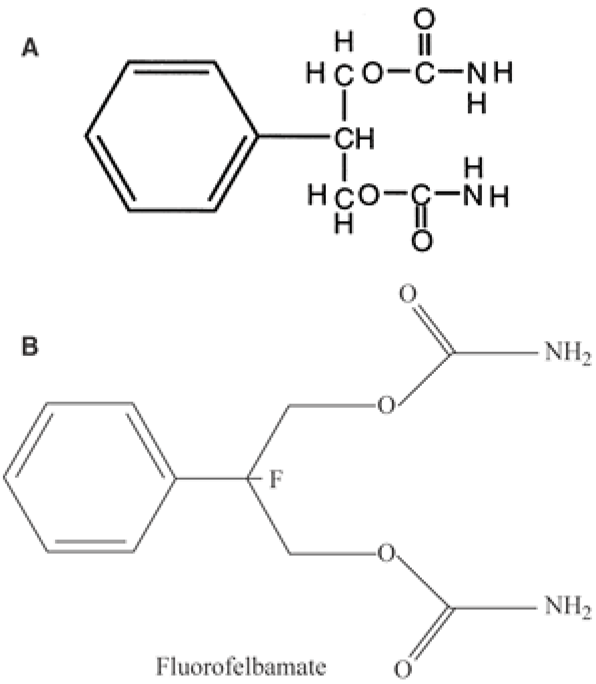

FIGURE 1. A: Structure of FBM. Although it resembles meprobamate, it has no anxiolytic effects. **B:** Structure of fluorofelbamate.

Some studies suggest that sodium (Na) channel blockade may contribute to antiseizure activity. FBM inhibited voltage-dependent Na^+ currents when α-subunits from rat and human brain were expressed in *Xenopus* oocytes, but only when

perfused on the intracellular side of the membrane.[77] FBM also blocked sustained repetitive firing in mouse spinal cord neurons.[90]

Activity in Other Models

In rats, FBM (100 and 300 mg/kg) attenuated overall naloxone-precipitated opiate withdrawal severity in a dose-related manner and reduced occurrences of chews, teeth chatters, and penile grooming, possibly due to glycine antagonist activity.[42] A similar mechanism may account for FBM's efficacy against D2 (haloperidol) but not D1 receptor–mediated akinesia, a pattern similar to other NMDA receptor complex glycine site antagonists.[43]

Toxicity Models

Early studies had shown only relatively nonspecific effects, such as decreased body weight and food consumption in mice, rats, and dogs, and increased liver weight without associated histopathological changes.[54] An increased incidence of hepatic cell adenoma and of interstitial cell tumors of the testes in rats also occurred.[53]

Recognition of FBM's idiosyncratic toxicity has triggered a search for possible mechanisms. Most studies have suggested that reactive intermediates, such as atropaldehyde (2-phenyl-propenal) an unsaturated aldehyde, may be the most important metabolites for hepatic and hematological toxicity.[14,33,34] 2-Phenylpropenal irreversibly inhibits GSTM1-1, the form of glutathione-S-transferase in liver.[15,16]

Glutathione might protect against reactive intermediate formation, although some toxicity mechanisms may be redox-independent.[29,60] Interestingly, the level of uridine diphosphoglucuronosyltransferase activity had no effect on the metabolic pathway in rats.[14] In human liver preparations, FFBM does not form reactive intermediates.[4]

Clinical pharmacokinetics

Formulations

FBM is available in 400- and 600-mg scored tablets, and in a suspension containing 600 mg/5 mL. Because there is no difference in bioavailability, the formulations should be interchangeable.

Absorption

FBM is about 90% absorbed after oral administration.[91] Bioavailability is similar for the suspension and both the chewable and standard tablets, and it is not affected by food.[58] Peak plasma concentration is reached 2 to 6 hours after dosing.[27,91]

Plasma Protein Binding and Distribution

Plasma concentration, area under the curve (AUC), and maximal concentration (C_{max}) increase linearly with dose.[58] The apparent volume of distribution, about 0.8 L/kg, is the same after a single dose or continued administration. FBM is relatively lipid-soluble and readily crosses the blood–brain barrier.[11] P-glycoprotein but not ABCC2/MRP2-mediated efflux may limit FBM brain access in rats.[61,62] FBM is 20% to 25% reversibly bound to plasma protein, mainly albumin. FBM does not show preferential accumulation in any peripheral organ or specific brain region. Pharmacokinetic parameters are stable during continued administration.[11]

Metabolism and Elimination

FBM is metabolized by the cytochrome P450 system, which probably accounts for its interactions with other

AEDs.[59] The terminal elimination half-life ranges from 13 to 23 hours. About 40% to 50% of the absorbed dose appears unchanged in the urine. Metabolites include *p*-hydroxyphenyl FBM, 2-hydroxy FBM, monocarbamate derivatives, and polar compounds (including conjugates), none of which has significant antiepileptic activity; these make up about 15% of plasma radioactivity when labeled FBM is given.[58] Children may metabolize the drug more quickly than adults. Beagle pups had decreased bioavailability but unchanged absorption and volume of distribution compared with adult beagles, suggesting faster elimination.[1] In humans, clearance is 40% higher in children than adults, and half-life approximately is 15 hours.[5,7] However, there do not seem to be any sex-related differences. FBM blood levels are stable during long-term treatment, with no evidence for autoinduction of metabolism.[17,68]

Elderly patients have lower clearance, longer half-life, as well as higher mean AUC and C_{max} values.[65] FBM clearance was decreased, and half-life, C_{max} and AUC values increased in subjects with renal dysfunction, in significant correlation with creatinine clearance.[21]

Drug Interactions

When FBM is used, drug interactions may be an important factor. FBM reduces blood carbamazepine levels by about 20%, whereas levels of the active metabolite, carbamazepine epoxide, are increased by 25% to 50%.[2,19,22,82,86]

Several investigators[22,45,85,91] have reported that FBM increases phenytoin, valproic acid, and phenobarbital levels. The doses of these drugs may need to be reduced by 10% to 30%

to maintain constant levels when FBM is given concurrently, although the effect varies from patient to patient. For phenytoin, the effect on blood levels may be related to increasing FBM doses.[71] FBM increases conversion of clobazam to its active metabolite N-desmethyl-clobazam (N-CLB), apparently to a greater degree than does phenytoin or carbamazepine.[10] Because the metabolite appears to be more potent than the parent drug, this effect could increase both efficacy and toxicity. FBM does not appear to have a clinically significant interaction with clonazepam, lamotrigine, or vigabatrin.[79,87]

In monotherapy, the FBM plasma concentration versus dose relationship was linear up to 6,000 mg/day.[70] Carbamazepine and phenytoin increase FBM clearance by about 30%, and consequently lower blood levels of FBM. On monotherapy at 3,600 mg/day, plasma concentrations of FBM ranged from 60 to 90 mg/L, whereas patients on hepatic enzyme-inducing drugs had levels of 30 to 70 mg/L. In patients receiving hepatic enzyme inducers and FBM at a maximum daily dose of 3,000 mg, FBM levels were in the range of 30 to 40 mg/L, compared with 70 to 80 mg/L in patients on FBM monotherapy at 3,600 mg/day.[17,45,68,80] Valproic acid decreased FBM clearance by about 15%[58] in some studies, particularly in children.[37] Protein binding of other AEDs does not seem to be affected by FBM.[19,58] FBM levels are not affected by erythromycin.[69] In a study reporting reduced AUC for the gestodene but not the ethinyl estradiol component of an oral contraceptive, one subject had intermenstrual bleeding but none had evidence for ovulation.[67]

Relationship Between Plasma Concentration and Effects: Value of Therapeutic Drug Monitoring

There are few data on the relation of plasma levels of FBM to clinical response. Children in the Lennox-Gastaut syndrome trial tended to have fewer seizures at plasma levels of 45 than of 18 mg/L.[18] Although the data are not directly comparable, the response in adult trials may have been better in the range of 60 to 80 mg/L than of 30 to 40 mg/L.[5,17,45,68,80] Some investigators have suggested a lower therapeutic range of about 30 to 60 mg/L (125 to 250 mmol/L).[32] Because FBM clearance is increased by carbamazepine and phenytoin, higher doses may be necessary to achieve comparable plasma levels when these drugs are given at the same time.

Adverse Effects

Dose-Related Effects

The median lethal dose (LD_{50}) could not be established in rats, because the animals did not succumb after ingestion of 3 g of FBM, the maximum dose that could be administered.[59] FBM was well tolerated in clinical trials; only about 7% of patients stopped treatment prematurely because of adverse events. In clinical trials, adverse effects that occurred significantly more often with FBM than placebo included nausea and vomiting, diplopia, blurred vision, headache, and ataxia.[30,31] However, these effects were more common in add-on than monotherapy trials, and they often disappeared when the other drugs, particularly phenytoin, were stopped.

In adults on monotherapy, insomnia and weight loss tend to be the most frequently reported side effects, followed by gastrointestinal distress and headache. Weight loss is reported in up to 75% of patients in clinical trials, averaging about 3 kilograms.[3] It tended to be lower in children.

Stimulant-like effects are prominent.[39] Some patients may experience psychiatric deterioration, particularly an anxiety-dysphoria syndrome associated with insomnia; but up to 50% may report modest improvement in mood. Children, in contrast, may experience sleepiness (perhaps analogous to the paradoxic effect of amphetamine-like drugs). FBM does not appear to have anxiolytic effects or attenuate the adverse psychological consequences of AED withdrawal.[39] Baseline insomnia and anxiety may be markers for poorer psychiatric responses to FBM. Isolated cases of tremor, involuntary movements, and psychosis have been reported, which may or may not have been caused by FBM.[28,38,41]

There have been several reports of crystalluria associated with FBM overdoses, leading to acute renal failure in at least one case when peak plasma levels were 200 μg/mL.[55,63] Acute urolithiasis occurred in a patient taking 3,000 mg/day with trough levels ranging from 52 to 170 μm/mL.[74]

Patients tend either to like FBM very much, feeling increased energy and well-being along with better seizure control, or to tolerate it poorly. FBM side effects such as anorexia, dyspepsia, headache, insomnia, or anxiety usually do not remit on continued treatment. Some patients not only lose weight, but develop a "washed out" appearance, rather like a ring-wraith in Tolkien.

Idiosyncratic

No evidence is noted of clinically significant hepatic or hematologic change in clinical trials, although mild elevation of serum liver enzymes and other abnormal clinical laboratory values occasionally were noted.[30,31,58] Rashes and hypersensitivity reactions, sometimes including fever and lymphadenopathy, occurred in 3% to 4% of patients; toxic epidermal necrolysis has been reported.[83] The number of patients studied, about 1,600, would have been too small to detect the incidence of hematologic and hepatic toxicity that has begun to be reported with wider clinical use of FBM.

Hematologic abnormalities, including fatal aplastic anemia, are more frequent in patients taking FBM than would be expected by chance. In an analysis of 31 cases, 23 met formal diagnostic criteria, excluding patients with other causes such as systemic lupus erythematosus.[36] Using an estimate of 110,000 patients exposed, the risk was estimated to range from 2 to 209 per million per year, depending on whether cases were included only when no other contributing cause was present, such as another AED, or all cases; the most "probable" estimate was 127 per million. The incidence seems higher in women. Patients had been taking FBM for up to a year before symptoms began.

At least 18 cases of liver failure (with eight deaths) ranged in age from 3 to 56 years; six were children. Exposure had ranged from 14 to 265 days; some of the patients had a rash as well as liver toxicity. All the patients were taking other AEDs.

Teratogenic Effects

Results of teratology studies in rats and rabbits have been negative, but no human data are available.

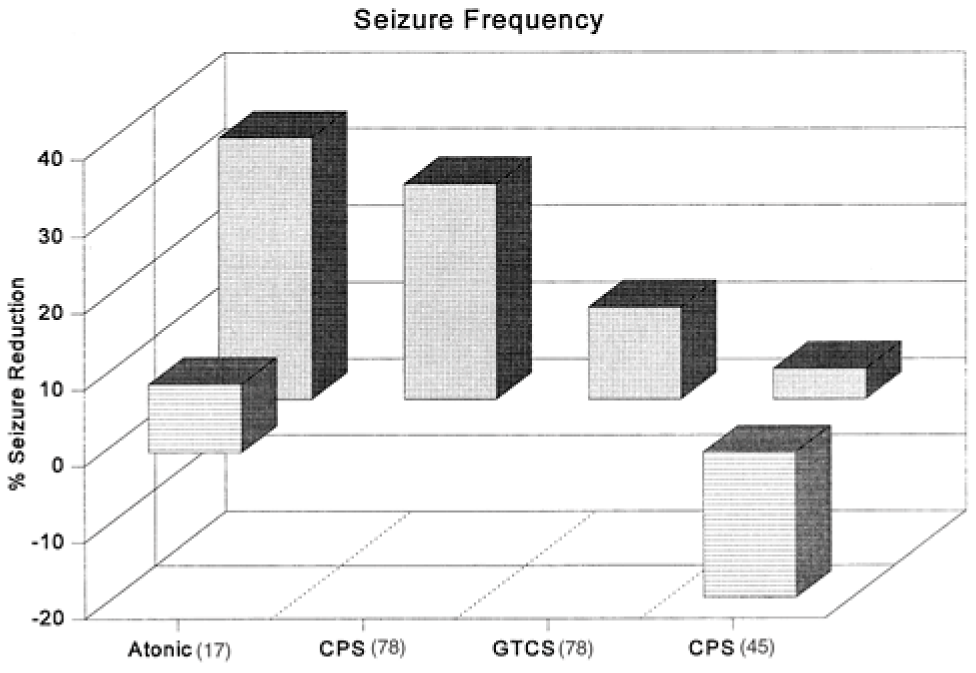

FIGURE 2. Percentage reduction of seizures in patients treated with FBM compared with placebo in double-blinded add-on trials of patients with complex partial (*CPS*), secondarily generalized tonic-clonic (*GTCS*), and atonic seizures. One study[78] compared FBM with placebo during the blinded phase, whereas the other two compared both treatments with baseline. Leppik et al. found the difference in effect in their study was mainly a consequence of increased seizures on placebo.[45] Numbers in parentheses are reference numbers.

Effects Related to Drug Interactions

Drug interactions may play an important role in the frequency of side effects experienced by patients on FBM. Increased levels of phenytoin and valproic acid may contribute to nausea and vomiting, diplopia, blurred vision, and ataxia. Even though carbamazepine levels fall, levels of the pharmacologically active

metabolite, carbamazepine epoxide, may increase. This compound could also contribute to side effects, because its protein binding is lower than that of carbamazepine itself, and it may penetrate the brain more readily.

However, it is possible that some of the therapeutic effects of FBM in add-on trials could also be related to drug interactions, particularly increased levels of phenytoin and valproic acid. One study suggested that the fall in carbamazepine levels might lead to reduced seizure control, despite increased levels of carbamazepine epoxide.[80] It may be valuable to measure epoxide as well as carbamazepine levels when patients are taking both FBM and carbamazepine. Considerable variation exists between individuals in the effect of FBM on other AEDs. Rather than automatically adjusting other drug doses, it is important to measure their levels. Because FBM does not have an appreciable effect on the protein binding of other drugs, it is not necessary to measure free AED levels.

Efficacy

Localization-Related Epilepsies

A series of published clinical trials showed that FBM is effective against simple partial, complex partial, and generalized tonic–clonic seizures in patients with localization-related epilepsy. These trials were carried out in patients with intractable seizures that had failed to respond to a number of other AEDs. Many were candidates for surgery. Two cross-over add-on studies showed a reduction of about 15% to 30% in seizure frequency, comparing FBM with placebo periods, at doses of 2,300 to 3,600 mg/day and plasma levels of 30 to 40 mg/L[45,80] (Fig. 2). One of these used a three-period design to obviate carry-over effects. Two trials used the AED withdrawal for a surgical monitoring scenario to conduct monotherapy studies. In one, 8 of 19 patients randomized to placebo, as compared with 13 of 21 receiving FBM, completed 18 days of monotherapy.[78] Two FBM patients dropped out because of seizures, and six dropped out because side effects, including anxiety, difficulty sleeping, abdominal discomfort, acute psychosis, and orobuccal dyskinesias. Ten placebo patients met the criteria for premature discontinuation owing to seizures, and one had an episode of panic. Overall, patients on FBM alone had a seizure rate only 25% that of patients on placebo alone. In the other trial, a nonsignificant trend occurred for patients on FBM to have fewer seizures over 10 days.[13]

Three studies used an endpoint of "survival" rather than seizure frequency. In an add-on trial after surgical monitoring, a fourth seizure was less likely to occur in 28 days in patients on FBM than in those on placebo[5] (Fig. 3). Two studies compared FBM at 3,600 mg/day with low-dose valproic acid (15 mg/kg/day) during 112 days.[17,68] Other AEDs were tapered by day 28. Of the patients on FBM, 18% to 40%, compared with 78% to 91% on valproic acid, dropped out because of increased seizure frequency or severity (Fig. 3). A reduction in seizure frequency of 50% or greater compared with baseline was noted in 29% of patients on FBM, compared with 11% of those on low-dose valproic acid.[30]

In an open-label study of 36 patients who had not responded to other AEDs, and a mean follow-up of 10 months (range 2–27), 5% of patients given FBM were seizure-free, 11% had seizure reduction of more than 75%, and 23% had seizure reduction between 50% and 75%.[6]

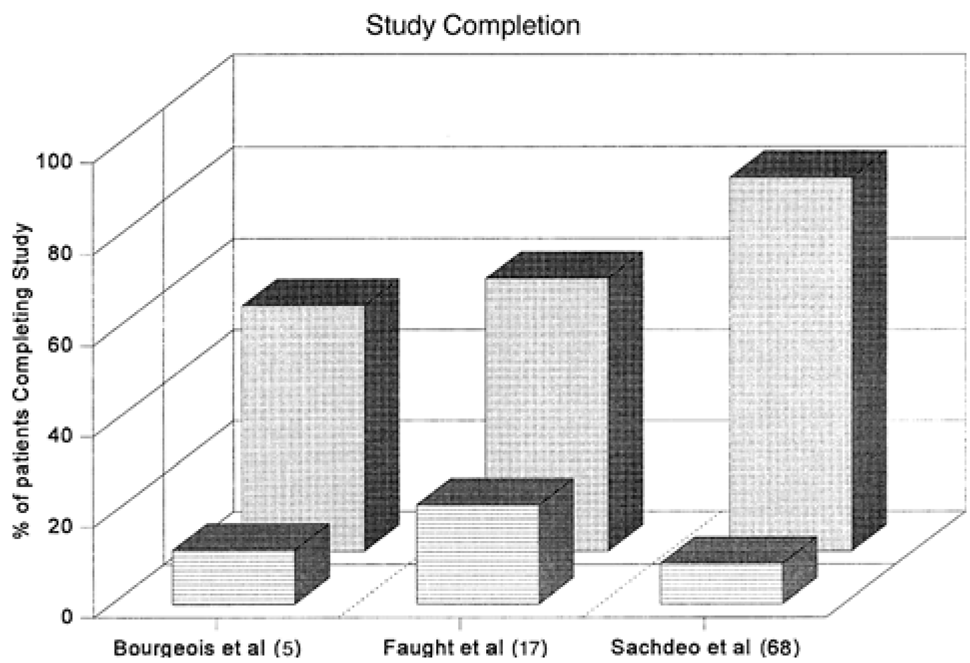

FIGURE 3. Percentage of patients taking FBM compared with placebo[5] or low doses of valproic acid[17,68] who reached a defined endpoint of seizure frequency or severity. Patients on FBM were more likely to complete the trial in each study. Numbers in parentheses are reference numbers.

Generalized Epilepsies

FBM is effective in patients with the Lennox-Gastaut syndrome.[18] Overall seizure counts by the parents or guardians of patients on FBM at a dose of 45 mg/kg (3,600 mg/day maximum; mean blood level, 43.8 mg/L) were 19% lower compared with baseline; they were only 7% lower in patients on placebo (p = 0.01). Atonic seizure frequency was reduced 34% by FBM but only 9% by placebo (p = 0.002). The effect of FBM may have been greater at 45 mg/kg per day than at 15 mg/kg per day. Subsequent data analysis[31] showed that 47% of patients had a reduction of at least 50% in total seizures, and of 57% in atonic seizures. In this study, phenytoin and valproic acid levels varied up to 22%. In another study, patients had 40% fewer drop attacks (p < 0.03) and 60% fewer total seizures (p < 0.02) on VPA and FBM compared with VPA alone. However, VPA levels rose by 12.7% when FBM was added (p < 0.01). In this study, multivariate analysis suggested that FBM's therapeutic

effect on drop attacks is caused in part by increased VPA levels, but the combination may be synergistic for the effect on total seizure number.[73]

Preliminary reports in small groups of patients have suggested that FBM may be effective in other generalized seizure syndromes and seizure types, such as absence or juvenile myoclonic epilepsy, when other drugs have failed.[79] Although the results are consistent with the effect found in Lennox-Gastaut syndrome, they have not yet been confirmed by controlled studies.

FBM may be more or less useful than other new drugs for any given patient. It is very difficult to compare efficacy data across clinical trials, or to judge the relative effectiveness of AEDs. Even within a single trial, the effect of the design may vary with seizure type. FBM appeared to be more effective against complex partial seizures than generalized tonic–clonic seizures[80] (see Fig. 2). However, the difference may have been a consequence of the better baseline control of the latter achieved by carbamazepine in this add-on study.

Most clinical trials have a relatively short duration, particularly compared with the course of seizure disorders. During long open-label follow-up periods, there is a tendency for patients gradually to discontinue most experimental drugs.[79] A high frequency of seizures on standard AEDs is a criterion for trial entry, and surgery is an alluring alternative. Although it proved difficult to taper baseline AEDs during open-label follow-up after FBM add-on studies, efficacy does appear to be maintained during long-term treatment with FBM in patients with Lennox-Gastaut syndrome as well as localization-related epilepsy.[30,31,85]

Because FBM appears to be less sedating than other AEDs, it may be useful for patients who find this side effect particularly debilitating.

Activity in Other Indications

Relatively little interest has been expressed in using FBM for other conditions. Several patients with trigeminal neuralgia and hemifacial spasm were said to have a favorable response.[7,56]

Role in epilepsy treatment

Indications

At this point, there are relatively few indications for FBM. Given the large number of new AEDs now available for patients with localization-related epilepsy, and the increasing attention to surgical therapy, few patients will be appropriate for FBM. Some children with Lennox-Gastaut syndrome and similar syndromes may benefit from FBM, because current therapy generally is disappointing, and none of the new AEDs has made a dramatic impact. FBM would have the advantage of minimal cognitive toxicity as well.[8,25] Some investigators have suggested that FBM could be used in patients with infantile spasms unresponsive to other therapy; here, other alternatives such as corticosteroid therapy or vigabatrin have severe toxicity as well.[57]

FBM appears to be effective for treatment of partial seizures in dogs.[66]

Dosing Recommendations

Starting Doses

Although rapid escalation of therapy has been performed in clinical trials, a slow titration schedule may lead to fewer initial adverse effects, particularly gastrointestinal disturbance, insomnia, and anxiety. The drug seems to be better tolerated when it is taken with meals and the doses are spread out as much as possible. FBM can be started at 400 mg three times a day, with increases of 400 to 600 mg/day every 1 to 2 weeks. Some patients, particularly the elderly, may need lower starting doses and slower increases. For children, an initial dose of 15 mg/kg per day with weekly increases to 45 mg/kg per day seems reasonable.

FBM decreases clearance of phenytoin and valproic acid. To maintain steady-state plasma levels of these drugs, it may be necessary to reduce their doses when FBM is started. However, this should be done cautiously to avoid seizure exacerbation,

because it may take several weeks to reach therapeutic doses of FBM.

Maximal Dose

The highest dose of FBM used in adult clinical trials has been 3,600 mg/day, but some patients have received 5,000 to 6,000 mg/day. The maximal dose tried in the Lennox-Gastaut trial was 45 mg/kg or 3,600 mg/day. Clinical experience will be required to determine the true upper limit of the dose. In some patients, because of gastrointestinal discomfort, the maximally tolerated dose is in the range of 2,400 to 3,000 mg/day. Children usually are more rapid metabolizers than adults, and therefore need relatively more drug (on a mg/kg basis) to maintain effective blood levels. The pharmacology of FBM has not been studied in elderly patients, but metabolism is likely to be reduced. Moreover, the elderly are usually more sensitive to the central nervous system side effects of AEDs. The starting dose, and subsequent increases, should probably be reduced by about one-third.

Stopping the Drug

Because of the risk for aplastic anemia or liver disease, FBM should be stopped when it is not effective. On the other hand, because it is likely to be used when all other agents have failed, patients may be able to tolerate side effects that are not life-threatening. Insomnia, gastrointestinal distress, and weight loss may be less discomforting to some patients than the side effects of other drugs, particularly if seizures are controlled.

There is little evidence for acute exacerbation of seizures during FBM withdrawal, which has been carried out rapidly in clinical trials. One study reported increased seizure activity during FBM withdrawal, but the effect persisted for 3 months, suggesting the effect was not a transient exacerbation but simply due to removal of an effective AED; moreover, levels of phenytoin and carbamazepine fell after withdrawal.[88] Patients who were placed on gabapentin had smaller seizure increases.

The drug should certainly be stopped abruptly if there is evidence of hematologic or liver disease. When reports of these complications began to appear, the FBM doses of many asymptomatic patients were tapered during 1 to 2 weeks without a sudden increase in seizures, although many patients experienced a long-term rise in seizure frequency despite higher doses or addition of other drugs.

Precautions and Contraindications

It may be prudent to avoid combining FBM with other drugs that can cause hepatic or hematologic dysfunction, such as valproic acid or carbamazepine. Aplastic anemia may be more likely to develop in women than in men. FBM should not be given to patients with a history of blood dyscrasias or autoimmune disorders. Patients with a history of psychiatric disorders may be more likely to experience acute anxiety or even psychosis on FBM. FBM was less well tolerated in elderly subjects compared with young subjects, with higher rates of adverse events and dropouts at the higher dose level.[65]

The manufacturer advises that patients on FBM have blood counts and liver function tests every 1 to 2 weeks. It is probably reasonable to continue this schedule for 3 to 4 months, followed by monthly testing. Unfortunately, even this high degree of caution may not detect incipient toxicity. Aplastic anemia and hepatic failure may not be reversible even if detected early. Moreover, symptoms may develop after the drug has been stopped. Platelets and white blood cells have a short life span, but red cells live 120 days, so peripheral evidence of marrow injury may have a delayed appearance. Mild elevations of hepatic enzymes are found often in patients taking AEDs, and may not be an indication of “toxicity.”

It may be possible to identify patients with reduced erythrocyte glutathione peroxidase, superoxide dismutase (SOD), and glutathione reductase activities compared with age-matched controls, who would be particularly at risk for aplastic anemia,[20] or to quantify production of 2-phenylpropena; patients with high levels might be at greater risk as well.[81]

Like many other AEDs, FBM appears to increase ALA synthase activity, and might provoke attacks of acute intermittent porphyria.[24]

Summary and conclusions

FBM has a broad antiepileptic spectrum. Children with the Lennox-Gastaut syndrome and related secondarily generalized epileptic syndromes, for whom few therapeutic options exist, may benefit most from FBM therapy. It can also be tried in patients with refractory partial and secondarily generalized seizures that have not responded to other drugs. For some patients, who can attain seizure control with other drugs only at the cost of unacceptable central nervous system depressant side effects and who are not candidates for surgery, the risk for systemic toxicity associated with FBM may be acceptable. FBM should be used only when seizures have not been controlled by other drugs. Results of clinical laboratory tests should be monitored closely and the drug stopped if any abnormalities are detected. When deciding to start a patient on FBM, it is important to assess the risk–benefit ratio very carefully.

Chapter 149
Gabapentin

David W. Chadwick

Thomas R. Browne

Introduction

Gabapentin is a novel antiepileptic drug (AED) related in structure to the neurotransmitter γ-aminobutyric acid (GABA) (Fig. 1). It was synthesized as a GABA-mimetic agent that could freely cross the blood–brain barrier (BBB). Despite its structural relationship to GABA and its recognized antiepileptic properties, it is doubtful that therapeutic activity results from any form of direct GABAergic effects.

Mechanism of Action

Gabapentin has been shown to prevent seizures in several animal models (Table 1) and in clinical studies. It has a mechanism of action that appears to be different from other AEDs; this topic has been recently reviewed by Sills.[35]

In vitro, gabapentin does not interact with neuronal sodium channels or L-type calcium (Ca) channels.[39] Gabapentin is inactive at concentrations up to 100 μmol in standardized tests for interaction at $GABA_A$, $GABA_B$, benzodiazepine, glutamate, *N*-methyl-D-aspartate (NMDA), quisqualate, kainate, glycine, MK-801, and strychnine-insensitive glycine receptors. In addition, many other neurotransmitter receptors have been screened, including A_1 and A_3 adenosine receptors; α_1, α_2, and β-adrenergic receptors; D_1 and D_2 dopamine receptors; $histamine_1$ receptors; S_1 and S_2 serotonic receptors; M_1, M_2, and nicotinic acetylcholine receptors; μ-, δ-, κ-, and σ-opiate receptors; leukotriene B_4, D_4, and thromboxane A_2 receptors; phorbol ester dibutyrate receptors; and binding sites on Ca channels labeled by nifedipine and diltiazem and on sodium channels labeled by batrachotoxinin.[39] These negative results support the idea of a novel mechanism of antiepileptic action for gabapentin.

Although gabapentin does penetrate the BBB effectively,[47] and has antiepileptic properties in vivo,[39] it does not interact with $GABA_A$ receptors, nor is it converted to GABA or a GABA agonist. Early evidence did not suggest that gabapentin is an inhibitor of GABA uptake nor of degradation by GABA transaminase at relevant concentrations. However, it can increase GABA accumulation in rat brain, by increasing GABA synthesis[41] and preventing metabolism.[20] In human brain slices[16] and in the intact brain, as measured by magnetic resonance (MR) spectroscopy,[32] it may indeed have modest effects in increasing brain concentrations. It may also have some effects on the GAT-1 GABA transporter system.[51] The degree to which this may contribute to its antiepileptic effects remains uncertain.

It may also possess some baclofen-like effects at the presynaptic $GABA_B$ receptor. It can reduce potassium-evoked Ca influx via voltage-gated channels in a pituitary cell line expressing functional subunits of the receptor, an effect reversed by other selective $GABA_B$ antagonists.[8,30] This may enable gabapentin to selectively reduce excitatory neurotransmitter release with relative sparing on inhibitory neurotransmission. This is despite any evidence that gabapentin can interact with the $GABA_B$ receptor.[39]

Specific binding of gabapentin is highest in the superficial layers of neocortex and dendritic layers of hippocampus, with low levels of binding in the white matter and brainstem.[19] This binding site, which doesn't bind any other conventional AED, has now been identified as the $\alpha_2\delta$ subunit of the voltage-gated Ca channel.[18,49] It appears that two of four isoforms of this subunit are capable of binding gabapentin and its structural analogs.[40] There is now a general consensus that this is the site of action responsible for the great majority of gabapentin's pharmacologic antiseizure activity. It does not appear to act as an inhibitor of any conventional subtype of voltage-gated Ca channel, but rather acts as a selective blocker of channels that contain the $\alpha_2\delta$-1 subunit.[11]

Pharmacologic Fundamentals

Gabapentin is absorbed via the L-amino acid transport system in the proximal small intestine. Absorption is rapid, with maximum plasma concentrations occurring 2 to 3 hours after oral administration.[46] Gabapentin appears to move across the gut and into the blood by a saturable transport mechanism competitively inhibited by L-leucine[36] (the amino acid transporter known as system L). Experiments with the system L transporter in cultured Chinese hamster ovary tumor cells also support the notion that gabapentin competes with L-leucine, L-valine, and L-phenylalanine and is itself a substrate for transport by system L. This may explain why gabapentin penetrates into the brain: The amino acid structure of gabapentin and the very high hydrophilicity of the compound would otherwise reduce its access across biologic membranes. The time of peak antiepileptic action with gabapentin is delayed about 2 hours after intravenous administration, past the time of peak drug concentration in either the blood plasma or the brain interstitial space.[50] Structure activity studies indicate that activity in seizure models correlate with affinity for this transporter system,[37,38] although it remains doubtful that the transporter has anything other than an indirect relationship to gabapentin's ultimate antiseizure activity.

Absorption is dose dependent due to saturation of the L-amino acid transport system. The bioavailability of gabapentin decreases from 0.54 ± 0.11% at a dosing rate of 400 mg three times daily, to 0.35 ± 0.07% at a dosing rate of 1,200 mg three times daily. The bioavailability of gabapentin is not affected by food.

Gabapentin is not bound to plasma proteins to any significant degree. Gabapentin is transported from plasma across the BBB to the brain via the L-amino acid transport system. Gabapentin concentration in a single specimen of human brain was 80% of plasma concentration, confirming animal distribution studies.[31]

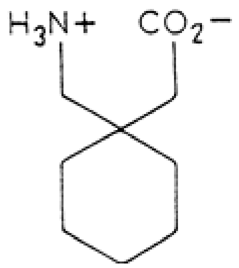

FIGURE 1. Structure of gabapentin.

Table 1 Activity of gabapentin in animal models of seizures

Species	Convulsant agent	Dose route	ED^{50} (mg/kg)
Mouse	Tonic extensor seizure (maximal electroshock)	IP	78
Rat	Tonic extensor seizure (maximal electroshock)	PO	9.1
Rat	Tonic extensor seizure (maximal electroshock)	IV	2.1
Rat	Behavioral seizure score (hippoc, kindled rats)	IP	30[a]
Mouse	Threshold clonic seizure (pentylenetetrazole)	IP	47
Mouse	Threshold clonic seizure (bicuculline)	IP	>500
Mouse	Threshold clonic seizure (picrotoxin)	IP	>500
Mouse	Threshold clonic seizure (strychnine)	IP	>500
Mouse	Tonic extensor seizure (thiosemicarbazide)	IV	6.3
Mouse	Tonic extensor seizure (isoniazide)	PO	20
Mouse	Tonic extensor seizure (*N*-methyl-D-aspartate)	IP	>240[b]
Rat	Tonic extensor seizure (kainate)	IP	>300
DBA/2J mouse	Tonic extensor seizure (audiogenic)	PO	2.5
Wistar rat	Absence seizure (EEG) (genetic predisposition)	IP	Not effective (25–100 mg/kg)

Gerbil	Tonic extensor seizure (genetic predisposition)	PO	15
Gerbil	Clonic forelimb seizure (genetic predisposition)	PO	19
Baboon	Photogenic myoclonus (genetic predisposition)	IV	Not effective (1.0 to 240 mg/kg)

All results are from unpublished studies.
[a]Lowest effective dose.
[b]At this dose, seizures were significantly delayed but not prevented.

Gabapentin is not metabolized.[46] It is excreted unchanged in urine, with a renal clearance approximately equal to

total clearance (120–130 mL/min) and an elimination half-life of 5 to 7 hours. The clearance and elimination half-life of gabapentin are not altered by increased dosing rates or by chronic administration.[44] The clearance of gabapentin is decreased in the presence of renal disease, requiring a decrease in dosing rate for persons having a creatinine clearance rate of less than 60 mL/min. This mechanism probably is responsible for the observed age-related decrease of gabapentin clearance in later life. Pharmacokinetic studies in children show an increased clearance in children under the age of 5 years.

A series of studies have been completed to detect possible interactions between gabapentin and other drugs. These have been conducted either in patients receiving antiepileptic monotherapy or in healthy subjects. An interaction between gabapentin and one of the established AEDs would influence the design and interpretation of phase II and III efficacy studies, and early evaluation of this possibility was important. Interactions in both directions have been sought: that is, an effect of gabapentin on the kinetics of the established drugs and vice versa. In addition, selected potential interactions have been examined with the following compounds:

- An aluminum/magnesium hydroxide antacid, because these preparations reduce the absorption of some drugs
- Cimetidine, which is a known inhibitor of the oxidative, drug-metabolizing system in the liver
- Probenecid, which can inhibit renal tubular secretion of acidic drugs
- The components of the combined oral contraceptive pill, the metabolism of which is enhanced by enzyme-inducing AEDs

No detectable interaction occurs between gabapentin and the four AEDs tested (carbamazepine, phenytoin, phenobarbital, valproate).[33] This would be expected of a drug such as gabapentin, which is renally eliminated and does not induce hepatic microsomal enzymes.

The aluminum/magnesium antacid Maalox TC (Rhone-Poulenc Rorer) caused a slight reduction in the absorption of gabapentin, but no more than 20%, which is probably not of clinical significance.[13] Cimetidine decreased glomerular filtration and caused a 12% decrease in the renal clearance of gabapentin; but again this is unlikely to be of clinical importance. Probenecid, however, did not affect renal clearance, indicating that gabapentin does not undergo renal tubular secretion by the pathway blocked by probenecid. Finally, no effect of gabapentin was seen on the kinetics of single doses of norethynodrel and ethinylestradiol, which is predictive of a lack of interference with oral contraception.

Gabapentin readily passes into breast milk. Milk-to-maternal plasma concentration ratios of gabapentin are close to 1. However, it appears that plasma concentrations of gabapentin attained in infants being breast-fed by mothers taking gabapentin are probably not clinically significant.[42] Umbilical cord-to-maternal plasma concentration ratios suggest gabapentin is accumulated in the fetus.

Table 2 Summary of the ten adverse events occurring most frequently in patients receiving gabapentin

	Controlled studies		
	Placebo (*n* = 307) No. (%)	**Gabapentin (*n* = 485) No. (%)**	**All studies Gabapentin (*n* = 1,160) No. (%)**
Patients with more than one adverse event	174 (56.7)	369 (76.1)	944 (81.4)
Adverse events			
Somnolence	30 (9.8)	98 (20.2)	283 (24.4)
Dizziness	24 (7.8)	87 (17.9)	235 (20.3)
Ataxia	16 (5.2)	64 (13.2)	202 (17.4)
Fatigue	15 (4.9)	54 (11.1)	171 (14.7)
Nystagmus	15 (4.9)	45 (9.3)	174 (15.0)
Headache	28 (9.1)	42 (8.7)	176 (15.2)
Tremor	12 (3.9)	35 (7.2)	174 (15.0)
Diplopia	6 (2.0)	31 (6.4)	124 (10.7)
Nausea and/or vomiting	23 (7.5)	29 (6.0)	108 (9.3)
Rhinitis	12 (3.0)	22 (4.5)	101 (8.7)

Gabapentin's pharmacokinetic profile has many of the features of the ideal AED, and implies that it should be a simple drug to use in clinical practice, in contrast to some of the currently available preparations.

P.1571

Adverse Effects

Within epilepsy regulatory studies using short-term, add-on gabapentin therapy, an increased frequency was noted of the types of adverse events that commonly occur with the use of currently marketed AEDs, particularly those symptoms related to the central nervous system (CNS), most particularly dizziness, ataxia, fatigue, and somnolence[22] (Table 2). These adverse events usually were transient, occurred early in gabapentin therapy, and diminished with time. Gabapentin has not been associated with liver injury, serious allergic reactions, or changes in the hematopoietic system. Clinical laboratory abnormalities have not been shown to change in association with gabapentin treatment.[12] These data from placebo-controlled add-on studies in epilepsy are now augmented by data from studies of neurogenic pain, in which the drug would be more likely to be given as monotherapy. The pattern of newly emerging adverse events was very similar in these trials.[5]

Insufficient data are available to demonstrate that gabapentin is safe during human pregnancy, although the malformation rates associated with its use appear low.[27,29] It showed no evidence of mutagenicity in vitro or in vivo. Its effects on pregnancies in mice, rats, and rabbits appear minimal. It may cause delayed ossification given at dosages of one to four times the maximum recommended human dosage, and there is also evidence of an increased incidence of hydroureter and hydronephrosis in rats. However, the incidence of other malformations was not increased.

It is still too early to make any statements about the potential chronic toxic effects of gabapentin. However, the longer-term, open, follow-up studies with the drug do not suggest any development of new adverse effects, and the absence of any significant effects on biochemical and hematologic parameters in the shorter term also appears reassuring.

One area that has caused some concern arose from the longer-term animal toxicologic studies. Toxicology data from 2-year bioassay studies conducted in rats and mice showed an increase in benign acinar cell tumors of the pancreas in male Wistar rats only. The tumors did not alter lifespan and were not seen in female rats or mice of either sex. In the study, designed to evaluate carcinogenicity, male and female rats were given gabapentin at 250 mg/kg, 1,000 mg/kg, or 2,000 mg/kg daily for 2 years. Mean plasma concentrations at these dosages were 84.6 μg/mL, 51.2 μg/mL, and 84.6 μg/mL, respectively. For reference, plasma concentrations from current clinical studies commonly range from 2 μg/mL up to peak concentrations of 15 μg/mL. The U.S. Food and Drug Administration reviewed this matter and concluded that it probably does not represent a significant clinical risk.

Role of the Drug

Adjunctive Therapy for Partial Seizures

The indications for gabapentin are best defined in randomized, placebo-controlled, add-on studies in partial epilepsies. Five studies, undertaken for regulatory purposes, shared a common parallel group design: four in adults and one in children.[3] These have been subject to a systematic review.[24]

Two of the trials[2,45] tested two doses of gabapentin and hence had three treatment groups (including the placebo group). These five studies recruited a total of 750 adults and 247 children. In the adult studies, patients were randomized to one of the following doses: 600, 900, 1,200, and 1,800 mg gabapentin per day. In Appleton's 1999 study, children received between 600 and 1,800 mg per day depending on weight.[3] A total of 61 patients were excluded from the reported analyses, 38 of whom did not complete the treatment phase and nine who had inadequate seizure data recorded. After a 12-week baseline assessment with standard AEDs, patients with partial seizures refractory to standard AEDs were randomly assigned to receive either placebo or gabapentin in addition to standard AEDs. Patients who completed double-blind treatment could continue gabapentin treatment as part of an open-label trial. All patients had partial (simple, complex, or secondarily generalized) seizures refractory to marketed AEDs.

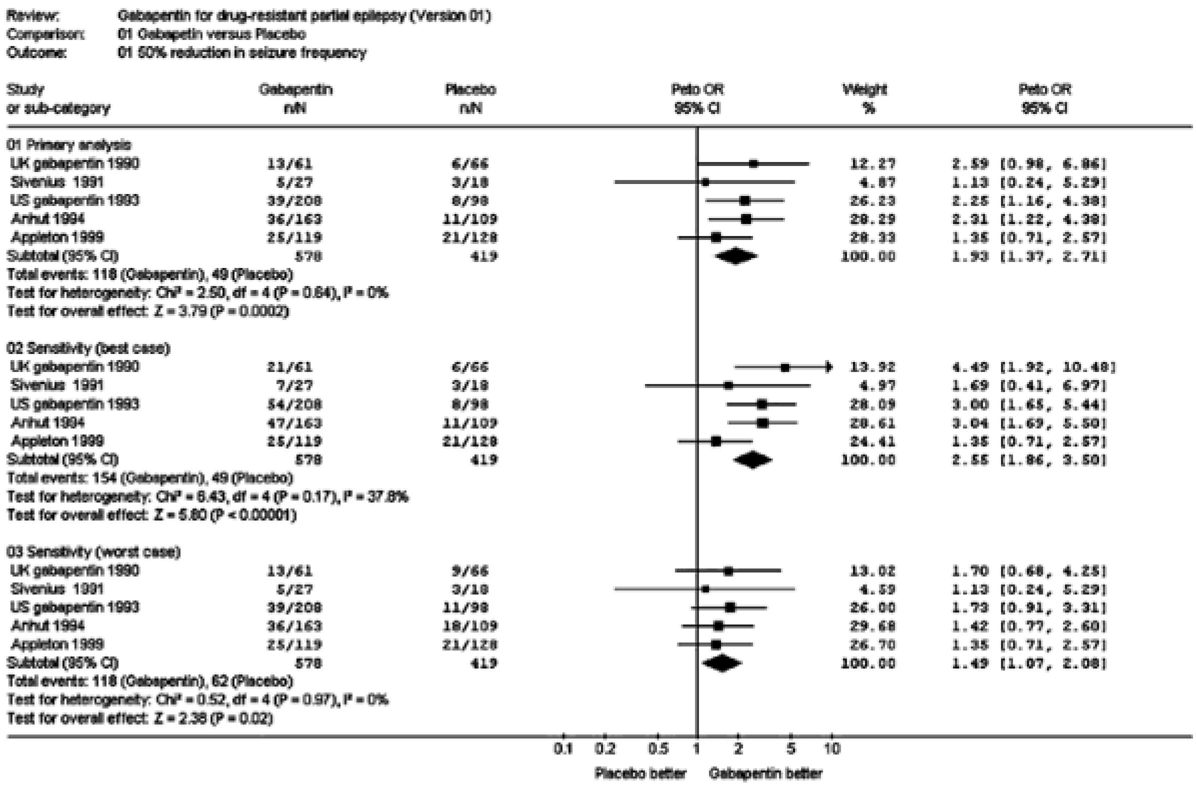

FIGURE 2. Systematic review and meta-analysis of placebo-controlled studies of gabapentin in the treatment of partial epilepsy.[23]

The primary efficacy criterion was reduction in the frequency of partial seizures from baseline to treatment levels. Seizure frequency was defined as the number of seizures per 28 days of observation. The primary efficacy parameters

P.1572

reported in the trials were response ratio (RR) and percentage change in frequency of seizure relative to the baseline.

The RR compares baseline seizure frequency (B) with treatment seizure frequency (T), as follows: RR = (T - B)/(T + B). The RR avoids the skewing associated with percentage change and, because RR is normally distributed around zero, it allows parametric statistics to be used in the interpretation of the data. Values for RR range between -1 and +1. The Cochrane systematic review computed more conventional odds ratios (OR) for a 50% reduction in seizure frequency between gabapentin and placebo. The overall OR (95% CIs) for 50% responders across all doses in all studies is 1.93 (1.37 – 2.71) (see Fig. 2), indicating a statistical superiority of gabapentin over placebo. There was a linear dose-response across all doses, with a log odds increase by 0.215 (SEM, 0.052) for a 300-mg increase in daily dose, which is roughly a 25% increase in odds of response for a 300-mg increase in dose. There was no evidence of plateauing of this dose–response relationship at the highest doses tested in these RCTs.

In addition to the double-blind studies, a total of 774 patients participated in five long-term, open-label studies of gabapentin as adjunctive therapy for partial seizures.[12] Patients were the same or were similar to those in the above double-blind studies. The majority of patients were receiving two concurrent AEDs. These results indicated no evidence that the efficacy of gabapentin is not maintained over time for these patient populations.

The above studies used gabapentin dosing rates of 2,400 mg/day or less. Further open-label studies of gabapentin at dosing rates up to 4,800 mg/day as adjunctive therapy for partial seizures also reported good long-term retention of efficacy with good tolerability.[6,28]

Gabapentin has been compared as add-on therapy to other AEDs in two RCTs. One study compared gabapentin and vigabatrin in 102 patients as a first add-on treatment. The study was stopped because of concern about the potential retinal toxicity of vigabatrin before any meaningful results were available.[21] Gabapentin was compared to lamotrigine in a randomized, but open-label, study of adults with learning disability. Similar numbers of patients achieved a 50% reduction in seizure frequency (50% and 48%, respectively) with maximal doses of 3,600 mg/day and 400 mg/day. The study did not recruit sufficient numbers of patients to detect clinically important differences.

No other direct comparisons between gabapentin and other standard or newer AEDs as add-on treatments for partial seizures are available. Information is available from indirect comparisons from systematic review and meta-analysis of similarly structured, placebo-controlled add-on studies of new AEDs.[26] These data indicate that gabapentin at the relatively low doses used in placebo-controlled regulatory studies is well tolerated (as judged by odds-ratios for withdrawal from studies) relative to other drugs, such as lamotrigine, tiagabine, levetiracetam, topiramate, vigabatrin, oxcarbazepine, and zonisamide, but shows a trend toward lesser efficacy (from odds-ratios for 50% reduction in seizure frequency). This view receives some support from a large postmarketing surveillance cohort in the United Kingdom, which showed that time to treatment failure was shorter for gabapentin than for lamotrigine or vigabatrin.[1]

P.1573

Monotherapy for Partial Seizures

An outpatient RCT of 275 patients with refractory complex partial and/or tonic–clonic seizures was performed in which patients were converted to monotherapy with 600, 1,200, or 2,400 mg/day of gabapentin.[9] Only 20% of patients completed the study, which provided no evidence of a dose–response relationship, most likely due to assay insensitivity in this type of design. A further monotherapy inpatient study using the presurgical paradigm did show a statistical difference between doses of 300 mg and 3,600 mg/day over a period of 8 days,[7] although extrapolation of this result to everyday clinical practice would be hazardous.

In an outpatient study of 271 patients with newly diagnosed partial epilepsy, 205 received gabapentin monotherapy at dosages of 300, 900, or 1,800 mg/day (blinded allocation) or carbamazepine 600 mg/day.[15] The outcome was retention in the trial, with exit allowed when patients experienced three partial seizures, one secondary generalized tonic–clonic seizure, or adverse events. The two higher doses of gabapentin were superior to 300 mg/day, with retention using 1,800 mg/day being similar to the outcomes in the group treated with 600 mg/day of carbamazepine.

Gabapentin has also been compared to other active AEDs in RCTs. In a 24-week parallel group study, 599 patients with newly diagnosed partial seizures were given gabapentin (daily dose up to 3,600 mg/day) or lamotrigine (daily dose up to 300 mg/day) with the primary outcome being the retention time in the trial. Similar numbers of patients completed the study (71% of gabapentin subjects, 67% of lamotrigine subjects), with similar numbers remaining seizure-free. Both drugs were well tolerated, but the study lacked sufficient power to determine whether the drugs were truly equivalent.[10] The same two drugs in doses of 1,500 mg/day and 150 mg/day, respectively, were compared with carbamazepine (600 mg/day) in a RCT in an elderly population of newly diagnosed epilepsy.[34] The primary outcome was retention over 12 months. Significantly more early terminations occurred with carbamazepine (65%), but there were no differences in the seizure-free rates at 12 months.

A much larger study of over 1,400 patients has compared gabapentin as a variable dose monotherapy to carbamazepine, lamotrigine, oxcarbazepine, and topiramate in a pragmatic randomized study.[25] Although well tolerated, gabapentin was inferior to the other drugs for efficacy and overall effectiveness, confirming the inferences drawn from other studies.

Generalized Seizures

The place of gabapentin in the treatment of generalized epilepsy syndromes is poorly defined. One placebo-controlled, add-on, parallel group RCT has been performed in refractory generalized epilepsies. This failed to show statistically significant effects for 1,200 mg/day of gabapentin, although there was a trend toward reduction in generalized tonic–clonic seizures.[14] There was no evidence of any adverse or beneficial effects on absence seizures from a cross-over, add-on study comparing gabapentin with placebo.[43] There are, however, some case reports of exacerbation of absence and myoclonus by gabapentin.[4,48] The balance of evidence would therefore argue against the use of gabapentin in patients with generalized seizures.

How to Use the Drug

Gabapentin is available in 100-, 300-, 400-, 600-, and 800-mg capsules. In adults, titration to a minimally effective dosage of 900 to 1,200 mg/day can be undertaken quickly in most patients.[17] The initial dosing rate is 300 mg/day. The dosing rate usually can be increased by 300 mg at 1-day intervals (i.e., 3 days to attain a dosing rate of 900 mg/day). An occasional patient develops CNS side effects with this starting regimen. Such patients usually develop tolerance to the drug with a slowed initiation protocol (e.g., 300 mg/day increases every 4–7 days). In view of the relatively short elimination half-life, the drug should be administered three times daily.

For children 3 to 12 years of age, the starting dose should range from 10 to 15 mg/kg per day in three divided doses, The effective dose of gabapentin in patients 5 years of age and older is 25 to 35 mg/kg per day, given in three divided doses. The effective dose in pediatric patients 3 and 4 years of age is 40 mg/kg per day, given in three divided doses. Doses up to 50 mg/kg per day have been well-tolerated in long-term clinical studies.

In the elderly and in those with renal impairment, the total dose of the drug given may need to be reduced in proportion to any impairment in creatinine clearance, given that the drug is largely eliminated by this route. Instructions for dosing in renally impaired patients are contained in the package insert.

Currently, the maximal dose is poorly defined. Early randomized clinical trials in partial epilepsy suggested increasing effectiveness at dosages of up to 1,800 mg/day, and such dosages are well tolerated. Evidence from ongoing studies indicates dosages of up to 3,600 or 4,800 mg/day are well tolerated and may be more effective than lesser dosages in some patients.

There seem to be relatively few indications for routine blood level monitoring with this drug. Its own pharmacokinetics are simple, and there seems to be no evidence of drug–drug interactions. Certainly no satisfactory studies define either a minimally effective serum level or a maximally tolerated serum level, although blood levels in the range of 2 to 20 μg/mL have been advocated. The only possible indications for blood-level monitoring may relate to testing compliance or to the possible rate-limiting absorption of the drug at higher doses. Thus, in patients tolerating the dose of the drug at high doses, but showing suboptimal therapeutic benefits, there may be temptations to increase the administered dosage above 3 g/day. In these circumstances, it would seem wise to monitor blood levels to show that further increases in dosage do indeed result in an increase in blood levels.

Discontinuing the Drug

Gabapentin should be discontinued in the absence of significant therapeutic benefit at the maximum tolerated dose, the maximum absorbed dose, or when unacceptable side effects occur. The dose can usually be reduced in decrements of 300 or 400 mg every 3 to 4 days.

Summary and Conclusions

Gabapentin has been shown to be effective in the management of partial epilepsies in randomized clinical trials exploring dosages of up to 1,800 mg/day. Such dosages seem to be exceptionally well tolerated, and additional benefits may be derived from higher doses. The drug has simple pharmacokinetics and little or no potential for drug–drug interaction. Its main use will continue to be as a second-line treatment in refractory populations of patients.

Chapter 150

Lamotrigine

Torbjörn Tomson

Linda J. Stephen

Martin J. Brodie

Introduction

Lamotrigine, a phenyltriazine derivative, has been available globally as an antiepileptic drug (AED) for more than 15 years. The drug was initially synthesized as one of a sequence of folic acid antagonists following the suggestion that antifolate drugs may have antiepileptic properties. Although this theory was subsequently discredited, lamotrigine was discovered to have multiple mechanisms of action that may account for its broad spectrum of activity.[62] Following regulatory studies during the 1980s and 1990s, lamotrigine became available as an adjunctive agent for the treatment of partial and primary and secondary generalized seizures in adults. More recently, it has been used in children, in patients with the Lennox-Gastaut syndrome (LGS), and as monotherapy in newly diagnosed epilepsy.[121]

Chemical structure, formulations, and methods for determination in body fluids

Lamotrigine (3,5-diamino-6-[2,3-dichlorophenyl]-1,2,4-tria-zine) (Fig. 1) is synthesized by reacting thionyl chloride with 2,3-dichlorobenzoic acid to make an acid chloride derivative, which is converted to the corresponding ketonitrile in the presence of cuprous cyanide.[34] When the ketonitrile is condensed with aminoguanidine under strongly acidic conditions, the resulting amidinohydrazone compound is cyclized in basic conditions to produce lamotrigine. The drug is poorly soluble in water and ethanol, and has a molecular weight of 256.09 and a pKa of 5.5.

Lamotrigine is available as Lamictal (GlaxoSmithKline) in 25-, 50-, 100-, and 200-mg tablets, and as dispersible chewable tablets in 2-, 5-, 25-, and 100-mg doses.[66] No difference has been shown in bioequivalency between the two formulations. A number of generic preparations are available. The drug can be measured in serum or plasma by high-performance liquid chromatography[27,39] and by immunofluorometric assay.[102]

Pharmacology

Seizure Models

The anticonvulsant activity of lamotrigine has been demonstrated in models of different seizure types. Positive results have been obtained with maximal electroshock (MES) and pentylenetetrazole-induced tonic seizures, which are thought to be models of partial and generalized tonic–clonic seizures.[82,120] The drug abolished hind limb extension in the MES model at an oral mean effective dose (ED_{50}) of 2.6 mg/kg in the mouse and 1.9 mg/kg in the rat.[81] The ED_{50} was smaller and the therapeutic index and duration of action greater than those of phenyt-oin, carbamazepine, sodium valproate and diazepam. Similar ED_{50} values were obtained in maximal seizure tests with pic-rotoxin and bicuculline but, like phenytoin and in contrast to ethosuximide and valproate, lamotrigine had no effect on leptazol threshold[64] or on clonus latency after leptazol,[81] suggesting lack of efficacy against absence seizures. The drug was ineffective in the genetic absence epilepsy rat from Strasbourg, although it did not aggravate spike-and-wave discharges, unlike some other antiepileptic drugs.[33]

Lamotrigine yielded positive results in the lethargic mouse model of absence epilepsy.[57] As with valproate and ethosuximide, lamotrigine inhibited visually evoked afterdischarges in the rat, which may also be interpreted to suggest efficacy against absence seizures.[65] Lamo-trigine delayed the development of electrical kindling and modified seizures, but failed to prevent subclinical afterdischarges during the kindling process in the rat.[89]

Mechanisms of Action

Lamotrigine acts by use- and voltage-dependent blockade of neuronal voltage-activated sodium (Na^+) channels[124] in a similar way to carbamazepine and phenytoin.[67]

Waldmeier et al. found that lamotrigine attenuated veratrine-induced glutamate, γ-aminobutyric acid (GABA), and dopamine release in rat brain slices, but much less potently inhibited electrical stimulation–induced GABA and dopamine release.[118] The drug also inhibited electrical stimulation–induced release of serotonin, acetylcholine and, to a lesser extent, noradrenaline. Leach et al. reported that lamotrigine inhibited veratrine-induced glutamate and aspartate release, but less potently inhibited GABA and acetylcholine release.[68]

Lamotrigine also has effects on other ion channels.[117,119] In rodents, the drug modulated transient potassium outward currents in CA1 pyramidal cells,[52] and inhibited cortical and striatal voltage-activated calcium currents.[111] Some studies have suggested that lamotrigine may have selective neuroprotective effects. Hippocampal neuronal loss and optic nerve axonopathy were reduced by the drug in rats.[31] Lamotrigine was also neuroprotective in gerbil[107] and pig[29] models of global ischaemia.

Clinical pharmacokinetics

Lamotrigine is rapidly absorbed after oral administration. The peak plasma concentration is achieved in 1 to 3 hours, and increases linearly with dosage (Table 1).[28] Bioavailability is almost 100%. The weight-normalized volume of distribution after intravenous administration and the weight-normalized apparent volume of distribution after oral administration vary between 0.9 to 1.5 L/kg.[28] Protein binding is approximately 55%.[43] Salivary concentrations appear to be similar to free plasma concentrations.[114]

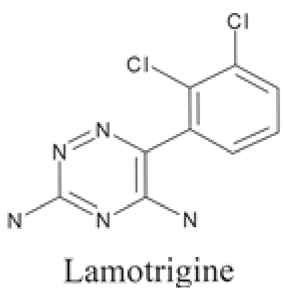

FIGURE 1. Structure of lamotrigine

Table 1 Pharmacokinetic properties of lamotrigine

Parameter	Mean ± SD
C_{max} (mg/L)	1.6 ± 1.3 (120 mg dose)
t_{max} (hours)	2.8 ± 1.3
F (%)	98 ± 5
Plasma protein binding (%)	55
F_e (%)	70
Vd/F (L/kg)	1.2 ± 0.1
CL/F (L/h)	2.5 ± 0.6
$T_{1/2\beta}$ (h)	24 ± 6

C_{max}, peak plasma concentration; t_{max}, time to c_{max}; F, absolute bioavailability; F_e, fractional urinary excretion; Vd/F, apparent volume of distribution; CL/F, apparent oral clearance; $T_{1/2\beta}$, plasma elimination half life.

Lamotrigine undergoes linear pharmacokinetics, with an elimination half-life varying between 24 and 35 hours.[28]

The drug is metabolized primarily by hepatic glucuronidation catalyzed by a number of different isoforms of UDP-glucuronosyltransferase converting lamotrigine to *N*-2- and *N*-5-glucuronides (80% and 10%, respectively) and other minor *N*-oxide metabolites.[28] The metabolites are almost entirely excreted in the urine, with 94% of radiolabeled lamotrigine being recovered in this way and 2% being found in the faeces.[35] There is conflicting evidence as to whether the drug induces its own metabolism.[58] As would be expected, the drug passes freely into breast milk.[90]

Lamotrigine's clearance is reduced in patients with unconjugated hyperbilirubinemia (Gilbert syndrome[96]) and in severe hepatic cirrhosis,[74] but not in end-stage renal failure.[42] There is little difference in lamotrigine pharmacokinetics in the elderly compared with younger adults.[58] In children, oral clearance and volume of distribution are greater, but half life is similar to corresponding values in adults.[25] Limited data available for different races suggests that clearance may be lower in Asians.[34]

Concentration–Effect Relationships

A variety of reports have been published regarding the relationship between lamotrigine dose and circulating plasma concentration. Of six large scale clinical trials, only two demonstrated a significant relationship between plasma concentration and efficacy.[70,104] Loiseau et al. found lamotrigine concentrations ranged from 0.3 to 4.9 mg/L on 150 to 300 mg/day.[70] Schapel et al. documented concentrations ranging from 0.66 to 4.65 mg/L in patients taking 150 or 300 mg daily.[104] Of the four studies that found no clinically statistical relationship,[60,80,99,110] Jawad et al. reported that 75 to 400 mg lamotrigine produced trough plasma concentrations of between 1.5 and 2.5 mg/L.[60] Using 200 to 400 mg lamotrigine daily, Smith et al. achieved mean plasma levels of 2.2 to 2.4 mg/L.[110] Messenheimer et al. achieved mean steady-state concentrations of 1.6 mg/L on 200 mg/day and 2.9 mg/L on 400 mg/day.[80] Concentrations of 3.8 mg/L on 200 mg and 2.06 mg/L on 100 mg were reported by Reunanen et al. when la-motrigine was used as monotherapy.[99]

Kilpatrick et al.[63] found widely varying lamotrigine doses in patients who were seizure-free (median dose 200 mg, range 25–850 mg; median concentration 3.8 mg/L, range 1.4–8.7 mg/L) and in those reporting side effects (median dose 300 mg, range 100–900 mg; median concentration 4.0 mg/L, range 0.4–18.5 mg/L). These results are partly at odds with those from Hirsch et al.,[55] who reported a significant relationship between increasing lamotrigine concentrations and toxicity. With concentrations of less than 0.5 mg/L, 7% of patients reported side-effects; with 5 to 10 mg/L, 14%; with 15 to 20 mg/L, 34%; and with greater than 20 mg/L, 59%. Increasing efficacy occurred with concentrations up to and exceeding 20 mg/L. A target range of 1.5 to 10 mg/L was recommended. Another study retrospectively examined the relationship between plasma lamo-trigine concentrations and dosage and concluded that a therapeutic range of 3 to 14 mg/L was realistic, although hardly precise.[85]

Chong and Dupuis argued that, although the majority of studies did not demonstrate a clear relationship between lamotrigine concentration and pharmacologic response, many of these were methodologically flawed.[26] They concluded that clinical end-points rather than plasma concentrations remain the most important guide for lamotrigine therapy. Certain special populations exist, however, in which obtaining a circulating concentration may be useful. These include patients in whom poor drug adherence is suspected and those with renal or hepatic failure.[55] Because lamotrigine concentrations are decreased markedly during pregnancy,[93,94] and dose adjustments are frequently needed under these circumstances to control seizures,[115] therapeutic drug monitoring has benefit in pregnant women with poor seizure control or symptoms of drug toxicity. The ethinylestradiol component of oral contraceptives can reduce circulating lamotrigine concentration by up to 50%.[98,101] Women taking the combined oral contraceptive pill could, therefore, also be candidates for lamotrigine measurement.

Clinical efficacy

The clinical effects of lamotrigine have been investigated in a wide range of seizure and epilepsy types in children and adults, in previously untreated patients, as well as in those with refractory epilepsy.

Partial Seizures and Localization-Related Syndromes

A series of randomized, double-blind, placebo-controlled studies have assessed the effectiveness of lamotrigine as add-on therapy in patients with refractory partial epilepsy. Three studies in adults[77,80,104] and one in children[36] met the Class I criteria in the American Academy of Neurology assessment of new AEDs.[46] In the largest, 191 patients taking enzyme-inducing AEDs were randomized to placebo, or lamotrigine 300 mg/day or 500 mg/day.[75] The responder rate (that proportion of patients with at least 50% seizure reduction from baseline) was 18% on placebo, 20% on lamotrigine 300 mg/day, and 34% on lamotrigine 500 mg/day. In a second study, 88 adult patients taking enzyme-inducing drugs were randomized in a cross-over design to placebo or lamotrigine 400 mg/day.[80] The

P.1577

responder rate with lamotrigine was 20% compared with 0% with placebo. The third study included only 41 patients on enzyme-inducers and or valproic acid randomized in a cross-over design to placebo or lamotrigine 300 mg/day (150 mg/day if on valproic acid).[104] The responder rate on lamotrigine was 22%, and 0% on placebo.

In a meta-analysis, Ramaratnam et al.[97] included eight additional randomized trials—two cross-over and six parallel studies.[10,14,60,70,99,103,106,110] A total of 1,243 patients (1,044 adults and 199 children) were included in this analysis of la-motrigine add-on for drug-resistant partial epilepsy. The overall odds ratio versus placebo for 50% or greater reduction in seizure frequency was 2.71 (95% confidence interval [CI] 1.87–3.91), demonstrating the efficacy of lamotrigine in this patient population. The odds ratio for treatment withdrawal in the same meta-analysis was 1.12 (95%; CI,0.78–1.61), indicating that patients were not more likely to discontinue lamotrigine than placebo.[97] One of these studies evaluated lamotrigine as add-on treatment in children with refractory partial epilepsy.[36] In this double-blind parallel group study, 199 children aged 2 to 16 years were randomized to placebo or lamotrigine (2.7–12.9 mg/kg/day). The responder rate was 45% with lamotri-gine and 25% with placebo, whereas the discontinuation rates were similar in the two groups, 5% and 6%, respectively.

One randomized double-blind study assessed lamotrigine as monotherapy in adults and adolescents with refractory partial epilepsy.[50] Overall, 156 patients with different baseline medications were randomized to receive lamotrigine 500 mg/day or a low dose of valproic acid (1,000 mg/day). Baseline medication was gradually withdrawn, aiming at monotherapy with lamo-trigine or valproic acid. More patients on lamotrigine (56%) compared to valproic acid (20%) were successfully maintained on monotherapy. Although this regulatory trial demonstrated the effect of lamotrigine as monotherapy in refractory partial epilepsy, it is difficult to translate the results into clinical practice.

Lamotrigine has also been assessed as monotherapy in new-onset partial epilepsy in adults. Three randomized double-blind parallel group studies met American Academy of Neurology Class I criteria.[45] The first study[18] randomized adult patients with partial seizures (n = 146) or primary generalized tonic–clonic seizures (n = 122) to lamotrigine (initial target dose 150 mg/day) or carbamazepine (initial target dose 600 mg/day). Of patients with partial seizures, 22% on lamotrigine and 31% on carbamazepine remained seizure-free during the last 40 weeks of treatment, compared to 35% and 37%, respectively, during the last 24 weeks. Retention was presented for partial and generalized seizure patients together. More lamotrigine (65%) than carbamazepine (51%) recipients completed the study. This difference was due to fewer withdrawals because of adverse events on lamotrigine.

Steiner et al.[112] randomized 90 patients with partial and 91 with primary generalized tonic–clonic seizures to lamotri-gine (modal dose 150 mg/day) or phenytoin (modal dose 300 mg/day). Of those with partial seizures only randomized to lamotrigine, 16% remained on treatment and were seizure-free during the last 40 weeks of the study, compared with 22% on carbamazepine. Corresponding figures for the last 24 weeks were 41% and 48%, respectively. These differences were not statistically significant, nor was there a significant difference between the drugs in time to discontinuation from the trial.

In a third study, 150 elderly (65 years and older) patients with newly diagnosed epilepsy were randomized in a 2:1 ratio to lamotrigine (median dose 100 mg/day) or carbamazepine (median dose 400 mg/day).[17] Although a proportion was classified as having idiopathic generalized epilepsy, the vast majority of patients had partial seizures. Significantly more patients continued on treatment with lamotrigine than on carbamazepine, 71% versus 42%. This was largely explained by a higher dropout rate due to adverse events on carbamazepine (42%) compared with lamotrigine (18%).

Lamotrigine has been assessed in an additional comparative study of new-onset partial epilepsy in older people.[100] In this double-blind, parallel group study, 593 patients aged 60 years or older were randomized to gabapentin (target dose 1,500 mg/day), lamotrigine (target dose 150 mg/day), or carbamazepine (standard tablets, target dose 600 mg/day). Although epilepsy was of new onset, 43% of the patients were already taking AEDs, which were tapered to zero during titration of the study medication. The primary outcome measure was retention in the trial for 12 months. Early termination, largely due to adverse events, was significantly more common with carbamazepine (65%) than with lamotrigine (44%) or gabapentin (51%). Seizure-free rates at 12 months were similar across treatment groups.

Lamotrigine has also been compared with gabapentin in adults with newly diagnosed partial or primary generalized tonic–clonic seizures.[16] In this double-blind, parallel group study, 309 patients were randomized to gabapentin (flexible dosage from 1,200 to 3,600 mg/day) or lamotrigine (100 to 300 mg/day). There was no difference in the primary end-point, time to exit, or in the proportion of patients completing the 24-week maintenance phase—72% on gabapentin and 67% on lamotrigine. Of those completing, 76% taking gabapentin or lamotrigine remained seizure free during the last 12 weeks of the trial.

Two additional open randomized studies compared the efficacy of lamotrigine and carbamazepine in newly diagnosed partial epilepsy[88] or partial and/or generalized tonic–clonic seizures,[99] both supporting the view that the two drugs are equally effective, although lamotrigine may be better tolerated. It should, however, be noted that the controlled-release formulation of carbamazepine has not been used in any of the comparative trials, and that the statistical power to detect differences in efficacy has been low.

The only sizeable data from randomized trials on children with newly diagnosed partial epilepsy come from the open comparison with carbamazepine.[88] This study included 233 patients aged 2 to 12 years, of whom 158 were randomized to lamotrigine (2–15 mg/kg/day) and 75 to carbamazepine (5–40 mg/kg/day). Of those with data for at least 18 weeks, 66% on lamotrigine were seizure-free for the last 16 weeks, which was not statistically different from the 75% on carbamazepine.

Generalized Tonic–Clonic Seizures

Two of the Class I studies of lamotrigine in newly diagnosed epilepsy included subgroups of adult patients with primary generalized tonic–clonic seizures.[18,112] In the study by Brodie et al.,[18] 37% of the 60 patients randomized to lamotrigine remained seizure free during the last 40 weeks, compared with 35% among the 62 assigned to carbamazepine. The corresponding numbers for the last 24 weeks were 47% for both treatment groups. In the study by Steiner et al.,[112] 42 patients with primary generalized tonic–clonic seizures were randomized to lamotrigine and 49 to carbamazepine. Of those taking lamotrigine, 30% were seizure-free and remaining on treatment during the last 40 weeks, compared with 32% on phenytoin. Corresponding figures for the last 24 weeks were 44% and 34%, respectively, which did not significantly differ.

Lamotrigine has also recently been assessed as add–on treatment in patients with refractory primary generalized tonic-clonic seizures.[13] In this double-blind, parallel group study, 121 patients aged 2 to 55 years (23 were 2–12 years of age) were randomized to adjunctive treatment with lamotrigine or placebo. The median percent reduction in frequency of generalized tonic–clonic seizures from baseline (primary efficacy endpoint)

was 67% with lamotrigine and 33% with placebo. The study included 33 patients who had myoclonic in addition to tonic–clonic seizures. Although not designed to assess effects on seizure types other than tonic–clonic, there was no evidence of deterioration in other seizure types with lamotrigine.

Idiopathic Generalized Epilepsy Syndromes

One double-blind study assessed the short-term effects of la-motrigine in children with newly diagnosed typical absence seizures.[44] It enrolled 45 patients into an open-label dose escalation phase of lamotrigine. Responders (*n* = 28) entered a 4-week double-blind, placebo-controlled comparison in which they were randomized either to continue lamotrigine or be weaned onto placebo. The proportion of patients remaining seizure free during the double-blind treatment phase was greater for lamotrigine (62%) compared to placebo (21%). There are no randomized trials of lamotrigine in juvenile myoclonic epilepsy (JME). Some case series and open uncontrolled studies indicate that the drug may be effective and that some patients can be switched successfully from valproic acid to lamotrigine.[20,48,84] There are, however, also reports of exacerbations in myoclonic seizures with lamotrigine.[30]

Lennox-Gastaut Syndrome

Adjunctive lamotrigine has been shown to significantly reduce the frequency of major seizures in a double-blind, placebo-controlled study of children with LGS.[87] In this parallel group study, 169 patients were randomized to treatment with lamo-trigine or placebo. The median frequency of all major seizures changed from 16.4 during baseline to 9.9 per week during lamotrigine treatment, and from 13.5 to 14.2 in the placebo group. Among patients receiving lamotrigine, 33% demonstrated at least a 50% reduction on seizures compared to 16% in the placebo group. Lamotrigine was assessed as add-on in 20 children with LGS and 10 with other therapy-resistant generalized epilepsy syndromes.[38] The 17 responding during open-phase treatment with lamotrigine went into a randomized, double-blind, placebo-controlled, cross-over study, 60% of whom demonstrated at least 50% reduction in seizure frequency.

Indications Other Than Epilepsy

Lamotrigine has been investigated as a mood stabilizer in bipolar disorders. Lamotrigine 50 mg/day or 200 mg/day was significantly more effective than placebo in improving depressive symptoms in a short-term, randomized, double-blind, controlled study of bipolar depression.[21] Lamotrigine, 50 to 400 mg/day, was also more effective than placebo in a 26-week, randomized, controlled study in the prophylaxis of rapid-cycling bipolar disorders.[22] A small cross-over study compared lamotrigine, gabapentin, and placebo in rapid-cycling bipolar patients resistant to other mood stabilizers.[47] Lamotrigine, but not gabapentin, was superior to placebo in this study. A larger randomized, double-blind, parallel group study compared lamotrigine (100–400 mg/day), lithium, and placebo in the long-term treatment of patients with bipolar I disorder with recent manic or hypomanic episodes.[15] In this study, lamotri-gine was particularly effective in the prevention of depressive episodes.

At a dose of 400 mg/day, lamotrigine was superior to placebo as add-on treatment in patients with refractory trigeminal neuralgia,[126] but randomized monotherapy studies are lacking. The effects of lamotrigine have also been studied in other pain syndromes. Although a randomized, placebo-controlled, double-blind study failed to show an effect of la-motrigine, 200 mg/day, in a mixed population of neuropathic pain syndromes[77] the same dosage was superior to placebo in the treatment of post-stroke pain in another randomized controlled trial.[116] Lamotrigine, 300 mg/day, also significantly reduced pain scores in a placebo-controlled, double-blind study of neuropathic pain in HIV patients.[109] The only double-blind, placebo-controlled study in the prophylaxis of migraine failed to demonstrate efficacy with 200 mg lamotrigine daily.[113]

Adverse effects

Dose-Related, Nonidiosyncratic Adverse Effects

The most common dose-related adverse effects affect the central nervous system. Headache, asthenia, nausea, sleepiness/somnolence/drowsiness, and dizziness are the most frequently reported symptoms in monotherapy trials of lamotrigine.[18,99,112] However, drowsiness was less common in patients on lamotrigine monotherapy (100–300 mg daily) than among those on carbamazepine (300–1,400 mg daily, non–controlled release tablets)[18,99] or on phenytoin (300–600 mg daily).[112] Fewer patients on lamotrigine (15%) than on carbamazepine (27%) withdrew because of adverse effects in the randomized comparative monotherapy study.[112] A similar difference was reported in an open study comparing fixed dosages of lamotrigine (100 or 200 mg/day) and carbamazepine (600 mg/day). The withdrawal rate due to adverse events was 4.3% to 4.5% with lamotrigine, and 10.3% for patients on carbamazepine,[99] whereas there was no difference between lamotrigine and phenytoin in discontinuation because of adverse events in a double-blind randomized trial.[112] A double-blind comparison between lamotrigine and carbamazepine in 150 elderly patients with new-onset epilepsy also reported a lower dropout rate due to adverse events with lamotrigine compared with carbamazepine, 18% versus 42%.[17]

In another comparative study of new-onset epilepsy in senior citizens, 12.1% taking lamotrigine terminated the study due to adverse events compared with 21.6% on gabapentin and 31% on carbamazepine.[17] It should be noted that standard carbamazepine tablets rather than controlled-release formulations were used in all these comparative trials. Nevertheless, the results indicate that lamotrigine is comparatively well tolerated in these patient populations. A systematic Cochrane review of lamotrigine as add-on for drug-resistant partial epilepsy included three parallel and eight cross-over, randomized, add-on trials.[97] In this meta-analysis, ataxia, dizziness, diplopia, and nausea were more likely to occur with lamotrigine compared to placebo, whereas odds ratios for fatigue and somnolence included unity.

Cross-sectional and short-term studies indicate that there are no major adverse effects of lamotrigine on endocrine function, body weight, or bone mineralization.[12,59,91]

Idiosyncratic Reactions

Skin rash has been the most concerning adverse effect of la-motrigine leading to withdrawal in 6.1% of adult patients in the early monotherapy trials,[78] which, however, should be compared to withdrawal rates due to rash of 8.9% for carbamazepine and 5.3% for phenytoin in the same trials. In a review of all clinical trials including 3,348 adult patients

and 1,096 children (<16 years of age) exposed to lamotrigine, the incidence of rash was 10.7% among adults and 12.6% in children.[79] Rashes were generally mild, often morbilliform in appearance, with onset usually within the first 2 to 3 weeks. However, serious skin reactions, such as anticonvulsant hypersensitivity syndrome, Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN), can occur.[6,53] Rash has been the single most frequently reported serious adverse event in both add-on and monotherapy trials of lamotrigine.[79] In the randomized trials, 3.5% of adults and 4.7% of children discontinued lamotrigine because of rash. Possible SJS or hospitalization for rash occurred in 0.3% of adults and 1.0% of children.[53]

The risk of SJS and TEN in relation to exposure to AEDs has recently been assessed using the German Registry for Serious Cutaneous Reactions.[83] Fifteen cases of SJS or TEN among lamotrigine users were reported during the period 1998 to 2001, all but one occurring within the first 63 days of starting treatment. The incidence per 10,000 person-years of use, based on sales data of defined daily doses in Germany, was 1.8 for lamotrigine compared to 0.5 for carbamazepine, 1.3 for phenobarbital, 1.2 for phenytoin, and 0.1 for valproic acid.[83] However, when an attempt was made to estimate the risk of SJS/TEN in new users of AEDs, the assumed incidence was 3.8 per 10,000 for lamotrigine, 1.5 for carbamazepine, 8.2 for phenobarbital, 6.9 for phenytoin, and 0.5 for valproic acid.[83]

The risk of severe rash appears to be higher in the pediatric population than among adults.[79] Comedication with valproic acid, high starting doses, and rapid dose-escalations have been identified as additional risk factors.[6,53,78] The highest incidence (19.5%) of all types of rash occurred when lamotrigine was combined with valproic acid in the absence of other AEDs, whereas the lowest incidence (6.7%) occurred in combination with enzyme-inducers. Severe rash associated with hospitalization was also more common when lamotrigine was combined with valproic acid.[78] Previous allergy to another antiepileptic drug, particularly carbamazepine, has been found to predict the risk of rash with lamotrigine.[9]

Other serious idiosyncratic adverse effects of lamotrigine are rare but have included a few cases of multiorgan failure with disseminated intravascular coagulation.[24,72,73,105]

At least 12 cases of serious liver toxicity induced by la-motrigine have been reported, five of which resulted in death.[73] A British prescription-event monitoring study of 11,316 patients, however, confirmed that such serious adverse events are rare. Only two cases of disseminated intravascular coagulation, four cases of neutropenia, and three cases of thrombocytopenia were identified.[71]

A potential association between the use of lamotrigine and the occurrence of sudden unexplained death in epilepsy (SUDEP) was discussed during the clinical development of the drug. However, the SUDEP rate in epilepsy patients exposed to lamotrigine in clinical trials was not found to be higher than expected in patients with severe epilepsy.[69] A postmarketing surveillance study reported similar SUDEP rates for those exposed to lamotrigine and gabapentin.[123]

Additional Safety Issues

Among the newer-generation drugs, lamotrigine has by far the most extensive documentation with respect to use in pregnancy and teratogenic outcome. The manufacturer, GlaxoSmithKline, set up an international lamotrigine pregnancy registry in 1992. The outcome of prospective pregnancies with first-trimester exposure to lamotrigine was recently summarized.[32] There were 12 outcomes with major malformations among 414 pregnancies with lamotrigine monotherapy, yielding a malformation rate of 2.9% (95% CI, 1.6%–5.1%). Among 88 first-trimester exposures to lamotrigine in combination with valproic acid, 11 outcomes were noted with major birth defects (12.5%; 95%; CI,6.7%–21.7%), an apparently higher rate than in association with lamotrigine in other combinations (*n* = 182, 2.7%, 95%; CI,1.0%–6.6%).

The UK Epilepsy and Pregnancy Register[86] reported a rate of major congenital malformations of 3.2% (95%; CI,2.1%–4.9%) among 647 prospective pregnancies with lamotri-gine monotherapy, similar to the 2.2% (95%; CI,1.4%–3.4%, *n* = 900) with carbamazepine, whereas the malformation rate associated with valproic acid monotherapy in the same study was 6.2% (95%; CI,4.6%–8.2%, *n* = 715). A positive dose-response relationship was noted with lamotrigine, as with valproic acid and carbamazepine, with a malformation rate of 5.4% (95%; CI,3.3–8.7%) for daily lamotrigine doses exceeding 200 mg. The malformation rate for pregnancies exposed to lamotrigine in combination with valproic acid was 9.6% (95%; CI,5.7–15.7%, n = 141).

In the North American pregnancy registry, 15 of 564 infants born to women taking lamotrigine in the first trimester had major malformations, 2.7% (95% CI 1.5%–4.3%), the relative risk (RR) compared with background rate was 1.7 (95% CI 1.0–2.7). Five of those exposed to lamotrigine had oral clefts, considerably higher than expected from the background rate, RR 32.8 (95% CI 10.6–101.3).[56]

Seizure Aggravation

Although lamotrigine is effective in the treatment of idiopathic generalized epilepsies (IGEs), reports of seizure aggravation also exist. Lamotrigine has been shown to worsen seizures in severe myoclonic epilepsy.[54] It has also been associated with exacerbation, de novo myoclonus, and myo-clonic status in patients with IGEs including JME, juvenile absence epilepsy, and IGE with isolated generalized tonic–clonic seizures.[11,23,30]

Drug interactions

Pharmacokinetic Interactions

Enzyme-inducing AEDs, such as phenobarbital, primidone, phenytoin, and carbamazepine enhance lamotrigine clearance and lead to reduced steady-state concentrations and shortened half-life, sometimes resulting in the need for dose adjustments.[2,5]

Oxcarbazepine, methsuximide, and possibly topiramate can also induce the metabolism of lamotrigine.[8,76,122] Among non-AEDs, rifampicin reduces lamotrigine concentrations.[37] Likewise, oral contraceptives induce lamotrigine metabolism, reducing steady-state concentrations by 40% to 65%.[101,108] This effect appears to be associated with the ethinylestradiol component, whereas progesterone-only contraceptives do not seem to affect lamotrigine plasma concentrations.[98] The de-induction of lamotrigine metabolism is fairly rapid. As a consequence, lamotrigine plasma concentrations become twofold higher during the pill-free week with use of sequential oral contraceptives.[108]

Table 2 Lamotrigine dosing and titration schedules

As add-on therapy Concomitant antiepileptic drugs		
Adults	**Valproate**	**Others**
Weeks 1 and 2	12.5 mg daily[a]	50 mg daily
Weeks 3 and 4	25 mg daily	50 mg twice daily
Maintenance	50–100 mg[b] twice daily	100–200 mg[b] twice daily
Children	**Valproate**	**Others**

Weeks 1 and 2	0.15 mg/kg	0.6 mg/kg
Weeks 3 and 4	0.3 mg/kg	1.2 mg/kg
Increments	0.3 mg/kg	1.2 mg/kg
Maintenance	1–5 mg/kg[b]	5–15 mg/kg[b]
As monotherapy	**Adults**	**Children**
Weeks 1 and 2	25 mg daily	0.5 mg/kg
Weeks 3 and 4	25 mg twice daily	1 mg/kg
Maintenance	50–100 mg[b] twice daily	2–8 mg/kg[b]

[a]25 mg every other day is more common in the United States.
[b]Higher doses can be tried if seizures persist and the patient's tolerance is good.

Valproic acid is a potent inhibitor of UGT1A4 and thus of lamotrigine metabolism,[1,125] which can result in a 200% increase in circulating concentration.[108] Maximal inhibition of lamotrigine metabolism can occur with valproate doses of 500 mg/day and above.[49] The antidepressant sertraline is another inhibitor, producing a substantial increase in lamotrigine concentrations.[61]

P.1580

Pharmacodynamic Interactions

Patients treated with lamotrigine in combination with carbamazepine or oxcarbazepine seem to be at a higher risk of developing clinical signs of central nervous system toxicity, such as diplopia and dizziness.[4,7] This is more common in patients with high serum concentrations of carbamazepine, and can be resolved by reduction in the carbamazepine dosage.[7] Independent studies suggest that lamotrigine in combination with valproate may be particularly effective in preventing seizures.[19,95] The pharmacokinetic interaction between the drugs is not sufficient to explain this synergistic effect, which can only be understood through a pharmacodynamic interaction.[95]

Role in Epilepsy treatment

Indications

Lamotrigine has a broad range of efficacy against partial-onset and primary generalized seizures and seizures associated with the LGS. The drug is licensed as adjunctive therapy for these indications in adults and in children over 2 years old and as monotherapy in adults and in children aged 12 years and over. It may also be useful in epilepsies with myoclonic seizures and typical absences.[3] The combination of lamotrigine and valproic acid appears particularly effective for partial and tonic–clonic seizures.[19,95] This effect has also been observed in patients with absence and myoclonic seizures.[40,41,92]

Dosing Recommendations

Recommended dosing schedules for lamotrigine are outlined in Table 2.[51] With adjunctive therapy, the titration rate depends on comedication, and the aim of the low starting dose and slow titration schedule is to minimize the risk of rash. Lamotrigine is usually prescribed twice daily in patients taking hepatic enzyme–inducing AEDs, but a single daily dose can be taken by patients on monotherapy or treated with valproic acid. Most patients receiving monotherapy respond to doses of 100 to 300 mg/day. Higher doses of 400 to 800 mg/day may be required in refractory epilepsy or when the patient is also taking an enzyme-inducing AED. An equivalent dose in valproic acid–treated patients would be 150 to 200 mg/day.

Precautions

Lamotrigine is usually well-tolerated, with rash in 3% of patients started on the drug as monotherapy being the most serious side-effect. Evidence suggests that a low starting dose and slow titration schedule help to minimize this problem, particularly in patients also taking valproic acid. For some patients taking carbamazepine or oxcarbazepine, the addition of lamotrigine can produce headache, dizziness, ataxia, and diplopia. In severe hepatic impairment (Child-Pugh grade C), initial and maintenance doses of lamotrigine should be reduced by 75%. Caution should also be exercised when treating patients with Gilbert syndrome. Although single-dose studies in people with end-stage renal failure showed no significant alteration of plasma lamotrigine concentrations, it might be expected that toxicity could occur due to accumulation of glucuronide metabolites. It is, therefore, prudent to exercise care if using lamotrigine in this population.

Contraindications

Lamotrigine can worsen severe myoclonic epilepsy and should be avoided in patients with this condition. Increasing evidence suggests that the drug can also exacerbate some other myo-clonic syndromes.

Summary and conclusions

Lamotrigine is a broad-spectrum AED that is widely used as an adjunctive agent and as monotherapy in adults and children. Its anticonvulsant activity has been demonstrated in several seizure models. The drug has been shown to operate via a variety of cellular mechanisms, including blockade of voltage-gated Na^+ channels. Lamotrigine undergoes linear pharmacokinetics and is metabolized mainly via hepatic glucuronidation. Controversy still exists over whether the drug is suited to routine therapeutic drug monitoring, although levels can be useful in pregnant women and in those starting or coming off the oral contraceptive pill. Lamotrigine is effective against most seizure types, although it may make certain types of myoclonic epilepsy worse. Adverse effects include nausea, headache, and ataxia, with rash being the most serious common problem. SJS and TEN have been reported, especially in children. Drug interactions are few, but combining lamotrigine with sodium valproate can be particularly efficacious, although at an increased risk of producing skin rash. Detrimental pharmacodynamic interactions can occur between lamotrigine and carbamazepine and oxcarbazepine. The licensing of lamotrigine in recent years for the treatment of bipolar I disorder serves to underline its therapeutic range.

Chapter 151
Levetiracetam

Michael D. Privitera

Jennifer Cavitt

Introduction

Levetiracetam, an antiepileptic drug (AED) with an interesting development history, has become widely used in the treatment of several types of epilepsy. Initial performance in standard animal screening models proved disappointing,[34] but the drug's success in clinical trials in humans have led some to question whether standard screening models should be reevaluated. Levetiracetam's newly discovered mechanism of action is unique among AEDs, and has led to development of new compounds with binding at the SV2A site.[45] For clinicians, levetiracetam has proved attractive because of its lack of hepatic metabolism, minimal drug interactions, activity against several seizure types, and ability to start an effective dose on day one.

Pharmacology

Levetiracetam—(S)-alpha-ethyl-2-oxo-pyrrolidine acetamide-—is a novel AED, chemically related to the nootropic agent, piracetam (Fig. 1).[44]

Standard animal models for screening and testing of AEDs indicate that levetiracetam may work differently than other AEDs. Klitgaard showed that levetiracetam did not stop seizures following acute maximal electrical shock (MES) and maximal pentylenetetrazol (PTZ) in rodents.[34] However, these investigators showed that levetiracetam did protect against generalized seizures in rodents that had been kindled (i.e., animals who developed seizures due to chronic, submaximal stimulation with electrical shock or PTZ administration). Additionally, levetiracetam was ineffective in various maximal chemoconvulsive tests, except for protection against secondarily generalized activity from partial seizures induced by pilocarpine in mice and pilocarpine and kainic acid in rats. The antiseizure activity of levetiracetam persisted with chronic administration of methyl-6,7–dimthoxy-4–ethyl-beta-carboline-3–carboxylate, and it did not lower the seizure threshold of an inverse benzodiazepine receptor agonist. This pattern of activity differs greatly from that of other AEDs. An evaluation of levetiracetam's major metabolite, (S)-alpha-ethyl-2–oxo-1–pyrrolidine acetic acid, using the same tests showed it to be inactive. There was a wide safety margin in normal and amygdala-kindled rats using the Rotorod impairment test.

Löscher et al. corroborated the findings of Klitgaard on the antiepileptogenic effects of levetiracetam in the kindling model of temporal lobe epilepsy.[43] Only two of the older AEDs, valproate and phenobarbital, demonstrate mild antiepileptogenic properties in similar animal models for kindled seizures. The dose required to produce this effect is much greater, and the strength of the effect is much less for valproate and phenobarbital, compared with levetiracetam.

At the time of initial studies and U.S. Food and Drug Administration (FDA) approval, the mechanism of action of levetiracetam was unknown. Now, several lines of evidence indicate that levetiracetam exerts its antiepileptic action through binding at the synaptic vesicle SV2A receptor.[45] Brain membranes and purified synaptic vesicles from mice lacking SV2A do not bind a tritiated levetiracetam derivative, indicating that SV2A is necessary for levetiracetam binding. Levetiracetam and related compounds bind to SV2A expressed in fibroblasts, indicating that SV2A is sufficient for levetiracetam binding. No binding was observed to the related isoforms SV2B and SV2C. A high degree of correlation occurs between binding affinities of a series of levetiracetam derivatives to SV2A in fibroblasts and to the levetiracetam-binding site in brain. Finally, a strong correlation exists between the affinity of a compound for SV2A and its ability to protect against seizures in an audiogenic mouse animal model of epilepsy. There appears to be some consensus that levetiracetam does not exert its antiepileptic activity through modulation or γ-aminobutyric acid (GABA) transmission or direct effect on sodium or calcium channels.[57,63] These new and intriguing findings on levetiracetam's mechanism have the potential to open a new avenue of investigation into proteins involved in vesicle exocytosis, and into SV2 in particular, as targets for the development of new AED therapies.

A study of levetiracetam's efficacy in an experimental model of self-sustaining status epilepticus (SE) induced in rats by electrical stimulation revealed that intravenous pretreatment with levetiracetam reduced or prevented the development of self-sustaining seizures, and levetiracetam treatment during self-sustaining seizures decreased or aborted seizures.[47] This study also found that levetiracetam significantly enhanced the anticonvulsant effects of diazepam, even at subtherapeutic doses.

Clinical Pharmacokinetics

Levetiracetam pharmacokinetics have been evaluated in pediatric, adult, and elderly patients, as well as in patients with renal and hepatic failure. Its rapid absorption, excellent bioavailability, minimal protein binding, lack of hepatic metabolism, and linear pharmacokinetics, make levetiracetam dosing straightforward.

Absorption

Following oral administration of 250 mg to 5,000 mg, the absolute bioavailability of levetiracetam is 95% to 100%.[52] Peak plasma concentrations of approximately 31 μg/mL are achieved within 1 hour of a 1,000-mg oral dose. Repeated doses of 1,000 mg twice daily yield steady-state peak concentrations of approximately 43 μg/mL within 2 days. Peak concentrations and area under the plasma concentration-time curve (AUC) were linear for doses ranging from 500 to 5,000 mg in healthy volunteers. Food and antacids (calcium carbonate and aluminum hydroxide) slowed the rate of absorption, but did not decrease the extent of absorption. Additionally, there was no change in bioavailability with administration of a single 500-mg tablet compared with administration of two 250-mg capsules.

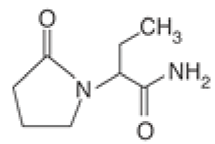

FIGURE 1. Levetiracetam's chemical structure (2-(2-oxopyrrolidin-1-yl)butanamide).

Table 1 Levetiracetam dosage adjustments in renal insufficiency (manufacturer's recommendations)

Group	Creatinine clearance (mL/min)	Dosage (mg)	Frequency
Normal	>80	500 to 1,500	Every 12 hours
Mild	50–80	500 to 1,000	Every 12 hours
Moderate	30–50	250 to 750	Every 12 hours
Severe	<30	250 to 500	Every 12 hours
ESRD patients using dialysis	—	500 to 1,000	[a]Every 24 hours

Following dialysis, a 250 to 500 mg supplemental dose is recommended.

Plasma Protein Binding and Distribution

Levetiracetam appears to be distributed to intracellular and extracellular fluid with a volume of distribution of 0.5 to 0.7 L/kg.[33] Less than 10% is bound to plasma proteins. Animal studies indicate that levetiracetam readily crosses the blood–brain barrier and appears to be evenly distributed throughout the brain.[19]

Metabolism and Elimination

Within 24 hours of an oral dose of levetiracetam, 93% of the drug has been excreted, 66% as unchanged drug in the urine and 27% as inactive metabolites.[52] One major inactive metabolite, L057, accounts for 24% of the dose, and is formed in blood by hydrolysis of an acetamide group. This deamination process does not involve either the cytochrome P450 or UDP-glucuronyl transferase isozyme (UGT) systems. Two other minor metabolites account for 3% of the dose, and their metabolic pathway has not been determined.

The renal clearance of levetiracetam is 40 mL/min/1.73 m^2 or 0.6 mL/min/kg and clearance of the major metabolite is 4.2 mL/min/kg.[33] Levetiracetam apparently undergoes glomerular filtration with some tubular reabsorption, whereas L057 is actively secreted in renal tubules in addition to tubular reabsorption. Concomitant administration of probenecid increased concentrations of L057, but not levetiracetam. Because L057 is inactive, this change in elimination should not result in changes in response to levetiracetam. In normal adult volunteers, the elimination half-life of levetiracetam is 6 to 8 hours and is unchanged by doses up to 5,000 mg, route of administration, or frequency of administration. Steady-state concentrations are reached within 48 hours.[52]

Pediatric and Elderly Populations

In children with epilepsy who are 6 to 12 years old, the elimination half-life of levetiracetam is approximately 6 hours, and apparent total body clearance is 30% to 40% lower than adults.[52] The peak concentrations and AUC adjusted for a dose of 1 mg/kg were also 30% to 40% higher than in adults. The fraction excreted unchanged in the urine was similar to that of adults, but the percent of L057 in the urine was lower in children. These values indicate that children may require doses that are 1.3 to 1.4 times a weight-normalized adult dose. For elderly patients, the elimination half-life is prolonged at 10 to 11 hours.[31]

Renal and Hepatic Impairment

The renal clearance of levetiracetam correlates directly with creatinine clearance, as does its primary metabolite.[52] Patients with mild to moderate renal impairment (creatinine clearance of 20–89 mL/min/1.73 m^2) had the total body clearance of levetiracetam decreased by 35% to 60%. Total body clearance was reduced by 68% in a patient with a creatinine clearance of <19 mL/min/1.73 m^2. As expected, the steady-state peak concentration, half-life, and AUC increased with declining renal function. During hemodialysis, the elimination half-life for levetiracetam is approximately 25 hours for the interdialytic period and 3.1 hours for the intradialytic period. Approximately 50% of levetiracetam is removed during dialysis. Based upon these data, the manufacturer recommends dosage adjustments for varying degrees of renal function (Table 1).[33]

In subjects with mild (Child-Pugh A) to moderate (Child-Pugh B) hepatic impairment, the pharmacokinetics of levetiracetam were unchanged. In patients with severe hepatic impairment (Child-Pugh C), total body clearance was 50% that of normal subjects, but decreased renal clearance accounted for most of the decrease. No dose adjustment is needed for patients with hepatic impairment.[33]

Race and Gender

Levetiracetam C_{max} and AUC were 20% higher in women (*n* = 11) compared with men (*n* = 12), however clearances adjusted for body weight were comparable. Formal pharmacokinetic studies of the effects of race have not been conducted. Cross-study comparisons involving whites (*n* = 12) and Asians (*n* = 12) show that the pharmacokinetics of levetiracetam were comparable between the two races. Because levetiracetam is primarily renally excreted and there are no important racial differences in creatinine clearance, pharmacokinetic differences due to race are not expected.[31]

Value of Plasma Concentrations

Plasma concentrations of levetiracetam were obtained in controlled trials. No study has demonstrated a relationship between plasma concentration and efficacy or adverse effects independent of dose. Levetiracetam does not undergo hepatic

P.1585

metabolism, is not protein bound, and lacks drug interactions with most other medications; thus routine monitoring of plasma concentrations does not appear indicated.

Intravenous Formulation

The equivalence of levetiracetam injection and the oral formulation was demonstrated in a bioavailability study of 17 healthy volunteers.[32] In this study, levetiracetam 1,500 mg was diluted in 100 mL 0.9% sterile saline solution and was infused over 15 minutes. The selected infusion rate provided plasma concentrations of levetiracetam at the end of the infusion period similar to those achieved at T_{max} after an equivalent oral dose. It is demonstrated that levetiracetam 1,500 mg intravenous infusion is equivalent to three 500-mg oral tablets of levetiracetam. The time-independent pharmacokinetic profile of levetiracetam was demonstrated following a 1,500 mg intravenous infusion for 4 days with twice-daily dosing. The $AUC_{(0-12)}$ at steady-state was equivalent to AUC_{inf} following an equivalent single dose. Equivalent doses of intravenous levetiracetam and oral levetiracetam result in equivalent C_{max}, C_{min}, and total systemic exposure to levetiracetam when the intravenous levetiracetam is administered as a 15-minute infusion.

Efficacy

Efficacy as Adjunctive Treatment in Partial Seizures

Levetiracetam is effective adjunctive treatment for medication-resistant partial seizures with or without secondary generalization. Several randomized, placebo-controlled trials have established that levetiracetam doses of 1,000 to 3,000 mg/day significantly reduce mean seizure frequency rates and produce significantly greater numbers of 50% responders when compared with placebo.

Shorvon et al.[56] studied 324 patients, aged 16 to 65 years, with medication-resistant partial seizures and found that add-on levetiracetam significantly reduced seizure frequency compared with placebo, and 50% responder rates were significantly greater in levetiracetam groups compared with placebo. The median percentage reduction in seizure frequency was 17.7% and 26.5% for levetiracetam doses 1,000 mg/day and 2,000 mg/day, respectively, compared with 6.1% for placebo. In addition, a 50% reduction of 50% or greater in seizure frequency was seen in 22.8% of patients on levetiracetam 1,000 mg/day and 31.6% of patients on levetiracetam 2,000 mg/day, compared with 10.4% of patients taking placebo. However, no significant difference was found between levetiracetam doses of 1,000 mg/day and 2,000 mg/day. Betts et al.[12] also failed to find greater efficacy with a higher dose of levetiracetam. In fact, in a study of 119 patients, aged 16 to 70 years, with medication-resistant epilepsy that included partial seizures with and without secondary generalization, as well as primary generalized tonic–clonic seizures, 2,000 mg/day add-on levetiracetam produced a significantly greater 50% responder rate (48.1%, $p < 0.05$) compared with placebo (16.1%). However, the 50% responder rate for patients on 4,000 mg/day levetiracetam (28.6%) was remarkably not significantly better than placebo, although no significant differences were found in seizure reduction by seizure type between the treatment groups.

In contrast, two other randomized, controlled trials did find a dose–response relationship for levetiracetam in medication-resistant partial seizures. In 324 patients, aged 16 to 65 years, studied by Boon et al.,[13] both 1,000 mg/day and 2,000 mg/day doses of add-on levetiracetam significantly reduced mean seizure frequency and increased 50% and 75% responder rates compared with placebo. Specifically, 26.2% of patients on levetiracetam 1,000 mg/day and 34.3% of patients on levetiracetam 2,000 mg/day had a ≥50% reduction in seizure frequency, compared with 12.2% of those on placebo. Furthermore, the 50% responder rate with levetiracetam 2,000 mg/day was significantly greater than that with levetiracetam 1,000 mg/day ($p = 0.018$). Of patients receiving 1,000 or 2,000 mg/day levetiracetam, 13.7% and 20% of patients, respectively, had ≥75% reduction in seizure frequency, compared with 4% in the placebo group.

Similarly, Cereghino et al.[15] found that both 1,000 mg/day and 3,000 mg/day add-on levetiracetam doses significantly reduced mean seizure frequency compared with placebo (32.5% and 37.1%, respectively, vs. 6.8% for placebo, $p < 0.001$) and significantly increased 50% responder rates compared with placebo in 294 patients aged 16 to 70 years. Of those taking 1,000 mg/day or 3,000 mg/day levetiracetam, 33% and 39.8%, respectively, had a ≥50% reduction in seizure frequency, compared with 10.8% of patients taking placebo. Moreover, a significantly greater number of patients in the 3,000 mg/day levetiracetam group (eight of 98 or 8.2%, $p = 0.01$), but not the 1,000 mg/day levetiracetam group (three of 94 or 3.2%) were seizure-free, compared with placebo (0 of 93).

Another randomized, controlled trial by Ben-Menachem et al.[10] evaluated in 286 patients, aged 16 to 70 years, with medication-resistant partial seizures the efficacy of add-on levetiracetam 3,000 mg/day versus placebo. The investigators found that median seizure frequency, median percentage seizure reduction, and 50% responder rates were all significantly better in the levetiracetam group (1.06 seizures/week, 39.9%, and 42.1%, respectively) compared with the placebo group (1.75 seizures/week, 7.2%, 16.7%, respectively).

Ben-Menachem et al.[9] also examined long-term efficacy of levetiracetam using data from 1,422 patients treated with levetiracetam in multiple studies. The investigators found that median percentage seizure frequency reduction did not decrease over time within cohorts of 6 to 54 months of levetiracetam exposure, suggesting that tolerance was not observed. In addition, 50% and 75% responder rates were similar (38.6% and 20.1%, respectively) for the whole treatment period of up to 54 months as those seen in randomized, controlled trials, indicating that short-term efficacy is sustained over a longer observation period as well.

French and Arrigo[21] evaluated the rapid onset of action of levetiracetam in a pooled analysis of data from three randomized, double-blind, placebo-controlled trials of 883 patients, aged 16 to 70 years, with refractory partial seizures started on levetiracetam 1,000 or 333 mg/day versus placebo. The proportions of seizure-free patients in each group were analyzed for 3 days before and after starting levetiracetam or placebo. In the 1,000 mg/day levetiracetam group, the increase in the proportion of seizure-free patients over the day prior to treatment initiation was 15% for the first day of treatment, 17% for the second day of treatment, and 17%

for the third day of treatment. All these differences were found to be statistically significant ($p < 0.001$). In the 333 mg/day levetiracetam group, the increase in the proportion of seizure-free patients over the day prior to treatment initiation was 7% for the first day of treatment, 9% for the second day of treatment, and 9% for the third day of treatment, but none of these differences was statistically significant. No major changes were observed in the proportion of seizure-free patients following initiation of placebo, with increases of 1%, 2%, and 1%, respectively, for days one, two, and three following treatment initiation, and these changes were also not statistically significant. Thus, rapid onset of action was noted when starting levetiracetam 1,000 mg/day.

A follow-up study[22] examined the proportion of seizure-free days each week for the 3-month period following treatment

initiation for those same 883 patients to determine whether a change in efficacy occurs during the duration of the trial. A significantly greater mean proportion of seizure-free days was observed beginning with the first week after treatment initiation in the levetiracetam group compared with placebo. Moreover, a significantly greater mean proportion of seizure-free days was also seen for each week of the 3-month period, suggesting sustained efficacy of levetiracetam. Interestingly, the difference in mean proportion of seizure-free days between the levetiracetam and placebo groups was most pronounced in the first week after treatment initiation (0.81 for levetiracetam vs. 0.69 for placebo). However, the efficacy was stable for the following weeks in the 3-month period.

Krakow et al.[35] analyzed the long-term continuation rate and efficacy of levetiracetam in 1,422 patients with medication-resistant epilepsy treated with adjunctive levetiracetam in several double-blind, placebo-controlled trials and open-label studies during the developmental program of the drug in Europe and the United States. Patients ranged in age from 5 to 78 years, but the majority of patients (95.2%) were 16 to 65 years old. The vast majority (93%) had localization-related epilepsy. Of 1,422 patients exposed to levetiracetam, 562 were still treated at the cut-off date. Kaplan-Meier survival analysis estimated continuation rates of 60%, 37%, and 32%, respectively at 1, 3, and 5 years. Adverse events led to treatment withdrawal in 225 of 1,422 patients (15.8%), and lack of efficacy led to withdrawal in 261 patients (18.4%). In 374 of 1,422 patients (26.3%), levetiracetam was discontinued due to reasons inherent in clinical trials, such as protocol violations, withdrawal of consent, study completed without starting open follow-up, lost to follow-up, and the like. Cox regression revealed four factors that significantly affected levetiracetam continuation: high maximum dose, low starting dose, presence of generalized seizures, and smaller number of AEDs at baseline. In 1,325 patients for whom seizure frequency data were available for both baseline and treatment periods, 512 (39.6%) had a ≥50% reduction in seizure frequency, 266 (20%) had a ≥75% reduction in seizure frequency, 183 (13%) were seizure-free for at least 6 months, 109 (8%) were seizure-free for at least 1 year, and 65 (4.5%) were seizure free from the first day of exposure.

Efficacy as Monotherapy in Partial Seizures

A large prospective trial demonstrated the effectiveness of levetiracetam as monotherapy. Ben-Menachem et al.[8] studied the efficacy of 1,000 to 3,000 mg/day levetiracetam monotherapy versus 400 to 1,200 mg/day controlled-release carbamazepine monotherapy in 472 patients with newly diagnosed, localization-related epilepsy followed for at least 12 months in a randomized, double-blind, head-to-head trial. Six-month seizure freedom rates were similar in the levetiracetam (73.0%) and carbamazepine (72.8%) groups. Twelve-month seizure-freedom rates were 56.6% in the levetiracetam group and 58.5% in the carbamazepine group. Significantly fewer patients taking levetiracetam (16.1%) discontinued therapy or had a dose change due to an adverse event compared with carbamazepine (23.0%).

In the randomized, controlled add-on trial described earlier, Ben-Menachem et al.[10] evaluated in 286 patients with refractory partial seizures—first the efficacy of add-on levetiracetam 3,000 mg/day versus placebo, then open-label conversion to monotherapy (levetiracetam 3,000 mg/day vs. placebo) for those study patients who qualified by virtue of a good response during the add-on phase. Although only 86 of 286 patients were eligible for the monotherapy phase, significantly more patients receiving levetiracetam completed the study compared with placebo.

In several small, retrospective studies Alsaadi et al.[3,4,5,6] examined the efficacy of levetiracetam monotherapy, both as a first-line treatment and as conversion to monotherapy. A chart review identified 46 patients with partial seizures who received levetiracetam monotherapy either as first-line treatment (n = 11) or as add-on therapy (n = 35) with subsequent conversion to monotherapy.[4] This review included some patients' data reported in an earlier study.[6] Of the 46 patients, three were lost to follow-up, five discontinued levetiracetam due to lack of efficacy, and three discontinued levetiracetam due to adverse effects. Thirty-five patients continued on levetiracetam monotherapy for 1 year, and 19 (54%) were at least 6 months' seizure-free at 1-year follow-up. Thirty-two of 35 patients (91%) had >50% reduction in seizure frequency at 1 year. A similar small, retrospective study evaluated the efficacy of levetiracetam monotherapy in 14 elderly patients, ages 62 to 92 years.[3] Five began levetiracetam as first-line therapy, and nine converted to levetiracetam monotherapy after failing initial AED trials. Thirteen (93%) continued levetiracetam for at least 6 months, and eight patients (62%) became seizure-free. Twelve of the 14 elderly patients (86%) had a >50% reduction in seizure frequency.

Efficacy in Generalized Seizures

Levetiracetam is approved in many countries for use in patients with partial-onset seizures. Although most randomized, double-blind, controlled clinical trials have focused on patients with partial-onset epilepsy, preliminary evidence suggests levetiracetam may be effective in primary generalized seizure types as well. Animal studies in genetic models of epilepsy[26,34,42] and open-label or single-blind trials in humans indicate levetiracetam may reduce the frequency of generalized-onset seizures, but few randomized, controlled trials have been conducted.

In a randomized, double-blind, placebo-controlled trial, Verdu et al.[60] studied the effect of adjunctive levetiracetam 3,000 mg/day in 122 patients, aged 12 to 65 years, with idiopathic generalized epilepsy with myoclonic seizures taking one concomitant AED. Of patients taking levetiracetam, 58.3% had a ≥50% reduction in days with myoclonic seizures, compared with 23.3% of patients taking placebo (p = 0.0002). In addition, thirteen patients on levetiracetam became seizure-free, compared with two seizure-free patients taking placebo.

In an open-label study of 55 patients, aged 16 to 67 years, with medication-resistant idiopathic generalized epilepsy treated with levetiracetam 500 to 4,000 mg/day, Krauss et al.[37] found that a majority of patients (76.4%) had a ≥50% reduction in seizure frequency, and 40% became seizure-free. The greatest 50% responder rate (23 of 26, 88.4%) was seen in patients with juvenile myoclonic epilepsy (JME). Fourteen of 18 patients with epilepsy with tonic–clonic seizures (77.8%) had a ≥50% reduction in seizure frequency, whereas five of 11 patients with absence epilepsy (45.5%) were 50% responders.

Labate et al.,[38] on the other hand, evaluated open-label levetiracetam monotherapy (n = 8) or adjunctive therapy (n = 27) for 12 months in 35 patients with different types of idiopathic and symptomatic generalized epilepsies, including JME, severe myoclonic epilepsy of infancy, Lennox-Gastaut syndrome, myoclonic-astatic epilepsy, myoclonic absences, benign myoclonic epilepsy in infancy, and undetermined generalized epilepsy syndromes, all with prominent myoclonic seizures. Levetiracetam doses ranged from 1,000 to 3,000 mg daily, with a mean dosage of 2,000 to 3,000 mg daily. All patients receiving levetiracetam monotherapy had JME. Twenty-nine of 35 patients (83%) had a ≥50% reduction in seizure frequency, including six of eight patients (75%) on levetiracetam monotherapy and 23 of 27 patients (85%) on levetiracetam

P.1587

add-on therapy. Fifteen of 35 patients (43%) were seizure-free, including five of eight patients with JME (62.5%). In four of 35 patients (11.4%), seizure frequency was unchanged and, in two of 35 patients (5.7%), seizure frequency increased. However, the greatest response was seen in patients with JME, lack of change or increase in seizure frequency was seen more often in patients with refractory generalized epilepsy, such as severe myoclonic epilepsy of infancy and Lennox-Gastaut syndrome.

Abou-Khalil et al.[1] studied individualized doses of levetiracetam 1,000 to 3,000 mg/day in an open-label study that included 37 patients, aged 16 to 70 years, with medication-resistant generalized epilepsy. Twelve of the 37 had the diagnosis JME, and four others had a combination of myoclonic and absence seizures with or without generalized seizures, suggesting the diagnosis of JME, even though the syndrome diagnosis was not specifically stated. One patient had juvenile absence epilepsy, and three patients had isolated generalized tonic–clonic seizures. Four had Lennox-Gastaut syndrome, four had unspecified symptomatic generalized epilepsy, and eight had generalized epilepsy that was not further specified. Nineteen of 37 (51.4%) patients had a ≥50% seizure reduction. This included three of seven patients (42.9%) on levetiracetam ≤1,000 mg/day, five of nine patients (55.6%) on 1,001 to 2,000 mg/day, ten of 20 patients (50%) on 2,001 to 3,000 mg/day, and one of one (100%) on 3,001 to 4,000 mg/day.

Another open-label study by Mohanraj et al.[49] of levetiracetam therapy in 156 patients, aged 16 to 78 years, with medication-resistant epilepsy of any type included 20 patients with idiopathic generalized epilepsy. Thirteen of those 20 (65%) had a ≥50% reduction in seizure frequency, including eight patients (40%) who became seizure free. JME was the most common type of idiopathic generalized epilepsy in this study (n = 11), and five (45%) of these patients became seizure free.

In addition, several small studies and case reports have suggested that levetiracetam reduces epileptiform activity on electroencephalogram (EEG) as well. An open-label, uncontrolled study of twelve patients with photosensitive epilepsy[30] examined levetiracetam's effect on photoparoxysmal response on EEG. Nine of twelve patients (75%) had a clear suppression or abolition of photoparoxysmal response after a single dose of levetiracetam. A dose-dependent response was seen, with complete abolition occurring only at 750- to 1000-mg doses. Although it was not one of the study objectives, two of the patients with myoclonic jerks noted a reduction in their myoclonus. One of these patients remained on levetiracetam for 3 years, with complete control of myoclonus and persistent suppression of photoparoxysmal response.

Gallagher et al.[23] quantitatively analyzed spike-and-wave density and spike-and-wave complex duration in ten patients with idiopathic generalized epilepsy treated with levetiracetam during continuous video-EEG monitoring. In three patients, entire EEG records were not available. Based on the available record, two patients had frequent spike-and-wave complexes before levetiracetam initiation and none after. The third patient had no response to levetiracetam. Of the seven patients for whom entire EEG records were available, all had a significant reduction in spike-and-wave density during levetiracetam treatment compared with periods without levetiracetam. Finally, a single case report[14] demonstrated an increase in generalized spike-and-wave discharges following discontinuation of levetiracetam, subsequent reduction of generalized spike-and-wave following reinstitution of levetiracetam, and corresponding changes in clinical absence in a patient monitored with continuous video-EEG. Four to 56 generalized spike-and-wave bursts per hour were noted at baseline, and this increased to 406 to 914 per hour following levetiracetam discontinuation. These bursts lasted ≥2 seconds and were associated with clinical absence. Subsequent reduction to 135 bursts of generalized spike-and-wave discharges per hour occurred 3 hours after reinstitution of levetiracetam.

Efficacy in Pediatric Epilepsy

Although levetiracetam has not been studied as extensively in pediatric epilepsy populations, one randomized, double-blind, placebo-controlled trial demonstrated efficacy in patients aged 4 to 16 years with refractory partial seizures,[24] leading to FDA approval of levetiracetam as adjunctive treatment for epilepsy in patients ≥4 years of age. This study evaluated 198 patients, aged 4 to 16 years, with refractory partial seizures with or without secondary generalization treated with levetiracetam 20 to 60 mg/kg per day versus placebo. A ≥50% reduction in seizure frequency was seen in 45 of 101 patients taking levetiracetam (44.6%), but in only 19 of 97 patients taking placebo (19.6%, p = 0.0002). In addition, 20 of 101 patients on levetiracetam (19.8%) had a ≥75% reduction in seizure frequency, compared with five of 97 patients taking placebo (5.1%), which was also statistically significant. Overall, the percentage seizure frequency reduction for levetiracetam over placebo was 26.8% (p = 0.0002).

Grosso et al.[28] conducted a prospective, open-label study to evaluate the efficacy of add-on levetiracetam 10 to 60 mg/kg per day in 110 children under 16 years of age with refractory epilepsy that was localization-related (n = 53), generalized (n = 45), or unclassifiable (n = 12). Forty-three of 110 children (39%) had a ≥50% reduction in seizure frequency, and ten children (9%) became seizure free. Twelve children (11%) had an increase in seizure frequency. Of those patients with a ≥50% reduction in seizure frequency, 58% had localization-related epilepsy. Among the patients with localization-related epilepsy with the highest responder rates were those with cryptogenic partial seizures.

Lagae et al.[39] examined the efficacy of open-label, add-on levetiracetam (12–62 mg/kg/day) in 67 children, aged 6 months to 16 years, with refractory partial, generalized, or mixed seizure types. At the same time, they evaluated open-label levetiracetam monotherapy in ten children, 4 to 16 years of age, six of whom had generalized seizures (two with childhood absences, two with myoclonic seizures, and two with tonic–clonic seizures), and four of whom had partial seizures. In the add-on trial, 33 of 67 patients (49%) had a ≥50% reduction in seizures, and three children became seizure-free. In the monotherapy trial, nine of ten patients had a ≥50% reduction in seizure frequency, and two children became seizure-free. Of note, 10 of 67 children (15%) in the add-on trial had an increase in seizure frequency, with a median increase of 50% (range 18%–420%). No differences in response were observed by seizure type or epilepsy syndrome. However, 85% of patients in the study population were mentally retarded.

Wheless et al.[61] evaluated the efficacy of open-label levetiracetam in 39 children, younger than 16 years of age, with refractory partial-onset and/or generalized seizures, all but one of whom received levetiracetam as add-on therapy. Twenty-five patients of 39 patients (64.1%) had a ≥50% reduction in seizure frequency, and three of these patients (7.7%) were seizure-free on a mean maintenance levetiracetam dose of 53.3 mg/kg per day. In a smaller, open-label study, Glauser et al.[25] found that twelve of 23 children (52%), aged 6 to 12 years, with medication-resistant partial-onset seizures, who were treated with 20 to 40 mg/kg per day levetiracetam, had a ≥50% reduction in seizure frequency. Finally, Lagae et. al.[40] studied the efficacy of add-on levetiracetam (17–60 mg/kg/day) in 21 children aged 11 months to 14 years, who had various refractory childhood epilepsy syndromes and mild or severe mental retardation. Ten children (47.6%) had a ≥50% reduction in seizure frequency, but none of the epilepsy syndromes showed

P.1588

a significantly better outcome. In addition, no significant differences were found in the responses of generalized, partial, and mixed epilepsy syndromes. However, in comparing response by seizure type, among the generalized seizures, the best response was seen for myoclonic seizures, with seven of 11 patients (64%) having a ≥50% reduction in seizure frequency; only in the myoclonic group was seizure frequency reduction statistically significant.

Efficacy in the Elderly

The incidence of epilepsy increases sharply after 60 years of age, and the physiologic changes that occur with aging, as well as the presence of comorbid medical conditions, present unique challenges in treating epilepsy in elderly patients. In particular, decreased rates of hepatic and renal metabolism and decreased serum albumin concentrations affect the metabolism and serum concentrations of many AEDs, leading to increased risk for toxicity with certain AEDs. The presence of comorbid medical conditions in elderly patients often requires long-term treatment with other medications, many of which may interact with AEDs on the basis of induction or inhibition of hepatic cytochrome P450 enzyme systems or through competitive protein-binding. Finally, elderly patients often are more sensitive to the cognitive adverse effects that are seen more frequently with older AEDs.[11]

Despite the high prevalence of epilepsy in the elderly, few studies examine the efficacy of AEDs in this population. Ferrendelli et al.[20] evaluated an elderly subset of 78 patients ≥65 years of age in a large (n = 1,030), open-label study examining the efficacy of levetiracetam in patients with refractory partial seizures. Maximum levetiracetam dose for most patients (41 of 78, 52.6%) was 1,000 mg/day, but for 16 patients (20.5%), it was 2,000 mg/day, and for 15 patients (19.2%), it was 3,000 mg/day. Overall, a ≥50% reduction in seizure frequency was seen in 76.9% of patients, whereas a ≥75% reduction was seen in 56.9% of patients, and 40% of patients were seizure free. Fifteen patients (19.2%) discontinued levetiracetam due to adverse events, including one for lack of efficacy and 14 for adverse effects. Somnolence and dizziness were the most common adverse effects noted in this elderly subgroup, as well as in the overall study population, and somnolence was seen more commonly in elderly patients taking two or more concomitant AEDs.

Alsaadi et al.[3] evaluated in a small, retrospective study the efficacy of levetiracetam monotherapy in 14 elderly patients, aged 62 to 92 years. Five began levetiracetam as first-line therapy, and nine converted to levetiracetam monotherapy after failing initial AED trials. Thirteen (93%) continued levetiracetam for at least 6 months, and eight patients (62%) became seizure free. Twelve of the 14 elderly patients (86%) had a >50% reduction in seizure frequency. The total dose ranged from 500 to 3,000 mg/day (mean 1,839.2 mg/day). Levetiracetam was well-tolerated in this small series of elderly patients, and in no patients was levetiracetam discontinued due to adverse effects.

Alore et. al.[2] examined the pattern of levetiracetam use in 39 hospitalized patients ≥65 years of age in a retrospective database review. Over half (54%) received levetiracetam during admission to a neurosurgery or trauma service, and intracranial hemorrhage was the most common cause of seizure. Most of these patients (80%) received levetiracetam as first-line monotherapy. Patients with stroke comprised the second-largest group (38%) of patients receiving levetiracetam, and a majority of these patients also received levetiracetam as first-line therapy. The average number of discharge medications was 9.4. A similar retrospective review examined the pattern of levetiracetam use compared with other AEDs in all patients admitted to a neuroscience intensive care unit.[48] Of 358 patients treated with AEDs, 124 received levetiracetam. In this population, intracranial hemorrhage and trauma were the most common diagnoses. Older patients and those with previous medical complications from AEDs or underlying disease were noted to be preferentially treated with levetiracetam.

Although data regarding the use of levetiracetam in older patients is quite limited, clinicians treating the elderly sometimes choose levetiracetam over standard AEDs, based on its favorable adverse effects profile, its lack of drug–drug interactions, minimal protein-binding, and lack of hepatic metabolism. Levetiracetam is renally excreted, and the rate of excretion correlates with creatinine clearance. Oral clearance of levetiracetam may be decreased in the elderly by 20% to 40%.[53] Thus, in prescribing levetiracetam for elderly patients, lower starting doses should be used for those with decreased creatinine clearance, a common finding in older patients. Osteoporosis often affects elderly patients, and this condition may be exacerbated by standard AEDs, especially the enzyme-inducing drugs. As levetiracetam neither induces nor inhibits hepatic enzymes, there is reason to expect that it would have less negative effect on bone health, but long-term data supporting this contention have not yet been published.

Efficacy in Status Epilepticus

Status epilepticus is a neurologic emergency defined as continuous or repeated seizure activity occurring for 30 minutes or more, without return to baseline between repeated seizures. Urgent treatment with benzodiazepines typically is followed by another AED given intravenously. Fos-phenytoin, phenytoin, phenobarbital, and valproic acid have all been shown to be effective in the acute treatment of SE. However, SE remains a clinical challenge, particularly in cases of refractory SE, which carries a mortality rate of 32%.[59] Although few published studies have examined the use of levetiracetam in the setting of SE, the development of an intravenous formulation of levetiracetam may increase levetiracetam use in the hospital setting, including cases of refractory SE.

Case series in humans have suggested that levetiracetam may be effective in treating SE. Rosetti and Bromfield[55] reported 13 cases of SE in which levetiracetam was administered enterally and compared these cases to age- and sex-matched controls from their SE database. Daily doses of 1,000 mg to 6,000 mg were used in combination with benzodiazepines (in all but one case) and other AEDs. In four patients (31%), levetiracetam was administered de novo. Three of the thirteen patients (23%) were identified as probable responders, and another patient (8%) reportedly responded but subsequently died. Responders were defined as patients in whom SE resolved within 3 days of start or increase of levetiracetam, without recurrence. Four patients (31%) were nonresponders, and five (38%) had an undetermined response. No significant difference in efficacy of SE treatment was seen between the levetiracetam group and the control group. The authors conclude that levetiracetam may be a valuable alternative treatment of SE.

Patel et. al.[51] reported their experience using oral levetiracetam in six patients, aged 16 to 91 years, to successfully treat SE refractory to two or more initial AEDs. Levetiracetam doses of 500 to 3,000 mg/day produced seizure control within 12 to 96 hours in patients with various types of refractory SE, including convulsive, focal, and nonconvulsive SE. Etiologies of SE also varied in this series, including ischemic and hemorrhagic infarcts, CNS vasculitis, posttraumatic epilepsy, static encephalopathy, and noncompliance.

Although preliminary evidence from animal studies and these few case series suggests potential efficacy of levetiracetam in refractory SE, other studies have suggested a

P.1589

paradoxical effect of levetiracetam in some patients, including new occurrence of SE following initiation of levetiracetam. Nakken et al.[50] prospectively examined adjunctive levetiracetam treatment in 78 adults and 44 children with intractable epilepsy in an uncontrolled clinical study. Although a >50% reduction in seizure frequency occurred in 40% of adults and 20% of children, including ten patients who became seizure free, the authors observed in 14 adults (18%) and 19 children (43%) a >25% increase in seizure frequency, including the development of SE in three adults and four children. This paradoxical effect occurred more frequently in mentally retarded patients during the first 2 months of treatment on relatively high doses (>30 mg/kg), although two children developed SE after 5 and 7 months, respectively. Withdrawal of the drug led to reduction in seizures. The numbers of different epilepsy types in each group were insufficient to determine a differential effect of levetiracetam in different epilepsy syndromes.

Atefy and Tettenborn[7] also reported two adult patients who developed nonconvulsive SE while on levetiracetam. Neither patient had a history of SE or mental retardation. Both patients had complex partial seizures, and both patients were treated with levetiracetam at only 2,000 mg/day. One patient had recurrent nonconvulsive SE after the levetiracetam dose was lowered to 500 mg/day and lamotrigine was added. Neither patient had recurrent SE after discontinuation of levetiracetam.

Thus, in light of the scant and somewhat contradictory information regarding levetiracetam and SE, its role in treatment of SE has yet to be clearly defined. Further study with randomized, controlled trials is needed to determine whether levetiracetam is effective in the treatment of SE or refractory SE, as well as what the potential adverse effects may be. Given the limited number of AEDs available in intravenous formulation, the limited efficacy of those drugs in refractory cases of SE, and the lack of drug–drug interactions with levetiracetam, the development of intravenous levetiracetam may increase the use of levetiracetam on inpatient neurology wards and intensive care units and lead to further examination of its potential efficacy.

Efficacy in Nonepilepsy Indications

Many of the standard and new AEDs have demonstrated efficacy in nonepilepsy indications such as headache, pain, or a variety of psychiatric disorders.[54] Levetiracetam has not shown efficacy in other nonepilepsy indications at this time.

Adverse Effects

In randomized controlled trials, levetiracetam was generally well tolerated. The most common adverse effects reported from clinical trials include somnolence, asthenia, infection (colds), and dizziness. The most common causes of discontinuation due to adverse effects were somnolence, dizziness, and asthenia. No serious hypersensitivity or Stevens-Johnson–type reactions were noted. Postmarketing experience includes case reports of leukopenia, neutropenia, pancytopenia, and thrombocytopenia, although evidence sufficient to establish causation is lacking. Betts et al.[12] noted in a randomized, controlled trial of levetiracetam 2,000 mg/day or 4,000 mg/day versus placebo that somnolence occurred more frequently in patients receiving 4,000 mg/day than in those receiving 2,000 mg/day or placebo, suggesting somnolence is a dose-related effect. Both somnolence and asthenia were noted to increase with escalating levetiracetam doses of 1,000, 2,000, 3,000, and 4,000 mg daily in another study by Grant et al.,[27] further supporting the dose-dependent nature of these adverse effects.

In a Cochrane meta-analysis, Chaisewikul et al.[16] found that only dizziness (OR 2.36, 99% CI 1.21–4.61) and infection (OR 1.82, 99% CI 1.05–3.14) were significantly more likely to occur with levetiracetam than with placebo. Furthermore, Marson et al.[46] performed a meta-analysis of levetiracetam treatment withdrawal across four randomized, controlled trials, and they found that relative risk for treatment withdrawal was 1.21 (95% CI 0.88–1.66), indicating levetiracetam was not significantly more likely to be withdrawn than placebo.

Behavioral and mood disturbances have been connected to levetiracetam therapy. In controlled trials, 13.3% of patients receiving levetiracetam experienced behavioral symptoms, such as aggression, agitation, anger, anxiety, apathy, depression, and emotional lability, compared with 6.2% of patients receiving placebo. Such adverse effects prompted discontinuation or dose reduction of levetiracetam in 2.5%. Furthermore, 0.5% of patients on levetiracetam attempted suicide, compared with no patients in the placebo groups. However, postmarketing experience suggests that behavioral side effects may be more common than initial studies indicate.

A case-control study by White et al.[62] examined the incidence of and risk factors for severe behavioral side effects of levetiracetam. In 553 patients studied, 38 (6.9%) discontinued levetiracetam due to behavioral abnormalities, including depression, irritability, aggression, and psychosis with hallucinations. In this study population, behavioral adverse effects were the most common reason for levetiracetam discontinuation. Three patients with depression were suicidal, ten patients were found to be a danger to themselves or others, and seven patients were aggressive toward others. No mortality or permanent psychiatric deficit was associated with levetiracetam, however. Such adverse effects led to levetiracetam discontinuation on average 3 months after initiation, but as late as 10 months after initiation. Patients who had severe behavioral side effects were significantly more likely to have symptomatic generalized epilepsy, a history of psychiatric disease, and a faster rate of levetiracetam titration to maximum dose. In addition, these patients had significantly lower maximum levetiracetam doses compared with controls, suggesting that such adverse effects do not necessarily reflect dose-related toxicity, but rather an idiosyncratic reaction.

Cramer et al.[18] analyzed the frequency of behavioral adverse effects with levetiracetam in placebo-controlled trials of patients with epilepsy compared with trials of patients with cognitive disorders or anxiety disorders. In an analysis of 3,252 patients exposed to levetiracetam during placebo-controlled trials, behavioral side effects were significantly more common among epilepsy patients than among patients with cognitive or anxiety disorders treated for similar time periods. This may indicate an underlying increased susceptibility of epilepsy patients to behavioral adverse effects with levetiracetam.

Anecdotal reports of improvement of behavioral adverse effects associated with levetiracetam following vitamin B_6 (pyridoxine) supplementation led Chez et al. to perform a retrospective chart review of 21 children started on levetiracetam who were observed for behavioral side effects and started on vitamin B_6 if behavioral side effects occurred.[17] Twelve of sixteen patients started on vitamin B_6 (50–400 mg/day, 118 mg/day average dose) for behavioral adverse effects with levetiracetam were noted to improve. Two patients did not improve, and two patients' charts had insufficient information to determine effectiveness. Although the 75% response rate appears promising, results from this small, retrospective study must be interpreted with caution, and a controlled trial is indicated.

Pregnancy and Lactation

Levetiracetam is categorized by the FDA as pregnancy category C.[31] In animal studies, levetiracetam exposure during pregnancy at doses similar to or greater than human therapeutic doses produced minor fetal skeletal abnormalities, growth

P.1590

retardation, behavioral alterations in offspring, and increased fetal mortality. One small case series of three women taking levetiracetam monotherapy during pregnancy reported no major or minor malformations or cognitive problems in infants followed for 1 year.[41] Another case series of 11 women on levetiracetam as monotherapy (n = 2) or in combination with other AEDs reported no fetal malformations in nine live births.[58] One spontaneous abortion occurred, in which no fetal malformations were detected. Another pregnancy was voluntarily terminated. Although no malformations were noted, two of the nine live-born infants had a birth weight below the tenth percentile, and one had a birth weight below the 23rd percentile. The data from these small series are insufficient to draw conclusions regarding the teratogenic effects of levetiracetam. However, the Keppra Pregnancy Registry, the European Registry of Antiepileptic Drugs and Pregnancy, and the Antiepileptic Drug Registry are collecting information about the effects of levetiracetam use during pregnancy.

Levetiracetam is excreted in breast milk. Kramer[36] reported a case of a breast-feeding woman taking phenytoin and valproic acid, who had levetiracetam added to her regimen. When the infant became hypotonic and had increasing difficulties feeding, levetiracetam levels in breast milk (99uM) were found to be three times higher than those in maternal serum. In contrast, a small study (n = 8) by Johannessen et al.[29] of breast-feeding women on 1,500 to 3,500 mg levetiracetam daily measured umbilical cord levetiracetam levels at birth, milk levetiracetam levels during lactation, and infant serum levetiracetam levels during breast-feeding. Similar levetiracetam concentrations were found in umbilical cord and maternal serum at birth. After delivery, similar levetiracetam concentrations were also found in maternal serum and breast milk 3 to 5 days after delivery and with sampling 2 weeks to 10 months after delivery. However, the breast-fed infants had very low serum levetiracetam levels (<10–15 uM) at 3 to 5 days after delivery and with continued breast-feeding, no adverse effects were noted in the infants. Nevertheless, this study was limited by its small sample size, and the potential risks to the infant of adverse effects due to levetiracetam must be weighed against the benefits of breast-feeding. If a mother elects to breast-feed, the infant should be observed closely for signs and symptoms of toxicity.

Role in Epilepsy Treatment

Indications

Levetiracetam is indicated as adjunctive treatment of partial-onset seizures in all countries where it is approved for use. A single, randomized, controlled noninferiority trial comparing it to carbamazepine supports its use as monotherapy in newly diagnosed partial epilepsy. Randomized controlled trials supporting its use in generalized-onset seizures or in SE have not been reported.

Dosing Recommendations

Onset of action is unknown, but peak plasma concentrations occur approximately 1 hour after an oral dose, with 100% bioavailability. Prescribing information in the United States recommends that adults receive an initial dose of 500 mg twice daily, increased by 1,000 mg/d every 2 weeks until good clinical response or a maximum of 3,000 mg/day (divided b.i.d.) is achieved.[31] Many clinicians start patients at 500 mg/day. There are no known drug interactions that affect dosing. The minimal effective dose in clinical trials is 1,000 mg/day; the maximum dose reported in randomized, placebo-controlled trials was 4,000 mg/day.[27] No published data are available regarding the value of a loading dose, but clinical trials started with 1,000 mg/day, which is the reported minimally effective dose. One study demonstrated onset of antiepileptic action on the first day of levetiracetam treatment.[21]

For pediatric patients, aged 4 to <16 years, treatment should be initiated with a daily dose of 20 mg/kg in two divided doses (10 mg/kg b.i.d.). The daily dose should be increased every 2 weeks by increments of 20 mg/kg to the recommended daily dose of 60 mg/kg (30 mg/kg b.i.d.). If a patient cannot tolerate a daily dose of 60 mg/kg, the daily dose may be reduced. In the clinical trial, the mean daily dose was 52 mg/kg. Patients with body weight >20 kg should be dosed with oral solution. Patients with body weight >20 kg can be dosed with either tablets or oral solution. Only whole tablets should be administered.[31]

Intravenous Formulation

When switching from oral levetiracetam, the initial total daily intravenous dosage of levetiracetam should be equivalent to the total daily dosage and frequency of oral levetiracetam and should be administered as a 15-minute intravenous infusion following dilution in 100 mL of a compatible diluent. At the end of the intravenous treatment period, the patient may be switched to levetiracetam oral administration at the equivalent daily dosage and frequency of the intravenous.

Precautions

For levetiracetam, the main precautions relate to somnolence, behavioral disturbances, and rare instances of hematologic dysfunction, as described earlier in the Adverse Effects sections.

Contraindications

This product should not be administered to patients who have previously exhibited hypersensitivity to levetiracetam or any of the inactive ingredients in Keppra tablets or oral solution.

Summary and Conclusions

Levetiracetam is an effective and well-tolerated AED. Mechanism of action is through a novel effect on the synaptic vesicle receptor SV2A, an effect that has already led to development of compounds in testing with similar mechanism of action. Levetiracetam has demonstrated efficacy as an adjunctive treatment for partial-onset seizures in adults and children, and as monotherapy in adults with newly diagnosed partial-onset seizures. The drug is well-tolerated, with the most common adverse effects being somnolence, dizziness, and asthenia. Less common but important adverse effects include psychiatric and behavioral abnormalities in adults and children. Levetiracetam has a favorable pharmacokinetic and drug interaction profile, with no hepatic metabolism, an absence of clinically significant drug interactions, and no appreciable protein binding. Future areas of investigation include levetiracetam's role in generalized epilepsies and SE.

Chapter 152
Oxcarbazepine

Ahmad Beydoun

Wassim M. Nasreddine

Fiorenzo Albani

Introduction

Although oxcarbazepine (OXC) has been available for many years in Europe, it was only approved by the Food and Drug Administration (FDA) for use in the United States in early 2000. Since its launch its use for partial epilepsy has increased, and it is currently considered by experts as a first-line medication for all partial-onset seizures.[32]

Chemical Structure and Methods for Determination in Body Fluids

OXC (10,11-dihydro-10-oxo-5H-dibenz[b,f]azepine-5-carb-oxamide; Trileptal, Timox, Tolep) is a derivative of carbamazepine, from which it differs by a ketone group at position 10. OXC is a white to faintly orange crystalline powder. It is slightly soluble in chloroform, dichloromethane, acetone, and methanol and practically insoluble in ethanol, ether, and water. Its molecular weight is 252.3. Its main metabolite, mono-10-hydroxy derivative (MHD), is a neutral lipophilic compound with a molecular weight of 254.3. Chemically, MHD is a racemic compound composed of *R*(–) and *S*(+)-MHD.

OXC and MHD levels can be determined in biologic matrices by high-performance liquid chromatography (HPLC) and gas chromatography.[23,36] HPLC is the most common procedure, and specialized methods continue to be developed for use in routine therapeutic drug monitoring,[19] in pharmacokinetic studies requiring the analysis of metabolites,[13] and in the separation of the MHD enantiomers.[58] Currently, no immunoassays for the determination of OXC or MHD are commercially available.

Pharmacology and Mechanisms of Action

In animal models, OXC and MHD are active against tonic extension seizures induced by maximal electroshock and against focal seizures in monkeys with chronic aluminum foci; they have little or no activity against clonic seizures induced by phenothiazine, picrotoxin, and strychnine. This anticonvulsant profile is similar to that of carbamazepine.[60] The main mechanism of action of OXC and MHD is assumed to be the use-dependent inactivation of voltage-gated brain sodium channels.[38,51] Limited experimental data suggest that some of their anticonvulsant effects are mediated through action at the potassium channels and at the high-threshold, voltage-gated type N- and/or P- and/or R-type Ca^{2+} channels,[38,51,60] actions that may differentiate OXC from carbamazepine.[49]

Clinical Pharmacokinetics

The clinical pharmacokinetics of OXC have been recently reviewed.[23,36] Plasma concentrations of OXC in chronically treated patients are very low with respect to MHD, and MHD is assumed to be the clinically relevant compound. Most pharmacokinetic and disposition studies focus on the racemic MHD, and only limited data are available for the separate enantiomers.

Absorption

After oral administration OXC is rapidly absorbed from the gastrointestinal tract, with a bioavailability >90%; peak concentration (C_{max}) of OXC and MHD occurs within 1 to 3 hours and 4 to 6 hours, respectively.[23,36]

The effect of food on the pharmacokinetics of OXC, at least with the currently marketed pharmaceutical preparation, is minimal, and without therapeutic relevance.[23,36]

Plasma Protein Binding and Distribution

The reported apparent volume of distribution (V_d) of MHD ranges from 0.3 L/kg (estimated from urine data) to 0.7 to 0.8 L/kg.[36]

Approximately 40% of the total MHD is bound to plasma proteins, mainly albumin. Data are consistent for healthy volunteers and patients with different pathologies. The binding seems to be independent of serum concentration within the therapeutically relevant range. Protein binding of OXC is slightly higher, at about 60%.[36]

The erythrocytes/plasma concentration ratio in various studies ranged from 0.88 to 1.34,[31] to 0.9 to 1.75,[27] to 1.4 to 1.9,[55] suggesting some accumulation in erythrocytes.

Published data on brain and cerebrospinal fluid (CSF) concentrations of MHD and OXC are scanty. May et al.,[36] citing their own unpublished data and data on three patients reported by Christensen et al.,[17] indicated that MHD CSF concentrations are 50% to 60% of total plasma concentrations. Similarly, citing their own unpublished data in 13 patients undergoing surgery for epilepsy, May et al.[36] reported slightly lower (by about 14 ± 6%) MHD concentrations in the neocortex as compared to serum. In a recent paper, Marchi et al.[35] studied nine patients undergoing brain surgery for epilepsy and found that brain and plasma concentrations of MHD did not correlate (brain-to-plasma ratio ranging from 1% to 103%), whereas in eight patients, the MHD brain-to-plasma ratios were correlated to the level of expression of the multidrug transporter MDR1 mRNA, measured in resected epileptic hippocampal or cortical tissues. The same paper showed that MHD is also a substrate for the multidrug transporter protein P-gp. Clinckers et al.[18] indicated that OXC is a substrate for multidrug transporters at the blood–brain barrier.

OXC and MHD can be transferred significantly through the placenta in humans, with comparable concentration in the maternal and umbilical cord serum. Concentrations of OXC and MHD in breast milk are about 50% of the corresponding plasma concentrations.[23,36]

Metabolism

After administration, OXC undergoes presystemic metabolic 10-keto reduction to MHD mediated by cytosol arylketone reductases. MHD is then cleared by uridine diphosphate glucuronyl-transferase (UGT)-mediated glucuronide conjugation and, to a lesser extent, by cytochrome P450 (CYP)-mediated oxidation to 10,11-trans-di-hydroxy metabolite (dihydroxy derivative [DHD]), an inactive metabolite also derived from carbamazepine.

The reduction of OXC to MHD is stereoselective, with the formation of (S)-(+)-MHD and (R)-(–)-MHD. After oral administration of OXC to healthy volunteers, the plasma concentration-time curves (AUC) of the (S)- and (R)-enantiomers were in the ratio of about 4:1.[10,23,36] As the two enantiomers seem to have similar anticonvulsant properties,[51] this pharmacokinetic imbalance probably lacks clinical relevance.

Elimination

OXC exhibits first-order linear kinetics during long-term administration. MHD plasma concentrations vary linearly with the OXC dose within patients, although marked interindividual variability was observed.

Elimination half-lives of 1 to 5 hours for OXC and of 7 to 20 hours (mean values) for racemic MHD were reported in studies of healthy volunteers after single or repeated doses of OXC. The half-life can be shorter in pediatric patients and in patients treated with enzyme-inducing antiepileptic drugs (AEDs).[36]

After single-dose administration in healthy volunteers, some authors described a monoexponential decay of MHD, whereas others observed a biphasic MHD concentration-time curve, suggesting that the metabolism of OXC is a saturable process, and that enterohepatic recirculation of OXC might occur. The possibility that OXC reduction is a saturable process at higher dosages is also suggested by a clinical case of attempted suicide with a large dose of OXC (about 30 g), where higher ratios of OXC to MHD concentrations were found.[57]

Reported values of renal clearance (CL_R) of MHD in healthy volunteers (young adults) ranged from 12 to 14 mL/min to about 58 mL/min.[36] Methodologic differences between the various studies probably contribute to the wide variability observed. Renal clearance did not differ between the (R)- and the (S)-enantiomers.[10]

Pharmacokinetics in Special Populations

Most available data on OXC and MHD kinetics in children are published as abstracts only. Children younger than 5 to 6 years show higher renal clearance, lower dose-normalized AUC of MHD, and a shorter MHD half-life than adults and older children.[23,36] Consequently, an increased dose in mg/kg body weight may be needed in children to achieve plasma levels similar to those of adults.

In elderly subjects aged 60 to 82 years, the dose-normalized AUC of MHD was higher than in young adults (18 to 32 years) and related to creatinine clearance, suggesting that the differences in pharmacokinetics are due to impaired MHD renal clearance with age. Consistently, a modest effect of age on MHD concentrations was observed in patients.[23,36]

Bulau et al.[14] reported similar plasma concentrations of OXC and MHD in a newborn girl and in the treated mother. Concentrations of both compounds in the newborn declined rapidly over days in spite of the availability of both compounds via breast milk.

Therapeutic Drug Monitoring

No clearcut relationship between plasma concentrations and clinical effects has been demonstrated for OXC or MHD. Therapeutic drug monitoring of MHD can be useful in titrating patients whose epilepsy is difficult to control and in cases of questionable compliance and drug–drug interactions, or to confirm concentration-related drug toxicity. As for many other AEDs, however, a precise optimal interval of MHD plasma concentrations has not been defined in prospective controlled studies, but derived from clinical trial data and clinical experience. The most often reported values range from 12.5 to 15.0 µg/mL to 30 to 35 µg/mL.[30]

Efficacy

Partial-Onset Seizures

OXC is approved in the European Union and the United States for initial monotherapy, conversion to monotherapy, and adjunctive therapy in children and adults suffering from partial-onset seizures. Its efficacy was established in a number of multicenter, double-blind, randomized clinical trials in varying patient populations with localization-related epilepsy, ranging in severity from the newly diagnosed to the medically refractory patients being evaluated for epilepsy surgery.

Active-Control Comparative Monotherapy Trials in Newly Diagnosed Epilepsy

The efficacy of OXC was evaluated in four comparative, double-blind, parallel-group trials conducted in adults[11,16,20] and children[29] with newly diagnosed epilepsy. The trial design was similar across all four trials. Patients who had experienced a minimum of two seizures in the preceding 6 months were randomized to treatment with OXC versus phenytoin,[11,29] valproate,[16] or carbamazepine.[20] The trials consisted of an 8-week titration phase followed by a 48-week maintenance phase. OXC was initiated at 300 mg/day on a tid schedule (150 mg/day in the trial conducted in children and adolescents) and gradually titrated biweekly based on the clinical response during the 8-week titration phase. The primary efficacy variable was the percentage of patients who remained seizure free throughout the 48-week maintenance phase. Secondary outcome variables included the percentage of patients who exited due to adverse events and treatment retention.

There were no significant differences in the primary efficacy variable between OXC and the comparator drugs in any of the trials (Table 1). The median daily doses of OXC during the maintenance phase of the three adult trials were 1,053 mg, 1,028 mg, and 1,040 mg (mean dose). The corresponding values for phenytoin, valproate, and carbamazepine were 313 mg, 1,146 mg, and 684 mg (mean dose), respectively. For the trial conducted in children and adolescents, the median daily doses of OXC and phenytoin were 18.8 mg/kg and 5.8 mg/kg, respectively. OXC was, however, better tolerated than phenytoin or carbamazepine based on significantly lower exit rates due to adverse events (Table 1). There was no significant difference in exit rates due to adverse events between OXC and valproate.

Although those trials are frequently alleged to demonstrate equivalent efficacy of OXC to that of the standard AEDs, it is important to note that these studies were not powered as

equivalence or noninferiority trials. The controversies surrounding the interpretative difficulties of equivalency trials were recently discussed.[7]

Table 1 Active-control Comparative Trials of Oxcarbazepine in Patients with Newly Diagnosed Epilepsy

	Patients (No.)	Daily dosage (mg)	Seizure free	Exit rate	Exit rate due to AE
OXC vs. PHT (5–18 yr)[29]	OXC (97) PHT (96) Total (193)	OXC (300–1,350) PHT (100–400)	OXC 61% PHT 60%	OXC 24% PHT 34%	OXC 2%[a] PHT 14%
OXC vs. VPA (15–65 yr)[16]	OXC (128) VPA (121) Total (249)	OXC (600–2,400) VPA (600–2,700)	OXC 56.6% VPA 53.8%	OXC 52% VPA 41%	OXC 15% VPA 10%
OXC vs. PHT (16–65 yr)[11]	OXC (143) PHT (144) Total (287)	OXC (600–2,100) PHT (100–650)	OXC 59.3% PHT 58.0%	OXC 56% PHT 61%	OXC 5%[a] PHT 16%
OXC vs. CBZ (14–63 yr)[20]	OXC (94) CBZ (100) Total (194)	OXC (300–1,800) CBZ (300–1,400)	OXC 52% CBZ 60%	OXC 16% CBZ 27%	OXC 14%[a] CBZ 25%

AE, adverse events; CBZ, carbamazepine; OXC, oxcarbazepine; PHT, phenytoin; VPA, valproate.

Monotherapy Trials in Patients with Refractory Focal Epilepsy

The definitive evidence of OXC efficacy as monotherapy was established in randomized, double-blind, placebo-controlled, and dose-response multicenter clinical trials.[8,44,48] In a 10-day trial, inpatients admitted for presurgical epilepsy monitoring were randomized to treatment with OXC at 2,400 mg/day versus placebo.[48] This trial incorporated specific exit criteria to maximize patient safety. Time to exit and completer rates were significantly in favor of the OXC-treated patients. This study demonstrated that OXC administered as monotherapy possesses short-term anticonvulsant properties.

The extended efficacy of OXC as monotherapy was demonstrated in two outpatient trials, conducted in patients with medically refractory localization-related epilepsy.[8,44] In the first trial patients experiencing two to 40 seizures per month while maintained on one or two baseline AEDs were randomized to OXC at 2,400 mg/day or 300 mg/day administered on a twice-daily schedule.[8] In this trial, patients randomized to the high daily OXC dose had a significantly longer time to exit, based on individualized exit criteria related to baseline seizure frequency. In addition, 42% of patients randomized to the OXC 2,400-mg/day group experienced a 50% or better improvement in their monthly seizure frequency compared to baseline and 12% remained seizure free throughout the 126-day double-blind treatment phase. This study established the efficacy of OXC as monotherapy, and demonstrated that conversion to OXC as monotherapy can result in significant improvement in seizure frequency in a proportion of patients with medically refractory partial epilepsy.[8]

The second trial was an enrichment design clinical dose-response study,[44] which also showed significantly better efficacy with high-dose compared to low-dose OXC.

Adjunctive Therapy Trial in Refractory Patients with Focal Epilepsy

The efficacy and tolerability of adjunctive therapy with OXC was evaluated in two large, multicenter, double-blind, placebo- and dose-controlled clinical trials.[5,26] In the adult trial, 694 patients with medically refractory partial epilepsy and experiencing at least four partial-onset seizures per month while maintained on one to three AEDs were randomized to add-on treatment with placebo, OXC 600 mg/day, OXC 1,200 mg/day, or OXC 2,400 mg/day.[5] There was a statistically significant reduction in seizure frequency at all three OXC doses compared to placebo. In addition, there was a dose-response relationship with mean reductions in seizure frequency of 8%, 26%, 40%, and 50%, for patients randomized to placebo, OXC 600 mg/day, OXC 1,200 mg/day, and OXC 2,400 mg/day, respectively.[5] The premature discontinuation rates because of significant adverse events were also dose related with 12%, 36%, and 67% exiting from OXC 600 mg/day, OXC 1,200 mg/day, and OXC 2,400 mg/day, respectively, compared to 9% for placebo. Although this study clearly demonstrated the efficacy of adjunctive therapy with OXC in adult patients with medically refractory partial epilepsy, it also showed that OXC can be associated with side effects in a substantial proportion of patients treated with high doses as adjunctive therapy.

In the pediatric trial, 267 children (3 to 17 years) experiencing at least eight partial-onset seizures during a 56-day baseline period while maintained on constant doses of one to two AEDs were randomized to placebo or OXC titrated to 30 to 46 mg/kg per day.[26] Adjunctive treatment with OXC resulted in significant improvement in seizure frequency with median reductions of 9% and 35% for the placebo and OXC groups, respectively. In this trial, OXC was better tolerated than the adult trial, with a 10% premature discontinuation rate due to adverse events.

Other Seizure Types

Although OXC was not evaluated in randomized clinical trials in patients with generalized epilepsies, there are anecdotal data that it might exacerbate seizures in juvenile myoclonic epilepsy[25] and in children with benign epilepsy of childhood with centrotemporal spikes.[15]

Adverse Events

Neurologic

In the pivotal and open-label long-term trials, OXC adverse events were most commonly related to the central

nervous system (CNS) and included dizziness, headache, and fatigue.[8,44,48,52] Less frequently reported neurologic events were insomnia, ataxia, diplopia, tremor, somnolence, and visual dysfunction.[9,44] These side effects were dose related and more frequent when OXC was used as part of a polytherapy regimen.[8,9]

Gastrointestinal

Gastrointestinal adverse events included nausea, vomiting, dyspepsia, and diarrhea.[8,9,44,48] These adverse events were mild to moderate in severity and typically occurred during the early phase of treatment.[8,44,52] Although OXC can cause elevation of liver function tests, it is not associated with significant hepatic toxicity.

Metabolic

Significant hyponatremia (defined as serum sodium below 125 mmol/L) was noted in 2.5% of the 1,524 patients who participated in the controlled epilepsy trials.[56] More recent data suggest that the incidence of significant hyponatremia is higher.[22] The frequency of mild hyponatremia (sodium level below 135 mmol/L) is higher and estimated at 20% to 30%[22,52] compared to 13.5% in carbamazepine-treated patients.[22] Mild hyponatremia is usually asymptomatic, and rarely results in morbidity or drug discontinuation.[24,42,43,49,52]

Hyponatremia is uncommon in children[12] and has higher incidence with increasing age and with the concomitant use of sodium-depleting drugs.[22,33,46]

The mechanism for OXC-induced hyponatremia is not due to the syndrome of inappropriate secretion of antidiuretic hormone and is possibly related to a direct effect of OXC on the renal collecting tubules or an enhancement of the effect of circulating antidiuretic hormone.[45]

Hyponatremia is managed through water restriction, reduction of the dose of OXC, and, if necessary, discontinuation of the medication.[53]

Other Side Effects

Skin rash occurred less frequently with OXC compared to carbamazepine. The frequencies of cutaneous reactions among 2,436 patients on OXC and 277 patients taking carbamazepine were 3% and 7%, respectively.[50]

More severe cutaneous reactions were also reported. Two cases of exfoliative dermatitis occurred with OXC treatment.[6] More recently, a labeling update issued by the FDA warned that serious dermatologic reactions occurred in adults and children on OXC, including Stevens-Johnson syndrome and toxic epidermal necrolysis. The reporting rate of those serious cutaneous reactions exceeded the background incidence rate estimates by a factor of three- to 10-fold. In a study that evaluated the risk of cross-sensitivity between OXC and carbamazepine, it was found that 27% of 51 patients with a rash on carbamazepine developed an allergic cutaneous reaction to OXC. In the majority of those cases, the rash on OXC appeared during the first month of treatment.[21]

Teratogenicity

A recent study of seven prenatal exposures to OXC monotherapy reported no major malformations.[40] In another cohort from Finland, one urogenital malformation was identified among 99 babies with prenatal exposure to OXC monotherapy.[4] Lastly, in 55 prenatal exposures to OXC (20 polytherapy and 35 monotherapy), only one cardiac congenital malformation in a patient receiving a combination of OXC and phenobarbital was identified.[39]

Drug Interactions

When OXC is substituted for an inducing drug in polytherapy, the clinical status of the patient and the plasma concentrations of other AEDs should be closely monitored, as partial or total enzyme deinduction may increase plasma concentrations of the other drug(s).[2]

In general, OXC treatment has a modest enzyme-inducing effect, more evident at high doses and related to the action on specific isoforms of CYP enzymes.[2] Indeed, in vitro studies showed that OXC and MHD induce only CYP3A4 and 5 isoforms. On the other hand, Lakehal et al.[34] showed in human liver microsomes that MHD is a competitive inhibitor of CYP2C19, an enzyme involved, for example, in the metabolism of phenytoin. OXC and MHD showed a modest inducing effect on UGT enzymes in vitro.[23,36]

Effects of Oxcarbazepine on Antiepileptic Drugs

In patients treated in polytherapy with OXC, carbamazepine concentrations can be reduced by about 15% on average, whereas the concentrations of phenytoin and phenobarbital may be increased to the same extent.[2,47] Particularly in patients treated with phenytoin at high doses and in the presence of high concentrations of MHD, the increase in phenytoin levels may be clinically relevant (up to +40%).[2]

A recent well-designed study in 47 healthy subjects[54] found no significant effect of OXC cotreatment on lamotrigine AUC or C_{max} at steady state. In patients cotreated with OXC, however, May et al.[37] reported a reduced lamotrigine level-to-dose ratio (–33%) with respect to lamotrigine monotherapy, and Weintraub et al.[59] reported that the clearance of lamotrigine was increased by approximately one third, an effect considered to be of possible clinical relevance. A similar trend was observed by Sallas et al.[47] in children with MHD concentrations in the range of 12 to 25 µg/mL, whereas only a nonsignificant reduction of the MHD concentration–to–OXC dose ratio (about –10%) was reported by Armijo et al.[3] in children and adults.

Effects of Oxcarbazepine on Other Drugs

In healthy volunteers, OXC did not significantly modify the action of warfarin as measured by prothrombin time (mean Quick values 36.6% at baseline, 38.1% after OXC), whereas it reduced the absolute bioavailability of the calcium antagonist felodipine from about 15% to about 10%. However, no patient data are available for either drug.[2]

OXC treatment reduces the bioavailability of the estrogen and Prostagen components of oral contraceptives, probably through induction of CYP3A-mediated metabolism. Thus, the same precautions exercised with enzyme-inducing AEDs also apply to OXC.[2]

In psychiatric patients OXC treatment did not modify the concentration of risperidone (and its active metabolite 9-hydroxy- risperidone) or olanzapine.[41]

Effects of Antiepileptic Drugs on Oxcarbazepine

Inducing AEDs like phenobarbital, phenytoin, and carbamazepine was found to decrease MHD AUC in adults and

children.[2,47] In most cases these changes of OXC and MHD are modest, but the interaction may become clinically relevant in some patients.

Theis et al.[54] reported that MHD kinetics was not significantly affected by lamotrigine treatment in healthy volunteers. However, Guenault et al.[28] reported a twofold higher ratio of MHD concentration to OXC dose in a small group of patients treated with lamotrigine cotherapy with respect to OXC monotherapy.

Gabapentin, felbamate, and benzodiazepines like clonazepam, diazepam, and possibly clobazam have no clinically relevant interactions with OXC. Similarly, valproic acid may decrease MHD plasma binding, but the interaction is probably clinically irrelevant and the association with valproic acid should not require any adjustment of OXC dosages.[2,47]

Effects of Other Drugs on Oxcarbazepine

Cimetidine and erythromycin (studied in healthy volunteers) and dextropropoxyphene (studied in patients) had no major influence on the pharmacokinetics of OXC and MHD. Verapamil (240 mg/day for 1 week) decreased the MHD AUC by 20% compared with baseline in healthy volunteers stabilized on OXC 900 mg/day, an effect that remains to be explained. A 10-day add-on treatment with viloxazine in six epileptic patients receiving chronic OXC monotherapy (1,500 ± 465 mg/day), increased MHD concentrations by 11% and decreased DHD concentrations by 31%, an effect considered by the authors not to be of clinical relevance.[2]

Clinical Use

The concordant results of a large number of well-controlled clinical trials have clearly established OXC as an efficacious and safe drug for the treatment of partial-onset seizures. Its advantages over phenytoin and carbamazepine include better tolerability and a more favorable pharmacokinetic profile. The package insert recommends a starting dose of 300 mg twice daily with weekly a increment of 300 to 600 mg until an efficacious dose is reached. Clinical experience, however, has shown that this titration schedule, derived from that used in the pivotal randomized clinical trials, is frequently associated with adverse events, predominantly somnolence, dizziness, fatigue, and gastrointestinal disturbances. This is particularly true for elderly patients and for patients with newly diagnosed epilepsy naive to antiepileptic drug treatment. It is therefore important to individualize the starting dose and the titration schedule based on seizure frequency and severity. In certain situations it is appropriate to initiate treatment at 150 mg twice daily with weekly increments of 300 mg until a target dose is reached. In certain cases, administering the total daily dose of OXC during the titration phase on a three-times-a-day schedule can improve tolerability. For the newly diagnosed patients with localization-related epilepsy, the active-control clinical trials have uniformly found that the median effective dose of OXC was around 1,000 mg/day. Breakthrough seizures in the compliant patient are managed by a 300-mg increment in the daily OXC dose.

For patients with localization-related epilepsy poorly controlled on another antiepileptic drug, conversion to OXC as monotherapy can be attempted acutely or gradually. Some have advocated a so-called “overnight switch” in which the baseline antiepileptic drug is stopped acutely and treatment with OXC at its full target dose is initiated.[1,21] This has been particularly advocated for patients converted from carbamazepine monotherapy, for whom the target dose of OXC has been recommended to be 1.2 to 1.5 times the daily dose of carbamazepine. Other reports have advocated a more gradual crossover with a gradual increment of OXC and a gradual taper of the baseline AED over 3 to 4 weeks.[21]

When used as part of a polytherapy regimen, the addition of OXC can result in a substantial improvement in seizure frequency, but can be associated with significant adverse events, especially at daily doses above 900 to 1,200 mg. When higher daily doses of OXC are deemed to be necessary, it usually requires a concomitant reduction in the dose of the baseline AED.

In addition to the CNS and gastrointestinal adverse events, OXC can be associated with lowering of the serum sodium level. Although this is usually of inconsequential clinical relevance, the hyponatremia can, on occasion, be severe enough and lead to obtundation, gastrointestinal disturbances, and worsening of seizure frequency. Although this can occur in any patient, those at particular risk include the elderly and those being treated with natriuretic drugs. It is therefore advisable to check the serum sodium level prior to initiating OXC and to have a follow-up sodium level determination during the first 2 to 3 months of therapy.[53]

Summary and Conclusions

OXC is believed to exert its anticonvulsant effect through use-dependent inactivation of voltage-gated brain sodium channels. Overall, it has a favorable pharmacokinetic profile and minimal drug-drug interactions when used with other hepatically metabolized drugs.

OXC is an effective first line AED for localization related epilepsy, and appears to be better tolerated than phenytoin and carbamazepine. It can be associated with dose-related CNS and gastrointestinal adverse events, and can lead to lowering of the serum sodium level especially in the elderly and with the concomitant use of natriuretic drugs.

Chapter 153

Phenobarbital and Other Barbiturates

Mervyn J. Eadie

Patrick Kwan

Introduction

The antiepileptic effect of phenobarbital (phenobarbitone) was described by Alfred Hauptmann as long ago as 1912,[29] a little more than half a century after Locock, in 1857, had recognized what proved to be the first effective antiepileptic agent, potassium bromide. Phenobarbital has been in continuous use as an antiepileptic agent for nearly a century. In recent years, its popularity in developed countries has declined, although it and its congener primidone still account for some 14% of all antiepileptic drug (AED) use in Britain.[52] It is more widely used in less affluent societies and, on a global scale, remains one of the most important AEDs. Phenobarbital possesses a broad spectrum of antiepileptic activity and an effectiveness similar to that of many other marketed AEDs. It is safe, cheap, and available in convenient oral and parenteral dosage forms. These advantages have led some investigators to call for renewed scientific study to enhance its proper use in the modern therapeutic era.[42]

Attempts have been made to modify the phenobarbital molecule to derive agents with greater efficacy and lesser toxicity. Primidone (desoxyphenobarbital) has gained a place as an established antiepileptic agent in its own right (see Chapter 158). However, at least part of its pharmacologic action is effected via phenobarbital, to which it is metabolized in the body. The *N*-methyl analog of phenobarbital, mephobarbital (*N*-methylphenobarbitone), was introduced into therapeutics by Blum in 1932.[8] In some places, it was preferred to phenobarbital although its use appears to be declining. Phenobarbital and mephobarbital analogs that lack an aromatic ring on the 5-carbon atom of the barbiturate ring (barbital and metharbital) also possess antiepileptic properties. However, few data concerning them are available, and they now appear to be little used. Eterobarb (1,3-dimethoxymethylphenobarbital) underwent some modern scientific studies, but thereafter it did not seem to achieve any widespread clinical use. Only phenobarbital, and to an extent mephobarbital, will be discussed further.

Chemistry, Formulations, Assay

Chemistry

Phenobarbital (5-ethyl-5-phenylbarbituric acid) is a white crystalline material with a pKa of 7.2. Mephobarbital (5-ethyl-1-methyl-5-phenylbarbituric acid) is chiral at the carbon atom at the 5-position of the barbiturate ring by virtue of the methyl group substituent on the 1-position of the barbituric acid molecule. It is supplied commercially as a racemate. The racemic material is more lipophilic than phenobarbital and has a pKa value of 7.8.

Figure 1 shows the formulas and metabolic pathways for phenobarbital (5-ethyl-5-phenylbarbituric acid), *r*-(-)-mephobarbital, and *s*-(+)-mephobarbital.

Formulations

Phenobarbital has been marketed either as the acid or the sodium salt in 15-, 30-, 50-, 60-, and 100-mg tablets. However, not all strengths may be available in all countries. Oral solutions of various strengths containing sodium phenobarbital can be prepared. Parenteral solutions of the drug usually contain 100 or 200 mg of the sodium salt.

Mephobarbital has been marketed as 30-, 32-, 50-, 60-, 100-, and 200-mg tablets.

Assay

Phenobarbital in biologic fluids has been measured by ultraviolet spectrophotometry, gas and liquid chromatography, and various immunoassay methods. Mephobarbital is usually measured by gas or liquid chromatography, although methyl derivative formation for gas chromatography results in any phenobarbital that is present after biotransformation being measured as mephobarbital.

Pharmacology

Mephobarbital is biotransformed to phenobarbital, and it is believed that most of the anticonvulsant action of mephobarbital depends on this metabolic product. However, there is some indirect evidence that intact *R,S*-mephobarbital probably has an antiepileptic effect[14] whose mechanism is not established. Only the mechanism of action of phenobarbital is considered further in this chapter.

Seizure Models

Inconsistent reports are available of phenobarbital's effects on epileptic activity in experimental seizure foci in animals.[23] The drug appears to limit the spread of activity from such foci, probably by interfering with synaptic neurotransmission.[25] Consistent with its clinical effect against generalized tonic–clonic seizures, phenobarbital is effective in the maximal electroshock model. It is also active against pentylenetetrazol-induced seizures, although it has no effect against human absence seizures.[81]

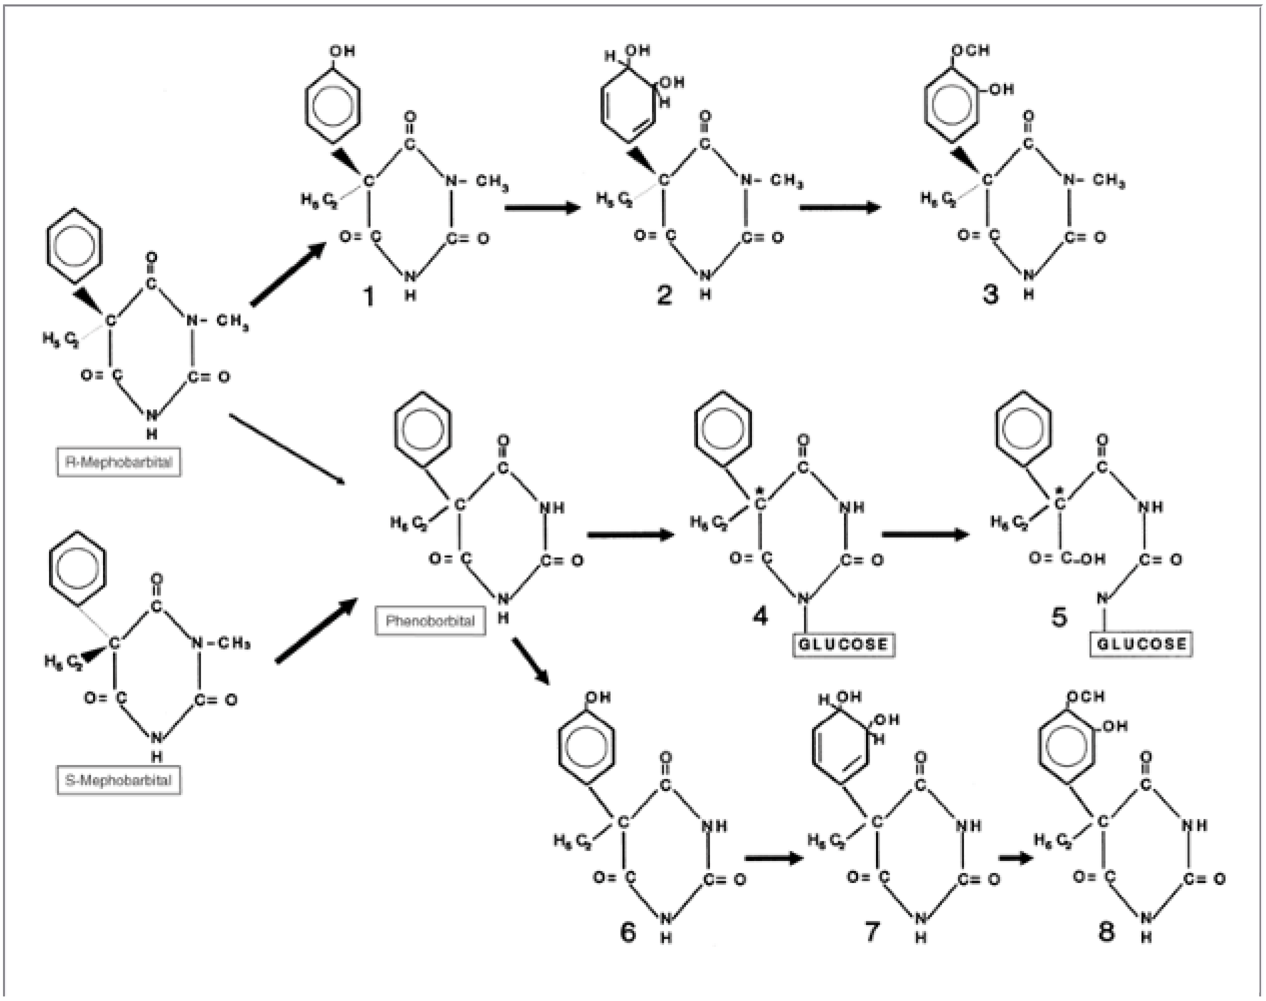

FIGURE 1. Chemical formulas and known metabolic pathways for mephobarbital and phenobarbital. *1*, *p*-Hydroxy derivative of *R*-mephobarbital. *2*, Diol derivative of *R*-mephobarbital. *3*, *O*-Methyl catechol derivative of *R*-mephobarbital. *4*, Phenobarbitone-*N*-glucoside (the asymmetric carbon atom is marked with an *asterisk*, but the structures of the separate enantiomers are not drawn). *5*, Barbiturate ring-opened derivatives of phenobarbitone-*N*-glucoside. *6*, *p*-Hydroxy derivative of phenobarbital. *7*, Diol derivative of phenobarbital. *8*, *O*-Methyl catechol derivative of phenobarbital. Many of the metabolites containing a hydroxyl group are excreted in part as glucuronides.

Mechanism of Action

Although a number phenobarbital's biochemical actions have been described, such as inhibition of mitochondrial electron transport, some are significant only at drug concentrations

P.1600

appreciably higher than those at which an antiepileptic effect occurs in clinical use. It is thought that phenobarbital acts as an anticonvulsant mainly by prolonging the opening of the postsynaptic cell membrane chloride (Cl^-) channel, a component of the γ-aminobutyric acid (GABA)-A receptor.[5] The resultant increase in Cl^- flux tends to hyperpolarize the postsynaptic neuronal cell membrane, thus impeding the transmission of epileptic activity. At concentrations higher than the usual human therapeutic ones, it may also affect voltage-dependent sodium (Na^+) channels to diminish rapid neuronal firing.[47]

Clinical Pharmacology

Absorption

Phenobarbital is virtually fully bioavailable after oral administration[54] and appears to be absorbed fairly rapidly. Eadie et al.[21] calculated the mean absorption half-time as 1.37 hours. It has sometimes been stated that the drug is slowly absorbed, but this assertion appears to be based on the finding that the peak plasma concentration did not occur until some 6 to 18 hours after intake.[46] However, the time of maximal concentration (T_{max}) of a drug occurs when its elimination rate equals its absorption rate. The slow elimination of phenobarbital could have accounted for its late T_{max}. More recent studies suggest a T_{max} of 0.5 to 4 hours after oral administration, compared with 2 to 8 hours after intramuscular injection.[54,80] Generally little difference is noted in T_{max} or bioavailability between the oral and intramuscular routes of administration.[78]

The oral dose of mephobarbital on a molar basis must be approximately twice that of phenobarbital to achieve the same steady-state plasma concentration of the latter. Because of this, it has sometimes been assumed that mephobarbital has only a 50% oral bioavailability. However, Hooper et al.[33] showed in two subjects that oral *R,S*-mephobarbital was 75% bioavailable, and in further work showed that the oral clearance of *R*-mephobarbital (approximately 0.5 L/kg per hour) was high enough to suggest that this enantiomer of the drug probably underwent significant presystemic elimination,[34] at least in extensive metabolizers of the enantiomer. Therefore, the reduced oral bioavailability of *R,S*-mephobarbital is probably due to appreciable presystemic metabolism rather than incomplete

P.1601

absorption. The absorption half-time for *R,S*-mephobarbital was 0.48 and 0.38 hours in two subjects,[33] and the mean T_{max} for *R*-mephobarbital was 2.29 ± SD 1.03 hours and that for *S*-mephobarbital was 3.50 ± SD 1.52 hours.[21] However, the absorption parameters of *R,S*-mephobarbital and its individual enantiomers are less relevant clinically than the time (around 4 or 5 days) when peak plasma concentrations of derived phenobarbital occur after a dose of mephobarbital.

Distribution

The value of the apparent volume of distribution of phenobarbital in humans (approximately 0.5 to 0.7 L/kg) suggests that the drug is distributed throughout body water, with little selective regional or tissue concentration. Some 50% to 60% of the phenobarbital in plasma is protein-bound. Concentrations of phenobarbital in the cerebrospinal fluid correlate with its unbound serum levels.[46] In vivo studies in rats have shown that phenobarbital is a substrate of the efflux drug transporter P-glycoprotein, which is expressed at cerebral capillary endothelium. The clinical relevance of this remains to be determined, but growing evidence suggests that, by extruding AEDs from their intended site of action in the brain, overexpression of P-glycoprotein could potentially play an important role in the pathogenesis of pharmacoresistance in epilepsy.[43]

Compared with phenobarbital, *R,S*-mephobarbital has a higher apparent volume of distribution (mean, 132 L in adults).[20] This value correlates with the greater lipophilicity of the drug, suggesting that it may achieve higher simultaneous concentrations in tissues than in plasma. Craig and Shideman[14] found brain concentrations of *R,S*-mephobarbital were about eight times its simultaneous blood concentrations in rats. The mean apparent volume of distribution of *R*- and *S*-mephobarbital was 5.32 ± SD 3.33 L/kg and 1.73 ± SD 0.31 L/kg, respectively,[44] but the value for the former may have been overestimated. Approximately 67% of *R*-mephobarbital and 59% of *S*-mephobarbital in plasma are protein bound.[44]

Metabolism

Figure 1 depicts a metabolic schema for both barbiturate derivatives.

Phenobarbital

At steady state, a mean of 25% to 27% of a phenobarbital dose is excreted unmetabolized in urine.[7,82] Because the pKa of phenobarbital (7.2) is slightly above the usual pH of urine, any increase in the alkalinity of urine is likely to increase the ionized fraction of the drug in urine and the amount of intact phenobarbital excreted.

The majority of a phenobarbital dose is eliminated by hepatic metabolism via hydroxylation and glucosidation, with wide interindividual variability in the contributions from these routes. Hydroxylation is attributed to the cytochrome P450 (CYP) enzyme system, yielding a phenolic derivative (*p*-hydroxyphenobarbital), most of which is then conjugated, mainly with glucuronic acid, before being excreted in urine. This phenolic metabolite is thought not to be biologically active. It accounted for 16 ± SD 10% of the drug dose in the steady-state metabolic balance study of Bernus et al.[7] There is uncertainty over the precise CYP isoenzymes involved, but they would appear to include CYP2C9, with minor contributions from CYP2C19 and CYP2E1.[1] Reports on the influence of genetic polymorphism of CYP2C19 on the clearance of phenobarbital are conflicting.[28,49] Whether variation of the CYP2C9 gene affects the overall metabolism of phenobarbital has not been reported.

The urinary excretion of unmetabolized phenobarbital and its phenolic metabolite (conjugated and nonconjugated) accounts for approximately 40% of a drug dose.[7,82] In addition, phenobarbital undergoes *N*-glucosidation,[56,71] yielding *R*- and *S*-enantiomers of the glucoside. Bernus et al.[7] found that, under steady-state conditions, 14 ± SD 11% and up to 4% of a phenobarbital dose were excreted as the *S*- and *R*-enantiomers of the glucoside, respectively. Paibir et al.,[56] working with human liver microsomes, found a *S:R* glucoside ratio of 6.75 ± SD 1.34:1.0. Even when *N*-glucoside formation is taken into consideration, a considerable discrepancy still exists between a phenobarbital intake and the measured output of the drug's identified urinary excretion products. However, the *N*-glucosides of phenobarbital are pH-labile and begin to decompose once the environmental pH exceeds 5, forming barbiturate ring-opened derivatives.[77] The subsequent fate of these ring-opened compounds is unknown. In vitro, at 37°C and a pH of 7.4, *S*-phenobarbital-*N*-glucoside has a half-life of about 15 hours.[7] It is therefore possible that the phenobarbital-*N*-glucosides may undergo significant breakdown to as yet untraced derivatives while still present in the blood and tissues of the body, and also in urine while in the bladder. Hence *N*-glucosidation may possibly be the main elimination pathway for phenobarbital in humans.

Mephobarbital

Less than 3% of a mephobarbital dose is excreted in urine unmetabolized.[20] The biotransformation of the *R*- and *S*-enantiomers of the drug is relatively stereoselective. The *R*-enantiomer is metabolized by CYP2C19 to yield phenolic derivatives;[40] which are then transformed to glucuronides. The key role of CYP2C19 is evidenced by the much slower elimination of mephobarbital by subjects with the slow metabolizing alleles of the enzyme.[39] Excretion of 4-hydroxyphenobarbital (*p*-hydroxyphenobarbital) glucuronide, predominantly as the *R*-enantiomer, accounts for some 35% of an oral dose of the racemic drug.[33] It is likely that some of this 4-hydroxyphenobarbital is further metabolized to dihydrodiol and *O*-methyl catechol derivatives. A small amount of *R*-mephobarbital is oxidatively dealkylated to produce phenobarbital. [R]-mephobarbital may accumulate in plasma in poor metabolizers of the drug,[34] although the extent of the biologic activity of this enantiomer is not known. In contrast, *S*-mephobarbital does not undergo aromatic hydroxylation, but is oxidatively dealkylated to yield phenobarbital, some of which is then further metabolized, as described earlier. Some 8% to 25% of a dose of *R,S*-mephobarbital appears in urine as phenobarbital,[20] and phenobarbital formed from mephobarbital seems to account for most, if not all, of the drug's biologic activity under steady-state conditions. It is not known whether *N*-glucosides are formed from either mephobarbital enantiomer.

Elimination

Phenobarbital is a low-clearance drug. Its total plasma clearance is about 0.004 L/kg per hour in adults, and declines in old age (0.0032 L/kg per hour in those over 65 years, as compared with 0.0041 L/kg per hour in adults aged 20–50 years [51]), but is up to 0.012 L/kg per hour in young children. Consequently phenobarbital has a relatively long half-life (3 to 5 days in adults and 1.5 days in children) that decreases with repeated administration of the drug,[78] consistent with autoinduction of metabolism. Lim and Hooper,[44] in six volunteers, all probably extensive metabolizers, showed that the clearance of *S*-mephobarbital was relatively low (0.017 ± SD 0.001 L/kg per hour) with an average half-life of 69.8 ± SD 14.8 hours. The oral clearance of *R*-mephobarbital was much higher (about

P.1602

0.47 ± SD 0.18 L/kg per hour) and its half-life comparatively short (mean value, 7.5 ± SD 1.7 hours). Some evidence suggests that the clearance of *R,S*-mephobarbital is higher in the presence of enzyme-inducing agents.[20] Details of the effects of age and sex on the disposition of the individual enantiomers of mephobarbital have been published.[34]

Because of its long elimination half-life, steady-state conditions may not be achieved until 2 to 3 weeks after a change in the dosage of phenobarbital. Although steady-state conditions would be reached earlier than this for *S*-mephobarbital when *R,S*-mephobarbital is used, the more clinically important consideration in mephobarbital use is the time when steady-state conditions also apply for the phenobarbital formed from the parent drug.

Concentration–Effect Relationships

Plasma phenobarbital concentrations may be used as a guide to dosing. Because of the long half-life of phenobarbital, under steady-state conditions, its plasma concentrations show very little fluctuation during interdose intervals of as long as 24 hours. Hence, steady-state predose measurement of the drug's plasma concentration rarely offers advantages over measurements carried out at random stages during the dosage interval.

It has been proposed that plasma phenobarbital concentrations of 15 mg/L or higher would seem necessary to control seizures of a type likely to respond to the drug.[22] However, target plasma phenobarbital concentrations recommended in the literature and employed in randomized clinical trials have ranged from 10 to 45 mg/L.[9,19,30,50] There is also wide variation in the dosage required for seizure control as well as in that tolerated between individual patients due to various factors. For instance, evidence suggests that higher plasma concentrations might be needed to control partial than generalized tonic–clonic seizures.[66] In general, plasma phenobarbital levels above 35 to 40 mg/L are increasingly likely to be associated with sedation.

No information is available concerning plasma levels of the individual enantiomers of mephobarbital. Steady-state plasma levels of racemic mephobarbital (probably mainly levels of the *S*-enantiomer) average 10% to 14% of the simultaneous plasma phenobarbital levels; in practice, the latter provide an adequate guide to treatment with mephobarbital.

Efficacy

In the past, phenobarbital was widely employed as a sedative and tranquilizer. In many countries, it is used almost exclusively for the treatment of epilepsy. It is effective against partial seizures (whether or not they become secondarily generalized), tonic–clonic seizures associated with generalized epilepsies, and in some varieties of myoclonic seizures. It is not effective against absence seizures.

Meta-analysis of randomized controlled trials showed that phenobarbital had similar efficacy to phenytoin and carbamazepine for the treatment of partial and generalized tonic–clonic seizures, but was more likely to be withdrawn because of a greater incidence of adverse effects.[72,74] Controlled and uncontrolled studies conducted in developing countries where the drug is widely used suggest that phenobarbital is effective and well tolerated.[42]

Adverse Effects

Because phenobarbital begins to appear within a few hours following the administration of mephobarbital, it is not known whether either of the enantiomers of the latter has adverse effects in its own right. Therefore, the effects of both drugs will be considered together.

Dose-Related Effects

Phenobarbital can produce a range of dose-related neurotoxic effects, including sedation, behavioral problems, impaired cognition, and depressed mood and affect. Some tolerance to sedation may develop, particularly if the drug is introduced gradually and in progressive stages. It is not known whether humans develop true pharmacologic tolerance to the drug. Most of the data on the neurotoxicity of phenobarbital is derived from pediatric populations. Before the presence of sedation becomes apparent, it may have already slowed the patient's cognitive processes and possibly caused difficulty in thinking and learning. This may result in educational difficulties when the drug is used on a long-term basis in children.[70] Secondary behavioral disturbances may follow these difficulties, in part determined by the subject's underlying personality traits. Some patients taking the drug may become irritable, short-tempered, and aggressive, whereas others become morose and depressed, particularly if the dose has been titrated up too rapidly. At higher doses, sedation and mental slowing become more obvious; at high enough doses, depression of consciousness occurs. Paradoxically, young children sometimes react to increasing phenobarbital dosage by becoming hyperexcitable,[63] although this does not seem to occur if the same patients are again treated with the drug when they have become adults.

Although phenobarbital has produced marked cognitive and behavioral toxicity in studies performed in developed countries, it has been reported to be relatively well tolerated when used in the developing world.[57] Possible explanation for this discrepancy in tolerability might include the use of lower dosage in the latter, bias in open-label studies, medicosocial factors, and genetic influence.[42]

Long-continued phenobarbital intake may be associated with dose-related acceleration in vitamin D catabolism via induction of CYP enzyme activity, leading to decreased calcium absorption, secondary hyperparathyroidism, and osteomalacia, resulting in a higher tendency to bone fractures.[76] Regular measurement of bone density, and calcium and vitamin D supplements, should be offered to those patients at high risk, such as elderly, nonambulatory patients. Phenobarbital may also cause folate depletion, which may ultimately result in macrocytic anemia if left untreated.[17] Other recorded but uncommon, possibly dose-related, adverse effects of protracted phenobarbital intake include thickening of the heel pad,[65] Dupuytren contracture,[16] and a peculiar thickening of the facial features and the occurrence of a “shoulder–hand” syndrome.[18]

Idiosyncratic Reactions

Phenobarbital use has been associated with a number of rare, presumably idiosyncratic, unwanted effects. These include skin rashes that range in severity from a fine punctate erythema through large erythematous macules to exfoliative dermatitis,[48] agranulocytosis, aplastic anemia, hepatitis, and jaundice. There is a 40%

to 60% risk of cross-sensitivity to rash with other aromatic AEDs (carbamazepine and phenytoin).[3]

Second-Generation Effects

Reports of an association between phenobarbital intake during pregnancy and fetal malformations first emerged over 30 years ago,[69] but the increased risk did not reach statistical significance in a number of these older studies. Because it is difficult to obtain control data on the malformation rates in adequately

sized populations of pregnant women with equally severe but untreated epilepsy, it is hard to determine whether and to what degree any increased malformation rate in phenobarbital-exposed pregnancies is a consequence of the AED therapy or of the epilepsy for which it was prescribed. In a retrospective study, Shapiro et al.[67] found no increase in the fetal malformation rate in nonepileptic Finnish women who took phenobarbital as a sedative during pregnancy. There are reports that the risk is enhanced if phenobarbital is used during pregnancy in combination with phenytoin[45] or with ethosuximide.[64] An early prospective study suggested that the incidence (4 out of 79; 5.1%) of malformations in offsprings exposed to phenobarbital monotherapy in utero is similar to those exposed to other established AEDs.[38] Preliminary results from the U.S. Antiepileptic Drug Registry, which included similar numbers of prospective pregnancies with in utero exposure to phenobarbital, suggested a fetal malformation rate of 6.5% (5 out of 77) compared with a presumed background rate of 1.62%.[31] In this preliminary analysis, the malformation rate associated with phenobarbital exposure was not statistically significantly greater than that associated with other AEDs (23 out of 796; 2.9%), but the identity of these drugs was not given in the report and the sample size for analysis was relatively small. Analyses with larger number of pregnancies from this and other ongoing prospective pregnancy registries are awaited before definite conclusion regarding the teratogenicity of phenobarbital can be drawn.

Phenobarbital intake during pregnancy can be associated with coagulation defects in the newborn due to vitamin K deficiency as a result of CYP enzyme induction.[53] As with other enzyme-inducing AEDs, prenatal vitamin K_1 supplementation of 10 mg per day from the 36th week of gestation until delivery is recommended.[2] If prenatal vitamin K has not been administered, the vitamin may be given intravenously to the neonate at birth. Infants born to mothers who were treated with phenobarbital during pregnancy may be hypotonic and irritable during their first 3 postnatal days, possibly due to drug withdrawal.[24] Short-term (median 3.4 days) exposure to phenobarbital immediately before birth did not seem to affect the intelligence, achievement, and behavior of children when assessed at the age of 7 years,[73] but a retrospective study suggested that longer exposure could lead to lower verbal intelligence in adulthood.[62]

Drug Interactions

Pharmacodynamic interactions can occur between phenobarbital and other drugs with sedative properties and between phenobarbital and other AEDs. Whether combinations of phenobarbital with other AEDs could result in synergistic (supra-additive) effects in seizure control has not been well studied.[11] Phenobarbital has a strong propensity for pharmacokinetic interactions with other drugs. There is no published material concerning interactions with mephobarbital.

Effects of Phenobarbital on Other Drugs

Phenobarbital is a potent and nonspecific inducer of various microsomal enzymes including those of the CYP system,[13] such as isoforms CYP 1A2, 2B6, 2C9, 2C19, and 3A4,5,7, resulting in enhanced clearance of a large number of endogenous substances and drugs that undergo hepatic biotransformation. These endogenous substances include bile salts, cholesterol, lipids, bilirubin, cortisol, folate, renin, unconjugated estriol, testosterone, and vitamins D and E. Table 1 lists some of the drugs whose clearances are increased (and plasma concentrations reduced) by phenobarbital. As the knowledge regarding the CYP isoforms responsible for the metabolism of various drugs accumulates, the number of alleged interactions with phenobarbital continues to expand. Many of the more important interactions have been recently reviewed,[59] and regularly updated information is available in Internet databases (e.g., http://medicine.iupui.edu/flockhart/table.htm). It has been suggested that impaired absorption from the alimentary tract may be relevant in the cases of the interactions between phenobarbital and cyclosporin, cimetidine, or griseofulvin.[58]

Phenobarbital also induces certain uridine glucuronyl transferase isoforms (e.g., UGT 1A9[68]), and by this means may increase the clearance, and decrease the plasma concentrations, of lamotrigine. Phenobarbital induces formation of epoxide hydrolase, responsible for further metabolism of the biologically active 10,11-epoxide metabolite of carbamazepine. It also induces the formation of γ-glutamyl transpeptidase[75] and produces increased plasma concentrations of sex hormone–binding globulin.[35]

Effects of Other Drugs and Therapies on Phenobarbital

Phenytoin and carbamazepine intakes may raise plasma levels of phenobarbital,[27] although this interaction may not be consistent.[22,59] The intake of methsuximide and phenylacetyl-urea may also raise plasma phenobarbital concentrations. Valproate causes considerable increases in plasma phenobarbital concentrations,[10] because of impairment of the body's capacity to form phenobarbital-*N*-glucoside.[6] A range of other drugs can alter the plasma concentration of phenobarbital (Table 2).

Making the urine alkaline (e.g., by administration of ammonium chloride) increases the excretion of phenobarbital and thus lowers its plasma concentrations.[61] Intake of activated charcoal impairs the absorption of phenobarbital from the alimentary tract.[55] The administration of multiple doses of activated charcoal has been found to be more effective than urinary alkalinization in enhancing phenobarbital elimination.[26] In cases of severe overdose, elimination of phenobarbital can be expedited by charcoal hemoperfusion or conventional hemodialysis.[36]

Table 1 Selected Pharmacokinetic Interactions Between Phenobarbital and Other Drugs

Phenobarbital reduces plasma level of drugs			Drugs that increase plasma level of phenobarbital
Antiepileptic drugs	**Non-antiepileptic drugs**		**Antiepileptic drugs**
Carbamazepine*	Acetaminophen	Griseofulvin	Carbamazepine
Ethosuximide	(paracetamol)	Haloperidol	Phenytoin
Felbamate	Amlodipine	Lignocaine	Valproate
Lamotrigine	Atorvastatin	Meperidine	
Methsuximide	Bishydroxycoumarin	(pethidine)	**NON-ANTIEPILEPTIC**
Oxcarbazepine**	Buspirone	Mesoridazine	**DRUGS**
Phenytoin[†]	Chloramphenicol	Methadone	Acetazolamide
Remacemide	Chlorpromazine	Nimodipine	Frusemide
Tiagabine	Cimetidine	Nortriptyline	Methylphenidate
Topiramate	Cisapride	Ondansetron	Propoxyphene
Valproate	Clobazam	Oral	
Zonisamide	Cyclosporin	contraceptives	**DRUGS LOWER PLASMA**
	Cyclophosphamide	Phenylbutazole	**LEVEL OF**
	Diazepam	Salbutamol	**PHENOBARBITAL**
	Dicophane	Simvastatin	Chloramphenicol
	Dicoumarol	Tacrolimus	Dicumarol
	Diltiazem	Tamoxifen	Folate
	Dipyrone	Theophylline	Phenylbutazole
	Doxycycline	Thioridazine	Pyridoxine

Ethinylestradiol	Vincristine
Felodipine	Warfarin
	Zolpidem
	(folate)

Table 2 Average Daily Doses of Phenobarbital and Mephobarbital

Reference	Age group, yrs	Phenobarbital mg/kg	Mephobarbital mg/kg
Eadie et al., 1977[22]	<4	3.1	5
	4–14	2.3	5
	15–40	1.75	4
	>40	0.9	1.8
Messina et al., 2005[51]*	20–50	1.51	—
	65–90	1.19	—

The doses expected to achieve steady-state plasma concentrations of phenobarbital of 15 mg/L in persons of different ages reported in 2 different studies. Note wide inter-individual variation (see text).
*No statistically significant age-related decline in dosage within individual age groups was observed in this study.

Role in Epilepsy Treatment

Indications

In most clinical situations, phenobarbital and mephobarbital can be considered interchangeable, provided allowance is made for the need to use between 1.7 and 2.0 mg of mephobarbital for each 1 mg of phenobarbital to compensate for the consequences of the rapid elimination of *R*-mephobarbital, except in slow metabolizers. However, there has been an argument for preferring mephobarbital to phenobarbital. Within the range of plasma concentrations of phenobarbital usually encountered therapeutically, steady-state plasma concentrations of phenobarbital in the individual subject increase in direct proportion to the dose of *R,S*-mephobarbital. In contrast, when phenobarbital itself is prescribed, its steady-state plasma levels tend to increase more with each increment in dose than would be expected from the plasma level-to-dose ratio when the increase is made.[22] Thus, steady-state plasma concentrations of phenobarbital in the individual patient behave in a more predictable way when a mephobarbital dose is increased than when a phenobarbital dose is increased. Hence, less chance exists of producing unexpected overdosage effects if mephobarbital is used. This may have contributed to the word-of-mouth reputation that mephobarbital acquired of being less likely than phenobarbital to produce sedation in patients.

Phenobarbital is employed to treat the following:

- Neonatal seizures, for which phenobarbital and phenytoin are the agents usually recommended. This is partly because both are marketed in preparations suitable for parenteral use, the administration route often required in neonates.
- As a second- or third-line option for generalized tonic–clonic seizures and myoclonic seizures when valproate and possibly other AEDs have failed or are contraindicated. Phenobarbital and mephobarbital possess reasonable efficacy against these seizure types but with, in most subjects, less desirable toxicity profiles, particularly in relation to the effect of sedation. However, Jha et al.[37] considered that phenobarbital was ineffective in juvenile myoclonic epilepsy.
- Partial seizures with or without secondary generalization in adults, although phenobarbital is often regarded as second- or third-line treatment in developed countries due to its neurotoxicity.
- As second-line therapy for convulsive status epilepticus when intravenous benzodiazepines (e.g., lorazepam, diazepam) have failed. In this situation, phenobarbital can be considered an alternative to phenytoin (or its prodrug fosphenytoin), because it is more convenient to administer parenterally than phenytoin itself and, in higher doses,

  it can be effective when other therapies fail.[15] The drug may produce temporary sedation when given in a sufficient parenteral dose, but this usually is not an unacceptable price to pay to achieve control of a life-threatening situation such as status epilepticus. Respiratory depression is another concern, but it is not common.
- Febrile convulsions, although it is nowadays generally believed that prophylactic therapy is rarely indicated.[4]

Because of its relatively long elimination half-life, phenobarbital may also be preferred to other agents for patients who are prone to short periods of noncompliance (e.g., binge drinkers).

Dosing Recommendations

Initiating Dosage

Because of the long half-life of phenobarbital, phenobarbital and mephobarbital may be taken once daily, conveniently at bedtime. Systematic data is lacking as to whether a target dose or a target serum concentration should be aimed for when initiating the drugs. The approach undertaken is, therefore, often dictated by the personal preference and practice of the individual treating physician, as well as the availability of therapeutic drug monitoring service. With either approach, titration should not be dogmatic but should be tailored to individual response in terms of efficacy and tolerability.

Dosages correlating with different plasma concentrations of phenobarbital and mephobarbital have been derived from routine therapeutic drug-monitoring databases. Although linear population regression lines for steady-state plasma drug levels and dosage could be drawn, there was wide scattering of individual data points, suggesting wide interindividual variation in the dose required to achieve a specific plasma concentration.[22] Table 2 sets out the average doses of phenobarbital and mephobarbital needed to achieve an initial target plasma phenobarbital concentration of 15 mg/L for different age groups based on population data from two such studies.[22,23,51] The nonuniformity in study populations and data presentation has made it difficult to compare results and has probably led to discrepancies in findings. These data should best serve as reference values that highlight the interindividual variability in dose-serum concentration relationship, and strengthen the argument for an individualized approach in dose titration. In particular, although it is generally agreed that the dose of phenobarbital required to achieve a specific plasma concentration declines with old age (65 years or above),[51] the degree to which this reduction occurs has not been consistently demonstrated, and whether any age-dependent effect on dosing can be observed in younger adults is unclear.

The optimal way to titrate the drugs to therapeutic dosages has not been properly studied. Phenobarbital can be tolerated even when taken in full therapeutic dosage at initiation,[60] although some clinicians prefer to introduce these drugs gradually due to fear of causing sedation and behavioral disturbance. Increasing the drug dosage slowly in stages may minimize or avoid these problems, but the onset of seizure control can then be a little more delayed. This should be explained to patients before treatment begins. Using this step-wise approach, titration to the target plasma concentration may take 6 to 12 weeks. A quarter to a third of the daily dose expected to achieve an initial target plasma concentration of, say 15 mg/L, might be prescribed for the first 2 or 3 weeks. After that, the dose might be doubled if no untoward effects occur. A further increment in dose would be made 2 or 3 weeks after that, and perhaps a final increment another 2 or 3 weeks later. With such a titration schedule, drug doses will be increased only when there has been time for near steady-state conditions to apply at the previous dose. The actual schedule adopted should be individualized based on the clinical response. Dosage should not be increased if mild but tolerable adverse effects appear and too little time has passed since the last dose increment for the state of seizure control to be known. However, if seizures continue and even mild adverse effects have appeared, there may be little sense in persisting with the drug unless no potentially satisfactory alternative is available.

Large-scale observational studies performed in developing countries have consistently demonstrated that phenobarbital can be successfully initiated and maintained based on clinical response without the aid of therapeutic drug monitoring.[42] For example, in a recent study conducted in China with 2,455 patients commenced on phenobarbital, only 1% withdrew from treatment due to adverse events.[79] A reasonable initiating phenobarbital dose for adults could be 60 mg per day and for children 1.5 to 3 mg/kg per day. Some patients may respond to this initiating dose level. This is particularly the case for newly diagnosed patients, many of whom will respond to moderate dose of the first AED.[41] Dosage can be adjusted subsequently according to clinical response. In these pragmatic studies, the most common maintenance doses were 120 to 180 mg per day for adults and 3 to 5 mg/kg per day for children, although higher doses, up to 240 mg per day and 8 mg/kg per day, respectively, might be required and tolerated by some patients.

Maintenance

Once the initial target plasma phenobarbital level or target dosage has been achieved, or the patient's seizures are known to be suppressed, and the drug is tolerated comfortably, it is reasonable to make no further change in dose until the patient's clinical response to the treatment has time to become clear. Obtaining a measurement of the plasma phenobarbital concentration when the patient's seizures appear fully controlled may serve to indicate the provisional therapeutic concentration for that particular patient and serve to as a reference value for interpretation of future clinical situations. When adjusting the dose, it should be remembered that steady-state plasma phenobarbital concentration may rise disproportionately more than the size of the dose increment of phenobarbital, but in proportion to that of mephobarbital.[22]

Using a staged, progressive introduction of barbiturate AEDs, patients may tolerate plasma phenobarbital concentrations of 40 mg/L or even higher, although by levels of 50 mg/L most patients experience some degree of mental dullness. The phenobarbital dose corresponding to these toxic plasma drug concentrations might be 240 to 300 mg per day, and that of mephobarbital 600 to 800 mg per day. If seizures cannot be controlled at maximally tolerated dose, a different AED should be prescribed, whether or not phenobarbital (or mephobarbital) is continued at reduced dose or is discontinued.

If for any reason the patient becomes unable to take phenobarbital or mephobarbital orally, phenobarbital may be given by daily intramuscular injection or intravenous infusion. The parenteral dose is the same as the clinically satisfactory oral dose of phenobarbital, or half the oral dose of mephobarbital.

Discontinuation of Therapy

Therapy with phenobarbital or its *N*-methyl analog is discontinued when (a) unacceptable adverse effects have developed, (b) the therapy has provided unsatisfactory seizure control, (c) the therapy has been associated with seizure control long enough for a trial withdrawal of the drug to appear indicated, or (d) the patient elects to cease treatment for any reason.

Because phenobarbital has a relatively long half-life, even if intake of the drug is ceased abruptly the antiepileptic effect

should decline progressively during the next 1 or 2 weeks, thus making withdrawal seizures perhaps less likely than when other AEDs are discontinued suddenly. However, progressive gradual withdrawal of the drug is still advisable. In the U.K. Medical Research Council Antiepileptic Drug Withdrawal Study, there was no evidence that gradual withdrawal of phenobarbital was more often associated with exacerbation of seizures, as compared with other established agents.[12] Most clinicians prefer to withdraw barbiturates in stages over a period of several weeks or months, unless there is a good medical reason for ridding the body of the drug more quickly, for example, because of a serious idiosyncratic adverse effect. Thus, the dose might be reduced by 25% of its initial value each month for 4 months, or by 33% each month for 3 months.

Precautions

Phenobarbital and mephobarbital should be used with caution in persons with medically important disorders that are being treated with drugs whose clearances are likely to be altered by the administration of a drug metabolism–inducing agent such as phenobarbital. An example is persons receiving oral anticoagulant therapy. Phenobarbital should also be used cautiously in persons with hepatic and renal insufficiency and in the elderly. In both of these populations lower-than-usual doses may be required.

Contraindications

Phenobarbital (or mephobarbital) is contraindicated in persons with histories of previous hypersensitivity reactions to the agent, and in individuals with porphyria. The drugs should preferably be avoided in patients allergic to other aromatic AEDs (carbamazepine and phenytoin) since there is a 40% to 60% risk of cross-sensitivity.[3]

Summary and Conclusions

Phenobarbital and its congeners are effective, relatively broad-spectrum antiepileptic agents that can be conveniently administered parenterally as well as orally. They are the cheapest AEDs available. To some extent, these advantages are offset by the tendency of the drugs to cause sedation and behavioral disturbance, although these unwanted effects may be sometimes caused by excessive doses or too rapid increases in doses that ignore the elimination characteristics of phenobarbital.

Phenobarbital is long out of patent, and there seems to have been less interest in studying its optimal clinical use compared with most other AEDs. It remains an important antiepileptic agent, but one that has been allowed to acquire a rather undeserved reputation for adverse effects without its merits receiving equal attention. There is a possibility that phenobarbital may be allowed to fade from use, at least in affluent societies, not so much because of its limitations but because its virtues are not adequately recognized. On a global scale, phenobarbital is the most prescribed AED. Modern, comprehensive, prospective evaluation programs to optimize its use are warranted.[42]

Chapter 154

Phenytoin, Fosphenytoin, and Other Hydantoins

John M. Stern

Emilio Perucca

Thomas R. Browne

Introduction

The hydantoins are derivatives of a common five-membered heterocyclic ring that differ according to their unique combinations of alkyl and phenyl substitutions at three positions on the ring (Table 1). Phenytoin (PHT) is the most commonly prescribed hydantoin, and fosphenytoin is a phosphate ester prodrug of PHT used for parenteral administration of PHT. Ethotoin and mephenytoin are prescribed less frequently than PHT but may be useful in specific situations.

Phenytoin

Chemistry

The structural formula of PHT (5,5-diphenylhydantoin) is shown in Table 1. PHT has a molecular weight of 252.26 and is a weak acid with a pK_a of 8.3 to 9.2 under different experimental conditions.[70] Because of its high pK_a, PHT is relatively insoluble in water at acid or physiologic pH but is quite soluble in water at alkaline pH. These relationships have important clinical consequences, discussed below. The sodium salt of PHT has a molecular weight of 274.25 and contains the equivalent of 91.98% PHT acid.[70]

Multiple reliable methods for determining the concentration of PHT in biologic fluids have been reported. These employ gas–liquid chromatography, high-performance liquid chromatography, and immunoassay techniques.[87]

Pharmacology

PHT has multiple effects on cell function, which presumably explain its therapeutic and toxic effects. Three of these functions seem particularly important. First, PHT causes use-dependent inhibition of sodium channels necessary for the "firing" of action potentials. Sodium channels exist in resting, open, and inactive states. Each time sodium channels open during the passage of an action potential, some sodium channels become inactivated for a period of time before reverting to the resting state. When enough sodium channels become inactivated, the cell can no longer propagate an action potential. By stabilizing the inactivated form of the sodium channel, PHT hastens the process of use-dependent inhibition of action potentials. This phenomenon at least partially accounts for PHT's ability to control ictal excitability. Second, the ability of PHT to regulate calmodulin and second messenger systems may account for some of its widespread effects on cellular function. Third, PHT has the ability to regulate voltage-dependent neurotransmitter release at the synapse, which may be related in part to its action on calcium or sodium ions. The mechanisms of action of PHT have recently been reviewed in detail elsewhere[53] (see Chapter 137).

Clinical Pharmacokinetics

Absorption by Oral Route: General Considerations

As a weak acid with a pK_a of approximately 9.0, PHT is <1% ionized and has a water solubility of 14 μg/mL[70,189] at a pH of 1 to 2. At a pH of 7.5, PHT is 3% ionized and has a water solubility of 100 μg/mL. Thus, only a small amount of PHT is absorbed in the stomach, and most PHT absorption takes place in the small intestine where its solubility is approximately 100 μg/mL.[189]

PHT's low solubility has several important consequences. Not all of an oral dose of PHT is absorbed, and some is lost in the feces. There also are apparently considerable differences in the amount of PHT absorbed by different people, especially when the capsule form is used. Some otherwise normal people require large doses of PHT to reach average drug plasma concentrations, and these people sometimes are accused incorrectly of being noncompliant. Altered PHT absorption is also influenced by certain physiologic states. Pregnancy may be associated with reduced gastrointestinal absorption of PHT.[156] Neonates absorb oral PHT incompletely and erratically.[16,140] A final consequence of the marginal intestinal solubility of PHT is that any substance that interferes with the dissolution of PHT or adsorbs PHT in intestinal fluids (e.g., nasogastric feedings, antacids, certain foods, and certain other drugs) will inhibit PHT's absorption.[7,189]

Peak plasma concentration of PHT is usually reached 4 to 8 hours after an oral dose, although the peak may be reached as early as 3 hours or as late as 12 hours.[187,189]

Differences in Oral Bioavailability among Formulations

There are three types of oral preparations of PHT: Prompt, sustained (extended) release, and liquid suspension. Prompt products are absorbed rapidly in the small intestine, result in an early peak plasma PHT concentration, and must be administered at least twice daily. Sustained-release products such as Dilantin Kapseals and Phenytek are the most commonly prescribed PHT products in the United States, deliver peak plasma concentration values 4 to 8 hours after administration, and may be administered once daily to adults. The liquid suspension is rapidly absorbed, has greater bioavailability than many capsule preparations, and also must be administered at least twice

daily.[146]

Table 1 Hydantoins

Substituents			
R_1	**R_2**	**R_3**	**Name**
H	C_6H_5[a]	C_6H_5	Phenytoin
$CH_2OPO_3Na_2$	C_6H_5	C_6H_5	Fosphenytoin
CH_3	C_6H_5	C_2H_5	Mephenytoin
C_2H_5	C_6H_5	C_2H_5	Ethotoin

[a]Phenyl ring.

Prompt and sustained-release preparations differ sufficiently in pharmacokinetic properties that they cannot be interchanged. Most generic PHT products marketed in the United States are prompt preparations and cannot be substituted for sustained-release preparations. It should be noted that some preparations (e.g., Dilantin suspension or Dilantin Infatab chewable tablets) contain PHT acid, while others (e.g., Dilantin Kapseals and Phenytek) contain the sodium salt. Because there is approximately an 8% increase in drug content with the free acid form over that of the sodium salt, dosage adjustments may be necessary when switching from a product formulated with the acid to a product formulated with the sodium salt or vice versa.

Generic substitution of prompt preparations for sustained-release preparations is furthermore problematic because of three risk factors for inequivalence among generic forms of a drug: (a) poor water solubility, (b) nonlinear pharmacokinetics, and (c) narrow therapeutic range of plasma concentration.[133,134] PHT possesses all three risk factors, so it is not surprising that comparisons of generic PHT products have yielded conflicting results, with more studies reporting inequivalence than equivalence.[39,45,57,127,144,145,146,149,169,192] Two generic sustained-release PHT products were introduced in the United States and later withdrawn because of concerns that they may not be equivalent to brand-name Dilantin.[15,64,169] Switching between preparations that are not equivalent may result in decreased drug plasma concentration (increased seizures) or increased drug plasma concentration (increased toxicity).[20] Based on this information, an American Academy of Neurology position statement recommends that patients be managed with one form of PHT preparation supplied by one manufacturer.[133,134]

The oral suspension form of PHT is useful for patients who have difficulty swallowing capsules, especially children. The oral suspension also is useful in patients who do not absorb PHT capsules well.

Absorption by Intramuscular Route

Dissolving PHT in a small volume of liquid for parenteral administration requires a solution pH of 12. When this preparation is injected intramuscularly (i.e., into a medium with a pH of about 7.4), the water solubility of the drug decreases substantially, PHT crystals precipitate in the muscle,[20] and the drug is absorbed very slowly.[20,88]

Peak plasma PHT concentrations occur approximately 24 hours after a single intramuscular injection and are considerably less than the peak concentration produced by the same dose given by intravenous infusion.[88] PHT should not be given via the intramuscular route in emergency situations (e.g., status epilepticus) because of the slowness of absorption and the relatively low peak plasma concentrations produced by that route.

Use of the intramuscular route for administration of maintenance doses of PHT remains controversial. Eventually, almost all of an intramuscular injection of PHT is absorbed, and regimens for administration of maintenance doses of intramuscular PHT have been reported. However, peak plasma PHT concentrations after an intramuscular injection are variable.[88] Furthermore, the plasma concentration may fall below therapeutic levels shortly after a switch to the intramuscular route from the oral or intravenous route and may ascend into the toxic range because of accumulation after switching back from the intramuscular to the oral route.[88] In most situations, maintenance doses of PHT should not be given by the intramuscular route because of the slowness and variability of absorption and because of the danger of over- and undermedication when switching to and from other routes of administration.

Fosphenytoin is a water-soluble phosphate ester prodrug of PHT that eliminates many of the problems of sodium PHT for injection. Fosphenytoin is described below.

Plasma Protein Binding and Distribution

Plasma Protein Binding.

PHT is 69% to 96% protein bound in adults.[81,110] In the absence of associated disease or displacing agents, the average extent of plasma protein binding is about 90%. Binding is lower in neonates[59,145] and in the elderly.[81]

Distribution into Tissues and Other Body Fluids.

The concentration of PHT in brain parenchyma and cerebrospinal fluid (CSF) reaches peak values 15 to 60 minutes after intravenous injection in humans.[189] However, the brain parenchyma concentration of PHT remains greater than the plasma concentration of free PHT once steady-state plasma concentrations are reached.

The concentrations of PHT in CSF, saliva, semen, and bile are essentially identical to the concentrations of free (non–protein-bound) PHT in plasma.[189]

PHT freely crosses the placenta.[189] It enters breast milk, with a milk:plasma PHT concentration ratio of about 0.2.[189]

Metabolism and Elimination

PHT is excreted in the urine and feces mainly as its metabolites, none of which has significant antiepileptic activity. Less than 5% is excreted in urine in an unmetabolized form.[28,189] The major route of biotransformation is *para*-hydroxylation of a phenyl ring by the liver cytochrome P450 system (primarily isoforms CYP2C9 and CYP2C19) to form 5-(*p*-hydroxyphenyl)-5-phenylhydantoin (*p*-HPPH).[6,28] Over 60% of a PHT dose is excreted in urine as *p*-HPPH, the majority of which is conjugated with glucuronic acid.[28,189] Minor metabolites include a dihydrodiol derivative; *meta*-HPPH (mHPPH); diphenylhydantoic acid; 5,5-bis(4-hydroxyphenyl) hydantoin; 5-(3,4-dihydroxyphenyl)-5-phenylhydantoin; and 5-(3-methoxy-4-hydroxyphenyl)-5-phenylhydantoin.[28,189]

PHT is a prochiral compound. Introduction of a hydroxyl group in one of the phenyl rings leads to the creation of a chiral center and results in the formation of enantiomeric phenolic metabolites. The *p*-HPPH from human urine consists of a 10:1 mixture of levo- and dextrorotatory isomers.[28,173] The amount of *m*-HPPH in human urine is too low to permit isolation and measurement of optical rotation. The majority of dihydrodiol in human urine is in the *S* configuration with varying *S:R* ratios.[2,111,113,114,152] The *S:R* ratio is due to an approximately 40 times greater stereoselectivity of CYP2C9 for the *S* isomer and CYP2C19's lack of stereoselectivity for either isomer.[6]

Occurrence of Nonlinear (Michaelis-Menten) Pharmacokinetics.

Nonlinear pharmacokinetic properties have major effects on PHT's clinical usage. The rate of change of plasma concentration (C) of a drug metabolized by an enzyme system can be expressed by the Michaelis-Menten equation:

$$\frac{dC}{dt} = \frac{V_{max} \times C}{K_m + C} \qquad (1)$$

where t is time, V_{max} is the maximum velocity of the enzyme system, and K_m is the Michaelis constant of the enzyme system (plasma concentration at which half of the maximum velocity of the enzyme system is attained). The mean steady-state plasma concentration (C_{ss}) of the drug can be expressed as:

$$C_{ss} = \frac{R \times K_m}{V_{max} - R} \qquad (2)$$

where R is the dosing rate. When C is similar to or greater than K_m, dC/dt will vary in a nonlinear fashion with C; when R is equal to or greater than $0.1 \times V_{max}$, C_{ss} will vary in a nonlinear fashion with R. These observations are the basis of nonlinear pharmacokinetics.

Based on 55 reported determinations, the mean apparent value for PHT's K_m in adults is 6.3 μg/mL and the range is 1.5 to 30.7 μg/mL. The mean apparent value for PHT's V_{max} in adults is 0.45 μg/mL/hr with a range of 0.14 to 1.36 μg/mL/hr based on 54 reported determinations.[3,27,60,66,68,69,79,121,155] These values appear to be determined principally by arene oxidase enzyme system K_m and V_{max} values. The other minor pathways of PHT metabolism potentially could have modifying effects on the apparent values of K_m and V_{max} for PHT.[108] However, attempts to demonstrate an effect of these other pathways on PHT pharmacokinetic parameters in humans have been negative.[28,35]

The apparent K_m values computed for humans are based on total (protein-bound and non–protein-bound) PHT plasma concentration. Because only non–protein-bound PHT can be acted on by the metabolizing enzyme system and the non–protein-bound fraction for PHT is approximately 10% in humans,[210] the K_m of the enzyme responsible for *para*-hydroxylation of PHT actually should be approximately 0.6 μg/mL. This prediction has been verified in rat liver microsomes.[193]

Eadie et al.[60] performed the first comprehensive comparison of PHT K_m and V_{max} values in children and adults. The K_m values from 21 adults (mean 5.8 μg/mL) and 15 children (mean 5.3 μg/mL) were not significantly different. The V_{max} values from 21 adults (mean 0.48 μg/mL/hr, assuming a PHT volume of distribution of 0.7 L/kg) were significantly (p <0.025) less than the V_{max} values from 15 children (mean 0.74 μg/mL/hr assuming a PHT volume of distribution of 0.7 L/kg). Suzuki et al.[67a,183] later confirmed these observations regarding K_m and V_{max} in children. These observations predict that the clearance [$V_{max}/(K_m + C)$] of PHT should be greater in children than in adults. This prediction is confirmed by the observations that the elimination half-life of PHT is shorter in children than in adults and that the average dosing rate of PHT (in milligrams per kilogram per day) required to achieve a given plasma concentration is greater in children than in adults.[20,56,90]

The V_{max} for PHT increases significantly during pregnan-cy.[54] This explains part of the observed decrease in PHT steady-state plasma concentration during pregnancy (Equation 2).

PHT will exhibit nonlinear pharmacokinetic properties in the majority of patients because the usual therapeutic plasma concentration values (10 to 20 μg/mL) exceed the usual K_m (6.3 μg/mL), and the usual dosing rate (0.15 to 0.45 μg/mL/hr) is greater than 0.1 times the usual value of V_{max} (0.45 μg/mL/hr). The consequences of nonlinear pharmacokinetics are discussed in the following sections.

Relationship between Plasma Concentration, Clearance, and Half-life.

According to the Michaelis-Menten equation, drug clearance is equal to $V_{max}/(K_m + C)$. Drug elimination half-life is equal to 0.693 × volume of distribution/clearance. Thus, PHT clearance will vary inversely with plasma concentration, and PHT elimination half-life will vary directly with plasma concentration (Fig. 1).[25,26,35] Browne et al.[27,35] described and validated a method for calculating PHT elimination half-life at any given PHT plasma concentration if the patient's K_m and V_{max} values for PHT are known. The results (plasma concentration and calculated elimination half-life) for a group of six adult men on PHT monotherapy were 1 μg/mL, 12.8 hours; 10 μg/mL, 25.8 hours; 20 μg/mL, 40.2 hours; and 40 μg/mL, 69.1 hours. Based upon these results, PHT's commonly believed elimination half-life of 24 hours applies principally to plasma concentration values in the low therapeutic range (10 μg/mL) and the elimination half-life often is longer at higher plasma concentrations (also see Fig. 1). The range of elimination half-life values at a PHT plasma concentration of 40 μg/mL was 37.1 to 96.8 hours. Because of PHT's long and variable elimination half-life values at toxic plasma concentration values, one cannot predict the time required for PHT plasma concentration to fall from a toxic value to a therapeutic value in a given individual. In such circumstances, one must withhold PHT and obtain daily plasma concentration determination values until the plasma concentration has fallen back into the therapeutic range.

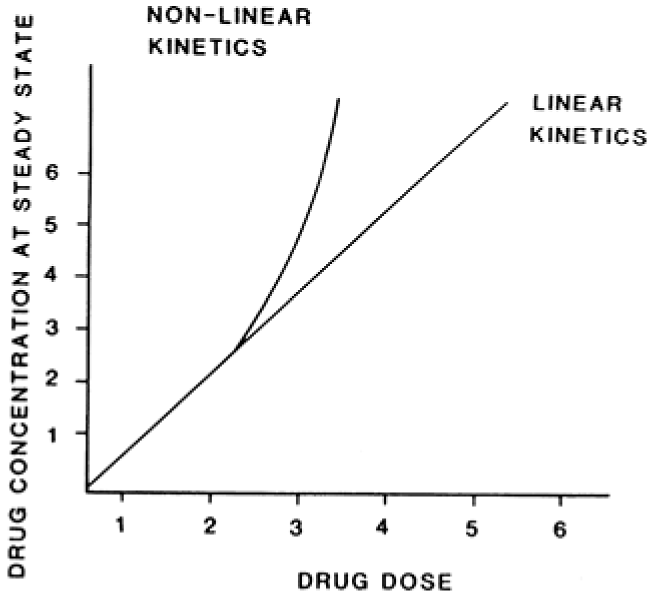

FIGURE 1. Relationship between dosing rate and steady-state plasma concentration for drugs with linear pharmacokinetics and for drugs with nonlinear Michaelis-Menten pharmacokinetics.

Relationship between Steady-State Plasma Phenytoin Concentration and Dosage.

For drugs with Michaelis-Menten pharmacokinetics similar to PHT's, steady-state plasma concentration increases to a greater extent than dosing rate

P.1612

when dosing rate is increased, and plasma concentration decreases to a greater extent than dosing rate when dosing rate is decreased (Equation 2) (see Fig. 2).[32,56,204] Thus, the steady-state plasma concentration of a drug with these Michaelis-Menten pharmacokinetics at one dosing rate does not directly predict the steady-state plasma concentration of the drug at another dosing rate.

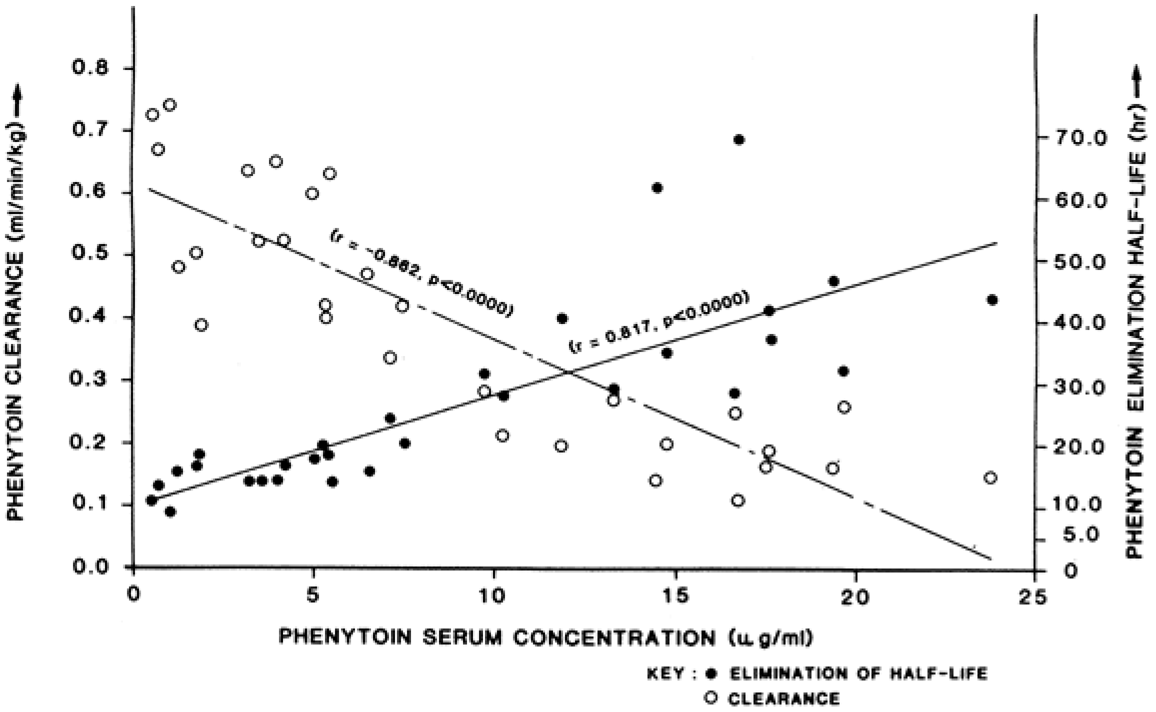

FIGURE 2. Phenytoin clearance and elimination half-life values determined by stable-isotope tracer techniques at 30 different serum concentration values in 18 adult men on PHT monotherapy. (From Browne TR, LeDuc B. Phenytoin: chemistry and biotransformation. In: Levy RH, Mattson RH, Meldrum BS, eds. *Antiepileptic Drugs*. 4th ed. New York: Raven Press; 1995:283–300, with permission.)

If the clinician attempts to increase or decrease PHT steady-state plasma concentration by simple linear extrapolation from a known plasma concentration versus dosing rate point, the result is often an unexpectedly high or low plasma concentration when the new steady-state value is attained (Fig. 2). Numerous mathematic and tabular methods have been published that claim to be able to predict the PHT dosing rate necessary to produce a given steady-state plasma concentration from a single steady-state plasma concentration versus dose point, and these methods have been critically reviewed elsewhere.[23,32,131,138,139] A useful rule of thumb in titrating PHT dosage upward in adults is to increase dosing rate in increments of 100 mg/day at monthly (see below) intervals until a steady-state PHT plasma concentration of 5 to 10 μg/mL (a value approximately equal to K_m) is attained; later increases should not exceed 50 mg/day at monthly intervals.

Nonlinear pharmacokinetics complicates the issue of generic equivalence of PHT products. The weighted mean value for absolute bioavailability of brand-name sustained-release PHT (Dilantin Kapseals, 100 mg, Parke-Davis) was 86% in three studies.[20] Less than complete absorption of brand-name PHT is at least in part a consequence of the use of a sustained-release preparation (see above). Different generic preparations of PHT have the potential to differ in bioavailability from the brand-name preparation by 14% or more. Because of PHT's nonlinear pharmacokinetics, a 14% difference in bioavailability is expected to result in a >14% increase or decrease in steady-state plasma concentration. For example, the bioavailability of a single dose of Mylan extended-release PHT given with a high-fat meal was found to be 13% lower than the bioavailability of Dilantin Kapseals taken under similar conditions.[206] Pharmacokinetic simulations based on these data showed that substituting the Mylan product for Dilantin in patients with baseline plasma PHT concentrations within or above the optimal range would be expected to result in a median 37% decrease in PHT concentrations, whereas substituting Dilantin for Mylan would be expected to produce a median 102% increase in PHT concentrations. A national epidemic of PHT intoxication occurred in Australia when a more bioavailable formulation was substituted for an older formulation.[154,199] Ludden et al.[108] and Browne et al.[36] have reviewed the effect of nonlinear pharmacokinetics on bioavailability studies in more detail.

Effect of Nonlinear Pharmacokinetics on Time to Reach Steady-State Plasma Concentrations.

According to the principles described above, as PHT plasma concentration rises, PHT clearance decreases and elimination half-life decreases (see Table 2 for typical values for these changes in a group of six patients started on PHT monotherapy). This results in a further rise in PHT plasma concentration and a further decrease in PHT clearance. This self-propagating cycle can require a long period of time to go to completion. The time (*t*) required to attain a given plasma concentration can be computed by the equation:

$$t = \frac{V_d (C_{s,t} - C_{s,0})}{(R - V_{max})} - \frac{V_d K_m V_{max}}{(R - V_{max})^2} ln \frac{(R - V_{max}) C_{s,t} + RK_m}{(R - V_{max}) C_{s,0} + RK_m} \quad (3)$$

where V_d is volume of distribution, $C_{s,t}$ is plasma concentration at time t, and $C_{s,0}$ is plasma concentration at time 0.[204] Assuming average values for K_m and V_{max}, it is possible to compute an accumulation half-life ($t_{1/2A}$) for PHT as follows:

$$t_{1/2A} = 0.270 \times C_{ss} \quad (4)$$

where $_{1/2A}$ has units of days and C_{ss} has units of micrograms per milliliter.[94] Equations 3 and 4 predict, and empirical data confirm, the following: (a) time to reach steady-state plasma

P.1613

concentration will vary nonlinearly with dosing rate; (b) time to reach steady-state plasma concentration will vary linearly with plasma concentration; and (c) the time required to attain new steady-state plasma concentration values after starting PHT therapy or increasing or decreasing PHT dosing rate may be as long as 28 days (Fig. 3).[26,32,94,204] Therefore, in some individuals, particularly when the plasma concentration of the drug is in the high range, a PHT plasma concentration value measured <28 days after a change in PHT dosing rate may not be an accurate indication of the ultimate new steady-state

P.1614

plasma concentration that will result from the change in dosing rate.

Table 2 Phenytoin pharmacokinetic values for six patients at three times during monotherapy determined with 150-mg tracer doses of stable-isotope-labeled phenytoin[a]

	Week 0[b]	Week 4[c]	Week 12[d]	Significance[e] (*p*)
Mean total (labeled and unlabeled)				
PHT plasma concentration (µg/ml)	1.2 ± 3.5[f]	5.4 ± 2.4	10.0 ± 6.1	<0.01
Clearance (ml/min per kg)[g]	0.587 ± 0.149	0.456 ± 0.147	0.387 ± 0.187	<0.05
Elimination half-life (hr)[g]	13.2 ± 3.6	18.4 ± 5.0	25.9 ± 9.7	<0.01

Factors Affecting Plasma Phenytoin Concentration Versus Dose Relationship: Age.

Neonates eliminate PHT more slowly than adults or children (see below). Young children metabolize PHT more rapidly than older children and adults, requiring higher milligram-per-kilogram doses of PHT to achieve a given plasma concentration and sometimes not maintaining therapeutic plasma concentrations with once-daily administration.[20,56] Plasma-unbound PHT concentrations for a given daily dose tend to be higher in the elderly than in young adults, probably because of a decreased metabolic rate, even though total plasma PHT concentrations may not differ to a major extent between young adults and elderly subjects.[5,6a,62] Elderly individuals may also show a wide (two- to threefold) intraindividual variability in plasma PHT concentrations despite unchanged daily doses, possibly due to day-to-day variability in absorption efficiency.[11]

Factors Affecting Plasma Phenytoin Concentration Versus Dose Relationship: Pregnancy.

Decreasing total PHT plasma concentrations are usually noted throughout preg-nancy.[102,147,186,187] However, the plasma concentration of free (unbound), pharmacologically active PHT falls much less than total PHT plasma concentration during pregnancy.[186,187] Monitoring of free PHT plasma concentration may be advan-tageous during pregnancy.

Factors Affecting Plasma Phenytoin Concentration Versus Dose Relationship: Hepatic Insufficiency.

The oxidative metabolism of PHT and many other drugs is slowed in patients with hepatic disease.[148] In addition, protein binding may be reduced by any of three occurrences: (a) hypoalbuminemia, (b) displacement by bilirubin or other substances, and (c) changes in the configuration of albumin. The overall result is usually an increase in the total plasma drug concentration, the free (unbound) drug concentration, or both.

Unfortunately, there is no formula for predicting the proper dose of an antiepileptic drug in a patient with hepatic dysfunction based on plasma albumin concentration or liver function tests. One must adjust drug dosage on the basis of clinical response and frequent determinations of the drug plasma concentration.

Factors Affecting Plasma Phenytoin Concentration Versus Dose Relationship: Renal Insufficiency.

Uremic patients receiving PHT have lower total plasma PHT concentrations, higher plasma *p*-HPPH concentrations, and shorter PHT elimination half-lives than nonuremic patients receiving the same dosage of PHT.[72,98,123] In renal insufficiency, the hepatic biotransformation processes continue and may accelerate, but renal excretion of metabolites is slowed. The high plasma concentration of *p*-HPPH is presumably a result of impaired renal excretion of the metabolite. The short elimination half-life is presumably caused by increased accessibility of PHT to hepatic biotransformation enzymes as a result of decreased protein binding from low plasma albumin concentration, displacement of PHT from protein-binding sites by *p*-HPPH and endogenous metabolites, and structural alterations of plasma proteins.[137] The low total plasma PHT concentration reflects primarily enhanced drug clearance as a result of increased accessibility of PHT to he-patic biotransformation enzymes. Because of the reduced PHT binding to plasma proteins and increased unbound fraction, total plasma PHT concentration in patients with uremia underestimates the concentration of free, pharmacologically active drug. Therefore, therapeutic and toxic effects occur in these patients at lower than usual total plasma PHT concentrations. In individuals with uremia, PHT therapy should be preferably monitored by measuring free (unbound) plasma PHT concentration.

Hemodialysis has little effect on the plasma concentration of PHT.[105]

Efficacy

Tonic–Clonic and Partial Seizures

The older literature on the effectiveness of PHT for tonic–clonic and complex partial seizures has been reviewed by Coatsworth.[46] More recently, a series of trials has compared PHT with other older antiepileptic drugs (carbamazepine, phenobarbital, primidone, and valproic acid) as initial therapy in neonates, in children, and in adults with tonic–clonic and partial seizures.[41,78,117,119,141,145,157,166,184,194,195,196,207] The results of these studies may be summarized as follows: (a) no drug was more effective than PHT in a randomized, prospective double-blind study; (b) PHT and carbamazepine were very similar in efficacy and toxicity; and (c) phenobarbital and primidone generally had more adverse effects than PHT or carbamazepine and, in some studies, were less effective when treating patients with partial seizures. There is also evidence-based data showing that PHT, oxcarbazepine, and lamotrigine have similar efficacy for the initial therapy of partial seizures.[10,71,130,181] Although there have been no direct comparisons of PHT with topiramate and gabapentin, a recent trial suggested that topiramate may have inferior tolerability, and gabapentin inferior efficacy, compared with carbamazepine in patients with newly diagnosed partial seizures.[114b] Among newer generations antiepileptic drugs (AEDs), only oxcarbazepine and topiramate are approved by the Food and Drug Administration (FDA) for this indication.

In most of the above studies, tonic–clonic seizures were mostly secondarily generalized seizures in patients with focal epilepsy. However, PHT is also effective for primarily generalized tonic–clonic seizures.[158,207] Although PHT is effective as prophylaxis against acute symptomatic seizures that may occur soon after traumatic brain injury, it does not decrease the risk of later developing remote symptomatic seizures or epilepsy.[44]

Status Epilepticus

PHT is an important therapy for status epilepticus manifesting with tonic–clonic or partial seizures. A randomized, double-blind trial of four treatments for status epilepticus found lorazepam to be more effective than PHT for seizure control at 1 hour, but it was equally effective to a combination of diazepam and PHT or phenobarbital alone.[188] PHT was inferior to valproic acid for terminating convulsive status epilepticus in a randomized comparison trial of intravenous formulations with each medication given without benzodiazepines and with efficacy measured at the end of the infusion.[129] However, valproic acid does not have FDA approval for this use.

Other Epileptic Disorders

Older studies, without adequate controls, yielded conflicting results in the value of PHT in treating alcohol withdrawal seizures.[1] However, two modern and well-controlled studies strongly indicate that PHT has no value in treating or preventing alcohol withdrawal seizures.[1,161]

Animal models predict that PHT should not be effective for controlling absence seizures, and clinical experience has shown this prediction to be correct.[205,207]

Other Indications

PHT controls trigeminal neuralgia in a smaller percentage of patients than carbamazepine, but the combined use of PHT and carbamazepine for trigeminal neuralgia is sometimes more effective than carbamazepine alone. PHT has been suggested as a therapy for a wide variety of organic and functional diseases of the nervous and cardiovascular systems, as well as for a variety of other conditions.[13]

P.1615

Adverse Effects

Dose-related Central Nervous System Adverse Effects

The usual dose-dependent adverse effects of PHT include nystagmus, ataxia, and drowsiness.[38,49] Nystagmus is usually horizontal but can include vertical movements at high drug plasma concentrations. The ataxia involves station and gait more than fine motor movements. There is an approximate correlation of signs of PHT intoxication with drug plasma concentration. In the majority of patients, nystagmus appears with drug plasma concentrations of about 20 μg/mL, ataxia with levels of about 30 μg/mL and drowsiness with levels of >40 μg/mL.[90] However, there is considerable variation among patients in the plasma PHT concentration at which a symptom occurs, and not all patients experience all symptoms. At high plasma concentrations (usually >40 μg/mL), a reversible external ophthalmoplegia may occur.[180] Patients also may experience an excited delirium rather than sedation with therapeutic and toxic PHT plasma concentrations.[49]

Perhaps the most important questions about PHT toxicity are concerned with what, if any, effects the drug has on cognitive function and behavior at typical therapeutic plasma concentrations. The cognitive effects of PHT have been studied extensively. Early studies were flawed by the fact that PHT slows motor speed, causing slowing of timed tests that is not related to slowed cognition. Recent studies indicate that (a) PHT has modest or little effect on cognition, (b) PHT and carbamazepine have similar and modest effects on cognition, and (c) barbiturates may have greater effects on cognition.[38,47,55,117,124,176,203]

A reversible syndrome of "PHT encephalopathy" has been described as a complication of chronic PHT therapy, usually with PHT plasma concentrations in the toxic range.[49,163] The syndrome is characterized by mental changes, increased slowing and increased paroxysmal activity on electroencephalograms (EEG), increased seizure frequency, and a change in seizure pattern involving development of more tonic components. The mental changes may include drowsiness, progressive decline in higher intellectual function, depression, or euphoria. Focal neurologic signs such as hemiparesis and hemisensory defects may occur. Ataxia and nystagmus may be present or absent, and the CSF protein value may be elevated. This encephalopathy is more common in children, and pre-existing brain damage may be a risk factor for it.[165] All these features generally disappear when PHT is discontinued.

Movement disorders (usually choreoathetosis and orofacial dyskinesia; rarely asterixis, ballismus, hyperkinesia, external ophthalmoplegia, periodic alternating nystagmus, or downbeat nystagmus) have been reported to be caused by PHT.[49,160,180] These disorders usually occur with toxic PHT plasma concentrations but may occur with plasma concentrations in a typically therapeutic range for a smaller minority of patients.[49]

Murphy et al.[131] reported 85 cases of PHT intoxication following unintentional overdose (PHT plasma concentration 30.3 to 95.0 μg/mL, median 46.5 μg/mL). The most frequent symptoms were nystagmus (95%), ataxia (80%), lethargy (22%), and seizures (19%). No patient had cardiac abnormalities attributable to PHT intoxication. Outcome was generally good, but three patients had serious complications (hip fracture, infections).

Dose-related Gastrointestinal Adverse Effects

PHT can cause nausea, vomiting, or constipation. Administration with or immediately after meals can reduce gastrointestinal discomfort.

Dose-related Cardiovascular Adverse Effects

Intravenous administration of PHT may cause hypotension, atrioventricular conduction block, and other dysrhythmias. These effects are related to dose and rate of administration, and conventional practice is to limit the rate of intravenous PHT infusion to 50 mg/min or less. Blood pressure and electrocardiographic (ECG) monitoring are recommended when PHT is administered intravenously, particularly at the higher dosages and infusion rates that are used for loading or for the treatment of status epilepticus. Some patients develop the cardiovascular side effects of the intravenous infusion even at the recommended maximum rate of 50 mg/min.

Chronic Adverse Effects

Effects on the Nervous System.

A loss of cerebellar Purkinje cells has been reported in association with PHT therapy.[49,163] However, loss of

Purkinje cells is a common finding in patients with epilepsy, whether or not they take antiepileptic drugs. Dam[49] reviewed the human and animal data on the effects of PHT on Purkinje cells and concluded that PHT in therapeutic doses does not lead to changes in the density or substructure of Purkinje cells. Reynolds[163] concluded that although much of the data on this topic are controversial, there are several convincing clinical reports of chronic cerebellar dysfunction following acute PHT intoxication. Since Reynolds' review, additional reports of cerebellar atrophy following PHT intoxication have emerged[38,116] as well as reports of PHT-related cerebellar degeneration in patients without seizures.[135,159] Conversely, Murphy et al.[131] found no evidence of permanent cerebellar dysfunction in 85 cases of severe PHT intoxication. Thus, permanent cerebellar dysfunction may be a rare complication of PHT intoxication and may be related to the duration of acute PHT toxicity or to pre-existing pathologic damage in the cerebellum from seizures, other drugs, or other causes.[163,164]

Chronic PHT administration may lead in some, but not all, patients to a bilateral peripheral neuropathy characterized by decreased reflexes, decreased nerve conduction velocities (especially motor), and sensory deficits.[49,100,163,175,178] Most patients are asymptomatic, although a minority of patients complain of weakness or dysesthesia. The occurrence of this complication correlates with the duration of PHT therapy. The neuropathy does not seem to be related to folate level, vitamin B_{12} level, hemoglobin, blood cell counts, or blood sugar. Administration of folic acid or withdrawal of PHT does not seem to improve the neuropathy.

Cosmetic Adverse Effects.

Gingival hyperplasia occurs in approximately 20% of adult patients on PHT,[117] and the incidence may be higher in children.[163] It usually becomes apparent within 2 to 3 months after commencing PHT therapy and reaches a maximum in 9 to 12 months.[163] Gingival hyperplasia can be reduced by good oral hygiene. Periodic gingivectomy can remove the excess tissue and improve cosmetic appearance. Discontinuing PHT will result in regression of the gingival changes in 3 to 6 months.[163] When severe, gingival hyperplasia may negatively impact dental health, so it is not always a purely cosmetic effect.

Enlargement of the lips and nose, coarsening of the facial features, hirsutism, chloasma-like pigmentation, and acne all have been reported to occur in patients on chronic PHT therapy.[163] Except for hirsutism, which is well documented, the evidence for a cause-and-effect relationship between PHT and these conditions is questionable. The evidence consists of retrospective, nonblinded studies of patients, many of whom took other drugs and had moderate to severe mental retardation, often with institutionalization. Thus, the effects of other drugs, genetics, and environment were not controlled.

Endocrine and Metabolic Adverse Effects.

PHT initially causes an increase in circulating adrenocorticotropic hormone

(ACTH) and cortisol, but levels of these hormones subsequently decline to below-normal concentrations.[163] Chronic PHT administration enhances hydroxylation of cortisol and increases urinary excretion of 6-*β*-hydroxycortisol.[163]

PHT depresses the release of antidiuretic hormone and oxytocin.[163] PHT also can displace thyroxine (T_4) and triiodothyronine (T_3) from thyroxine-binding globulin,[49,163,214] which can result in decreased serum T_4 and T_3 to maintain normal free T_4 and free T_3 concentrations and a euthyroid state.[182] Therapeutic plasma concentrations of PHT decrease the insulin secretory response of the pancreas to glucose.[163] This can result in hyperglycemia.[49,163]

Biochemical abnormalities suggesting metabolic bone disease are common in patients on chronic PHT. These include elevated plasma alkaline phosphatase and reduced plasma calcium and plasma 2-hydroxycholecalciferol.[38,163] Bone biopsy studies of patients on chronic PHT therapy reveal decreased bone density in approximately half of patients.[8,151] These findings may be secondary to decreased intestinal absorption of calcium, increased hepatic metabolism of vitamin D, or altered parathyroid hormone function.[38] Although laboratory abnormalities are common, clinically significant osteomalacia is uncommon in patients taking PHT.[38,163] Testosterone and estradiol metabolism are enhanced by PHT.[38] Chronic PHT therapy may be associated with elevated plasma concentrations of sex hormone–binding globulin in men and women.[48] The significance of these findings is uncertain.

PHT may precipitate porphyric attacks in patients with acute intermittent porphyria.

Hematologic Adverse Effects.

Aplastic anemia, leukopenia, thrombocytopenia, erythroid aplasia, and pancytopenia have all been associated with PHT therapy.[73,150] These side effects are very rare, usually occur during the first few months of therapy, are unrelated to dosage, and are often associated with other evidence of hypersensitivity phenomena.[150] Mild leukopenia (total white blood count 3,000 to 5,000/mm^3) is common with chronic administration of many antiepileptic drugs, including PHT.[117] This does not usually require discontinuing the drug until the count for segmented forms falls below 1,500/mm^3.

Macrocytosis is found in 0% to 36% of patients on chronic PHT therapy.[163] Subnormal serum folate levels are found in 27% to 91% of patients on chronic PHT therapy, and subnormal CSF folate levels are found in 0% to 45% of such patients.[38,163] The mechanism of producing low serum folate levels is not known for certain; possible mechanisms have been reviewed.[38] Despite the high incidence of macrocytosis and folate deficiency in patients on PHT, only 0.15% to 0.75% of patients develop megaloblastic anemia.[158] Subnormal serum vitamin B_{12} levels are found in 0% to 11% of patients on chronic PHT therapy, probably because of malabsorption of vitamin B_{12} as a secondary effect of low serum folate levels.[158]

The clinical importance of these findings is controversial. Megaloblastic anemia that is reversible with folate can occur with PHT, and there is highly controversial evidence that folate deficiency may lead to psychiatric disturbances in patients on PHT that are reversible with folate.[158] These considerations favor routine detection and treatment of folate deficiency in patients on PHT. However, animal research indicates that folate antagonizes the antiepileptic effect of PHT, and there is conflicting clinical evidence that administration of folate may increase seizure frequency in patients taking PHT.[163] Folate levels are an expensive laboratory test. Indications for folate treatment, the dose and duration of therapy, and the question of whether to give vitamin B_{12} as well as folate all remain to be clarified. The prophylactic use of folic acid to reduce the risk of birth defects in women of childbearing potential is discussed in Chapters 110 and 114.

Idiosyncratic Reactions (Including Immune-mediated Adverse Effects)

Table 3 signs and symptoms in 38 cases of phenytoin hypersensitivity reaction[a]

Sign or symptom	Percentage of patients
Rash	
Morbilliform or licheniform	66
Erythema multiforme	18
Stevens-Johnson syndrome	13

Total	74
Fever	13
Abnormal liver function tests	29
Lymphoid hyperplasia	24
Eosinophilia	21
Blood dyscrasias	
Leukopenia	16
Thrombocytopenia	5
Anemia	16
Increased atypical lymphocytes	3
Total	31
Serum sickness	5
Albuminuria	5
Renal failure	3

[a]From Haruda, ref. 67, with permission.

A variety of signs and symptoms in various combinations may occur as a result of PHT hypersensitivity reactions (see Table 3). The majority of such reactions occur during the first 3 months of PHT therapy.[75,118] One exception to this is the "purple glove syndrome," which is a triad of edema, pain, and discoloration in the limb distal to the infusion site of intravenous PHT that typically occurs within a day of receiving PHT. The reaction occurs in about 2% to 6% of patients and usually resolves with conservative treatment; however, surgical treatment sometimes is necessary.[40,136]

Rashes, which are most common in children (especially when large starting doses are used) and young adults, usually occur within the first 10 days of PHT therapy and may be accompanied by fever, leukopenia, or lymphadenopathy.[49] The incidence of rash in adults starting PHT is approximately 10%.[117,118] These symptoms disappear when the drug is discontinued and reappear with readministration of PHT.[49]

More serious dermatologic disorders that can be rare side effects of PHT include erythema multiforme, exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis.[49] The relative risk of PHT causing Stevens-Johnson syndrome or toxic epidermal necrolysis has been estimated to be about 290 (95% confidence interval, 9 to 9,239).[104]

A “serum sickness”-like illness with rash, fever, arthralgias, and atypical lymphocytes may occur with PHT administration.[49] In addition to discontinuing PHT, cortico-steroids may be helpful in treating this disorder.[49]

Hepatitis (hepatic necrosis, inflammation, cholangitis) is a rare but serious complication that usually occurs during the first 6 weeks of PHT therapy.[49,143] It usually occurs in association with other symptoms of hypersensitivity such as rash (100%), fever (90%), lymphadenopathy (75%), or blood dyscrasias.[49,143]

Systemic lupus erythematosus (SLE) has been reported in association with PHT therapy.[49] In some cases, SLE appears to result from PHT administration, but in other cases, pre-existing

P.1617

SLE probably caused a seizure disorder that caused PHT to be prescribed.[49]

Although lymphadenopathy is not uncommon with PHT therapy, the question of whether PHT can cause malignant lymphomas remains controversial.[150,173] Cases with features such as lymphadenopathy, fever, eosinophilia, hepatomegaly, splenomegaly, and certain malignant-appearing features on lymph node biopsy that remitted when PHT was stopped have been reported.[49,150] A smaller number of cases of persistent malignant lymphoma after PHT was discontinued has been reported.[49,150] It is difficult to know whether such symptoms are caused by PHT, other drugs, or the spontaneous appearance of malignant lymphoma. Nevertheless, it is prudent to discontinue PHT in a patient with lymphadenopathy.

PHT may suppress both humoral and cellular immune mechanisms.[179] Production of immunoglobulin A (IgA) is reduced.[38] Antinuclear antibodies and lymphocytotoxins of the IgM class have been found in patients taking PHT.[138]

Idiosyncratic reactions involving primarily the bone marrow may also occur, and have been listed in the section on hematologic adverse effects.

One case of fatal allergic interstitial nephritis in association with PHT therapy has been reported.[123] PHT has been reported to precipitate autoimmune myasthenia gravis in patients not known to have the disease and to exacerbate the disease in patients known to have it.[66,178]

Teratogenicity

The absolute and relative (compared to other therapeutic options) teratogenicity of PHT is an extremely complex topic. The following general observations apply.[38,51,52,115] First, there may be an increased risk of malformations (cleft lip and palate, cardiac defects, cranial anomalies, limb anomalies, hypospadias, intestinal atresia, and possibly mental retardation) in infants born to mothers with epilepsy taking no medication. This, however, has not been established conclusively, and was not found to occur in a large population-based case-control study.[80] Second, these malformations, which were formerly termed “fetal hydantoin syndrome,” are more common in mothers taking most antiepileptic drugs. Third, the risk is especially high in mothers taking two or more drugs in combination. Fourth, there is significant additional risk, especially for neural tube defects, in infants born to mothers taking valproic acid.[211] Genetics, severity of epilepsy, nutritional status (including folic acid intake), and drugs all may play a role in determining risk of malformation.[38,51,52] Available evidence does not support the notion that prenatal exposure to PHT involves a greater teratogenicity risk compared with exposure to other established antiepileptic drugs.[146a] For more information on existing data and the management of epilepsy in women of childbearing potential and during pregnancy, the reader is referred to recent reviews[51,52,146a] and to Chapters 110 and 114 in this book.

Drug Interactions

Effects of Other Drugs on the Pharmacokinetics of Phenytoin

A comprehensive description of drug–drug interactions affecting PHT pharmacokinetics can be found in recent reviews,[114a,144a,144b,146b] and only the most relevant examples will be discussed in this section.

Administration of PHT with some antacids[144b] or with certain nasogastric or enteral feedings[7,210a] can result in impaired PHT absorption and a marked fall in plasma PHT concentration, with the attendant risk of loss of seizure control.[147b]

Highly protein-bound drugs can displace PHT from plasma protein-binding sites. Unless additional mechanisms are involved, these interactions are not clinically significant because the displaced drug redistributes rapidly into a large volume of distribution and is eliminated through a compensatory increase in drug clearance: The overall result is a fall in total PHT concentration, but the concentration of free, pharmacologically active PHT is unchanged.[144a] Clinicians need to be aware of the interaction when interpreting plasma PHT concentration in these patients, especially because the presence of a displacing drug may produce both therapeutic and toxic effects of PHT at low total plasma PHT concentrations. Therefore, a decrease in total plasma PHT concentration caused by these interactions should not lead to an automatic increase in PHT dosage. Valproic acid is the drug most commonly responsible for displacing PHT from plasma protein-binding sites, and it may also inhibit PHT metabolism. When valproic acid is added on to the therapeutic regimen of patients stabilized on PHT, total plasma PHT concentrations usually decrease, whereas free PHT concentrations remain unchanged or even may increase.[120,210a]

Most drug interactions causing a change in PHT pharmacokinetics involve interference with PHT metabolism.[91,144b,148] The metabolism of PHT can be accelerated or slowed by drugs that induce or inhibit CYP2C9 and CYP2C19.[33,91,95,99,148] As described by Kutt,[91] marked changes in plasma PHT concentration occur commonly with only a few drugs and less commonly with other drugs in unusually susceptible individuals. Most interacting combinations can be used if clinically indicated with careful clinical and laboratory monitoring to guide dosage adjustments as necessary. Interactions that involve an acceleration in PHT metabolism and a decrease in plasma PHT concentration include rifampicin and folic acid.[144b] Vigabatrin,[29] cisplatin, and other antineoplastic drugs[201a] also may lower plasma PHT concentrations, but the mechanism underlying these interactions is unclear. Drugs that have been reported to inhibit PHT metabolism and to increase plasma PHT levels, at least in some patients, include felbamate, oxcarbazepine, valproic acid, carbamazepine, clobazam, topiramate, methsuximide, sulthiame, stiripentol, fluoxetine, fluvoxamine, imipramine, sertraline, trazodone, viloxazine, chloramphenicol, fluconazole, isoniazid, miconazole, sulfaphenazole, some antineoplastic drugs (doxifluridine, fluorouracil, tamoxifen, tegafur), allopurinol, amiodarone, azapropazone, cimetidine, chlorpheniramine, dextropropoxyphene, diltiazem, disulfiram, omeprazole, phenylbutazone, sulfinpyrazone, tacrolimus, ticlopidine, and tolbutamide. In the case of highly protein-bound drugs that displace PHT from plasma protein-binding sites (e.g., valproic acid, tolbutamide, phenylbutazone), the increase in plasma PHT concentration may be limited to the free, unbound fraction, and may not be apparent when only total PHT concentrations are monitored.[21,91,114a,114b,146b,208]

Effects of Phenytoin on the Pharmacokinetics of Other Drugs

PHT is a potent inducer of microsomal drug-metabolizing enzymes and by this mechanism it accelerates the metabolism of a large number of concurrently administered drugs, thereby decreasing their plasma concentrations.[114a,114b,146b] Antiepileptic drugs whose plasma concentration is decreased by PHT include carbamazepine, lamotrigine, topiramate, tiagabine, zonisamide, felbamate, and many benzodiazepine drugs.[101,146b,215] PHT also lowers the plasma concentration of valproic acid[122] and increases the production of the "4-en" valproic acid metabolite, thought to be responsible for hepatic toxicity.[100] Other drugs whose plasma concentration may be lowered by PHT include oral contraceptive steroids, dexamethasone and other glucocorticoids, nisoldipine, felodipine and most

P.1618

other dihydropyridine calcium antagonists, cyclosporin A, certain antineoplastic agents, meperidine, methadone, acetaminophen, theophylline, chloramphenicol, itraconazole, indinavir, doxycycline, praziquantel, folic acid, digitoxin, bishydroxycoumarin, warfarin (for which an initial decline in the plasma concentration may be followed by an increase in plasma warfarin concentration and increased anticoagulant response), metyrapone, 25-hydroxycholecalciferol, and thyroxine.[91] Many of the above interactions are clinically important and may result in loss of pharmacologic effect of the affected drug. Coadministration of PHT has been reported to raise the plasma concentration of phenobarbital derived from primidone and N-desmethylmethsuximide derived from methsuximide.[21,91,95]

Indications

Oral Treatment

PHT is indicated for the treatment of partial seizures, with or without secondary generalization, and for the treatment of primarily generalized tonic–clonic seizures. Because PHT may potentially aggravate other generalized seizure types such as absence and myoclonic seizures,[147a] it is not the best choice to treat primarily generalized tonic–clonic seizures in syndromes associated with other generalized seizure types. As discussed in more detail in Chapter 118, the choice of an AED is dictated not only by its efficacy spectrum, but also by other considerations such as adverse effects, drug interaction potential, cost, and individual characteristics of the patients. The use of PHT varies considerably across countries and across different clinical settings. While many physicians consider PHT as a valuable treatment option for initial treatment, others prefer to utilize PHT as a second-line agent due to concerns with its dose-dependent pharmacokinetics, cosmetic side effects (particularly in young women), and potential for drug interactions (particularly in the elderly).

Intravenous Treatment

PHT is an important therapy for tonic–clonic and partial status epilepticus. Its best use for status epilepticus is in combination with a benzodiazepine, which should be given first because of the benzodiazepine's faster onset of antiseizure effect.[125] A more detailed discussion of the role of PHT in the treatment of status epilepticus is provided in Chapter 127.

Dosing Recommendations

Initiation of Treatment and Dose Adjustment

The usual initial dosage in adults is 300 mg/day, and the usual initial dosage in children is 5 mg/kg/day. Because of the very slow metabolism of PHT in premature and term infants, the usual doses of PHT can produce toxic plasma concentrations in these infants.[106] It is often impossible to predict the proper dosage of PHT in such patients, and the dosage must be adjusted by frequent monitoring of PHT plasma concentration.

Clinical response should be monitored carefully after initiating treatment. In patients with unusually slow rates of PHT metabolism, the usual starting dosage may result in excessively high plasma PHT concentrations and occurrence of adverse effects. More commonly, the usual daily dose of 300 mg/day may not produce good seizure control, and the dosage must then be raised until seizure control is obtained or toxicity precludes further increases. In raising the dosage of PHT, one is faced with two conflicting considerations. In some patients, a small increase in PHT dosage will result in an unexpectedly great increase in plasma concentration and drug toxicity owing to the phenomenon of concentration-dependent metabolism. This result argues for increasing the dosage in small increments. Other patients absorb PHT poorly and require large increases in dosage to achieve therapeutic drug plasma concentrations. This would argue for increasing dosage in large increments. One workable compromise is to increase PHT dosage in 100 mg/day increments until a plasma concentration of 10 μg/mL is reached. After that, further increments of 50 mg/day or 30 mg/day can be added. Only one increment should be added every 4 weeks or longer because it may take that much time to reach a steady-state plasma concentration and to discern the full therapeutic and toxic effects of the dosage regimen. Monitoring plasma PHT concentration is invaluable during the process of dose individualization, or whenever there is an unexpected change in clinical response (Chapter 104).

As noted above, some patients who do not absorb PHT capsules well will absorb the oral suspension form much better. If a patient is taking a dose of 500 mg/day and does not have a therapeutic plasma concentration and noncompliance has been excluded, it may be helpful to switch from the capsule form to the oral suspension form. This often results in therapeutic (and sometimes toxic) plasma concentrations. PHT oral suspension must be shaken well before each dose to prevent the drug from settling in the bottom of the bottle, resulting in undermedication when the suspension is taken from the top of the bottle and overmedication when it is taken from the bottom of the bottle.

Divided Dose Versus Single Daily Dose

Several groups have shown that once-daily administration of extended-release PHT will maintain therapeutic plasma concentrations in the majority of adults, although there can be a twofold difference between maximum and minimum PHT plasma concentrations because for some patients, particularly when the plasma PHT concentration is in the low range, the elimination half-life can be <24 hours.[20,28,90,187] Because once-daily administration is the most convenient dosage schedule for many patients, it probably encourages increased compliance. However, there are four groups of patients who should receive PHT in two divided doses. The first group is patients of any age taking immediate-release PHT. The second group is adults who have side effects associated with peak plasma concentrations after once-daily administration. The third group includes patients of any age with poorly controlled seizures. Dividing the dose of PHT will result in a smaller fall in PHT plasma concentration at times of minimum drug serum concentration. The fourth group is children, because children metabolize PHT more rapidly than adults and cannot always maintain a therapeutic plasma concentration with once-daily administration.[20,56,106] Even with their more rapid rate of elimination of PHT, children can maintain therapeutic plasma concentrations with twice-daily administration.[56]

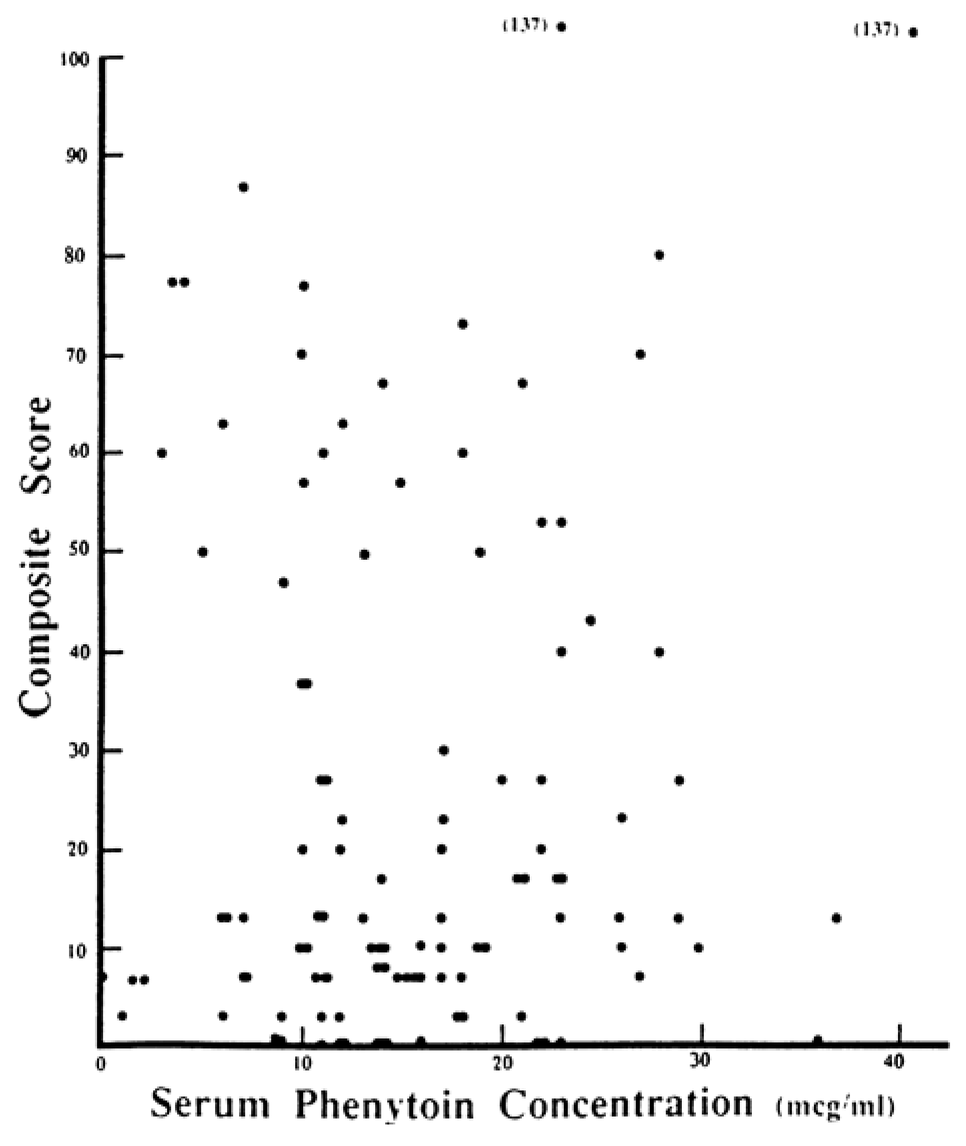

FIGURE 4. Plot of plasma phenytoin concentration versus composite score for overall response (efficacy and toxicity) to drug (0, no seizures and no side effects; 1–20, good response; 21–49, acceptable but less than optimal response; 50+, unacceptable seizure frequency or toxicity). (From Schumacher GE, Barr JT, Browne TR, et al., and the Veterans Administration Epilepsy Cooperative Study Group. Test performance characteristics of the serum phenytoin concentration [SPC]: the relationship between SPC and patient response. *Ther Drug Monit*. 1991;13:318–324, with permission.)

Administration of PHT in three or four divided doses is almost never necessary and should be avoided. Patients often omit doses of drugs that must be taken at school or work, and three- or four-dose daily regimens often lead to increased noncompliance.[20]

The largest dose of PHT is usually given at bedtime. This reduces drowsiness, ataxia, and other side effects that can be associated with peak PHT plasma concentrations.

Loading Dose

It can take several weeks to reach a steady-state plasma PHT concentration when therapy is initiated with the usual

maintenance doses. If it is necessary to achieve a plasma concentration in the therapeutic range rapidly, a loading dose can be given. Therapeutic plasma concentrations can be achieved very quickly with an intravenous loading dose in emergency situations. The intravenous loading dose of PHT is 15 to 20 mg/kg (see Chapter 127). Specific information on intravenous dosing recommendations for the treatment of status epilepticus is provided in Chapter 127.

Administration of an oral loading dose of PHT is less rapid but less dangerous than intravenous loading. In adults, administration of 400 mg followed after 4 hours with 300 mg followed after 4 hours with a final 300-mg dose will result in therapeutic PHT plasma concentrations 14 to 20 hours after the first dose and steady-state plasma concentrations 36 to 40 hours after the first dose.[198] More rapid administration of oral PHT in alert patients may result in gastrointestinal upset, drowsiness, and "spacey" feelings.

In children, oral loading with PHT can be accomplished by administering four doses of 5 to 6 mg/kg at 8-hour intervals. With this regimen, plasma concentrations of 10 μg/mL or more are reached 16 to 38 hours after the first dose.

Administration of a loading dose of PHT via the intramuscular route is not possible using injectable sodium phenytoin (see above). However, a loading dose of PHT can be administered via the intramuscular route using fosphenytoin (see below).

Plasma Phenytoin Concentration as an Aid to Dose Adjustment

The average dosage (in milligrams per kilogram) required to achieve a given plasma PHT concentration is greater in children than in adults.[20,90] However, the plasma concentration produced by a given dose of PHT varies so much that it is impossible to predict a given patient's drug plasma concentration from the dosage.[90] Laboratory tests are the only assured method of determining a patient's drug plasma concentration.

The commonly provided target range provided by clinical laboratories for PHT plasma concentration is usually 10 to 20 μg/mL. The lower limit of 10 μg/mL is determined by the observation that the majority of patients with PHT plasma concentrations <10 μg/mL do not achieve good seizure control.[20,90] The upper limit of 20 μg/mL is determined by the observation that the majority of patients will show signs or symptoms of PHT intoxication with plasma concentrations above this value.[20,90] However, the range of 10 to 20 μg/mL is only a guideline or set of reference points. In a study of optimally managed patients, Schumacher et al.[171] found that approximately 25% of patients on PHT monotherapy had plasma concentrations in each of four groups: 5 to 10 μg/mL, 10 to 15 μg/mL, 15 to 20 μg/mL, and 20 to 25 μg/mL (Fig. 4). Other reports also confirm that some patients do best with PHT plasma concentrations above or below the provided range.[77,109] The use of plasma concentration monitoring as

a guide to dosage adjustment is discussed in more detail in Chapter 104.

Precautions

PHT should be used cautiously in patients with generalized epilepsies, due to the potential of precipitating or aggravating seizure types against which the drug is ineffective, particularly absence and myoclonic seizures. The use of PHT in patients with liver impairment also requires caution because of the increased likelihood of dose-related adverse effects. Observation for rash, especially after initiation of treatment, is warranted because of the possibility of a serious dermatologic reaction such as Stevens-Johnson syndrome or toxic epidermal necrolysis.

Contraindications

PHT is contraindicated in patients with known hypersensitivity to hydantoin drugs. Other contraindications include progressive myoclonic epilepsy of the Unverricht-Lundborg type[146a] and acute intermittent porphyria.

Because of its effect on ventricular automaticity, the intravenous use of phenytoin is contraindicated in sinus bradycardia, sinoatrial block, second- and third-degree atrioventricular block, and patients with Adams-Stokes syndrome.

Fosphenytoin

Chemistry

Fosphenytoin (disodium phosphate ester of phenytoin; ACC-9653; CI 982; Cerebyx) (Table 1) is a phosphate-ester prodrug of PHT developed as a replacement for standard injectable sodium PHT.[28] After absorption, PHT is cleaved from the prodrug by phosphatase enzymes. Fosphenytoin has a molecular weight of 406.3. Thus, 1.5 mg of fosphenytoin releases 1.0 mg of phenytoin. To simplify discussion, all fosphenytoin doses in this paper have been converted to “PHT equivalent doses” (fosphenytoin dose divided by 1.5). Unlike PHT, fosphenytoin is freely soluble in aqueous solutions (including standard intravenous solutions). The water solubility of fosphenytoin at 37°C is 7.5×10^4 μg/mL (vs. 20.5 μg/mL for PHT).[34] Because it is much more water soluble than PHT, fosphenytoin is formulated as a simple aqueous solution in trimethamine (Tris) buffer at pH 8.8.[142] In contrast, injectable sodium PHT is formulated with 40% propylene glycol and 10% ethanol in water adjusted to pH 12 with sodium hydroxide. The propylene glycol and high pH can cause local toxicity at injection sites (see below).

Pharmacology

The pharmacologic activity of fosphenytoin on the nervous system is via PHT released from fosphenytoin. The mechanism of action of PHT is discussed above.

Clinical Pharmacokinetics

Absorption

The extent of absorption (absolute bioavailability) of fosphe-nytoin has been determined by measurements of the ratios of the area under the plasma concentration versus time curve (AUC) for PHT derived from fosphenytoin versus the AUC values for standard injectable sodium PHT administered by the intravenous route. A ratio of 1.0 indicates complete bioavailability. In single-dose studies in drug-free volunteers by the intravenous[24,85] and intramuscular[24] routes and in single-dose intravenous studies in patients with therapeutic PHT plasma concentrations,[34] the AUC ratios obtained were close to 1.0. Bioavailability studies of drugs with nonlinear pharmacokinetics (such as PHT) present special difficulties, which have recently been reviewed.[28,34,36] Unlike intravenous administration, which has peak serum fosphenytoin concentration at the end of the infusion, the peak serum concentration of intramuscularly administered fosphenytoin occurs approximately 30 minutes after the injection. For both intravenous and intramuscular administration, the time of peak fosphenytoin serum concentration is not as clinically meaningful as the time of peak PHT serum concentration, which results from enzymatic conversion. When fosphenytoin is given intravenously, peak total (free + bound) PHT concentrations occur 30 to 60 minutes after starting the infusion, whereas peak free PHT concentrations occur at 15 to 30 minutes.[65a] The difference in time to peak between total and free PHT is due to the fact that fosphe-nytoin displaces PHT from its plasma protein-binding sites in a concentration-dependent manner.[65a] The peak in plasma PHT concentration after intramuscular injection of fosphenytoin occurs at about 1.5 to 4 hours, and it is significantly lower compared with the peak concentration produced by intravenous fosphenytoin or PHT.

Plasma Protein Binding and Distribution

Fosphenytoin is a very polar, water-soluble molecule with a volume of distribution of 0.04 to 0.13 L/kg, and it remains largely in the plasma compartment, distributing more widely after its cleavage into PHT and the phosphate moiety.[13,34,65a,99,103]

Fosphenytoin binds competitively to the same plasma protein-binding sites as PHT.[62,63,84] Thus, in the presence of fosphenytoin, the free PHT plasma concentration (for PHT derived from fosphenytoin or from previous administration) is higher than expected. The free PHT fraction increases with increasing fosphenytoin plasma concentration and with increasing fosphenytoin infusion rate (especially rates >50 mg/min). Prior administration of diazepam has no effect on the protein binding of fosphenytoin.[84]

Metabolism and Elimination

PHT is cleaved from fosphenytoin by phosphatase enzymes present in liver, red blood cells, and other tissues.[142] The half-life for conversion of fosphenytoin to PHT is approximately 8 to 15 minutes with modest interindividual variability.[3,14,19,24,28,34,63,68,103,142] The conversion half-life of fosphenytoin appears to be independent of plasma concentration of fosphenytoin or PHT.[19,24,34,63,103] The clearance of fosphenytoin is approximately 200 mL/min at lower dosing and infusion rates and increases to approximately 400 mL/min at higher dosing and infusion rates, presumably because of changes in distribution (see above).[19,24,34,63,103] The conversion half-life of fosphenytoin to PHT is shorter in patients with he-patic or renal disease, possibly because of differences in protein binding.[4]

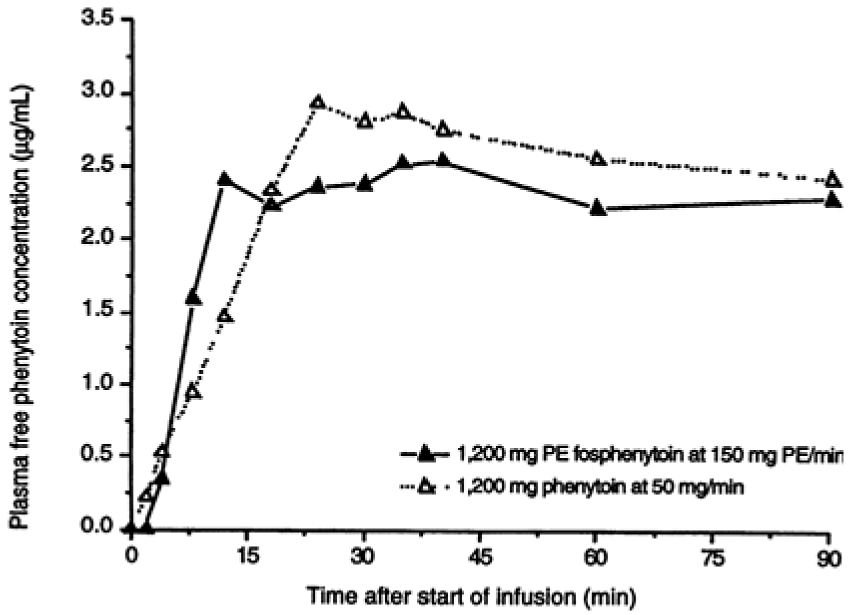

FIGURE 5. Mean free plasma phenytoin (PHT) concentration following administration of 1,200-mg doses of PHT and fosphenytoin (in PHT equivalents) to 12 healthy subjects. (From Browne TR, Kugler AR, Eldon MA. Pharmacology and pharmacokinetics of fosphe-nytoin. *Neurology*. 1996;46(Suppl 1):S3–S7. with permission.)

Direct renal excretion of fosphenytoin is small (0% to 4% of dose) and clinically insignificant.[34,142] PHT derived from fosphenytoin is eliminated in the same way as PHT administered as such.[19,24,34,103]

Efficacy

Being a prodrug of PHT, fosphenytoin has an efficacy profile equivalent to that of PHT.

Adverse Effects

Animal[93,177,197,199,200,205] and human[50,60,62,63,86,87,103,209] studies show convincingly that fosphenytoin causes fewer local adverse effects (burning and pain) when given by the intramuscular route (20% incidence, usually mild) or the intravenous route (<5% incidence, usually mild) compared with standard injectable sodium PHT. This is presumably a result of differences in the physicochemical characteristics of the formulations (see above).

Animal and human work indicates that most of the toxicity associated with fosphenytoin is attributable to enzymatically derived PHT.[19,43,50,62,63,74,97,103,168,177] The most common side effects reported for fosphenytoin in large clinical trials are nystagmus, headache, ataxia, and somnolence.[50,97] Pruritus or paresthesias of the groin, back, lower abdomen, head, or neck rarely occur during PHT infusions, but have been reported in 0% to 30% of volunteers or patients in various studies of parenteral fosphenytoin.[19,103,142] Pruritus and paresthesias usually occur during intravenous administration of higher doses and at higher dosing rates and rapidly resolve without sequelae.[19,103,142]

The maximum rate of infusion of standard sodium PHT for injection is determined by cardiac depression (hypotension, atrioventricular block). This rate is usually stated to be 50 mg/min, although there are no definitive published data to establish it. Similarly, the maximum rate of infusion of fosphenytoin is determined by cardiac depression, presumably from PHT derived from fosphenytoin. It has been found that infusion of fosphenytoin at a rate of 150 mg PHT equivalents/min produces free PHT plasma concentrations similar to those produced by standard injectable sodium PHT infused at 50 mg/min (Fig. 5). The incidence of cardiac depression with fosphenytoin infused at 150 PHT equivalents/min is similar to or less than the incidence with sodium phenytoin infused at 50 mg/min, possibly because of elimination of propylene glycol from the fosphenytoin preparation.[22]

Role in Epilepsy Treatment

Indications

Fosphenytoin is a valuable alternative to parenteral PHT. Its main indications are the treatment of status epilepticus and as parenteral replacement therapy for oral PHT in patients temporarily unable to take PHT orally.

Dosing Recommendations

Intravenous Treatment of Status Epilepticus.

The half-life for conversion of fosphenytoin to PHT is 8 to 15 minutes, potentially slowing its effectiveness in treating status epilepticus. However, this observation is offset by two other observations. First, fosphenytoin can be infused safely at a rate of 150 mg/min of PHT equivalents, whereas the maximum safe infusion rate for PHT is 50 mg/min. Second, the free fraction of plasma PHT is increased in the presence of fosphenytoin, especially at high fosphenytoin infusion rates. Volunteers and patients receiving fosphenytoin infusions at 150 mg/min have free PHT plasma concentrations equivalent (in time and extent) to those produced by standard injectable sodium PHT infused at 50 mg/min (Fig. 5).[28,62,63] As expected, the dosing rates of these two drugs produce similar systemic toxicity, but there is less local toxicity with the fosphenytoin preparation.[28,62,63]

The administration of fosphenytoin for status epilepticus is recommended in the FDA-approved prescribing information to be 15 to 20 mg PHT equivalents/kg intravenously at a rate of 100 to 150 mg PHT equivalents/min. A reduction of the infusion rate by 25% to 50% has been suggested when infusing fosphenytoin in patients with renal or hepatic disease, hypoalbuminemia, and the elderly.[65a] In all patients, continuous monitoring of electrocardiogram, blood pressure, and respiratory function is recommended during the infusion and for 20 minutes after the infusion has completed, although the risk of autonomic complications is less than that from intravenous PHT. Because of the delay related to the conversion of fosphenytoin to PHT, a benzodiazepine or other more immediate-acting antiseizure medication is recommended to be given concomitantly with fosphenytoin.

Intramuscular Loading Dose.

An intramuscular loading dose of fosphenytoin equivalent to 9 to 12 mg/kg of PHT will produce a maximum PHT plasma concentration of approximately 12 μg/mL 4 hours after injection.[50] These parameters are acceptable for management or prophylaxis of chronic epilepsy but not for status epilepticus. Intramuscular loading doses of fosphenytoin often need to be divided into two injection sites because of the associated large fluid volume.

P.1622

Intramuscular Maintenance Dose.

After administering a loading dose of PHT (or in patients on chronic PHT therapy with therapeutic PHT plasma concentration values), therapeutic PHT plasma concentrations can be maintained with equimolar (equal to usual oral PHT dosing rate) doses of intramuscular fosphenytoin for at least 14 days.[50,58,209] When switching patients from oral PHT to equimolar doses of intramuscular fosphenytoin, however, plasma PHT levels may increase significantly, due to greater bioavailability of intramuscular fosphenytoin compared with oral PHT.[65a] Therefore, regular monitoring of PHT levels is recommended in these patients. Numerous studies report less local toxicity at injection sites with fosphenytoin than with PHT.[50,58,209]

Role of Plasma Level Monitoring.

Determinations of fosphenytoin plasma concentration are of little clinical value because fosphenytoin largely remains in the plasma compartment and is rapidly converted to PHT. However, methods for determination of fosphenytoin plasma concentration have been developed for research purposes.[68,103,168] For clinical purposes, fosphenytoin therapy can be monitored by measuring plasma PHT concentrations.

Ethotoin

Chemistry

Ethotoin (3-ethyl-5-phenylhydantoin; Table 1) is a white crystalline compound with a molecular weight of 204.22.[89] Ethotoin contains a chiral center at the 5 position of the hydantoin ring. The specific rotation of the *R* (-) enantiomer is 88 degrees. Ethotoin is insoluble in water but is soluble is most organic solvents. Published methods of detection include gas chromatography, mass spectrometry, and high-performance liquid chromatography (HPLC).[89]

Pharmacology

The addition of an ethyl group in position 3 and the deletion of one phenyl group from position 5 in the hydantoin ring (Table 1) result in a compound that is both less potent against maximal electroshock seizures in animals and less toxic than PHT.[89,128] Ethotoin has some activity against pentylenetetrazol seizures in animals but has proved to have little effect on absence seizures in patients.[46,89,128] The mechanisms of action of ethotoin have not been studied but may be similar to those of PHT.

Clinical Pharmacokinetics

Peak plasma concentrations of ethotoin occur 2 to 4 hours after oral doses.[89,190] Ethotoin is 46% protein bound.[190] The elimination half-life of small, single doses of the drug is 3 to 12 hours, and the drug has no active metabolites.[82,89,190] The absorption and elimination of the two isomers of ethotoin are similar.[82] Therefore, the package insert states that ethotoin must be given in four or more divided doses to minimize fluctuations between peak and trough plasma concentrations.

The major metabolic pathway of ethotoin is ring hydroxylation, similar to PHT.[89] Also similar to PHT, ethotoin appears to have nonlinear pharmacokinetic properties.[82,126,213] Because drugs with nonlinear pharmacokinetic properties have longer elimination half-lives at steady-state plasma concentrations than at the low plasma concentrations of single-dose studies, it may be possible to administer ethotoin three times daily.[30] The details of ethotoin metabolism have been reviewed recently elsewhere.[89]

Efficacy

There are no controlled trials of ethotoin. Uncontrolled studies indicate that ethotoin has some efficacy against tonic–clonic and complex partial seizures but probably does not control such seizures as efficiently as PHT.[46,128,172] The lack of efficacy of ethotoin may be related in part to the large doses necessary to obtain seizure control and to the necessity to administer the drug in four to six divided doses daily. The drug has little or no efficacy against simple partial and absence seizures.[46,128]

Adverse Effects

Side effects occur less frequently than with PHT and include rash (2%), anorexia and vomiting (3%), drowsiness, nystagmus, and occasionally lymphadenopathy.[128] Ataxia occurred only with large doses.[128] Gingival hyperplasia has not been reported.[128] Congenital malformations similar to those associated with PHT have been reported in association with ethotoin.[65]

Role in Epilepsy Treatment

Indications

Ethotoin is approved by the FDA for the treatment of tonic–clonic and complex partial seizures. However, due to the lack of sound evidence for efficacy from controlled trials, ethotoin is very rarely used in the current treatment of epilepsy. Uncontrolled reports have suggested that ethotoin may be used for the treatment of patients with (a) tonic–clonic seizure disorders and hypersensitivity to more potent agents[128]; (b) refractory partial or generalized seizures[12,126]; and (c) good therapeutic effect but cosmetic side effects with PHT. However, due to the availability of many alternative agents with better documented efficacy and safety, switch to ethotoin therapy rarely is justified.

Dosing Recommendations

In adults, the initial dose should be 1,000 mg/day or less. Dosage is then gradually increased for several days until the optimal dosage is reached. Most adults require 2,000 to 3,000 mg daily. Doses of <2,000 mg/day seldom are effective.

In children, the initial dose should be 750 mg/day or less. The usual maintenance dose is 500 to 1,000 mg/day, although daily doses of up to 3,000 mg are sometimes necessary.

Ethotoin usually is administered in four to six divided doses daily because of its short elimination half-life in single-dose studies. The drug should be taken after meals, and the doses should be divided as evenly as possible. The optimal range of ethotoin plasma concentration is estimated at 15 to 50 μg/mL.[42,96,191] Because of the concentration-dependent pharmacokinetics, it may be possible to administer ethotoin three times per day once steady-state plasma concentration has been reached.[30]

Mephenytoin

Chemistry

Mephenytoin is a white crystalline substance with a molecular weight of 218.25 (Table 1). Because of the asymmetric carbon atom at position 5 of the hydantoin ring, mephenytoin is produced as a racemic mixture. The chemical details of the isomers

of mephenytoin have been reviewed elsewhere.[89] Mephenytoin, Nirvanol (active metabolite), and other mephenytoin metabolites can be quantified by HPLC,[89] and other methods exist to quantify the enantiomers of these molecules.[89]

Pharmacology

N-methylation at position 3 in the hydantoin ring and substitution of an ethyl for one phenyl group at position 5 provide a broader spectrum of action in animal screening tests for antiepileptic activity than PHT. Mephenytoin has some protective effect against pentylenetetrazol seizures, whereas PHT does not.[89,128] However, these structural changes in mephenyt-oin also result in greater neurotoxicity and smaller potency and protective index against maximal electroshock seizures than seen with PHT.[89,128] The basic mechanisms of action of mephenytoin have not been studied but may be similar to those of PHT.

Clinical Pharmacokinetics

Peak plasma concentrations of mephenytoin occur 45 to 120 minutes after an oral dose.[89,190] Mephenytoin is partly hydroxylated, and partly demethylated to the active metabolite Nirvanol (5-ethyl-5-phenylhydantoin).[89,185,190] Nirvanol is partly eliminated by renal excretion and partly by *p*-hydroxylation and glucuronide formation.[89,209a] A number of other minor metabolic pathways of mephenytoin have been reported.[89] The protein binding of mephenytoin is 39%, and that of Nirvanol is 29%.[190]

There is a marked enantioselectivity in the metabolism of mephenytoin. While the S-enantiomer is rapidly hydroxylated by CYP2C19 and eliminated with a half-life of about 1 hour, the R-enantiomer has a half-life of about 70 hours and is slowly demethylated to R-Nirvanol, which, in turn, is eliminated very slowly (half-life of 150 to 200 hours), mostly by renal excretion, and accumulates in plasma at concentrations much higher than those of the parent drug.[89,190,191] Subjects with genetically determined CYP2C19 deficiency (about 4% of Caucasians and 20% of Japanese) do not hydroxylate S-mephenytoin efficiently and, as a result, both enantiomers are converted to Nirvanol. S-Nirvanol derived from S-mephenytoin in these subjects is also cleared more slowly, and also accumulates at high concentrations.[89,204a,209a] Because of the high levels of S-mephenytoin and Nirvanol in poor CYP2C19 metabolizers, these subjects are at increased risk for concentration-dependent toxicity. Because of the long elimination half-life of Nirvanol, mephenytoin needs to be given only once or twice a day, and many weeks may be required to reach steady-state plasma concentrations.[191,209a]

Efficacy

There have been no controlled clinical trials of mephenyt-oin. Uncontrolled trials reported that a majority of patients with tonic–clonic or simple partial seizures will experience a considerable reduction in seizure frequency with mephenyt-oin, whereas only a minority of patients with complex partial seizures respond favorably.[46,89,128] Absence seizures do not seem to be affected.[46,128]

Adverse Effects

Compared with PHT, mephenytoin causes less ataxia, less gingival hyperplasia, and less nausea and vomiting.[128] These advantages are offset by a greater incidence of drowsiness, serious dermatitis, agranulocytosis, aplastic anemia, and hepatitis.[128] The incidence of fatalities and serious side effects appears to be greater with mephenytoin than with PHT.[128,191] The package insert should be consulted for instructions on monitoring for adverse affects.

Drug Interactions

The drug interactions of mephenytoin are numerous and complex.[190,191] Autoinduction of metabolism of mephenyt-oin and Nirvanol occurs, leading to a downward drift of plasma concentration of both drugs with chronic administration. Also, mutual induction of metabolism occurs when mephenytoin is coadministered with carbamazepine or barbiturates. At low plasma concentrations of mephenyt-oin, Nirvanol, and PHT, there is mutual induction of biotransformation (with a fall in drug plasma concentrations), whereas at high plasma concentration, there is mutual inhibition of biotransformation (with an increase in drug plasma concentrations).

Role in Epilepsy Treatment

Indications

Mephenytoin is approved by the FDA for treatment of tonic–clonic, simple partial, and complex partial seizures. Because of the availability of safer, newer drugs, mephenytoin is used very rarely in the current treatment of epilepsy.

Dosing Recommendations

The initial dosage is 50 to 100 mg/day during the first week. The daily dosage is then increased by 50 or 100 mg at weekly intervals until seizure control is obtained or toxicity precludes further increases. Increases in dosage should not be made more often than once a week. Because of the toxicity of mephenytoin, one should attempt to control seizures with the smallest possible dose. The average daily dose required is 200 to 600 mg in adults and 100 to 400 mg in children.

Total combined mephenytoin plus Nirvanol plasma concentration must be determined for therapeutic drug monitoring. Total concentrations of 1.5 to 40 μg/mL have been reported for patients having a good response.[172,190,191]

Summary and Conclusions

PHT is a well-established option for the initial treatment of partial and generalized tonic–clonic seizures. It possesses proven efficacy and, in its extended-release formulation, may be administered once daily for many adults. Prescribers of PHT should be familiar with its nonlinear pharmacokinetic properties, its potential drug interactions, and its several formulations. PHT is an important therapy for status epilepticus, and fosphenytoin is a parenterally administered PHT prodrug that offers some advantages in terms of local tolerability and safety over injectable formulations of PHT. Ethotoin has been reported to be of benefit in treating complex partial and tonic–clonic seizures, but there are no controlled trials supporting this claim and its usage is limited by labeling indicating administration four to six times per day. Mephenytoin has also been reported to be effective for the treatment of partial and tonic–clonic seizures, based on results of uncontrolled trials. However, its use is limited by a number of side effects including

P.1624

drowsiness, dermatitis agranulocytosis, aplastic anemia, and hepatitis.

Chapter 155

Pregabalin

Gregory K. Bergey

Introduction

Pregabalin is the most recent antiepileptic drug (AED) introduced in the United States; it received approval as adjunctive therapy for partial seizures in 2005. Pregabalin has also been approved for treatment of neuropathic pain associated with diabetic neuropathy[55,57] and postherpetic neuralgia.[22,59] Several controlled trials have been done with pregabalin in generalized anxiety disorder (GAD), and approval for GAD exists in other countries, but not in the United States.[44,45,48,49,52] Pregabalin is a congener of gabapentin (Chapter 149), an AED approved in 1994.[60] Although pregabalin and gabapentin share certain features, important distinctions also exist. Because these two compounds are chemically related, and there is considerable experience with gabapentin, this chapter will specifically include a discussion of the similarities and differences between the two drugs, where they are known. Although comments regarding efficacy will be limited to the epilepsy studies, discussion of adverse reactions will, where appropriate, include the pain and anxiety studies, because these provide additional information from controlled studies.

Chemical Structure, Formulations, And Methods For Determination In Body Fluids

Pregabalin (Lyrica) is S-3-(aminomethyl)-5-methylhexanoic acid, a compound with a molecular weight of 159.23.[3] It is freely soluble in water. Although a structural analog of γ-aminobutyric acid (GABA) (Fig. 1), the additional side chain alters the distance between the GABA subunit terminals, with the net result that it is not a GABA mimetic. Gabapentin has a ring structure whereas pregabalin is a branched structure. Pregabalin development was the result of screening gabapentin analogs to develop an agent with greater antiepileptic efficacy, first by studies of inhibition of [3 H] gabapentin binding and then by animal studies.[8] The S-isomer binds to the α-2-δ receptor, the same receptor involved in gabapentin-specific binding.[12] Although freely soluble in water, at present approved formulations are only capsules. Development of liquid formulations are in progress, and the potential for a parenteral formulation exists. Therapeutic levels have not yet been established, but pregabalin can be assayed in plasma and other fluids using high-performance liquid chromatography.[10]

Pharmacology

Mechanism of Action

Like gabapentin, pregabalin binds to the α-2-δ subunit of voltage-gated calcium (P/Q) channels, and allosterically modulates calcium (Ca) influx, reducing it by up to 40%—with the greatest reduction occurring in states in which high neuronal activity is present.[63] There are four subtypes of the α-2-δ subunit; pregabalin binds to subtypes 1 and 2 only. This modulation has been shown to reduce the presynaptic release of neurotransmitters, including noradrenaline,[20,21] substance P,[26] and the excitatory amino acid glutamate.[19,42] These effects require binding of pregabalin at the α-2-δ subunit. Although the α-2-δ type 1 knockout is a lethal mutant, studies have been performed using the R217 A knock-in mice with α-2-δ type 1 receptors that have preserved function but markedly reduced binding of pregabalin,[12,63] especially in the neocortex, hippocampus, basolateral amygdala, and spinal cord. In these mice, pregabalin has no benefit on pain, and has reduced anxiolytic and antiepileptic effects.[28,63] These studies supplement the binding studies by showing that binding of pregabalin to the α-2-δ receptor is necessary for maximal therapeutic effects. In addition, in cultured hippocampal neurons, some evidence suggests that the effects of pregabalin on synaptic vesicular release are greatest before and early in the course of a train of electrical stimuli.[42] In neuromuscular preparations, pregabalin reduced nerve-evoked muscle contractions by 16%.[38] When pregabalin cannot bind to the α-2-δ receptors, as in mutant R217 A mice, it has no effect. There has been no demonstrated effect of pregabalin on L-type Ca channels in muscle. α-2-δ Type 1 and 2 receptors are present outside the central nervous system (CNS) (e. g., in spleen, liver, lung) but at much lower concentrations.[61]

Despite the structural similarity of pregabalin to the inhibitory amino acid GABA, the addition of the side chain changes the configuration of the GABA subunit, with the net result that no binding to pre- or postsynaptic GABA (A or B) receptors occurs.[51,62] Pregabalin does not have any GABA mimetic properties, and there is no effect on GABA or chloride flux. In addition, brain GABA levels are not significantly altered by pregabalin,[24] and there is no effect on GABA uptake or degradation. Studies to date have not revealed significant effects of pregabalin on other known antiepileptic mechanisms (e.g., voltage-dependent sodium conductances), nor is there evidence that pregabalin affects the postsynaptic responses of any neurotransmitters. Therefore, at present, pregabalin appears to have a specific binding site that modulates and reduces the presynaptic release of neurotransmitter through a mechanism of action that does not depend on any GABAergic actions.

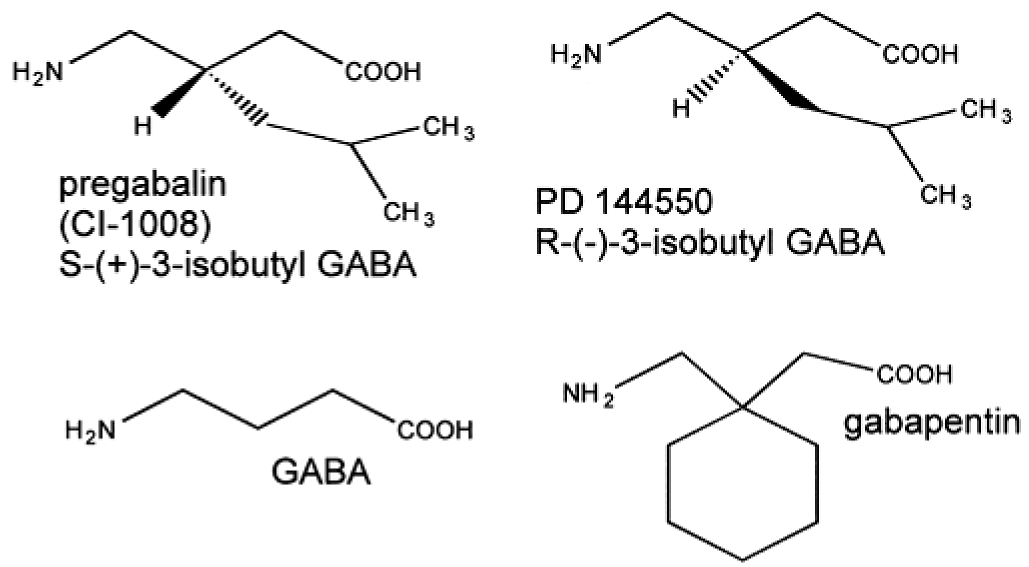

FIGURE 1. Chemical structures of gabapentin and pregabalin (3-isobutyl GABA) and the inhibitory neurotransmitter GABA.

Activity in Experimental Models of Epilepsy

The efficacy of pregabalin has been investigated in various animal models of epilepsy.[63,64] Pregabalin potently inhibits tonic extensor seizures in the electroshock model (ED50 = 1.8 mg/kg, administered orally), and it also prevents tonic extensor seizures in the DBA/2 audiogenic mouse model (ED50 = 2.7 mg/kg, administered orally). The time course of action of pregabalin reflects the time course of radiolabeled drug in the CNS. In a kindled rat model of partial seizures, pregabalin prevented the more fully evolved stage 4 and 5 behavioral

P.1630

seizures (lowest effective dose 10 mg/kg, intraperitoneally) and also reduced the duration of the electrographic discharges. All these are models of partial epilepsy or models that predict AED efficacy in partial epilepsy (maximum electroshock; MES).

At much higher doses (ED50 = 31 mg/kg, orally), pregabalin prevented seizures in the pentylenetetrazole (PTZ) model of epilepsy in mice. However, pregabalin did not prevent spontaneous absence-like seizures in the genetic absence epilepsy rats from Strasbourg (GAERS) and, in fact, seizures actually increased.[64] At one time, it was thought that AED efficacy in the PTZ model predicted anti-absence efficacy, but more recently[35,36] this has not been thought to be as reliable as the various genetic models for testing anti-absence efficacy of AEDs. Pregabalin does not appear to have significant anti-absence efficacy.

In one study[4] using the lithium pilocarpine model of status epilepticus in rats, early treatment with pregabalin delayed the appearance of later epilepsy and reduced neuronal damage in the piriform cortex and entorhinal cortex but not the hippocampus. At present, however, insufficient evidence is available to conclude that pregabalin is neuroprotective or antiepileptogenic; additional studies are needed.

Clinical Pharmakokinetics

Absorption

When fasting, oral bioavailability of pregabalin is excellent with >90% absorbed within 1 to 1.5 hours.[14] Absorption is linear for both single doses up to 300 mg and multiple doses up to 900 mg/day (Fig. 2). This is an important difference and advantage of pregabalin compared with gabapentin, which is absorbed slowly, reaching peak doses in 3 to 4 hours. Although both compounds are transported across the gut and blood–brain barrier by an L-amino acid transport system, pregabalin has linear kinetics across and even above the clinical dosing range. This is quite different from the case with gabapentin, where even a 900 mg daily dose, given as 300 mg three times a day, has only 60% bioavailability, and a 3,600 mg daily dose has only 33% bioavailability when given as 1,200 mg three times a day.[14] In comparing these two compounds, dose ranges of gabapentin from 900 mg to 3,600 mg per day and of 150 mg to 600 mg per day of pregabalin are commonly used, recognizing that these doses exceed the maximum approved dose for gabapentin in the United States (1,800 mg/day). Although the rate of pregabalin absorption is decreased slightly with food, the total amount absorbed is not affected.

Plasma Protein Binding and Distribution

Like gabapentin, pregabalin has negligible protein binding. The volume of distribution is approximately 0.5 L/kg.[3]

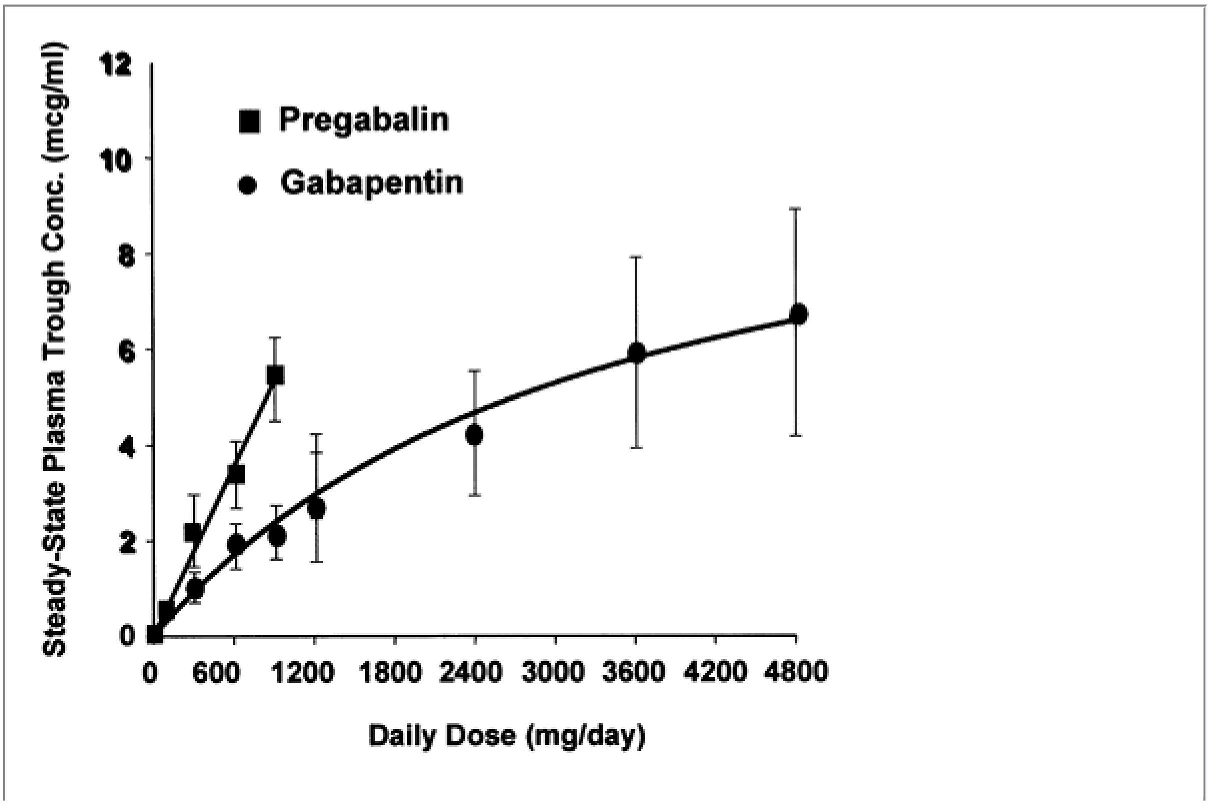

FIGURE 2. Comparison of gabapentin and pregabalin pharmacokinetics. (Bockbrader H MR, Spiegel K, Barrett J, et al. The Pharmaco-kinetic and pharmacodynamic properties of pregabalin and gabapentin in epilepsy. Differences and similarities. *Elepepsia.* 2005;46(Suppl 8):261. used with permission.)

Metabolism

Pregabalin is not metabolized significantly; more than 90% is excreted unchanged in the urine. Pregabalin is not metabolized in the liver to any extent, nor does it induce or inhibit any of the P450 isoenzymes.[3,9] The major metabolite, an *N*-methylated derivative, accounts for <1% of the dose.

Elimination

Elimination of pregabalin is primarily renal; the drug has a mean elimination half-life of 6.3 hours. Pregabalin clearance is proportional to creatinine clearance (CLcr), and patients with renal insufficiency (CLcr <60 mL/min) will need appropriate dose reductions. A 50% reduction in dose is recommended

for patients with a CLCr between 30 and 60 mL/min.[54] Because of pregabalin's low protein binding, it will be removed by hemodialysis, and postdialysis adjustments may need to be made. Elderly patients with reduced CLcr will have proportionately reduced pregabalin clearance.

Relationships Between Plasma Concentration and Effects (Including the Value of Therapeutic Drug Monitoring)

Therapeutic levels for pregabalin have not been established, and there are no recommendations for monitoring of plasma levels. Because of the 6-hour half-life, steady-state levels are achieved rapidly after initiation or dose adjustment, in about 30 hours (five half-lives). Arroyo et al.[6] found that steady-state doses of 150 mg/day produced mean plasma pregabalin levels of 1.27 μg/mL (range 0.29–2.84 μg/mL), and doses of 600 mg/day produced mean plasma pregabalin levels of 4.88 μg/mL (range 0.87–14.2 μg/mL).[34] The dose range study of French et al. had similar findings.[32] Beydoun et al.[11] reported that 600 mg, given three times a day, produced mean plasma pregabalin levels of 5.82 μg/mL (range 0.38–18.2 μg/mL); twice-daily dosing produced mean plasma pregabalin levels of 6.84 μg/mL (range 0.32–14.80 μg/mL). Although twice-daily dosing resulted in higher peak levels and lower daytime trough levels than the three-times-daily regimen, morning trough levels were similar in both groups. Efficacy in reducing seizures correlated with these mean levels. Because of pregabalin's rapid elimination, it would be expected that broad fluctuations in serum levels would occur even at steady state, and this is reflected in the broad ranges of plasma levels obtained for a given dose. This characteristic reduces the utility of random pregabalin sampling except to document compliance. It is possible that morning trough levels of pregabalin might be useful, but the range of such levels has not been established. It is not known how the pharmacokinetic profile of pregabalin in the serum relates to the pharmacodynamic profile in the CNS. The fact that efficacy with twice-daily dosing is not significantly different from three-times-daily dosing suggests the possibility of a pharmacodynamic effect distinct from plasma pharmacokinetics, but this has not been studied.

Efficacy

Pregabalin's efficacy in reducing seizures has been studied in three double-blind controlled pivotal trials involving a total of 1,052 patients with intractable partial epilepsy.[6,11,32] Although the criteria for entry into these trials were similar to other new AED trials—three seizures per month and failure with one AED—patients enrolled in the pivotal trials had frequent seizures and highly refractory epilepsy, with an average duration of epilepsy of 24 to 25 years, a mean monthly seizure frequency of 22, and a median monthly seizure frequency of 10. Approximately half the patients randomized to pregabalin were already taking two AEDs, and another quarter were on three AEDs, meaning that, during the actual trial, 75% of patients receiving active compound were taking three or four AEDs, including pregabalin. As predicted by pregabalin's lack of known interactions with any AEDs, no significant effects on concomitant AEDs were observed.

One study[32] was a dose-ranging study using from 50 mg/day to 600 mg/day given twice daily. A second study[6] compared placebo with 150 mg/day and 600 mg/day of pregabalin given three times a day, and a third study[11] directly compared 200 mg three times a day with 300 mg twice daily. The primary outcome variable in the first two studies was reduction of seizure frequency measured by the RRatio. The RRatio is defined as $[(T - B) / (T + B)] \times 100$, where B is the patient's 28-day baseline seizure frequency, and T is the patient's 28-day seizure frequency during treatment. Although statistically rigorous, the RRatio yields numbers ranging from –100 to +100, with a value of –100 equivalent to no seizures and –33 equivalent to a 50% reduction in seizures. The RRatio was statistically significant for pregabalin doses of 150 mg/day and above. Doses of 50 mg/day did not produce significant reductions in seizures. Because these numbers are difficult to equate with clinical situations, most of the discussion here will focus on the more clinically relevant measures: seizure frequency and responder rates (here defined as a 50% reduction in seizures).

Converting the RRatio data to seizure frequency and responder rate yields similar results, although in one instance, the 150 mg/day dose in the Arroyo et al. study, the *p* value was not quite significant ($p < 0.08$). However, the number of seizures at this dose was significantly reduced. Indeed, the seizure numbers paralleled the illustrated responder rates. At the highest total daily dose, 600 mg per day with twice-daily or three-times-daily dosing, results were remarkably consistent from trial to trial, with responder rates of 43% and 51%, respectively. Although caution is warranted about extrapolating from one series of clinical trials to another, these responder rates at 600 mg/day of pregabalin compare favorably with the best results obtained with other new AEDs in similar patient populations characterized by highly refractory partial seizures.[30]

Although seizure control is the goal of treatment, becoming seizure-free with any new AED is extremely rare in such patients, and therefore one should be cautious about conclusions claiming seizure freedom based on short clinical trials. Brodie[15] reports this short-term seizure free data in his recent review. Seizure-free rates ranged from 3% to 17% at all effective dose ranges (150 mg–600 mg/day) during the last 28 days of the trial. At the highest dose (600 mg/day, given in a divided dose three times a day), 11% of patients achieved seizure freedom during this interval.

No significant differences were noted between twice-daily and three-times-daily dosing, either in the trial using direct comparison between 200 mg three times a day and 300 mg twice daily,[11] or comparing across trials. FIGURE 3 illustrates the responder rates for these trials, specifically 43% versus 49% in the twice- versus three-times-daily direct comparison. The reduction in seizure number was 44% for 300 mg twice daily and 51% for 200 mg three times a day (*p* = not significant [NS]). Based on these studies, pregabalin received approval for twice-daily or three-times-daily dosing. The lack of significance between the two dosing regimens may reflect pharmacodynamic effects at the CNS receptor that are different from the plasma half-life of 6 to 7 hours. One commentary[25] speculated that the study was not sufficiently powered to detect a difference (something acknowledged by the authors of the original paper), and that showing that there is no difference is not the same as proving equivalence. This remains a possibility, although the number of patients in this study was similar ($n = 313$ entering) to the other two studies. Many more patients would probably be needed to demonstrate any difference, if indeed such a difference exists.

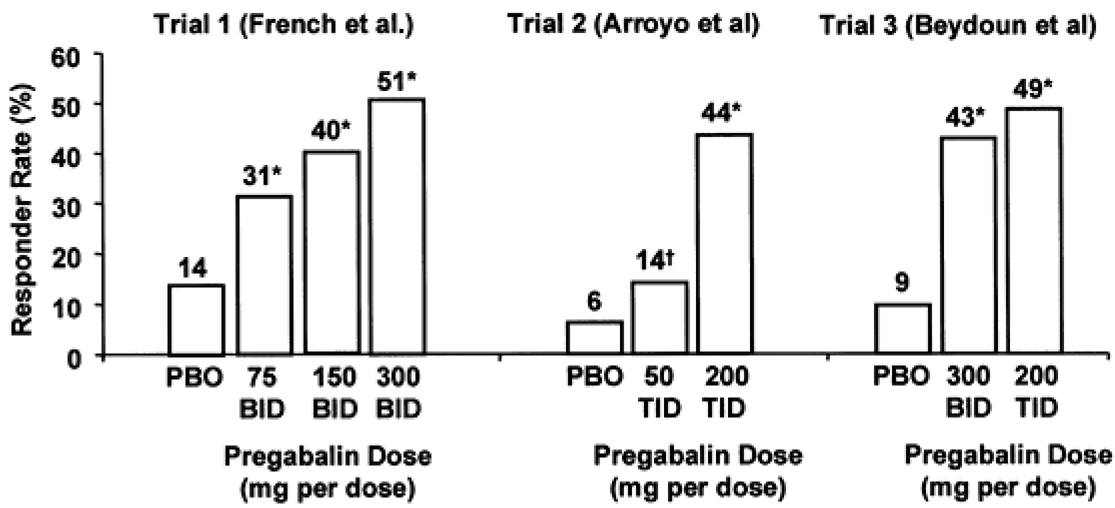

FIGURE 3. Responder rates (patients with >50% reduction in seizures compared to baseline) for the three pivotal epilepsy trials. PBO, placebo, $^*p \leq 0.01$, $^\dagger p \leq 0.08$. As noted, the pregabalin amount is per dose (e. g., 300 mg twice daily = 600 mg daily).

To address whether certain subgroups (e.g., those with less frequent seizures or more readily reduced seizures) were more likely to respond to pregabalin, analyses were performed examining patient groups by number of concomitant AEDs and average number of seizures. There was no significant difference in response whether patients were taking one, two, or three other AEDs. There was no difference in response based on seizure frequency (stratified from <5 seizures/month to >23 seizures/month). There is no evidence, therefore, that pregabalin responders were patients with less severe or less refractory epilepsy. Having said this, there may be subgroups who respond better than others. A model of exposure–response

analysis of pregabalin response in the three pivotal trials revealed that 25% of patients did not have a significant decrease in seizure frequency, whereas 75% had a dose-related decrease.[43] In the 75% who had significant seizure reduction, less than 200 mg/day was expected to reduce seizures by 50%. The characteristics of patients who might be more likely to experience a reduction in seizure frequency with pregabalin therapy have not been determined.

In another well-controlled, double-blind study comparing a fixed dose of pregabalin (600 mg/day using twice daily dosing) with flexible dosing, the fixed-dose arm achieved highly significant reductions in RRatio and seizure number.[23] The fixed-dose arm achieved a 49.3% seizure reduction, and 45.3% of patients had a >50% reduction in seizures, very similar to the three pivotal trials. In the flexible arm (average daily dose at conclusion of study was 508 mg/day), seizure reduction was 35.4%. This study provides further evidence for efficacy using a twice-daily dosing regimen.

The 600 mg/day dose appears to have been an appropriately selected upper range. Subjects have taken up to 900 mg/day on a regular basis, but a higher incidence of side effects was observed. There are no studies of efficacy at these higher doses.

In contrast to the pregabalin trials, the three pivotal trials that led to approval of gabapentin as adjunctive therapy for partial seizures had responder rates of 22% to 28% at the highest doses for each trial.[1,2,5] The highest dose utilized was 1,800 mg/day in divided doses. Although higher doses may well have resulted in greater efficacy, this has not been demonstrated in double-blind trials. The nonlinear absorption of gabapentin resulting from the rate-limiting L-amino acid transport becomes much more significant at higher gabapentin doses. A dose of 3,600 mg/day of gabapentin (a commonly used dose in clinical practice, although outside of the U. S. Food and Drug Administration [FDA]-approved dose range), given as a divided dose three times a day, has only 33% bioavailability.[14] These pharmacokinetic characteristics of absorption make it less likely that higher doses of gabapentin would have produced responder rates comparable to those of pregabalin, although direct controlled trials comparing the efficacy of pregabalin to gabapentin have not been done.

Adverse Effects

The parallel pivotal controlled trials of pregabalin in epilepsy, pain, and anxiety resulted in a larger cohort of patients to assess adverse events than if only epilepsy studies were performed. However, it should be recognized that these patient populations may differ significantly. For example, patients with diabetes will typically be older and have more significant medical comorbidities than will epilepsy patients. Postherpetic neuralgia is also much more common in the elderly.

In any assessment of adverse events, it is important to separate safety-related side effects from other complications. Gabapentin is an extremely safe medication. The American Academy of Neurology (AAN) review of new AEDs in 2004 concluded that gabapentin was one of only two AEDs with no associated serious adverse effects.[31] Pregabalin had not yet been approved at the time, and whether pregabalin will enjoy an equivalent safety record is now being determined. Because pregabalin has been approved for both pain and epilepsy in the United States and, additionally, for anxiety in the European Union, many more patient exposures have occurred than would have occurred in the same time for epilepsy alone. To date, over three million patient exposures to pregabalin have occurred, and no safety-related side effects have been attributed to the drug.

Dose-Related, Nonidiosyncratic Adverse Effects

Most dose-related adverse events with pregabalin involve nonspecific CNS side effects, many of which occur at the time the drug is started and either abate with time or can be reduced in severity with more gradual titration. Table 1 lists the most common adverse events reported in the controlled clinical trials for epilepsy. Nonspecific CNS side effects (dizziness, somnolence, ataxia, and blurred vision) were most common, and resulted in 15% of participants taking pregabalin withdrawing from the trials, compared with 6% of those taking placebo.

Some of these side effects may reflect initiation side effects related to the fixed-dose nature of the trial design, which was different from the gradual titration typical of clinical practice. In the pregabalin flexible-dose study,[23] 33% of the fixed-dose group (600 mg/day) withdrew due to an adverse event, compared to 12% of the flexible-dose group and 7% of the placebo group. The two most common treatment-emergent side effects were dizziness and ataxia. Dizziness was reported in 43% of the fixed-dose group and resulted in a 14% withdrawal rate, compared with 24% of the flexible-dose group and 5% discontinuations. Ataxia occurred in 21% and 9% of the fixed-dose and flexible-dose groups, respectively, resulting in 13% and 3% discontinuations, respectively.

Table 1 Discontinuation Rates Due to Adverse Effects (AEs) in Pregabalin Epilepsy Studies

	Percentage of patients		
	Incidence of AEs*	**Discontinuation* (treatment group)**	**Discontinuation* (placebo group)**
Dizziness	32	6	<1
Somnolence	22	3	0

Ataxia	15	3	<1
Weight gain	14	<1	0
Blurred vision	10	2	0
Diplopia	9	2	1
Tremor	8	2	0
Thinking abnormal	8	2	0
Increased appetite	5	<1	0
Peripheral edema	5	<1	0
Amnesia	5	<1	0
Speech disorder	5	1	0

*Excludes 50 mg/day dosage.

Lyrica® (pregabalin) capsules CV [package insert]. New York, NY: Pfizer Inc; 2005; Data on file, Pfizer Inc.

Further support that most nonspecific CNS side effects with pregabalin are initiation-related is provided by an analysis of the duration of adverse events in patients participating in the double-blind trials.[7] By week 2, the incidence of dizziness dropped to 2.7% for all doses, and for weeks 2 to 12, it was 1.6% in the groups taking 300 mg twice daily compared to 27.7% reporting dizziness in the first week in this group. Similar changes were seen in reports of sleepiness and ataxia. The lower incidence of side effects was not due just to patient

withdrawal; the intensity of adverse effects did not affect their duration.

Weight Gain

In the double-blind pivotal trials for epilepsy, weight gain (defined as ≥7% of baseline) occurred in from 5% (150 mg/day) to 16% (600 mg/day) for the various dose groups (10.4%) overall. This was slightly higher than that seen in the trials for diabetic neuropathic pain or postherpetic neuralgia, in which only 6% and 7% of those patients taking 600 mg/day of pregabalin gained weight. Weight gain, however, resulted in withdrawal from the studies in <1% of participants. The average weight change in all patients in the controlled trials for epilepsy was 2.1 kg.[15] In a postmarketing survey from a single center of 40 patients taking an average of 2.7 concomitant AEDs, 56% reported some weight gain, with the mean weight gain being 4.6 pounds and the median weight gain, 4.6 pounds.[53] In this short-term study of several months' follow-up, 22% of patients reported weight loss (average 4.6%). In the pivotal trials for epilepsy, 2.9% of patients taking gabapentin had weight gain but, as mentioned earlier, these trials had 1,800 mg as a maximum dose.

Idiosyncratic Reactions

Hypersensitivity reactions associated with pregabalin administration are uncommon; less than 1% of the patients in the three pivotal trials had rashes, and similar low incidences were reported in the neuropathic pain and anxiety trials. No severe hypersensitivity reactions (e.g., Stevens-Johnson syndrome, toxic epidermal necrolysis) have been reported.

Teratogenicity

The data on pregabalin in human pregnancy are insufficient at this time to establish the safety of pregabalin in pregnancy. It is classified as pregnancy category C (no human data). Animal data have not shown any malformations at plasma levels up to two times that achieved in humans taking 600 mg/day. Decreased ossification, body weight, and organogenesis in animals was demonstrated at plasma exposures 5 to 16 times levels seen in humans at the maximum recommended dose (600 mg/day).[3]

Based on human studies with gabapentin[47] and animal studies with pregabalin,[3] it is anticipated that pregabalin will be excreted in human breast milk. In one small study of six breast-fed infants, plasma concentrations of gabapentin were 12% of the mothers' plasma levels, and no adverse effects were seen.[47] Pregabalin excretion and concentrations in breast milk would be expected to be similar to gabapentin. General guidelines for breast-feeding for mothers with epilepsy recommend breast-feeding while on AEDs unless this produces sedation in the infant. Even with the limited available human data from pregabalin, it is reasonable to recommend breast-feeding for women taking pregabalin who desire to breast-feed, because the multiple benefits of breast-feeding to the child are well known.

Carcinogenicity

Hemangiosarcomas were seen in a dose-dependent relationship in two strains of mice treated with 200 to 1,000 mg/kg per day of pregabalin for 2 years; the lowest dose produced plasma levels comparable with 600 mg/day in humans.[3] No similar tumors have been found in other animal tests, and none has been reported in humans, either in pre- or postmarketing studies and surveillance.

Table 2 Pregabalin and Gabapentin: Comparative Characteristics

Differences between pregabalin vs. gabapentin	Pivotal trials demonstrate higher responder rates with pregabalin*
	Efficacy demonstrated with b.i.d. dosing regimen of pregabalin
	More rapid absorption of pregabalin (peak conc in 1–1.5 hrs vs. 3–4 hr)
	Increased oral bioavailability for pregabalin (≤90% at all doses)

	Linear absorption for entire dose range of pregabalin
	Possibly higher incidence of weight gain with pregabalin
Similarities of pregabalin and gabapentin	Similar spectrum of action: partial seizures and secondarily GTCSs
	Binds to α-2-δ subunit of the voltage-gated calcium channel
	Similar mechanism of action, modulation of neurotransmitter release
	No effects on hepatic enzymes
	No known significant interactions with other drugs
	Not affected by other drugs
	Total absorption not significantly affected by food
	Negligible metabolism
	Negligible binding to plasma proteins
	Renally excreted
	Low incidence (≤1%) of allergic or hypersensitivity reactions
	Side-effect profile similar for most reported adverse events
	Favorable cognitive profile
	No safety-related issues to date

*Note: Direct comparative trials between pregabalin and gabapentin have not been performed.

Controlled Substance Classification

Pregabalin is a controlled substance (Schedule V).[3] This classification resulted from the trials required for generalized anxiety. In 15 patients who were recreational drug users, there were reports of a single 450-mg dose of pregabalin producing pleasant drug effects comparable to a single 30-mg dose of diazepam. In

all the controlled clinical trials (pain, epilepsy, anxiety), overall, 4% of patients reported euphoria (vs. 1% with placebo), but interestingly <1% of patients in the epilepsy and postherpetic neuralgia trials reported euphoria, and only 2% of patients in the diabetic peripheral neuropathy trials reported euphoria. There were some reports as well that discontinuing pregabalin resulted in transient insomnia, nausea, or headache. Although gradual discontinuation is desirable when possible, there is no danger (other than increased seizure frequency) from rapid discontinuation. No dependency on pregabalin has been reported, and pregabalin is not active at sites known to produce addictive behavior. Therefore, the controlled classification is a caution, but should not restrict clinical use for most patients.

Overdosage

Data are limited regarding overdosage with pregabalin; no serious side effects have been reported. It should be expected that more pregabalin will be absorbed than a corresponding amount of gabapentin because of the nonlinear kinetics of gabapentin. Although no data exists on hemodialysis with overdose, pregabalin, because of its low protein binding, is readily hemodialyzed should the perceived need arise.

Drug Interactions

Because pregabalin has negligible protein binding and no significant hepatic enzyme induction, no significant drug interactions have been reported. Specific studies have not demonstrated significant interactions with other AEDs (carbamazepine, gabapentin, lamotrigine, phenytoin, valproate), oral contraceptives, lorazepam, or oxycodone.[3,13,16] Conversely, pregabalin has not been demonstrated to have effects on other coadministered drugs such as diuretics, hypoglycemics (glyburide, insulin, metformin), and AEDs (carbamazepine, lamotrigine, phenobarbital, phenytoin, topiramate, valproate).

Role in Epilepsy Treatment

Indications

The current FDA-approved indications reflect the double-blind pivotal trials performed and submitted for approval. Pregabalin is approved as adjunctive therapy for partial seizures. This includes simple and complex partial seizures. The policy of the FDA to include generalized tonic–clonic seizures in the indication has been amended in recent trials of new AEDs because the number of secondarily generalized tonic–clonic seizures (GTCSs) is not a primary or secondary outcome variable. It is, however, appropriate and within indications to use pregabalin for both partial and secondarily GTCSs, because GTCSs are a type of partial seizure (i.e., partial onset). Therefore, the lack of mention of GTCSs in the indications does not imply any lack of efficacy for these secondary seizures. In actual practice, the secondarily GTCS of patients with partial seizures are often more readily controlled than are the partial seizures. In the report by Brodie,[15] there was no significant difference in RRatio by seizure type between simple partial, complex partial, and generalized tonic–clonic (presumed secondarily generalized) seizures, and all seizure types had similar dose–response characteristics.

Monotherapy trials of pregabalin are currently being planned. The FDA requires specific monotherapy trials to receive this indication.[33] Although this requirement for specific monotherapy trials is not unreasonable, the demand that monotherapy trials employ a superiority trials design, using either placebo or active control treatment arms, makes these trials extremely difficult to do. While acknowledging that the superiority trial design is more statistically rigorous, such trial designs may violate the Helsinki agreement for human trial design and may be unethical to do. Such trial designs are not required for monotherapy approval of AEDs in the European Union, where noninferiority trials in new-onset epilepsy are sufficient. The FDA also does not typically require such superiority trials in cardiology, oncology, and many other disease states. Alteratives to superiority trials, such as historical controls, which would eliminate the need for placebo or active control arms are being proposed.[29]

Pregabalin's spectrum of action is similar to that of gabapentin. It is not expected that pregabalin will be effective for myoclonic or absence seizures. New-onset focal or multifocal myoclonus has been reported in patients taking pregabalin, particularly at higher doses (e. g., 600 mg/day).[37] These effects resolved or improved with reduction in dosage. Whether pregabalin exacerbates primary generalized myoclonic seizures or absence epilepsy has not been determined.

Dosing Recommendations

Pregabalin was the first AED with which the FDA implemented the policy of requiring determination of the least effective dose. This provides important information to supplement the demonstration of efficacy at various doses. One of the pivotal trials was a dose-ranging trial. The least effective dose for significant seizure reduction was 150 mg/day; therapy can be initiated at this dose and titrated upward as needed and tolerated. Treatment can begin as either 75 mg twice daily or 50 mg three times a day in adults. Steady state is achieved within 1 to 2 days. Periodic increases can be made after steady state has been reached, as appropriate. If adverse events are significant, introduction and titration can be adjusted, recognizing that many of the side effects observed are initiation-related and transient. The 600 mg/day dose approved is a reasonable upper range if needed. Although doses of 900 mg/day have been administered, there is no evidence for improved efficacy at these doses, and side effects are increased.

Pregabalin is available in 25-, 50-, 75-, 100-, 150-, 200-, 225-, and 300-mg capsules. These various dose strengths can facilitate titration and reduce pill number in patients on stable dose regimens. Because the pricing in the United States is similar per pill regardless of strength, considerable economies can be achieved by using the largest pill strength.

Pregabalin is readily soluble, and liquid formulations are in development.

Effects on Mood

The comorbidity of epilepsy and mood disorders is well established, and many studies have emphasized the coexistence of depression and epilepsy. From 20% to 50% of patients with epilepsy may have coexisting depression.[39] Recently, it has been acknowledged that coexisting anxiety disorders may also be common. One study in children found that anxiety was the most common mood disturbance, occurring in 33% of children with epilepsy, compared with 6% of controls.[17] Another study found a prevalence of anxiety in 48% of patients with partial epilepsy, with 23% reporting (using the Hospital Anxiety and Depression Scale and QOLIE-10) moderate to severe anxiety, compared with 38% of patients reporting depression (18% moderate to severe).[18]

A number of AEDs have psychotropic effects.[46] Although it is beyond the scope of this chapter to discuss pregabalin's effects on mood in detail, comorbidities in patients with epilepsy can influence the selection of AED therapy. Several positive placebo-controlled trials have all demonstrated significant benefits of pregabalin on GAD when compared to placebo and comparable efficacy to comparative drugs.[27,44,45,48,49,50,56] Pregabalin has approval for the treatment of GAD in Europe; approval has not yet been granted in the United States. Symptoms from abrupt cessation were similar in rates and intensity to serotonin specific reuptake inhibitors and less common than those seen with benzodiazepines.

Cognitive Function

Gabapentin has been demonstrated to have a favorable cognitive profile in several well-controlled studies in healthy subjects and patients with epilepsy.[41] To date, there have been relatively few well-designed studies with pregabalin. Because of the high degree of polypharmacy in the patients participating in the pregabalin pivotal trials, attributing adverse effects on cognition to pregabalin is problematic. Nonetheless, 8% of patients reported “thinking abnormal” in these studies. A recent small, well-designed (double-blind, placebo-controlled, crossover) study in 24 healthy volunteers indicated that pregabalin did not differ from placebo on most measures, producing only minor, transient impairment on a few of the cognitive and psychomotor measures.[34] This was in contrast to the positive control alprazolam, which produced significant changes in all objective measures. A recent preliminary report evaluating cognitive function in elderly patients (*n* = 89, mean age 70.4) being treated with pregabalin for anxiety demonstrated a significant improvement in mood and no measurable effect on cognitive function.[34] Additional studies are needed, but pregabalin appears to have a favorable cognitive profile. Gabapentin had many advantages that made it one of the preferred AEDs for use in the elderly.[40,58] Pregabalin appears to share these advantages based on the known pharmacokinetic profile and available data on side effects.

Precautions and Contraindications

Precautions regarding pregabalin relate mainly to the adverse events detailed earlier. No safety related issues have been raised to date. Patients with a known hypersensitivity to pregabalin should not take pregabalin. It is not known whether any cross-reactivity occurs between hypersensitivity for pregabalin and gabapentin. They have distinct chemical structures, and each has a low incidence of hypersensitivity reactions. Like all antiepileptic medications, pregabalin should be withdrawn gradually over days or weeks unless a serious associated adverse event requires more prompt cessation.

Summary and Conclusions

Pregabalin is the most recently approved AED. Although related to gabapentin, with which it shares a number of characteristics (see Table 2), pregabalin was the result of a screening program to identify compounds with a similar mechanism of action but with greater potency. The double-blind studies to date, in highly refractory patient populations, have demonstrated consistent levels of response. Although comparative clinical trials comparing pregabalin with other AEDs are lacking, responder rates with pregabalin at the highest doses tested in the clinical trials are as good as any seen with second-generation AEDs in similar populations. This is in contrast to the more modest responder rates seen in the gabapentin trials. Pregabalin's linear pharmacokinetics contrast sharply with the highly nonlinear profile for gabapentin and represent an important advantage.

Although pregabalin's spectrum of efficacy is likely to remain focused on partial seizures with or without secondary generalization, it is likely to be useful as monotherapy and in children. Trials are currently being planned to assess these uses. The lack of drug interactions make pregabalin an attractive agent for patients requiring AED polypharmacy or comedications for medical illnesses. Although pregabalin's lack of hepatic enzyme induction would suggest that it should not be a major potentiator of osteoporosis, this issues should be looked at specifically. Pregnancy data are limited at this time. The use

of pregabalin for pain has significantly increased the number of patient exposures, and no significant safety-related adverse events have been demonstrated. Pregabalin's side-effect profile is predominantly one of nonspecific CNS effects, and these often abate during the initiation period. Weight gain occurs in a minority of patients; it may be somewhat more common than that seen with gabapentin. Formal cognitive studies with neuropsychological testing remain to be done, but early reports suggest that pregabalin will have a favorable cognitive profile, particularly when tested as monotherapy. Its potential usefulness as an anxiolytic agent makes it an attractive choice when anxiety or depression coexists with epilepsy. Pregabalin should also be an AED useful in the treatment of epilepsy in the elderly, an important group of patients with a high incidence of new-onset epilepsy.

Chapter 156

Primidone

Blaise F. D. Bourgeois

Introduction

Primidone has been in clinical use since 1952. Based on its chemical structure, primidone is not strictly a barbiturate. Therapeutically, however, it is appropriate to consider primi-done a barbiturate, because its clinical effect can be attributed in part to the phenobarbital produced by hepatic biotransformation. It has never been clearly established whether primidone is a phenobarbital prodrug, or whether treatment with primidone can be clinically distinguished from treatment with phenobarbital. Primidone does have independent antiepileptic activity in experimental models. If some of the therapeutic effect in humans can also be attributed to primidone, long-term therapy with primidone can be regarded as an obligatory combination therapy. In addition, independent antiepileptic activity has been demonstrated experimentally for the other main metabolite of primidone, phenylethylmalonamide (PEMA). These unique qualitative aspects of primidone biotransformation must be integrated into any discussion of its pharmacokinetics, pharmacodynamics, and clinical use.

Chemical Structure

Primidone was first synthesized in 1952.[8] Chemically, primi-done differs from phenobarbital only by the lack of the carbonyl group in position 2 of the pyrimidine ring, and it is therefore a desoxyphenobarbital (Fig. 1). The exact chemical composition is 5-ethyldihydro-5phenyl-4,6(1*H*,5*H*)-pyrimidinedione. It is very poorly soluble in water, somewhat soluble in ethanol, and virtually insoluble in organic solvents. Primidone can be synthesized by reduction of phenobarbital, desulfuration of thiophenobarbital, or ring closure of phenylethylmalonamide.[1,10] The molecular weight of primidone is 218.25, and the factor to convert from milligrams to micromoles is 4.59. Thus, a concentration of 1 mg/L is equivalent to 4.59 μmol/L (Table 1). Because the pyrimidine ring of primidone contains only two carbonyl groups, and not the three carbonyl groups that characterize barbituric acid, primidone is not a barbiturate in the strict sense. However, it is appropriate to list the clinical use of primidone among the barbiturate therapies because of the biotransformation to phenobarbital, which accumulates to therapeutic levels during long-term administration of primidone to patients.

Pharmacology

The basic pharmacologic mechanism of action of primidone itself has received relatively little attention. One reason is that it remained uncertain for some time whether primidone itself actually has independent antiepileptic activity. In addition, primi-done is never present alone during long-term therapy, and at least one active metabolite, phenobarbital, is present after repeated administration in humans as well as in experimental animals. As discussed later, a second active metabolite, PEMA, may be involved in the overall pharmacodynamic effect of primidone. All the evidence regarding the individual pharmacodynamic properties of primidone, phenobarbital, and PEMA is derived from experiments in animals in which seizures were provoked. Because the metabolites begin to accumulate a few hours after administration of the first dose, a possible long-term protection by primidone alone against seizures occurring spontaneously cannot be assessed in humans. Independent anticonvulsant activity of primidone was first demonstrated in dogs; the animals were found to be protected against induced seizures at a lower concentration of phenobarbital when primi-done was also present.[22] Subsequently, it was shown that rats were protected against induced seizures after a single dose of primidone before the active metabolites were detectable[4]; similar protection was achieved in mice when the biotransformation of primidone was delayed by the preadministration of a metabolic blocker.[14,32] In terms of potency against seizures induced by maximal electroshock, primidone and phenobarbital are quite similar. Against seizures induced chemically by pentylenetetrazol or bicuculline, phenobarbital is effective but primidone is totally ineffective.[14] This suggests that the experimental anticonvulsant spectra of primidone and phenobarbital differ and that the two compounds may be two different antiepileptic drugs (AEDs) with different mechanisms of action. The experimental anticonvulsant spectrum of primidone is similar to that of carbamazepine and phenytoin. Primidone and phenobarbital differ pharmacodynamically not only on the basis of their anticonvulsant spectrum, but also on the basis of their protective or therapeutic index. In terms of brain concentrations in mice, primidone was found to be 2.5 times less neurotoxic than phenobarbital, with a correspondingly higher therapeutic index.[14] When phenobarbital and primidone were administered together in single-dose experiments in mice,[15] their anticonvulsant activity was found to be supra-additive (potentiated), and their neurotoxic effect was found to be infra-additive. The best therapeutic index was achieved using a combination of the two drugs at a brain concentration ratio of 1:1. The results of interactions between primidone and phenobarbital obtained in mice were confirmed by experiments in amygdala-kindled rats. After single doses, the anticonvulsant effect of phenobarbital was potentiated by primidone, whereas side effects of phenobarbital, such as ataxia and muscle relaxation, were not increased by combined treatment with primidone.[35]

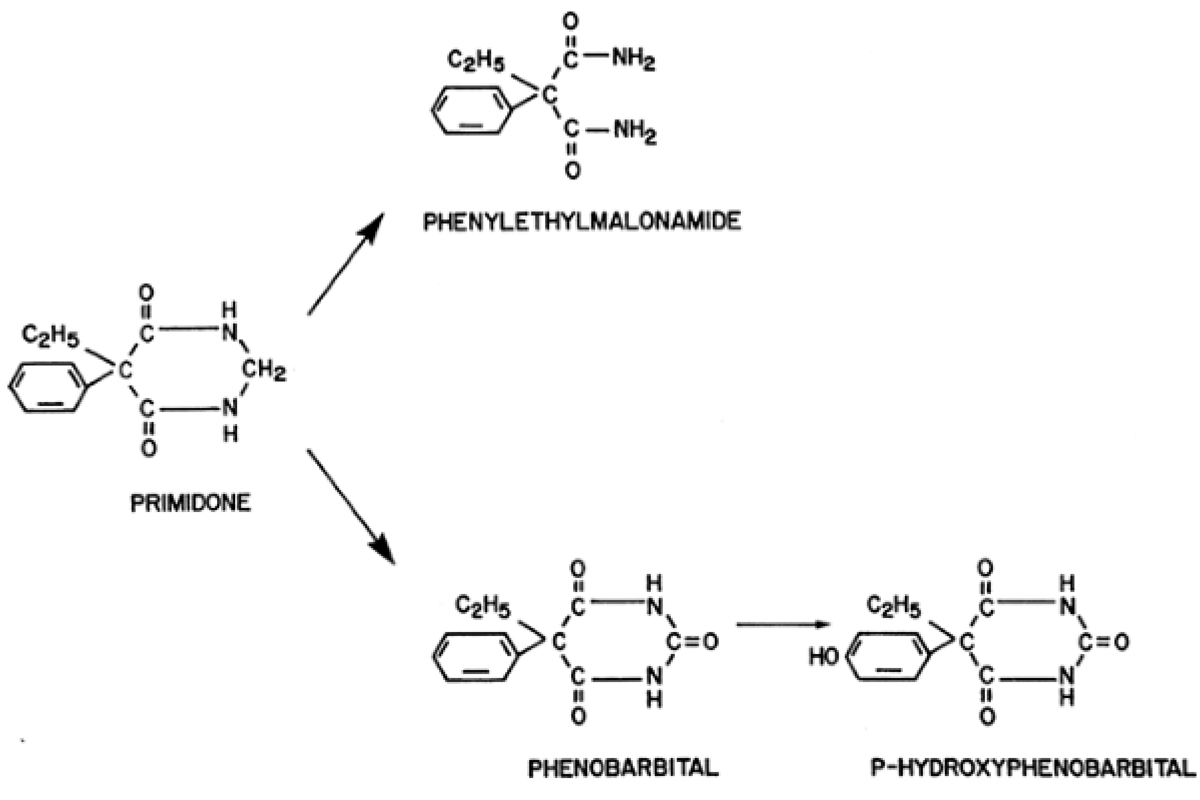

FIGURE 1. The two main pathways of primidone metabolism.

Table 1 Conversion

Primidone

Conversion factor:

CF = 1,000/mol wt = 1,000/218.3 = 4.58

Conversion:

(μg/mL) × 4.58 = μmol/L

(μmol/L)/4.58 = μg/mL

PEMA

Conversion factor:

CF = 1,000/mol wt = 1,000/206.2 = 4.85

Conversion:

(μg/mL) × 4.85 = μmol/L

(μmol/L)/4.85 = μg/mL

After direct administration, PEMA was found to have a relatively weak independent anticonvulsant activity in rats[5] as well as in mice.[14,32] When neurologic toxicity and protection against maximal electroshock-induced seizures were quantified in mice in terms of brain concentration,[14] PEMA was found to be 16 times less potent than phenobarbital in terms of seizure protection, and eight times less potent than phenobarbital in terms of neurotoxicity. However, PEMA potentiated both the neurotoxic effect[15] and the anticonvulsant effect[5,14] of phenobarbital. However, a quantitative analysis of these experimental results, together with the blood levels measured in patients on long-term therapy with primidone, suggests that PEMA

P.1640

probably contributes little or not at all to the antiepileptic effect or clinical toxicity in patients.

Primidone's basic anticonvulsant pharmacologic mechanism of action has been studied in mouse neurons in cell culture.[36] Primidone was compared with phenobarbital for its effect on amino acid responses and on sustained, high-frequency firing. In contrast to phenobarbital, primidone had no effect on postsynaptic γ-aminobutyric acid (GABA) and glutamate responses at concentrations up to 50 μg/mL. However, both primidone and phenobarbital limited sustained, high-frequency, repetitive firing at relatively high concentrations (>50 μg/mL). Primidone and phenobarbital together limited sustained, high-frequency, repetitive firing at clinically relevant concentrations of 12 μg/mL for primidone and 20 μg/mL for phenobarbital. The authors concluded that primidone and phenobarbital may act synergistically to reduce sustained, high-frequency, repetitive firing.[36] These in vitro findings are all in good agreement with the observations made in whole animals.

Clinical Pharmacokinetics

Absorption

Only oral preparations of primidone are available, and these include tablets and syrup. The extremely low solubility of pri-midone precludes its parenteral administration. Pharmacokinetic parameters of phenobarbital, the main active metabolite of primidone, are not reviewed here. The time to peak serum concentration of primidone after oral ingestion of tablets was found to be 2.7 hours[24] and 3.2 hours[23] in adult patients with epilepsy. In children, the peak blood concentration after a single oral dose was reached after 4 to 6 hours, and 72% to 123% of the total dose (average, 92%) was recovered in the urine as unchanged primidone and as metabolites.[31] This suggests that the oral bioavailability of primidone is fairly complete. The concomitant administration of acetazolamide reduced the oral bioavailability of primidone.[54] One report has suggested that the bioavailability of a generic preparation is lower than that of the brand product.[57]

Distribution and Protein Binding

Reported values for the volume of distribution of primidone vary: 0.54 L/kg (after acute administration)[38] and 0.86 L/kg.[43] In a study involving direct oral administration of PEMA, a volume of distribution of 0.69 L/kg was found for this metabolite of primidone.[44] The protein binding of both primidone and PEMA in human plasma was found to be less than 10%.[5,23,44]

Primidone brain concentrations were lower than the simultaneous plasma concentrations, both in mice[14,32] and in rats.[4] In humans, variable brain-to-blood concentration ratios of pri-midone have been reported. An average brain-to-plasma concentration ratio of 87% was measured in a group of patients undergoing surgery for intractable epilepsy.[28] In a different group of six patients, also undergoing epilepsy surgery, brain concentrations of primidone ranged between 0 and 2.2 µg/g, whereas the average plasma concentration was 6.3 µg/mL.[32] Reported values for the cerebrospinal fluid-to-plasma ratio of primidone in humans range from 0.8 to 1.13.[23,28,39,51] These values are similar to saliva-to-plasma concentration ratios for primidone,[39,51] and they reflect the low affinity of primidone for plasma proteins. The brain penetration of PEMA seems to be good. In mice, brain concentrations of PEMA were found to be 93%[32] and 77%[14] of the simultaneous plasma levels.

Metabolism

More than for any currently used AED, an understanding of the qualitative and quantitative aspects of primidone metabolism is a prerequisite for the rational clinical use of this drug. This is because, after repeated administration, clinically significant accumulation of at least one active metabolite, phenobarbital, and possibly of a second, PEMA, occurs (Fig. 1). Phenobarbital is further metabolized to *p*-hydroxyphenobarbital, an inactive metabolite. It would be desirable for optimal clinical use of primidone to know the relative antiepileptic potency and toxicity, as well as the expected ratios of blood levels, of primidone and its two active metabolites. The ratios of blood levels have been well studied, but, as outlined earlier, information on the pharmacodynamic aspects is limited mostly to data in animals; corresponding data are virtually impossible to obtain in humans. Following the introduction of primidone, PEMA was the first metabolite to be identified. It was found initially in rats[7] and then in every species studied thereafter. A few years later, phenobarbital and *p*-hydroxyphenobarbital were identified,[17] and this identification was soon followed by the first descriptions of clinical intoxications that were considered to be caused by the derived phenobarbital.[45] Although other metabolites of primidone have been identified, they have no practical significance because of their low concentrations and lack of pharmacologic activity. The quantitative aspects of the biotransformation of primidone to phenobarbital and PEMA have been the object of several clinical studies. The fraction of primidone that is metabolized to phenobarbital was estimated by comparing the ratios of serum phenobarbital levels to the maintenance dose of either phenobarbital or primidone given as long-term therapy in the same patients. One such analysis suggested that 24.5% of the ingested primidone is converted to phenobarbital,[41] based on the observation that the dose of primidone (in milligrams per kilogram per day) required to maintain a certain phenobarbital level was approximately four times higher than the dose of phenobarbital necessary to maintain the same level. The results of another study indicated that the primidone requirements for a given phenobarbital level are about five times higher than the corresponding phenobarbital dose.[6] The extent of the biotransformation of primidone and the ratios of the blood levels of primidone and its metabolites are so sensitive to interactions with other AEDs that they are best discussed under that heading.

Elimination

The elimination half-life of primidone is quite variable, and this is a consequence of the different degrees of enzymatic induction that depend on whether a patient is on monotherapy with primidone or is taking other AEDs known to be enzymatic inducers. The elimination half-life of primidone was calculated to be 10 to 15 hours in adults on long-term primidone monotherap.[9,18,58] In contrast, in adults taking other AEDs in addition to primidone, values for the half-life ranged between 6.5 and 8.3 hours.[18,23,24,58] In 12 children, of whom four took primidone alone and eight also took phenytoin, estimates of the half-life of primidone ranged from 4.5 to 11 hours, with a mean of 8.7 hours.[31] The ability of newborns to metabolize primidone to phenobarbital or to PEMA appears to be very limited,[46] and in neonates the half-life of primidone was calculated as 23 hours, on average, with a range of 8 to 80 hours.[40] It is not possible to calculate accurately the elimination half-life of PEMA in patients who are on long-term therapy with primi-done, because production of PEMA by the liver takes place as long as primidone remains in the body. In a study based on direct oral ingestion of PEMA by adults, the average half-life of PEMA was 15.7 hours.[44] The pharmacokinetics of phenobarbital are discussed in Chapter 153.

Adverse Effects

As with the antiepileptic effect, it is difficult to separate long-term side effects of primidone therapy from those of phenobarbital therapy. Although depression may be more common with primidone than with other AEDs,[34] it is difficult to determine whether depression is more common than with phenobarbital. Because phenobarbital is always present during long-term therapy with primidone, it is not possible to attribute side effects clearly to one or the other, and it can be said that primidone shares all the side effects of phenobarbital. Consequently, it is also impossible to establish a therapeutic range for primidone with any degree of certainty. The primidone-to-phenobarbital concentration ratio can be quite variable, and at a primidone level of 15 mg/L, the patient is more likely to experience side effects if the concomitant phenobarbital level is 50 mg/L than if it is 20 mg/L. In children, monotherapy with primidone was found to be tolerated as well as, if not better than, monotherapy with phenobarbital, phenytoin, or carbamazepine.[27] Overall, however, there is no qualitative difference between the dose-related, long-term side effects of primidone therapy and those of comparable phenobarbital therapy. The same applies also to idiosyncratic side effects and potential teratogenicity. No specific teratogenic pattern has been associated with primidone therapy, as opposed to phenobarbital therapy. Birth defects described in the offspring of women who took primidone during pregnancy include ventriculoseptal defects, microcephaly, and poor somatic development.[3,47]

Table 2 Serum Level Ratios[a]

		Ratios of serum levels to PRM dose[b]			Ratios of serum levels[b]	
	N	**PRM**	**PB**	**PEMA**	**PB:PRM**	**PEMA:PRM**

Monotherapy	10	0.78 ± 0.25	1.47 ± 0.53	0.64 ± 0.39	1.65 ± 0.74	0.70 ± 0.36
Comedication[c]	53	0.40 ± 0.15	2.40 ± 0.98	0.75 ± 0.42	5.83 ± 2.62	1.71 ± 0.75

Ratios of serum level of PRM, PB, and PEMA to PRM dose, and ratios of serum levels of PRM, PB, and PEMA at steady state. PRM, primidone; PB, phenobarbital; PEMA, phenylethylmalonamide.

[a]All blood samples were drawn before the morning dose in hospitalized patients.
[b] Mean ± SD;PRM dose in mg/kg/d, serum levels in mg/L.
[c] Comedication consisted of phenytoin, carbamazepine, or both.

One aspect of side effects that clearly distinguishes primi-done from phenobarbital is acute initial toxicity. Even after a low initial dose of primidone, some patients can experience transient side effects so debilitating that they may be reluctant to take another dose of primidone. These side effects usually include drowsiness, dizziness, ataxia, nausea, and vomiting.[37] This acute toxicity can be shown to occur before phenobarbital or PEMA is detected in the blood, and it must therefore be caused by primidone itself. Because much larger doses of primi-done are tolerated by the same patients later during long-term therapy, tolerance to primidone must develop. This tolerance probably develops quite rapidly, in a matter of hours to days. The ratio between a clinical toxicity score and serum primidone levels was determined in a group of patients receiving their first dose of primidone.[33] This ratio was shown to begin to decrease significantly as early as 6 hours after the ingestion of primi-done. Cross-tolerance to primidone following phenobarbital exposure could be demonstrated unequivocally in experimental animals. To achieve the same degree of seizure protection and the same level of neurotoxicity, higher brain concentrations

P.1642

of primidone were necessary in mice that had received phenobarbital daily for 2 weeks than in mice not previously exposed to any drug.[11]

Clinical evidence also is available that phenobarbital produces a cross-tolerance to acute primidone toxicity, because patients on long-term phenobarbital therapy are less likely to experience the same degree of toxicity when first exposed to primidone.[25,33] Bourgeois et al.[16] took advantage of this pharmacodynamic interaction to develop a protocol for rapid introduction of primidone, using a gradual phenobarbital loading protocol over 4 days, followed by the introduction of primidone at full maintenance dose on day 5. More recently, Kanner et al.[30] confirmed the feasibility of the rapid introduction of primidone following prior loading or exposure to phenobarbital. Under this protocol, two of 30 patients tolerated the introduction of primidone at 500 mg per day with minimal or no adverse events.

Drug Interactions

Primidone is the cause as well as the object of numerous pharmacokinetic interactions. The biotransformation of primidone to phenobarbital and PEMA can be both markedly induced and markedly inhibited by other drugs, and this results in pronounced interindividual variability not only in the relative concentrations of the three compounds, but also in the ratio between primidone dose and the blood levels. The effect of induction was studied extensively in a group of adult patients with epilepsy who received an intravenous injection of ^{14}C-labeled primidone, followed by urinary assay of primidone and its metabolites for 5 days.[58] Group 1 consisted of patients taking no other AED, and group 2 consisted of patients on combination therapy. The total urinary recovery was similar in the two groups, 75.5% and 77.4%. However, 64% of the dose was excreted as unchanged primidone in group 1, and only 39.6% in group 2. The difference was even more pronounced for PEMA recovery, which represented 6.6% of the primidone dose in group 1 and 27.9% in group 2. The corresponding numbers were 2.1% and 3.3% for phenobarbital, and 3% and 6.5% for unidentified metabolites. In addition to being more sensitive to induction, the conversion of primidone to PEMA appears also to be more rapid, because PEMA can be detected in the blood within a few hours after a first dose of primidone, as opposed to phenobarbital, which may not be detectable for 24 hours.[9,23,24] Similar data were obtained from 24-hour urine collections in 12 children on long-term primidone therapy.[31] The total urinary recovery was 92%, on average: 42.3% as unchanged primidone, 45.2% as PEMA, and 4.9% as phenobarbital and *p*-hydroxyphenobarbital. Of these 12 children, four were taking primidone monotherapy and eight were on combination therapy.

The most pronounced acceleration of the enzymatic biotransformation of primidone appears to be caused by phenyt-oin, which is a known potent enzymatic inducer.[2,18,21,48] This causes a decrease in the primidone-to-phenobarbital serum concentration ratio. Carbamazepine also accelerates the conversion of primidone, but to a lesser extent.[2,18] Rarely, carbamazepine may even inhibit the conversion of primidone to phenobarbital, causing a rise in the primidone-to-phenobarbital serum concentration ratio.[13] The effect of comedication with phenytoin, carbamazepine, or both on the concentration-to-dose ratios and on the ratios between the concentrations of primidone, phenobarbital, and PEMA are summarized in Table 2. Morning trough levels of primidone in relation to the daily dose of primidone are reduced by about 50% in the presence of phenytoin or carbamazepine in comparison with primidone monotherapy. This is a consequence of accelerated biotransformation, and phenobarbital levels are accordingly raised (by a factor of 1.6) in relation to the maintenance dose of primidone. The practical application is that dosage requirements of primidone to achieve a given phenobarbital level are about 1.6 times lower in patients taking phenytoin or carbamazepine than in patients taking primidone alone. This is the opposite of what is usually seen with enzymatic induction, when the drug dose must be increased to maintain the same drug level. In the case of primidone, phenobarbital is the product, not the substrate, of the induced enzymatic step, yet its concentration is usually the one relevant for the clinical effect. Thus, adding an inducing drug to a pre-existing primidone monotherapy may actually raise phenobarbital levels into the toxic range. It can also be seen in Table 2 that the morning trough serum concentration ratio of phenobarbital to primidone is more than three times higher in the presence of phenytoin or carbamazepine. The practical meaning of these numbers is that, in a patient with a primidone level of 10 mg/L, the simultaneous average phenobarbital level would be 16.5 mg/L if the patient is on primidone monotherapy, but the average phenobarbital level would be 58.3 mg/L if the patient is also taking phenytoin or carbamazepine. Different effects of valproate on primidone kinetics have been described. In one study, transient elevations of primi-done levels were observed after the addition of valproate[56]; phenobarbital levels were not included in this analysis. Other authors[20] found no consistent changes in the levels of primidone or phenobarbital after the addition of valproate to pri-midone therapy.

Inversely, the antituberculosis drug isoniazid was shown to inhibit the conversion of primidone to phenobarbital markedly and thereby produce high levels of primidone in relation to phenobarbital levels.[53] The same effect has been described with

nicotinamide.[13] Primidone therapy can also be the cause of drug interactions and thus influence the levels of other drugs. There is no information on the potential of primidone itself to inhibit or induce the biotransformation of other drugs. However, because of the derived phenobarbital, primidone treatment causes the same interactions as those described in conjunction with phenobarbital treatment, mainly induction of the biotransformation of many other drugs.

Role in Epilepsy Treatment

Indications

Primidone has been used in the treatment of epilepsy since 1952,[7] but its neurologic side effects have prevented it from becoming a drug of first choice for any seizure type. Because it is metabolized to phenobarbital during long-term therapy, it has been virtually impossible to determine with any certainty whether primidone is merely a phenobarbital prodrug, or whether treatment with primidone differs clinically from treatment with phenobarbital. In view of the demonstrated independent antiepileptic activity of primidone in animal models, it is likely that primidone is potentially antiepileptic in humans. If this is the case, long-term treatment with primidone represents an obligatory combination therapy involving pharmacodynamic interactions between primidone, phenobarbital, and possibly PEMA.

Primidone is used generally for the same indications as phenobarbital, but because primidone is not available in a parenteral formulation, it is not used in the acute treatment of status epilepticus. Several studies have addressed the issue of the comparative antiepileptic efficacy of primidone and phenobarbital. In most studies, primidone could not be shown to be more or less effective than phenobarbital.[26,41,55] In a cross-over study, the efficacies of primidone and phenobarbital were compared sequentially in the same patients.[42] Similar phenobarbital levels were maintained during both therapies, and primidone treatment was found to be slightly more effective against generalized tonic–clonic seizures than phenobarbital treatment. Primidone is as effective as any other drug against generalized tonic–clonic seizures. Primidone was used as a drug of choice in the treatment of juvenile myoclonic epilepsy.[19,29] Because of its greater efficacy and overall better tolerability, valproate has generally replaced primidone for this indication. The degree of seizure control achieved by primidone in partial and secondarily generalized seizures is similar to that achieved by phenytoin or carbamazepine.[49,55] The most comprehensive and systematic controlled comparisons among carbamazepine, phenytoin, phenobarbital, and primidone in the treatment of partial and secondarily generalized seizures was the study by Mattson et al.[37] Virtually no difference was noted in efficacy among the four drugs, but treatment with primidone was associated with the highest rate of failures, mainly as a consequence of a higher incidence of side effects during the early phase of treatment. In this study, the percentage of failures was lowest with carbamazepine and phenytoin.

Primidone is rarely indicated as treatment for any type of seizures besides partial and secondarily generalized seizures. In particular, it has little or no role in the generalized epilepsies encountered in childhood, such as absence epilepsy and the Lennox-Gastaut syndrome. Although it has been shown to be potentially useful in the treatment of neonatal seizures,[46,50] primidone is almost never used for this indication. Primidone is contraindicated in any patient who has previously had an allergic reaction or a severe idiosyncratic reaction to primidone or phenobarbital. It is also contraindicated in patients with hepatic porphyria.

How to Use Primidone

Only oral formulations of primidone are available, and these include 250-mg and 50-mg tablets as well as a syrup containing 50 mg/mL. Because of the potentially severe acute toxic reaction after the first exposure to primidone, it is more important than with any other antiepileptic drug to start primidone therapy at a low dose. Most patients can tolerate a first dose of 125 mg (one-half tablet) at bedtime, but some cannot even tolerate this dose, in which case the second dose must be reduced to one-quarter tablet (62.5 mg). The dose can be increased again as tolerated at intervals of 3 days, up to a final daily maintenance dose of 10 to 20 mg/kg. A schedule that allows rapid advancement to the full maintenance dose of primidone was developed[16] on the basis of observations in patients and in experimental animals that phenobarbital produces cross-tolerance to the effects of primidone.[11] The principle is based on giving phenobarbital initially, titrating the serum level as rapidly as tolerated up to 20 mg/L, and then switching abruptly to the full maintenance dose of primidone. Experimentation with various schedules of phenobarbital titration revealed that the following increases in levels are tolerated with minimal or no sedation by most patients: 5 mg/L after 24 hours, 10 mg/L after 48 hours, 15 mg/L after 72 hours, and 20 mg/L after 96 hours (end of day 4). These levels can be quite accurately achieved by giving 3 mg/kg of phenobarbital orally on the first day (two doses of 1.5 mg/kg each, 12 hours apart), 3.5 mg/kg on the second day, 4 mg/kg on the third day, and 5 mg/kg on the fourth day. On the fifth day, the patient can be switched abruptly to a full daily maintenance dose of primidone of 12.5 to 20 mg/kg, with no significant new toxicity.

As can be derived from Table 2, primidone monotherapy at a daily dose of 20 mg/kg will result, on average, in phenobarbital levels of 30 mg/L. The steady-state levels of phenobarbital will be reached only after 2 to 3 weeks on a constant dose of primi-done. In patients comedicated with drugs like carbamazepine or phenytoin, the same phenobarbital level of 30 mg/L will be achieved with an average daily dose of primidone of 10 to 15 mg/kg. As with most AEDs, average dose requirements may be higher in children and lower in the elderly.

Because of the relatively short half-life of primidone, it is usually recommended to divide the daily dose into three doses, although the necessity to do so has never been documented. If the dose of primidone is adjusted on the basis of blood levels, it is probably preferable to base a decision on phenobarbital levels rather than on primidone levels because, as stated earlier, at the usual concentration ratios occurring in patients, further dosage increases are more likely to be limited by the phenobarbital levels. A therapeutic range of about 3 to 12 mg/L has been suggested for primidone,[52] but monitoring these levels has very limited clinical value. Because PEMA, at the levels observed in patients, probably does not contribute significantly to the pharmacologic effect of primidone therapy, there seems to be no reason to monitor PEMA levels during primidone therapy.

Primidone should be used preferably alone or in combination with a noninducing drug like lamotrigine, levetirace-tam, gabapentin, or a benzodiazepine. As discussed earlier, inducing drugs such as carbamazepine and phenytoin shift the primidone-to-phenobarbital ratio so much in favor of phenobarbital that the situation becomes practically equivalent to prescribing phenobarbital instead of primidone. For the same reason, prescribing primidone and phenobarbital simultaneously in the same patient makes no sense. Valproate may also increase phenobarbital levels, on the basis of its demonstrated inhibition of phenobarbital elimination. Animal experiments suggest that the maximal benefit from primidone therapy is obtained at a primidone-to-phenobarbital concentration ratio of about 1:1. This ratio is rarely seen in patients,

even on primidone monotherapy, and never in patients comedicated with carbamazepine, phenytoin, or phenobarbital. Attempts have been made to raise the primidone level in relation to the phenobarbital level so as to increase the pharmacologic contribution of primidone. This shift in ratio could be achieved by adding nicotinamide to primidone.[13] However, the doses of nicotinamide necessary to obtain this change in concentration ratio may cause gastrointestinal side effects and hepatotoxicity.

Discontinuing Primidone

Although abrupt discontinuation of an AED is clearly associated with an increased risk for seizure recurrence and even status epilepticus, the rate at which a given drug should be tapered has never been adequately documented. However, withdrawal of barbiturates and benzodiazepines seems to be associated with a higher overall risk for withdrawal seizures. Unless there is a specific reason to proceed faster, it is appropriate to taper primidone in a linear fashion over the course of 3 to 6 months, with dosage reductions at monthly intervals.

Summary and Conclusions

In conclusion, primidone is a drug that is still widely used in the treatment of epilepsy, and it is an intriguing drug because of the unique quantitative and qualitative aspects of its metabolism. Primidone is both a drug in itself and a phenobarbital prodrug. Its clinical indications and its side effects do not differ much from those of phenobarbital. The clinical use of primidone represents an obligatory combination between a drug with a short elimination half-life and a drug with a long elimination half-life. If primidone is prescribed under the assumption that it differs from phenobarbital, the primidone-to-phenobarbital serum concentration ratio should be maintained as high as possible. Drugs causing enzymatic induction, such as phenytoin and carbamazepine, invariably lower the primidone-to-phenobarbital concentration ratio. The lower the primidone-to-phenobarbital concentration ratio, the more unlikely it becomes that primidone therapy differs from phenobarbital therapy. Therefore, it makes little clinical sense to prescribe primidone in combination with such drugs, and it makes even less sense to prescribe primidone in conjunction with phenobarbital.

Chapter 157
Rufinamide

Tracy A. Glauser

Meir Bialer

Introduction

Rufinamide is a broad-spectrum antiepileptic drug (AED) with documented ability to block sodium (Na) channels.[24,34] Following discovery of antiepileptic activity in animal models, it has been undergoing Phase II and III clinical trials. Rufinamide has demonstrated efficacy against partial seizures in adults and generalized seizures in patients with the Lennox-Gastaut syndrome (LGS).[5,10,14] Clinical trials have reported a good tolerability profile. Rufinamide is currently under evaluation by the European Medicines Agency and the United States Food and Drug Administration (FDA).

Chemistry

Rufinamide (1–(2,6-difluorophenyl)methyl-IH-I,2,3triazole-4–carboxamide) (Fig. 1) is a triazole derivative structurally dissimilar to currently marketed AEDs.[2,17] Rufinamide is a lipophilic compound with a partition coefficient (logP = 0.88) and solubility in water and in gastric and intestinal fluids of 40 to 70 mg/L.[9] There are no currently marketed formulations of this compound. In clinical trials, film-coated tablets have been used.[9]

Plasma concentrations for rufinamide and its inactive carboxylic acid major metabolite (Fig. 1) are determined using high-performance liquid chromatography (HPLC).[27] The limit of quantification of this validated HPLC assay is 25 ng/mL for rufinamide in plasma, 2.5 μg/mL for rufinamide in urine, and 5 μg/mL for rufinamide's carboxylic acid major metabolite in urine.[27]

Pharmacology

Activity in Experimental Models of Seizures/Epilepsy

Rufinamide exhibits broad-spectrum anticonvulsant properties at nontoxic doses.[34] In animal models, rufinamide's protective index (PI = TD_{50}/ED_{50}) was superior to AEDs such as phenobarbital, phenytoin, ethosuximide, and valproic acid.[2,34]

The maximal electroshock (MES) test can identify AEDs with potential efficacy against partial seizures and generalized tonic–clonic seizures.[20,22,26] Rufinamide given orally was protective against MES-induced tonic–clonic seizures in both mice and rats with an ED_{50} of 23.9 mg/kg and 6.1 mg/kg, respectively. Rufinamide's anticonvulsant potency in the MES test was comparable to standard AEDs (Table 1).[9] In rats and mice, tolerance was not noted over 5 days.[34]

The subcutaneous pentylenetetrazole (PTZ) test can identify AEDs with potential efficacy against clonic or absence seizures.[20,22,26] Rufinamide's efficacy in the subcutaneous PTZ test was species and route dependent. In mice, rufinamide suppressed PTZ-induced seizures with an ED_{50} of 45.8 mg/kg.[34] Although orally administered rufinamide's ED_{50} is less potent than phenobarbital's ED_{50} (12.6 mg/kg), it is lower than the ED_{50} values for ethosuximide, valproic acid, and phenytoin[9] (Table 2). Intraperitoneal rufinamide suppressed PTZ-induced clonus with an ED_{50} of 54.5mg/kg in mice.[34] In rats, oral rufinamide was inactive against subcutaneous-induced PTZ seizure[9] (Table 2).

Intraperitoneal rufinamide blocked clonic seizures induced by subcutaneous bicuculline and picrotoxin in mice with ED_{50} values of 50.5 mg/kg and 76.3 mg/kg, respectively.[34] Similar to its results in the PTZ test, rufinamide was less potent than phenobarbital but more potent than ethosuximide and valproic acid (phenytoin is inactive in this test).[9] For seizures induced by intraperitoneal picrotoxin, rufinamide had lower potency (ED_{50} of about 300 mg/kg). Rufinamide's lowest potency was seen in mice in the glycine-related subcutaneous or intraperitoneal strychnine test, where the maximum protection rate of 37.5% occurred at a dose of 125 mg/kg.[9,29] Overall, rufinamide's tolerability (determined by either the chimney test in rats or the Rotorod test [6 rpm] at time of peak neurotoxic effect in mice) was similar to or exceeded that of any established AED except phenytoin administered orally to rats.[34]

Once-daily threshold electrical stimulation of the amygdala in animals induces epileptic electroencephalogram (EEG) afterdischarges and results in the kindling phenomenon.[15,16,20,28] In rats treated daily with oral rufinamide (20 mg/kg and 60 mg/kg) an increase in afterdischarge duration occurred, but no change in convulsive behavior was seen compared with controls.[29] Carbamazepine and phenytoin produce similar effects.[23,30] In cats, oral rufinamide (100 mg/kg and 300 mg/kg) delayed kindling development and suppressed afterdischarges in fully kindled animals. Carbamazepine (40 mg/kg) and valproic acid (180 mg/kg) produced similar effects.[9] Rufinamide antagonized kindling but did not provoke motor disturbances.[9]

Electrically induced hippocampal and cortical afterdischarges are also used to investigate the effects of AEDs against seizures originating from a focus. In cats, intraperitoneal rufinamide (300 mg/kg) reduced hippocampal and cortical afterdischarge duration by more than 50%.[9] Rhesus monkeys with aluminum hydroxide implants in the motor cortex provide an animal model of chronically recurring partial seizures with or without secondary generalization. Subchronic treatment with oral rufinamide (30–50 mg/kg daily for 15 days) reduced seizure frequency by 75% to 100% without a significant change in mean seizure duration.[9]

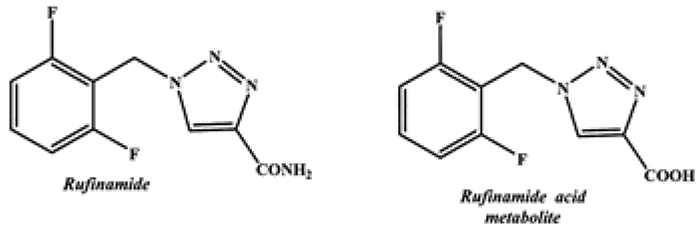

FIGURE 1. Chemical structure of rufinamide and its major acid metabolite.

Table 1 Rufinamide and other orally administered AEDs. ED_{50} for the MES test in rodents (performed at NIH and Novartis pharmaceuticals)[9,29]

	Mouse: ED_{50} in mg/kg		Rat: ED_{50} in mg/kg	
Compound	NIH	Novartis	NIH	Novartis
Rufinamide	23.9	19.2	6.1	8.0
Carbamazepine	n.r.	13.7	n.r.	8.0
Phenytoin	9.0	11.0	29.8	26.0
Lamotrigine	n.r.	6.1	n.r.	4.7
Topiramate	n.r.	35.7	n.r.	17.3
Phenobarbital	20.1	16.5	9.1	5.5
Valproic acid	664	220	489	450
Ethosuximide	Ø 2,000	>1,000	Ø 1,200	>600

Pretreatment period: variable (NIH), 1 hour (Novartis); n.r., not reported; Ø, no effect at indicated dose; >, less than 50% protection at indicated dose.

Mechanism of Action

Rufinamide's full mechanism of action is not yet known in detail. Some of its anticonvulsant effect is thought to result, in part, from blocking Na channels.[24] In rat cortical neurons, over a wide range of concentrations, rufinamide caused rest- and use-dependent block of Na currents coupled with slowed recovery from inactivation.[24] The rufinamide concentration that limited firing in 50% of neurons was 3.8 μmol /L (range 2–10 μmol/L).[24]

P.1648

Rufinamide does not significantly interact with neurotransmitter systems, including γ-aminobutyric acid (GABA), adenosine, monoaminergic and cholinergic binding sites, *N*-methyl-D-aspartate (NMDA), and other excitatory amino acid binding sites.[17,29]

Clinical Pharmacokinetics

Absorption

During Phase I clinical trials, single- and multiple-dose studies were performed in healthy subjects to assess the pharmacokinetic profile of rufinamide. Based on urinary recovery of radioactivity following oral administration of C^{14}-labelled drug (600 mg as capsules) with food, the bioavailability of low doses of rufinamide was estimated to be approximately 85%.[9] Peak plasma concentration (C_{max}) of rufinamide was reached 5 to 6 hours after dosing.[2,3,7] The intersubject variability in the mean area under curve (AUC) and

C_{max} values of rufinamide were less than 26% for both tablets and suspension. Contribution of the intrasubject variability to the overall variability was small (20%).[2,7] The tablet formulation was bioequivalent to the suspension in terms of rate and extent of absorption. Rufinamide exhibited dose-limited absorption; doses higher than 400 mg for both fasted and fed healthy subjects demonstrated less than proportional increase in peak concentrations (C_{max}) and plasma AUC.[9] Similar to the single-dose healthy volunteer studies, multiple-dose studies found a less than dose proportional increase in steady-state rufinamide plasma levels, due to dose-limited absorption.[9]

After intake in the fasting state, rufinamide has an oral bioavailability of approximately 60%; however, food increases rufinamide's extent of absorption and plasma exposure (AUC).[3,15] In a 1998 Phase I study using an older formulation, food increased the extent of absorption or plasma exposure AUC by 44% and the C_{max} by 100%.[6] The time to reach C_{max} (t_{max}) was 8 hours in fasted conditions and 6 hours in those fed after breakfast.[6] However, unpublished data using a newer formulation of rufinamide indicates food increases rufinamide's extent of absorption or plasma exposure AUC by 34% and the C_{max} by 56%.[9] The increase in rufinamide's AUC when administered concomitantly with food might be due to a change in gastrointestinal absorption and dissolution of the parent drug. The low water solubility and high lipophilicity (as indicated by its relatively large partition coefficient; logP = 0.88) supports the hypothesis of an increased solubility in the presence of food due to a larger volume of liquid and stimulated biliary secretion.[5]

Plasma Protein Binding and Distribution

Rufinamide's protein binding is low (34%).[2,17] Binding is predominantly to albumin. Rufinamide is evenly distributed between erythrocytes and plasma, and its apparent volume of distribution (V/F) is similar to the total body water (50–80 L).[3,9]

Metabolism and Elimination

Rufinamide is extensively metabolized, and the metabolites are mainly excreted in the urine. Only a small fraction of the dose is eliminated unchanged in the urine (2%) and feces (2%).[2,17] Rufinamide's major metabolic pathway is hydrolysis of the carboxamide group to form the acid metabolite previously called CGP 47292.[2,17] Minor additional metabolites have been detected and appear to be acyl-glucuronides of the acid metabolite.[9] This hydrolytic metabolism does not appear to involve the hepatic microsomal cytochrome P450 isozyme system.[9]

Rufinamide metabolites are predominantly renally excre-ted.[17] A single-dose study in three fed healthy male volunteers using 600 mg of [^{14}C] rufinamide administered as microcrystalline solid in capsules found 80% of the total plasma radioactivity was rufinamide, and 16% its acid derivative.[9] Rufinamide oral clearance (CL/F) is dose-dependent and, at

P.1649

a median dose level, ranges between 2.7 L/hour (children) and 6.6 L/hour (adults). The half-life of rufinamide ranges from 6 to 10 hours.[2,17]

Pharmacokinetics in Epilepsy Patients

Rufinamide's pharmacokinetics in patients with epilepsy was studied in a trial involving 647 adults (ages 15 to 65 years), taking one to three concomitant AEDs, with treatment-resistant partial seizures (with or without secondary generalization). Patients were randomized equally to either rufinamide 200 mg/day, rufinamide 400 mg/day, rufinamide 800 mg/day, rufinamide 1,600 mg/day, or placebo. Rufinamide was given twice daily (b.i.d.) in all trials except the monotherapy trials, where it was given three times a day (t.i.d.). Plasma rufinamide levels increased approximately dose-proportionally with doses of 800 mg/day or less, but when doses were more than 800 mg/day, a less than proportional increase in rufinamide plasma levels was observed.[10]

Rufinamide did not demonstrate linear pharmacokinetics in a study of ascending doses in 16 pediatric patients with inadequately controlled seizures receiving one to two other concomitant AEDs.[1] In this study, rufinamide was administered orally (b.i.d. dosing) over 14 days at a starting dosage of approximately 10 mg/kg per day (days 1–7) and then increased to 30 mg/kg per day (days 8–14). A 12–hour pharmacokinetic profile was obtained on days 7 and 14. A threefold increase in rufinamide dose provided only a 2- to 2.5-fold increase in the AUC_{0-12h}, C_{maxss}, and minimum concentrations (C_{minss}) at steady state.[1] There were no differences between any 2 of the 3 pediatric subgroups (under 6 years, 7–12 years, and 13 to under 18 years) for AUC_{0-12h}, C_{maxss}, and C_{minss}.[1]

In a trial of 65 patients with LGS, rufinamide's CL/F increased linearly with increased body surface area, independent of patient age, sex, or race.[8] Using a patient of median body surface area and taking a median dose level for the relevant age group, the typical values of rufinamide's CL/F in adults was 6.6 L/hour, adolescents 4.5 L/hour, and children 2.7 L/hour. The median body sizes used for this calculation were 24.0, 40.5, and 66.2 kg, respectively, for the three groups. Clearance was not affected by kidney function.[8] Rufinamide's bioavailability decreased with increasing doses.[8]

Gender did not appear to have a significant influence on rufinamide pharmacokinetics.[9] Age (4–65 years) was tested as a covariate in population pharmacokinetic studies and in two studies (one pediatric, one elderly). Age itself was not a significant covariate after taking into account body size.

Table 2 Rufinamide and other orally administered AEDs. ED_{50} for the s.c PTZ test in rodents (performed at NIH)[9]

Compound	Mouse: ED_{50} in mg/kg	Rat: ED_{50} in mg/kg
Rufinamide	45.8	Ø–1000
Phenytoin	Ø–300	Ø–800
Phenobarbital	12.6	11.6
Valproic acid	388	179
Ethosuximide	192	54.0

Pretreatment period: variable; Ø, no effect at indicated dose.

Efficacy

Overview of Clinical Efficacy Trials in Humans

Following a proof-of-principle study in adults with partial or primary generalized tonic–clonic seizures,[25] rufinamide had been studied in randomized controlled trials of adults with treatment-resistant partial onset seizures either as adjunctive therapy[5,10] or monotherapy,[21,32] children with treatment-resistant partial onset seizures,[12] adults with treatment-resistant generalized tonic–clonic seizures,[4] and children with LGS.[13,14] Adjunctive rufinamide therapy was more efficacious than placebo adjunctive therapy in adults with treatment-resistant partial onset seizures and children with LGS.

Proof-of-Principle Study

A small, double-blind, placebo-controlled, randomized, parallel-group, weekly rising dose (400–1,600 mg/day) study was performed as the first proof-of-principle clinical trial examining the efficacy and tolerability of rufinamide therapy. Fifty patients with therapy-resistant partial or primary generalized tonic–clonic seizures were equally randomized to rufinamide and placebo treatment groups; rufinamide doses were increased weekly (to 400, 800, 1,200, and 1,600 mg/day over the course of the 4-week study). In the evaluable population, the rufinamide group had a larger median percentage change in seizure frequency compared with the placebo group (41% reduction, $n = 23$ vs. 52% increase, $n = 21$, $p = 0.0397$). The 50% responder rate (i.e., patients experiencing ≥50% reduction in seizure frequency per 28 days from Baseline Phase) was higher in the rufinamide group compared with the placebo group (39% vs. 16%, $p = 0.096$); this trend was seen despite the small sample size. Based on this proof-of-principle study, further studies were conducted to better delineate rufinamide's anticonvulsant efficacy.[25]

Adults with Partial Onset Seizures: Adjunctive Therapy

The results of a double-blind, randomized, placebo-controlled, parallel-group study examining the efficacy of rufinamide versus placebo in adults with inadequately controlled partial seizures had been reported in abstract.[10] Adults (ages 15–65 years) on one to three concomitant AEDs with nine or more partial seizures (with or without secondary generalization) during a 3-month baseline were eligible for a 3-month double-blind treatment phase. Patients were randomized equally to either rufinamide 200 mg/day, rufinamide 400 mg/day, rufinamide 800 mg/day, rufinamide 1,600 mg/day, or placebo. Among the 737 enrolled patients, 647 were randomized at the end of the baseline period. Rufinamide demonstrated a linear trend for dose response for seizure frequency per 28 days in the double-blind period ($p = 0.003$) and for treatment responders ($p = 0.0035$). Compared with the placebo group, the median seizure frequency ratio was significantly reduced in patients treated with rufinamide 400 mg/day (11%, $p = 0.0274$), rufinamide 800 mg/day (16%, $p = 0.0123$), and rufinamide 1,600 mg/day (17%, $p = 0.0163$). The seizure frequency ratio for each patient was the number of seizures that occurred during the double-blind phase divided by the number of seizures that occurred during the baseline phase. This was expressed per 28-day intervals. The authors concluded that rufinamide's efficacy was demonstrated in a dose-dependent manner.[10]

P.1650

Another multicenter, double-blind, placebo-controlled, randomized, parallel-group study that assessed the efficacy of adjunctive rufinamide therapy in adult patients with inadequately controlled partial seizures was reported in an abstract form.[5] Adults (ages 16 and older) on one or two concomitant AEDs with six or more partial seizures during a 56-day baseline were eligible for a 91-day double-blind treatment phase. Eligible patients were then randomized to rufinamide adjunctive therapy (3,200 mg/day) or placebo adjunctive therapy. The titration period was 14 days, and the maintenance period was 77 days. The 313 randomized patients were evenly divided between the two treatment arms (rufinamide, $n = 156$; placebo, $n = 157$). The median reduction in partial seizures per 28 days relative to baseline was better in the rufinamide group compared with the placebo group (rufinamide 20.4% reduction; placebo 1.6% median increase, $p = 0.0158$). The percentage of treatment responders (patients with ≥50% reduction in partial seizure frequency) was higher in the rufinamide group compared with the placebo group (28.2% vs. 18.6%, $p = 0.0381$). The study concluded that rufinamide adjunctive therapy (3,200 mg/day) was generally effective for adult patients with inadequately controlled partial seizures.[5]

Children with Partial Onset Seizures: Adjunctive Therapy

Based on the efficacy of rufinamide in adults with partial seizures, a randomized, double-blind, placebo-controlled, adjunctive therapy trial was conducted to assess the efficacy and safety of rufinamide as adjunctive therapy in pediatric patients with inadequately controlled partial seizures taking stable dosages of one or two other AEDs. The results have been reported in abstract form.[12] Following a 56-day baseline phase, 268 patients (4–16 years) were randomized to either rufinamide or placebo adjunctive therapy. Study drug dosages were titrated to 45 mg/kg per day over 14 days, followed by a 77-day maintenance period. There was no difference in the mean reduction in partial seizure frequency per 28 days between the adjunctive rufinamide patients and the placebo patients (7.0% vs. 12.8% respectively, $p = 0.621$). There was no difference in the percentage of treatment responders (defined as patients with ≥50% reduction in partial seizure frequency) between the adjunctive rufinamide group and the placebo group (27.2% vs. 18.3%, respectively, $p = 0.060$). This study did not demonstrate the efficacy of adjunctive rufinamide therapy for pediatric partial seizures.[12]

Adults with Partial Onset Seizures: Monotherapy

Two studies investigated the efficacy of rufinamide as monotherapy in patients with treatment-resistant partial seizures.[21,32] One study employed a double-blind, placebo-controlled, parallel-group, monotherapy design in adolescent (≥12 years) and adult patients with treatment-resistant partial seizures who had completed an inpatient evaluation for epilepsy surgery.[21] Following a 48-hour baseline phase, patients were randomized to double-blind monotherapy of either rufinamide or placebo for 10 days. During the double-blind phase, the rufinamide doses were initiated at 2,400 mg/day on day 1, then increased to 3,200 mg/day on day 2, and maintained at that dose for the remainder of the 10 days. Patients exited in the double-blind phase if they met any of four defined sets of types and numbers of seizures. A total of 104 patients were evenly randomized to rufinamide ($n = 52$) or placebo ($n = 52$). During the double-blind phase, the group's mean daily rufinamide dose was 2,970.7 mg/day. The rufinamide-treated patients had a greater median number of days to meet one or more exit criteria versus placebo-treated patients (4.8 vs. 2.4 respectively, $p = 0.0499$). The rufinamide group had significantly greater median times to first, second, and third partial seizures than did the placebo group ($p < 0.0348$). This study demonstrated that rufinamide was more effective than placebo as monotherapy for the short-term treatment of refractory partial seizures.[21]

A second monotherapy study examined the efficacy of high- versus low-dose rufinamide monotherapy in patients with treatment-resistant partial seizures using a double-blind, randomized, parallel-group study design.[32] Eligible patients with treatment-resistant partial seizures on one or two AEDs were randomized to either a low rufinamide dose (300 mg/day, $n = 70$) or a high rufinamide dose (3,200 mg/day, $n = 72$) for 112 days. During the first 42 days of the double-blind phase, rufinamide was titrated upward and concomitant AEDs were simultaneously tapered. Patients either exited the study by meeting criteria based on severity and frequency of seizures or completed the entire 112 days of therapy. A total of 142 patients (12 years and older) were randomized: 70 to rufinamide 300 mg/day and 72 to rufinamide 3,200 mg/day. There was no significant difference between the groups for the primary outcome variable: the percentage of patients meeting one exit criterion (high-dose 66.7% vs. low-dose 72.5%, $p = 0.4402$). The median time to meeting one exit criterion was not different between the two groups (high-dose, 56 days vs. low-dose, 32 days, $p = 0.0968$). Overall, the efficacy analysis did not show a significant difference between the high- and low-dose groups for the efficacy outcome variables.[32]

Adults with Primary Generalized Tonic–Clonic Seizures

A multicenter, double-blind, placebo-controlled study examined the efficacy of adjunctive rufinamide therapy (800 mg/day) for patients with treatment-resistant primary generalized tonic–clonic (GTC) seizures.[4] A 56–day baseline phase was followed by a 140–day double-blind phase. Eligible patients were 4 years and older, with treatment-resistant primary GTC seizures, taking one or two concomitant AEDs, and they had at least three GTC seizures during the 56–day baseline phase (at least one seizure during each of two consecutive 28-day baseline periods). During baseline, the median number of GTC seizures per 28 days during baseline was 3.5 (range, 1.5–84). Following the baseline period, 153 patients (mean age 29.3 years, range, 4–63 years) were randomized to either rufinamide ($n = 78$) or placebo ($n = 75$). There was no difference in the median percent change from baseline in GTC seizure frequency per 28 days between the rufinamide and placebo groups (36.4% vs. 25.6%, respectively; $p = 0.633$). The responder rate (the percentage of patients who had ≥50% reduction in GTC seizure frequency relative to baseline) was not different between the two groups ($p = 0.3162$).

Lennox-Gastaut Syndrome

The efficacy of adjunctive rufinamide therapy for treatment-resistant LGS was examined in a multicenter, double-blind, placebo-controlled, randomized, parallel-group study.[13,14] The study began with a 28-day baseline phase followed by an 84-day double-blind phase (14-day titration phase followed by a 70-day maintenance phase). Patients were eligible if they were between 4 and 30 years, had 90 seizures in the month prior to the baseline phase, and were taking one to three concomitant AEDs. The rufinamide target dose was 45 mg/kg per day. A total of 138 patients, mean age of 14.1 years (range, 4–37 years),

P.1651

was randomized to either rufinamide (n = 74) or placebo (n = 64). The median dose in both groups was 1,800 mg/day (42–45 mg/kg/day). In the rufinamide group, the median percent reduction in total seizure frequency per 28 days relative to the baseline phase was significantly higher than in the placebo group (32.7% vs. 11.7%, p = 0.0015). The median percent reduction in tonic–atonic seizure frequency per 28 days relative to the baseline phase was significantly higher in the rufinamide group compared to the placebo group (42.5% vs. 1.4%, p < 0.0001). The tonic–atonic seizure responder rate was significantly higher in the rufinamide group compared with the placebo group (42.5% vs. 16.7%, p = 0.0020) (Fig. 2). An improvement in seizure severity was observed in 53.4% of the rufinamide group compared with 30.6% of the placebo group (p = 0.0041). The authors concluded that rufinamide was efficacious as an adjunctive therapy for the treatment of resistant seizures in patients with LGS.

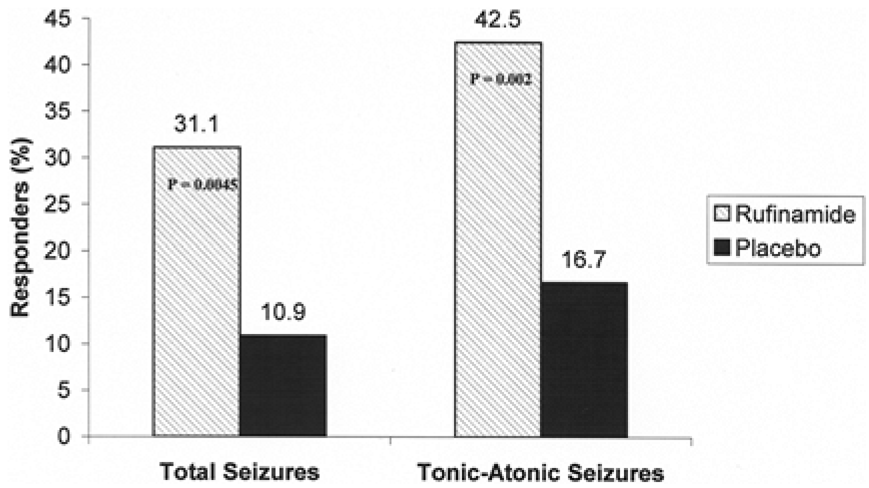

FIGURE 2. Percentage of Lennox-Gastaut patients with ≥50% reduction in tonic–atonic and total seizure frequency (per 28 days during the double-blind phase relative to baseline).

Adverse Events

Dose-Related, Nonidiosyncratic Adverse Effects

In animal studies, rufinamide's safety ratio (defined as the toxic dose in 3% of animals/effective dose in 97% of animals, the TD_3/ED_{97}) was 3 to 900 times greater than for other AEDs.[2]

In humans, the short- and long-term safety of rufinamide in patients with epilepsy was evaluated in a pooled analysis of the adverse event reports from clinical studies.[19] Safety data from all patients with epilepsy who received one or more doses of study drug in any of 12 double-blind, placebo-controlled studies or 12 controlled or open-label studies of rufinamide for short- and long-term therapy were included. The analysis of adverse events used the *Medical Dictionary for Regulatory Activities,* and results were presented by system organ class. The results were reported in abstract form and only common adverse events that occurred in 10% or more of patients were identified. In addition, the analysis examined the time to onset of the common adverse events in only the double-blind, placebo-controlled studies.[19]

Table 3 Adverse events in placebo controlled rufinamide trials

	Rufinamide (*n* = 1,240)	Placebo (*n* = 635)
Headache	22.9	18.9
Dizziness	15.5	9.4
Fatigue	13.6	9.0
Somnolence	11.8	9.1
Nausea	11.4	7.6

Short-term safety data from 1,240 rufinamide-treated patients and 635 placebo patients (mean ages, 31.7 and 28.6 years, respectively) were analyzed. The median duration of exposure of rufinamide (2.8 months) and placebo (3.0 months) was similar. The group's mean rufinamide dose was 1,373 mg/day. The most frequently reported short-term adverse events are shown in Table 3.[19] The time to onset of these short-term adverse events was comparable between the groups. The most commonly reported serious adverse events were epilepsy-related, such as convulsions. Overall, serious adverse events were noted in 6.3% of rufinamide-treated patients compared with 3.9% of placebo-treated patients. Treatment discontinuations due to adverse events were higher among rufinamide-treated patients compared with placebo-treated patients (8.1% vs. 4.3%).[19]

The long-term safety of rufinamide was assessed in 1,978 patients (mean age, 31.3 years) who took rufinamide in controlled or open studies of less than 1 month to more than 4 years in duration. Almost half the patients (47%) had taken rufinamide for 12 months or longer. In this long-term exposure group, the mean rufinamide dose was 1,700 mg/day, with a maximum dose of 7,200 mg/day. The most common organ systems involved were the nervous (64.7%) and gastrointestinal systems (42.3%).[19] The most frequently reported adverse events seen in patients receiving long-term rufinamide therapy were headache (29.5%), dizziness (22.5%), and fatigue (17.7%). Adverse events led to rufinamide discontinuation in 13.1% of the patients.[19] The most common serious adverse events were convulsion, status epilepticus (SE), and pneumonia; overall, 13.2% of patients reported serious adverse events. As the median rufinamide dose increased, the rates of adverse events generally increased. The authors concluded that overall, rufinamide was well tolerated, the commonly occurring short-term adverse events had an early onset with rapid resolution, and long-term rufinamide use was safe and well tolerated.[19]

In the placebo-controlled adjunctive rufinamide pediatric partial seizure trial, the most commonly reported adverse events were headache (rufinamide, 19.1% vs. placebo, 9.8%), somnolence (14.7% vs. 8.3%), vomiting (13.2% vs. 6.1%),

P.1652

and upper respiratory tract infection (6.6% vs. 11.4%). All adverse events classified were mild to moderate in severity. Ten rufinamide-treated patients (7.4%) and four placebo-treated patients (3.0%) prematurely discontinued the study due to adverse events. Ten rufinamide-treated (7.4%) and nine placebo-treated (6.8%) patients had nonfatal serious adverse events.[12]

In the controlled trial involving LGS patients, the most common adverse events experienced included somnolence (24.3% rufinamide, 12.5% placebo), vomiting (21.6% rufinamide, 6.3% placebo), pyrexia (13.5%

rufinamide, 17.2% placebo), and diarrhea (5.4% rufinamide, 10.9% placebo). Cognitive/psychiatric adverse events of interest, such as psychomotor hyperactivity and lethargy, occurred in a lower percentage of patients in the rufinamide group (17.6%) than the placebo group (23.4%).[13,14]

To date, rufinamide is not associated with consistent clinically significant changes in vital signs, physical examinations, electrocardiogram (ECG) recordings, or laboratory tests.[1,4,5,12,13,14,21,32,33] No deaths have been reported in the volunteer-treated population.[9] Twenty-eight deaths have been reported in patients who received either rufinamide or placebo to date.[9] All deaths occurred in patients with epilepsy. For all treated patients with epilepsy, the rate of deaths was 0.71 per 100 patient-years of exposure to rufinamide. The rates were 0.69 per 100 patient-years of exposure to rufinamide and 2.67 per 100 patient-years of exposure to placebo for all patients with epilepsy who received study drug in double-blind studies. None of the deaths was considered to be causally related to rufinamide therapy by either the investigator or the Novartis Medical Monitor.[9] The rate of sudden death was 0 per 100 patient-years for rufinamide and 2.67 per 100 patient-years for placebo.

Idiosyncratic Reactions

The incidence of skin rash is not higher in rufinamide-treated patients compared with placebo (3.1% vs. 3.3%). None of the 1,978 patients included in the clinical database experienced erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. However, a total of five patients in the clinical database might have suffered an AED hypersensitivity syndrome (fever, rash, and any evidence of internal organ involvement). In all cases, the reaction appeared during the first 4 weeks of treatment. All patients were children. None of them had mucosal involvement or blistering of the skin. All patients quickly recovered after discontinuation of rufinamide.

Status Epilepticus

Estimates of the incidence of treatment-emergent SE among patients treated with rufinamide are difficult because standard definitions were not employed. In controlled trials, 11 of 1,240 (0.9%) patients had episodes that could be described as SE in the rufinamide-treated patients compared with none in the placebo-treated patients.

Teratogenicity

To date, no reports of newborn malformations have been associated with maternal rufinamide use. Thirteen pregnancies occurred during the clinical studies (database includes 979 females treated with rufinamide). Six of the 13 pregnancies were known to have resulted in the birth of six healthy babies. One pregnancy was ended by a spontaneous abortion, and three by elective abortions. No information was provided to the sponsor about the outcome of the remaining three pregnancies. However, the overall patient exposure is too low to make any definitive conclusions. Rufinamide is likely to be excreted in breast milk.

Drug Interactions

In vitro testing using human liver microsomes demonstrated that rufinamide did not act as a competitive or mechanism-based inhibitor of the following human P450 enzymes: CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2D6, CYP2El, CYP3A4/5, or CYP4A9/11.[17,18] These results indicate that rufinamide should not be expected to inhibit the pharmacokinetics or biotransformation of coadministered drugs metabolized primarily by CYP isozymes.[17]

In patients taking AED polytherapy, rufinamide does not cause clinically significant effects on the pharmacokinetics of concomitant AEDs.[11] A pooled analysis of rufinamide effect on the pharmacokinetics of carbamazepine, lamotrigine, phenobarbital, phenytoin, topiramate, and valproate was performed using five rufinamide multicenter, double-blind, placebo-controlled, randomized, parallel-group studies. The results have been reported in abstract form.[11] These studies involved pediatric and adult epilepsy patients treated with one to three AEDs.[11] The population pharmacokinetic analysis used nonlinear mixed-effect modeling (NONMEM). Six separate populations were analyzed based on the concomitant AEDs: carbamazepine (n = 903, median age 32.3 years, range 3.9–68.8 years); lamotrigine (*n* = 200, median age 22.7 years, range 4.7–68.5 years); phenobarbital (*n* = 149, median age 34.5 years, range 4.3–62.6 years); phenytoin (*n* = 299, median age 34.4 years, range 4.5–72.3 years); topiramate (*n* = 69, median age 15.6 years, range 4.1–53.7 years), and valproic acid (*n* = 488, median age 27.2 years, range 4.3–68.6 years). Rufinamide did not change the CL/F of topiramate and valproic acid but did increase to a minor extent the CL/F of carbamazepine and lamotrigine, while decreasing to a minor extent the oral clearance of phenobarbital and phenytoin (as a function of rufinamide plasma concentration). Rufinamide-induced changes in AED oral clearance were similar among age groups; rufinamide adjunctive therapy is predicted from the modeling to lead to a less than 18% change in the pre-rufinamide AED CL/F at a rufinamide concentration of 15 ug/mL (i.e., a typical steady-state rufinamide concentration in a patient taking either 45 mg/kg per day in children or 3,200 mg/day in adults). The changes in concurrent AEDs' oral clearance would result in changes of steady-state AED concentrations of less than 21%.[11]

Rufinamide's pharmacokinetics does not appear to be affected by carbamazepine, clobazam, oxcarbazepine, or vigabatrin.[17] Valproic acid decreases rufinamide's CL/F by approximately 22%; phenytoin and barbiturates increase rufinamide's CL/F by approximately 25%.[9,17]

The effect of rufinamide on low-dose oral contraceptives was examined in a single-center, open-label, multiple-dose 56-day study.[31] Overall, 18 healthy female volunteers took Ortho-Novum 1/35 for at least two cycles prior to randomization and throughout the entire study. Rufinamide 1,600 mg/day was given on days 22 through 35. Coadministration of rufinamide and Ortho-Novum 1/35 resulted in a mean decrease in the ethinyl estradiol $AUC_{0\text{-}24}$ of 22% and norethindrone $AUC_{0\text{-}24}$ by 14% on day 34, as compared with baseline levels taken on day 7. The clinical significance of this decrease is unknown since this study did not measure any markers of ovulation.[17,31]

Role in Epilepsy Treatment

Indications

Rufinamide is not yet approved for prescription use. In controlled clinical trials, it has demonstrated efficacy against partial seizures in adults and in patients with LGS.[5,10,14]

Dosing Recommendations

In clinical trials, the best rufinamide efficacy results have been seen with doses of 3,200 mg/day in adults and 45 mg/kg per day in children. In adults, treatment should be initiated with a daily dose of 400 to 800 mg/day, as twice-daily dosing. Additional dosing increments may be given (400–800 mg/day every 2 days in two equally divided doses) to a maximum recommended daily dose of 3,200 mg. Doses greater than 3,200 mg/day have been used in open-label studies for periods of 48 months and longer. In general, no clinical trial evidence indicates that doses greater than 3,200 mg/day confer additional benefit. Dose titration should be guided by clinical outcome. In children, treatment should be initiated at a daily dose of approximately 10 mg/kg per day administered in two equally divided doses. The dose should be increased by approximately 10 mg/kg increments every other day to a maximum of 45 mg/kg per day or 3,200 mg/day, whichever is less, administered in two equally divided doses. Some patients have responded at lower doses, whereas others have needed higher dosages (up to 4,800 mg/day in adults). A more complete understanding of the optimal dosing for rufinamide must wait for a larger patient experience (e.g., through large-scale postmarketing clinical trials).

Precautions

In addition to hypersensitivity reactions and the incidence of SE mentioned earlier, rufinamide should be withdrawn gradually to minimize the risk of precipitating seizures, seizure exacerbation, or SE. If abrupt discontinuation of the drug is medically necessary, the transition to another AED should be made under close medical supervision. In clinical trials, rufinamide discontinuation was achieved by reducing the dose by approximately 25% every 2 days.

Contraindications

Rufinamide is contraindicated in patients with a known hypersensitivity to rufinamide, triazole derivatives, or to any excipients used in the formulation.

Summary and Conclusions

Both in animal models and in human clinical trials, rufinamide appears to have efficacy against a broad spectrum of seizure types. Efficacy is well documented as adjunctive therapy against partial-onset seizures in adults and generalized seizures in patients with LGS. Although overall patient exposure is still relatively low, its dose-dependent adverse event profile is encouraging, and there appears to be a low risk of idiosyncratic reactions. Rufinamide undergoes dose-dependent absorption, is eliminated with a half-life of 6 to 10 hours, and it shows a limited potential for drug interactions. It is not yet approved for prescription use.

Based on its characteristics and clinical trial results, rufinamide shows promise as a valuable addition to the currently approved assortment of AEDs.

Chapter 158
Tiagabine

Reetta Kälviäinen

Introduction

Tiagabine (Gabitril) (Fig. 1) is a selective γ-aminobutyric acid (GABA) reuptake inhibitor (SGRI), which increases synaptic GABA availability via inhibition of the GAT-1 GABA transporter on presynaptic neurons and glial cells.[10] It is structurally related to nipecotic acid, but has an improved ability to cross the blood–brain barrier. Tiagabine has been approved for add-on therapy in patients with refractory partial seizures with or without secondary generalization in approximately 30 countries.

Mechanism of Action

Potentiation of GABA is regarded as one of the most important mechanisms of action for novel antiepileptic agents. GABA uptake inhibitors represent a new class of antiepileptic drugs (AEDs), of which tiagabine was the first to be introduced into clinical practice. Tiagabine prevents GABA uptake by inhibiting selectively the GAT-1 GABA transporter, with little or no activity on GAT-2, GAT-3, or BGT-1, which are the GABA transporters responsible for the uptake of the neurotransmitter into neurons and glial cells after synaptic release.[10,60] Tiagabine's affinity for inhibiting glial GABA uptake is 2.5-fold greater than that for neuronal uptake.[11] Tiagabine is not a substrate for the GABA uptake carrier and is therefore unlikely to act as a false transmitter at GABAergic neurons.[11] Blockade of GABA uptake temporarily sustains levels of endogenously released GABA in the synapse.[60] This is the only known mechanism of tiagabine action.

Although both tiagabine and vigabatrin act by enhancing GABA neurotransmission in the central nervous system (CNS), preclinical data show that vigabatrin and tiagabine have different pharmacologic profiles and different mechanisms of action at the cellular level.[55] Tiagabine prolongs the duration, but not the magnitude, of the peak inhibitory postsynaptic current, consistent with temporarily sustained levels of endogenously released GABA in the synapse.[49] By contrast, vigabatrin inhibits presynaptic GABA degradation by selective, enzyme-activated irreversible blockade of the mitochondrial enzyme GABA transaminase, and thus it induces a persistent fivefold increase in whole brain GABA concentration, and also high concentrations in the retina.[56] Tiagabine does not induce the widespread increase in total brain GABA concentrations that accompanies GABA-T inhibition. Moreover, viga-batrin seems to accumulate in the retina, whereas tiagabine does not.[56]

Experimental Studies

The anticonvulsant action of tiagabine has been studied in animal models of epilepsy induced by electrical, chemical, and sensory stimuli, and in genetic models of epilepsy. When administered intraperitoneally to amygdala-kindled rats, tiagabine attenuates the expression of secondarily generalized seizures and completely blocks the expression of partial seizures.[20] Tiagabine also suppresses amygdala kindling–induced epileptogenesis in a dose-dependent manner in the rat.[21]

Intraperitoneal tiagabine was shown to be an active anticonvulsant in experimental studies by protecting against audiogenic and methyl-6,7-dimethoxy-4-ethyl-β-carboline-3-carboxylate- and pentylenetetrazol (PTZ)-induced tonic or clonic seizures in mice and PTZ-induced tonic or clonic seizures in rats.[46] However, tiagabine did not protect against maximal electroshock-induced tonic seizures in mice or rats.[20,46] Tiagabine did not prevent tonic or clonic seizures induced by the potassium channel antagonists dendrotoxin or 4-aminopyridine in mice.[16,64]

In common with GABA agonists, tiagabine may enhance the occurrence of spike-and-wave discharges in animal models of nonconvulsive epilepsy. In WAG/Rij rats, a genetic model of generalized nonconvulsive absence epilepsy, spike-and-wave discharges were increased by tiagabine 3 and 10 mg/kg administered intraperitoneally, but not by a 1 mg/kg dose.[15] Walton et al.[63] reported that tiagabine was effective in treating status epilepticus (SE) in cobalt-lesioned rats. At doses ≥5 mg/kg intraperitoneally, it produced rhythmic high-voltage discharges. At even higher doses, a similar pattern could be produced in normal rats as well. Exacerbation of absence seizures has been found also in rats with genetic absence epilepsy (GAERS) and in the lethargic mouse model.[29]

Tiagabine reduced both seizure-induced damage to pyramidal cells in the hippocampus and impairment of spatial memory associated with hippocampal damage in the perforant pathway stimulation model of SE in the rat.[28] Neuronal cell death was also reduced by tiagabine in the hippocampus of gerbils subjected to cerebral ischaemia[30] and in the rat cerebral ischaemia model of delayed pyramidal cell death.[31]

Pharmacokinetics

Tiagabine is rapidly and nearly completely absorbed after oral administration, with peak concentrations seen within 30 to 90 minutes of dosing.[27] Food delays the time to peak concentration from a mean of 0.9 to a mean of 2.6 hours, but does not change the total quantity absorbed. Because tiagabine has a short elimination half-life, the smoother absorption produced by concomitant intake of food helps in reducing excessive fluctuations in plasma drug levels during the dosing interval and, for this reason, it is recommended that the drug be taken at meal times, preferably at the end of the meal.

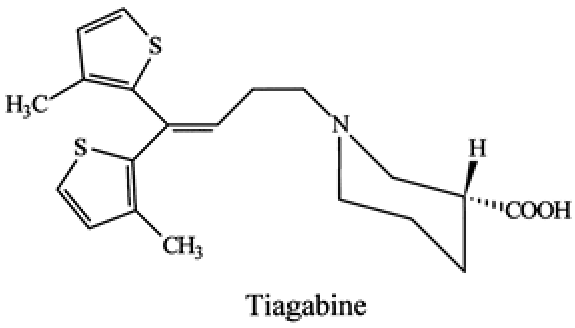

FIGURE 1. Chemical structure of tiagabine.

Table 1 Efficacy of tiagabine as add-on therapy in partial epilepsy

	Responder rate (>50% seizure reduction) for all partial seizures

Reference	Number of patients	Daily dose mg/day	Tiagabine	Placebo
Richens et al., 1995	42	33	52%	24%[b]
Crawford et al., 1993	36	46	40%	14%[a]
Uthman et al., 1998	297	16	10%	4%
		32	20%	4%[b]
		56	31%	4%[c]
Sachdeo et al, 1997	318	32 (16 mg b.i.d.)	28%	8%[c]
		32 (8 mg q.i.d.)	23%	8%[b]
Kälviäinen et al. 1998	154	30	10%	5%
Ben-Menachem 1995	951	16–56	23%	9%

[a]$p < 0.05$, [b]$p < 0.01$, [c]$p < 0.01$
Data from five double-blind, placebo-controlled trials and from an integrated analysis of these studies.

Protein binding is high at 96%, but tiagabine does not displace highly protein-bound drugs such as phenytoin and valproic acid from their binding sites. The volume of distribution is approximately 1 L/kg. Tiagabine is widely metabolized in humans, mainly by isoform CYP3A4 of the cytochrome P450 family. Less than 1% is excreted unchanged in the urine, and no active metabolites have been identified.[45]

P.1656

Tiagabine pharmacokinetics are linear at doses up to 80 mg/day.[58] There is no evidence that tiagabine either causes induction or inhibition of cytochrome P450 enzymes.[27] Consequently, tiagabine has shown no action on hepatic metabolism, which would be expected to alter the pharmacokinetics of cimetidine, carbamazepine, digoxin, erythromycin, oral contraceptives, phenytoin, theophylline, valproate, and warfarin.[12] However, enzyme-inducing AEDs such as carbamazepine, phenytoin, phenobarbital, or primidone increase the hepatic clearance of tiagabine when given in combination.[32] The plasma half-life, which is normally 5 to 9 hours,[27] is reduced to 2 to 3 hours in combination with enzyme-inducing drugs.

Clinical Efficacy

Evidence from Randomized Controlled Trials

Tiagabine has proven effective as add-on therapy in patients with refractory partial seizures with or without secondary generalization. The primary clinical evidence for this efficacy is based on five controlled add-on trials in adults with epilepsy unsatisfactorily controlled with current AEDs (Table 1).

The first phase II multicenter trials were two small, placebo-controlled cross-over studies. In an initial titration period lasting up to 8 weeks, patients started with a tiagabine dose of 8 mg/day, and the dose was titrated either to reduce seizures sufficiently or to produce unacceptable adverse events. Patients then entered a 4-week fixed-dose period on the dose attained in titration. The maximal dose allowed in the first study was 52 mg/day.[48] Patients were eligible to enter the double-blind cross-over phase if their seizure frequency had been reduced by at least 25% during the fixed-dose period. In this two-period crossover study, patients were randomized to placebo/tiagabine or their previously determined dose of tiagabine/placebo, remaining on each of these two regimens for 7 weeks. The 7-week treatment periods were separated by a 3-week washout period. The median daily dose of tiagabine in the double-blind phase was 32 mg/day. Of the total of 42 patients who contributed data for both periods of the crossover phase, 26% of those with complex partial seizures and 63% with secondarily generalized tonic–clonic seizures (n = 27) experienced a reduction of at least 50% in seizure frequency during the tiagabine period compared with the placebo period. The median seizure rate during the tiagabine treatment period was significantly lower than during the placebo treatment period for complex partial seizures ($p = 0.05$) and secondarily generalized tonic–clonic seizures ($p = 0.009$).

The second phase II study used the same design but allowed a maximal dose of 64 mg/day.[18] The intent-to-treat group comprised 36 patients who received a mean total daily dose of 46 mg in the tiagabine treatment periods. Tiagabine was significantly better than placebo in reducing all partial seizures ($p = 0.002$), complex partial seizures ($p < 0.001$), and partial seizures with secondary generalization ($p = 0.030$). A total of 46% of patients with complex partial seizures had at least a 50% reduction in weekly seizure rates.

Altogether 769 patients took part in the three multicenter, parallel-group, double-blind add-on studies in which tiagabine was compared with placebo—a dose-response study, a dose-frequency study, and a three-times-a-day (t.i. d.) dosing study.[35,50,62] The dose-ranging multicenter study in the United States had a fixed-dose, placebo-controlled parallel-group design (n = 297)[62]. During a 4-week period, tiagabine-treated patients were given increasing doses until the dose level to which they had been randomized was reached (16, 32, or 56 mg/day, divided in four equal doses). The patients then remained on a fixed dose for 12 weeks of double-blind treatment. Median decreases in 4-week complex partial seizure frequency for 32 mg (–2.2) and 56 mg (–2.8) tiagabine groups were significantly greater than for the placebo (–0.7) group ($P = 0.03$ and $P < 0.03$, respectively); 20% and 29% of patients in the 32- and 56-mg groups had a 50% or greater reduction in the

frequency of complex partial seizures compared with 4% in the placebo group ($P = 0.002$ and $P < 0.001$, respectively).

The dose-frequency study was also a randomized, double-blind, placebo-controlled U.S. multicenter study with a parallel-group, add-on design (n = 318).[50] The study lasted for 24 weeks and consisted of an 8-week baseline, a 12-week double-blind treatment phase, and a 4-week termination period. During the first month of treatment, doses were increased weekly to 32 mg/day. The treatment groups were placebo, 16 mg tiagabine twice a day (b.i.d.) and 8 mg tiagabine four times a day. The median changes in 4-week complex partial seizure rates were –1.6 ($p = 0.055$) for the 16 mg twice-a-day group and –1.2 ($p < 0.05$) for the 8 mg four-times-a-day group, versus –0.2 for placebo. Statistically significant differences between placebo and two tiagabine groups occurred in the proportion of patients experiencing >50% rate reduction for complex partial, simple partial, and all partial seizure rates.

The thrice-daily dosing study was a Northern-European multicenter parallel-group study that compared a dose of 30 mg/day tiagabine with placebo as add-on therapy (n = 154).[35] The study included 12-week baseline, an 18-week double-blind treatment phase, and a 4-week termination period. The median change from baseline in complex partial seizure rates was –1.3 for patients on tiagabine, whereas placebo patients had a median increase of 0.1 in complex partial seizure rates ($p < 0.05$). Tiagabine was significantly more effective than placebo in patients with simple partial seizures with respect to the proportion of patients achieving a seizure reduction of at least 50% (21% vs. 6%; $p < 0.05$).

The meta-analysis across all these three trials for 50% responders showed an odds ratio of 3.03 (95%; CI 2.01–4.58) in favor of tiagabine.[44] The summary odds ratios for each dose indicate increasing efficacy with increasing doses, with no suggestion that the effect of the drug had reached a plateau at the doses examined in these studies. A 16-mg dose has a fairly small effect of 2.40 (95%; CI 0.65–8.87). There is a substantial increase with doses of 30 or 32 mg to odds ratio of 3.17 (95%; CI 2.03–4.96) and a smaller additional gain for a dose level 56 mg, odds ratio 7.95 (95%; CI 3.09–20.49).

A multicenter, open-label, randomized, parallel-group study compared the efficacy, tolerability, and safety of twice- and thrice-daily dosing of tiagabine as an adjunctive therapy for the treatment of refractory patients with partial seizures.[8] A total of 347 patients were randomized and treated (175 t.i.d and 172 b.i.d.). Each group was administered the same daily dose of tiagabine incremented stepwise during a 12-week fixed-schedule titration period to a target 40 mg/day. The patients were followed for a further 12-week flexible continuation phase. The proportion of 50% responders was similar for both groups (44% for b.i.d. and 48% for t.i.d.) during last 8 weeks of treatment. The long-term efficacy and safety of twice-daily dosing was verified by another similar study by Arroya et al.[4]

A multicenter trial has also been performed to determine whether the combination of AEDs with different mechanisms of action may be superior to the combination of AEDs with similar mechanism of action. In this study, patients on carbamazepine or phenytoin monotherapy with inadequately controlled complex partial seizures were randomized to add-on tiagabine or phenytoin (if previously on carbamazepine) or add-on tiagabine or carbamazepine (if previously on phenyt-oin) and titrated to an optimal dose in a double-blind trial.[9] In this trial, tiagabine ($n = 170$) showed similar efficacy to traditional AEDs (carbamazepine or phenytoin) ($n = 175$) adjunctive therapy for complex partial seizures at low average doses of 24 to 28 mg/day. The study also suggested that tiagabine may be better tolerated when added to phenytoin or carbamazepine than when carbamazepine or phenytoin are added to each other.

Evidence from Other Studies

Data are available from six long-term open-label trials. More than half of the 2,248 patients have been treated with tiagabine for more than 1 year. For each type of partial seizure, 30% to 40% of the patients obtained considerable treatment effect, which was maintained after 12 months of treatment.[5] Daily dosages in the long-term studies were between 24 and 60 mg in the majority of patients, and mean and median doses were 45 mg/day for most studies. However; up to 15% of patients received a dose of between 80 and 120 mg/day after their first year of treatment.[42]

Pragmatic trials use larger patient numbers and a longer follow-up than do the trials required for drug registration and they more closely mimic routine clinical practice. Three such pragmatic studies have been conducted using add-on tiagabine in patients with refractory partial epilepsy and using the newly recommended titration schedule in a total of 1,151 patients, aged 3 to 93 years, who were followed for up to 6 months.[6,19,51] Tiagabine was given three times a day, at an initial dose of 5 mg per day and, following the new schedule, with increases of 5 mg per week. The average dose was 30 mg (range 5–90) per day. Rates for 50% responder varied from 41% to 61%, and 8% to 22% of patients became seizure-free.

Efficacy as Monotherapy

The efficacy of tiagabine during monotherapy in patients with chronic partial epilepsy not satisfactorily controlled by other drugs has been studied in a double-blind, parallel-group study in 198 patients with refractory epilepsy, comparing 6 mg per day tiagabine with 36 mg per day after gradual withdrawal of other AEDs over 29 weeks.[52] Altogether 33% of the patients on the low dose completed the study, compared with 47% taking the higher dose. For both dose groups, the median complex partial seizure rates decreased significantly during treatment compared with baseline ($p < 0.05$). However, a higher proportion of patients in the 36 mg/day group experienced a reduction in complex partial seizures of at least 50% compared with the 6 mg/day group

(31% vs. 18%, $p < 0.05$). In addition to showing a dose–response relationship, this study suggested that even as low a dose as 6 mg/day of tiagabine may be effective when used as monotherapy or with noninducing AEDs.

The second study was a double-blind, randomized comparison of a slow and fast switch to tiagabine monotherapy from another monotherapy, followed by an open-label evaluation of the safety and efficacy of tiagabine as monotherapy for chronic partial epilepsy.[37] If the patients did not tolerate the double-blind titration scheme for tiagabine, even slower open-label up-titration of tiagabine could be used. Thirty-four (85%) of the 40 patients were successfully switched to tiagabine monotherapy in either the double-blind or open-label drug switching schemes. According to this trial, it seems that the open-label up-titration using 5 mg/day with weekly increments of 5 mg/day should be recommended in clinical practice. Monotherapy in newly diagnosed partial epilepsy has been studied comparing the efficacy and safety of tiagabine versus carbamazepine as monotherapy in a double-blind, randomized, parallel-group trial (n = 290).[13] During the 6-week titration period, patients were titrated from tiagabine 5 mg/day or carbamazepine 200 mg/day to tiagabine 10 or 15 mg/day or carbamazepine 400 or 600 mg/day in a step-wise fashion. During the 44-week assessment period, dosage could be adjusted within the ranges for carbamazepine 10 to 20 mg/day for tiagabine or 400 to 800 mg/day. All doses were administered twice daily. The study has so far only been published in abstract form, showing a significant difference between the study groups with regard to

P.1658

the end-point "time to meeting the exit criterion" ($p < 0.05$). An exit criterion was either SE or the occurrence of the second seizure at maximum tolerated or maximum allowed dose level. In the tiagabine group 41% (60 of 146) and in the carbamazepine group 53% (77 of 144) completed the assessment period either seizure-free or with a single seizure ($p < 0.05$). It has been suggested that failure of tiagabine monotherapy to show efficacy comparable to carbamazepine in this trial might have been related to the relatively low maximum dose of tiagabine that was used.

Efficacy in Pediatric Patients

Use of tiagabine in children has been studied as adjunctive therapy in over 200 pediatric patients. A European study was carried out at two centers in Denmark and one center in France.[61] This 4-month, single-blind study evaluated the tolerability, safety, and preliminary efficacy of ascending doses (0.25–15 mg/kg/day) of tiagabine add-on therapy in 52 children over 2 years of age with different syndromes of refractory epilepsy. Tiagabine appeared to reduce seizures more in localization-related epilepsy syndromes than generalized epilepsy syndromes. Seventeen of the 23 patients with localization-related epilepsy syndromes entered the fourth dosing period. The 17 patients had a median reduction of seizure rate in the fourth month of treatment of 33% compared with baseline. In comparison, 13 of 22 children with seven different generalized epilepsy syndromes entered the fourth dosing period with a median change of seizure rate of 0%. Among generalized seizures, tonic seizures and atypical absences responded best, with median percentage reductions in the weekly seizure rate of 77% and 63%. The overall maximum daily tiagabine dose level received and tolerated (mean ± S.D.) was 0.65 ± 0.37 mg/kg.

In the United States, the long-term use of tiagabine has been studied also in an open-label extension study in 152 children, aged 2 to 11 years, from antecedent double-blind studies.[17] Of the 140 evaluable patients, 10 were seizure-free with tiagabine add-on therapy, and 13 achieved seizure-freedom with tiagabine monotherapy for periods ranging from 9 to 109 weeks. The shortest seizure-free or monotherapy durations represented patients with recent enrollment dates at the time of report. Dose range was from 4 to 66 mg/day, and average dose was 23.5 mg/day. In a recent preliminary open trial in infantile spasms, six of 12 infants had at least 50% seizure reduction at dosages of 0.5 to 3.1 mg/kg per day.[39]

Table 2 Treatment-emergent CNS-related adverse effects

Adverse event	Placebo	Tiagabine

	(*n* = 275), n(%)	(*n* = 494), n(%)
Dizziness	41 (15)	131 (27)[b]
Asthenia	39 (14)	99 (20)[a]
Nervousness	8 (3)	50 (10)[b]
Tremor	9 (3)	46 (9)[a]
Difficulty with concentration/attention	6 (2)	30 (6)[a]
Depression	2 (<1)	17 (3)[a]
Language problems	0 (0)	8 (2)[a]

[a]$p < 0.05$; [b]$p < 0.01$
Significantly higher treatment-emergent CNS-related adverse events reported by ≤1% of tiagabine-treated patients during the experiment period in the three placebo-controlled, parallel-group, add-on epilepsy studies by Leppik et al.[42]

Clinical Safety

From short-term trials compared with placebo, it was clear that some CNS-related adverse effects are particularly common with tiagabine treatment (Table 2). Dizziness is most frequent. This is a feeling of light-headedness or unsteadiness, and develops usually within 1 or 2 hours of taking a tiagabine dose. It is associated with the peak concentration of the drug. Also more common with tiagabine than with placebo were asthenia (lack of energy), nervousness, tremor, concentration difficulties, depressive mood, and language problems (difficulty in finding words or initiation of speech). The increased risk of CNS-related adverse events compared to placebo occurred during the titration period only. There was no difference in side effects during the fixed-dose period.[42] This experience suggests that tiagabine should be titrated slowly. It is recommended, on the bases of these studies, that initial dosages of tiagabine can be given twice a day, but a change to three times daily dosing is recommended with dosages above 30 mg/day. Tiagabine should always be taken with food to avoid rapid rises in plasma concentrations. Individually, four times daily dosing may also be helpful at least with higher doses. Somnolence or drowsiness were not seen more frequently in tiagabine patients than in patient receiving placebo.

No idiosyncratic reactions have as yet been linked to the use of tiagabine.[41] No systematic abnormalities have been noted in hematology values or common chemistry values; therefore, no specific guidelines are available for routine monitoring of laboratory values during tiagabine treatment.[42] The relationship of adverse events has correlated more strongly with dose than with the plasma concentration of tiagabine.[42] Therefore, it is most important to up-titrate the dosage according to the tolerability of the individual patient, and there is no need to follow-up routinely on the plasma concentration.

Because of its action on GABAergic mechanisms, the question has been raised as to whether tiagabine, like vigabat-rin, can result in visual field abnormalities. To date, however, no evidence suggests that the increased risk of concentric visual field defect is a class effect of GABAergic drugs. A cross-sectional study compared vigabatrin add-on patients with tiagabine add-on patients and controls and found that, unlike vigabatrin, tiagabine treatment seemed to be associated with normal electroretinography and visual fields.[33] The first ophthalmologic study of 15 patients using tiagabine as monotherapy (mean daily dosage 21 mg, range 5–60 mg; mean duration of therapy 38 months, range 23–55 months) did not show any evidence of a relationship between visual field constriction and tiagabine treatment.[47] A larger cross-sectional study was set up in newly diagnosed patients with partial epilepsy receiving tiagabine, carbamazepine, or lamotrigine as initial monotherapies.[36] Neurologic and ophthalmologic tests, including Goldmann and Humphrey perimetries, were performed. A neuro-ophthalmologic expert blindly reviewed all visual charts. Seventy-three patients were included and completed the study. The population eligible for analysis included 68 patients, of whom 32 were treated with tiagabine (median duration, 25 months), 24 with carbamazepine (21 months), and 12 with lamotrigine (15 months). No clinically relevant abnormalities in visual fields resembling those known with vigabatrin were detected, particularly in patients treated initially with tiagabine monotherapy. These findings support the evidence that tiagabine is not associated with retinal toxicity. The results of a small study (n = 20) of newly diagnosed patients with partial epilepsy suggest that tiagabine does not have

P.1659

an effect on visual contrast sensitivity but may interfere with color perception, a phenomenon common to many of AEDs.[59]

There has also been concern that tiagabine may be associated with an increased incidence of psychosis, particularly with rapid titration. Evaluation of psychosis-related adverse effects showed no excess risk of this disorder attributable to tiagabine beyond what would be expected from the population with difficult-to-control partial seizures. The incidence of psychosis was 0.8% in the tiagabine-treated patients and 0.4% in the placebo-treated patients in the three parallel group add-on trials.[42] However, the addition of tiagabine in clinical trials was associated significantly more often with depression than was the use of placebo (5% vs. 2%).[42] Because of this concern, if a history of behavioral problems or depression is present, treatment with tiagabine should be initiated at a low initial dose under close supervision, because there may be an increased risk of recurrence of these symptoms during treatment with tiagabine.

The cognitive effects of tiagabine add-on therapy and monotherapy have been widely evaluated. In the largest short-term double-blind study, 162 adults completed a multicenter, dose–response study with random assignment to placebo or 16, 32, or 56 mg/day tiagabine.[23] Results on 19 measures of cognitive abilities and 18 measures of adjustment and mood showed only findings attributable to chance. Long-term cognitive results have been presented in a double-blind, placebo-controlled, parallel-group add-on study with an open-label extension study with 18- to 24-month follow-up.[34] The neuropsychological and electroencephalogram (EEG) evaluation did not indicate any adverse effects of tiagabine during the double-blind phase at low doses or the long-term open-phase at higher doses up to 80 mg /day. One study compared the cognitive effects of add-on tiagabine therapy to add-on topiramate therapy and found that topiramate, but not tiagabine appeared to be associated with persistent cognitive side-effects.[25] Dose-related impacts of tiagabine on cognition and mood were studied in a conversion-to-monotherapy study comparing doses of 6 mg/day and 36 mg/day of tiagabine as monotherapy in previously uncontrolled epilepsy patients.[22] The study showed modest improvements in cognitive abilities and adjustment compared to the more traditional AEDs given at baseline. In patients with inadequately treated chronic partial seizures, an evaluation of the effects of tiagabine monotherapy on cognition and mood was performed.[2] The results from the 18 patients who successfully converted to 1-year tiagabine monotherapy[2] or even longer[3] treatment suggest that tiagabine does not have an adverse effect on cognition or mood. A pooled analysis of two studies in newly diagnosed patients with partial seizures showed that, after 52 weeks of tiagabine (20–30 mg/day) monotherapy (n = 42), there were no detrimental effects on cognition; and the results was similar to the results with carbamazepine monotherapy (400 and 800 mg/day) (n = 42 and n = 1, respectively).

Several cases of nonconvulsive SE have been reported, with disappearance of the status after withdrawal of the drug or reduction in dosage.[38] In double-blind, placebo-controlled trials on patients with partial epilepsy, however, the incidence of spike-and-wave SE, or any kind of SE, was 3% (8 of 275 patients) on placebo and 4%

(22 of 494 patients) on tiagabine, the difference being not statistically significant.[54] Further study of individual cases suggested that most of the subjects with apparently tiagabine-associated nonconvulsive status had pre-existing spike-and-wave patterns and, that, in some cases, the condition was related to drug-induced encephalopathy rather than SE. However, it might be wise not to use tiagabine in patients with unclassified epilepsy or patients with generalized epilepsy, especially those with a history of absence or myoclonic seizures, with a history of spike-and-wave discharges on EEG, or nonconvulsive SE.[53] Tiagabine has not been shown to be effective in these patients, and other evidence suggests that those AEDs that increase GABAergic transmission may exacerbate or induce absences or myoclonus.[43] In patients with a history of spike-and-wave discharges, cognitive or neuropsychiatric disturbances can be associated with exacerbation of the EEG abnormalities. In 2005, the U.S. Food and Drug Administration (FDA) announced that a Bolded Warning will be added to the labeling for tiagabine to warn prescribers of the risk of seizures in patients without epilepsy being treated with this drug. The FDA had become aware of reports of the occurrence of seizures in more than 30 patients prescribed tiagabine for conditions other than epilepsy.[24] Most of these uses were in patients with psychiatric illnesses. In addition to the occurrence of isolated seizures, FDA has received several reports of SE in patients without epilepsy. The use of tiagabine in psychiatric disorders, sleep disorders, and drug dependence has been studied in several small trials,[7] but the safety and efficacy of tiagabine have not yet been systematically evaluated for indications other than epilepsy and, therefore, its off-label use should be discouraged.[24]

Role in epilepsy treatment

Tiagabine is recommended as add-on treatment of adults and children over 12 years with partial seizures, with or without secondary generalization, that cannot be satisfactorily controlled with other AEDs. In the preclinical and clinical studies, the tiagabine dose was expressed in terms of milligrams (mg) of hydrochloride. A conversion factor of 0.91 has been used to calculate the dose as tiagabine free base, which is available as 2.5-, 5-, 10-, and 15-mg tablets, except in the United States, Canada, and Mexico, where 2-, 4-, 12-, 16-, and 20-mg tablets of tiagabine hydrochloride are used. The current labeling with tiagabine free base states that the initial dosage is 7.5 to 15 mg/day, followed by weekly increments of 5 to 15 mg /day. In the United States, Canada, and Mexico, labeling is already modified toward a lower initial dose of 4 mg/day tiagabine hydrochloride, followed by weekly increments of 4 to 8 mg/day.

Phase IV trial and clinical experience to date would suggest starting tiagabine with 4 or 5 mg/day and gradually increasing the dosage by weekly increments of 4 or 5 mg /day, to minimize CNS-related side effects. Initial dosages can be given twice a day, but a change to three-times-daily dosing is recommended with dosages above 30 to 32 mg/day. Tiagabine should always be taken with food, and preferably at the end of meals, to avoid rapid rises in plasma concentrations. Individual dosing four times daily may also be helpful, at least with higher doses.

Population pharmacokinetic analyses indicate that tiaga-bine clearance is 60% greater in patients taking enzyme-inducing AEDs. The usual initial target maintenance dosage in patients taking enzyme-inducing drugs is 30 to 32 mg/day and, in patients not taking enzyme-inducing drugs, 15 to 16 mg/day.[53] The usually recommended range of maintenance dosage in patients taking enzyme-inducing drugs is up to 50 to 56 mg/day and, in patients not taking enzyme-inducing drugs, up to 30 to 32 mg/day. However, high daily doses of at least 70 to 80 mg are well tolerated for some individual patients. Patients taking a combination of inducing and noninducing drugs (e.g., carbamazepine and valproate) should be considered to be enzyme-induced. No AED should be suddenly withdrawn, and although there are no clinical data, it seems sensible to withdraw tiagabine gradually over at least 2 to 3 weeks.[53]

The pharmacokinetics of tiagabine in elderly patients are similar to those observed in younger patients, hence there should be no need for dosage modification.[57] The pharmacokinetics of tiagabine has not been investigated in adequate and

P.1660

well-controlled clinical trials in patients younger than 12 years. The apparent clearance and volume of distribution of tiagabine per unit body surface area or per kilogram were fairly similar in 25 children (aged 3 to 10 years) and in adults taking enzyme-inducing AEDs. In children who were taking a noninducing AED, the clearance of tiagabine based on body weight and body surface area was 2- and 1.5- fold higher, respectively, than in noninduced adults with epilepsy, thus suggesting that dosage requirements (on a mg/kg basis) may be higher in children.[26] In the pediatric study, the maximal tolerated doses for children over 2 years old on inducing AEDs were only slightly higher than in children on noninducing AEDs, but the difference was not significant (0.73 ± 0.44 mg/kg vs. 0.61 ± 0.32 mg/kg).[61]

The pharmacokinetics of tiagabine is unaffected in patients with renal impairment or in subjects with renal failure requiring hemodialysis.[14] Patients with mild or moderate liver function impairment have been shown to have higher and more prolonged plasma concentrations of both total and unbound tiagabine after administration, compared with normal subjects. The patients with hepatic impairment also had more neurologic side effects. Tiagabine should therefore be given with caution to patients with epilepsy who have impaired hepatic function. Patients with impaired liver function may require reduced initial and maintenance doses of tiagabine and/or longer dosing intervals, compared with patients having normal hepatic function. The patients should be monitored closely because of the potential for an increased incidence of neurologic side effects.[40] Tiagabine should not be used in patients with severely impaired liver function.

Summary and Conclusions

Tiagabine, a selective GABA-uptake inhibitor, is effective against all partial seizures and has a relatively favorable safety profile. The frequency of idiosyncratic drug-related reactions, including cutaneous reactions, is low with tiagabine. Moreover, tiagabine has a favorable cognitive profile. The characteristic concentric visual field defect seen with vigabatrin treatment has not been observed in two tiagabine monotherapy trials. Thus, tiagabine is recommended for use as an add-on treatment in partial epilepsy, for example after failure with the first-line sodium-channel–blocking AEDs or if the first-line AED has caused idiosyncratic reactions. Tiagabine is suitable also for patients for whom it is particularly important that the AED does not cause any deterioration in cognitive performance. If a history of behavioral problems or depression is present, treatment with tiagabine should be initiated at a low initial dose under close supervision, because there may be an increased risk of recurrence of these symptoms during treatment with tiagabine. Tiagabine should not be used in patients with unclassified epilepsy or patients with generalized epilepsy, especially those with a history of absence or myoclonic seizures, or with a history of spike-and-wave discharges on the EEG or nonconvulsive SE.

Chapter 159

Topiramate

Edward Faught

Tracy A. Glauser

Introduction

Topiramate (TPM) is a broad-spectrum antiepileptic drug with multiple mechanisms of action. It was originally synthesized as part of a search for fructose-related compounds with hypoglycemic activity.[63] It was not developed for that purpose, but was discovered to have antiepileptic activity in animal models in the 1980s. Phase II clinical trials began in 1988 and it was approved for prescription use in the United States in 1996. It is available in over 80 countries.

Chemistry

Topiramate(2,3:4,5-bis-*O*-(1-methylethylidene)-β-D-fructop- yranose sulfamate) is a monosaccharide derived from D-fructose, and is not structurally related to other antiepilepsy drugs (Fig. 1). It exists as a white crystalline powder, has a molecular weight of 339.37 and empirical formula of $C_{12}H_{21}NO_8S$, and is soluble in water and organic solvents at physiologic pH.[54]

Pharmacology

Activity in Experimental Models of Seizures/Epilepsy

TPM is effective in the rodent maximal electroshock model, inhibiting tonic hind-limb extension;[101] this indicates an action against seizure spread. It raises seizure thresholds lowered by pentylenetetrazole and bicuculline, but this effect is less robust.[100] TPM is effective in the amygdalar kindling model[71,114] and in genetic models including DBA/2J mice, spontaneously epileptic rats,[72] genetic absence epilepsy rats, and Wistar rats with audiogenic convulsions.[87]

Mechanisms of Action

TPM has at least five putative mechanisms for its antiseizure effects, but their relative importance is unknown. The first action described was sodium channel modulation,[19] which occurs at therapeutic concentrations and correlates with inhibition of sustained repetitive firing in a voltage- and use-dependent manner.[64] It also has a modulatory action against glutamate-mediated excitatory neurotransmission, acting primarily on the kainate receptor type.[99] It antagonizes the action of kainate receptors of the GluR5 subtype in cultured rat amygdalar neurons, apparently postsynaptically.[42] Furthermore, unlike carbamazepine, it protects against seizures in mice induced by the convulsant substance ATPA, a GluR5 kainate receptor agonist.[49] Although TPM also antagonizes the action of the *α*-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) subtype of glutamate receptor, this effect is less striking than that seen with carbamazepine. TPM has no effect on the *N*-methyl-D-aspartate (NMDA)-mediated glutamate receptor type, unlike felbamate.[19] Modulation of calcium currents may occur via the glutamate receptor effects,[83] but direct effects on L-type voltage-sensitive calcium currents have also been described.[120]

In addition to these antiexcitatory mechanisms, TPM may enhance inhibition by promoting *γ*-aminobutyric acid

(GABA) activity. TPM, like benzodiazepines, increases the frequency of opening of $GABA_A$-mediated chloride channels, but does not bind to the benzodiazepine receptor site on the postsynaptic membrane.[116,117] It appears to increase GABA content in human brain as measured by magnetic resonance spectroscopy in vivo,[55,82] but how this may occur is uncertain. TPM may further enhance inhibition by increasing potassium channel conductance, as observed in rat neurons.[47] Finally, TPM is a carbonic anhydrase inhibitor, but this effect is much weaker than that of acetazolamide and may contribute little to its efficacy.[21]

Activity in Other Models

Neuroprotective effects against neuronal injury from hypoxia[53] and status epilepticus[77] have been demonstrated in animal models.

Clinical Pharmacokinetics

Absorption

Across all age groups, TPM has linear pharmacokinetics. In adults, after administration of single, oral doses ranging from 100 to 1,200 mg, TPM was rapidly absorbed from the gastrointestinal tract.[23] Estimated bioavailability is approximately 80%.[75,113] TPM's absorption is not significantly affected by food.[23]

Plasma Protein Binding and Distribution

Topiramate is not highly bound to plasma proteins (9% to 17%).[81] The volume of distribution in healthy adult volunteers was 0.6 to 0.8 L/kg, consistent with a distribution into total body water.[26] Ninety percent of the maximal plasma concentration (C_{max}) was achieved within 2 hours (range 1.4 to 4.3 hours) after oral administration.[23] Mean values for C_{max} and area under the concentration-time curve (AUC), reflections of drug absorption and clearance, increased linearly with respect to dose in adults.[48] Steady state is achieved in about 4 days when renal function is normal.[113]

Metabolism and Elimination

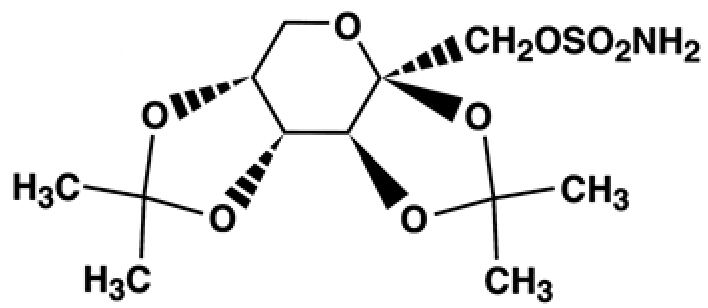

FIGURE 1. Structure of topiramate.

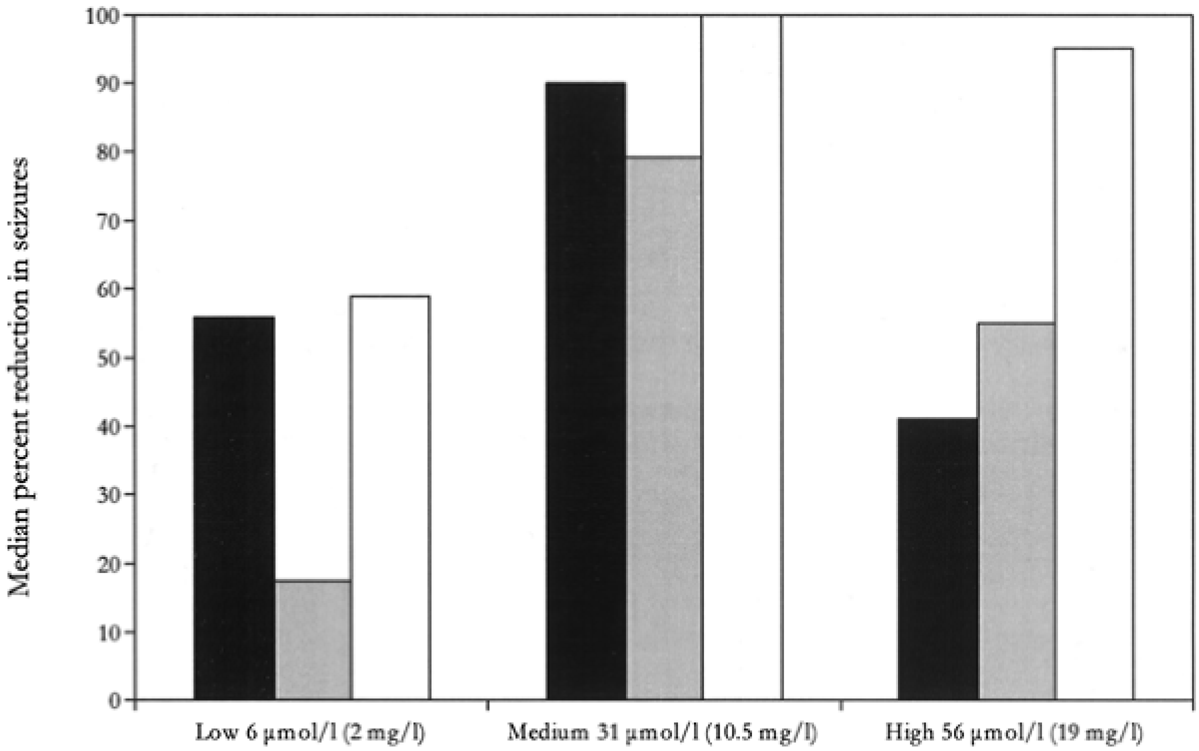

FIGURE 2. The relationship of serum level to median percent seizure reduction for three ranges of topiramate levels: *Black,* simple partial; *gray,* complex partial; *white,* secondarily generalized tonic–clonic. (Reproduced with permission from Christensen J, Andreasen F, Poulsen JH, et al. Randomized, concentration-controlled trial of topiramate in refractory focal epilepsy. *Neurology.* 2003;61(9):1210–1218.)

In monotherapy, TPM is not extensively metabolized.[48] Six trace metabolites of TPM, formed by hydroxylation,

P.1664

hydrolysis, and glucuronidation, have been identified;[118] none exhibits significant antiepileptic activity.[48,118] In adults, the elimination half-life ($t_{1/2}$) values for TPM when used as monotherapy range from 19 to 25 hours.[95]

Renal excretion is a major route of TPM elimination.[118] In adults, estimates are that at least 51% of the dose is excreted by the kidney within the dose range of 200 to 1,200 mg.[23] The renal clearance of TPM is much lower than its glomerular filtration rate,[23] suggesting that it may undergo tubular reabsorption. A twofold increase in AUC and $t_{1/2}$ occurs with renal failure (creatinine clearance <30 mL/min/1.73 m^2),[35] implying that patients with renal impairment may require reduced dosages. During hemodialysis, TPM is cleared from plasma roughly nine times faster than in patients with normal renal function, implying that patients may need additional doses after hemodialysis.[34] Although moderate/severe liver impairment increased TPM's half-life and lowered its oral clearance, there was not a clinically significant increase in plasma TPM concentration following a single 100-mg oral dose in adults.[24]

TPM pharmacokinetics in children and adolescents was determined from a single-center, open-label outpatient trial of 18 patients with epilepsy.[89] Patients aged 4 to 17 years received oral adjunctive TPM therapy up to a target dose of 9 mg/kg/day. Plasma clearance was not affected by TPM dose. Compared to adults, clearance values were 54% greater in children when TPM was administered in the presence of enzyme-inducing drugs and 44% greater in the absence of enzyme-inducing drugs.[89]

Two studies have examined TPM pharmacokinetics in young children. In a study of five children (2 to 2.5 years old), mean plasma clearance was slightly higher than that reported for children and adolescents and higher in infants on concomitant enzyme-inducing antiepileptic drugs (AEDs) than in those on non-enzyme-inducing concomitant AEDs.[38] A more recent study of 22 children (6 months to 4 years) found TPM oral clearance significantly higher in infants and young children on concomitant enzyme-inducing AEDs (85.4 ± 34.0 mL/hr/kg) compared with those taking valproic acid (VPA; 49.6 ± 13.6 mL/hr/kg) or non-enzyme-inducing AEDs (46.5 ± 12.8 mL/hr/kg).[68]

Plasma Concentrations

TPM plasma concentrations can be obtained through most large clinical laboratories. A randomized, concentration-controlled trial of topiramate in adults with treatment-resistant partial epilepsy demonstrated that optimal treatment response is most likely to occur at plasma concentrations ranging of about 10.5 μg/mL (Fig. 2). Another study found that for older children (6 to 12 years) on TPM monotherapy, serum concentrations ranged from 1.5 to 20.4 μg/mL, while children aged

5 and younger had higher TPM serum concentrations (3.2 to 28.8 μg/mL).[98]

Efficacy in Adults and Children

Partial-onset Seizures in Adults: Adjunctive Therapy

Results from eight multicenter, randomized, placebo-controlled trials of TPM as adjunctive therapy for refractory partial-onset seizures in adults have documented efficacy at all dosages of 200 mg/day or more.[10,29,41,43,84,102,106,119] In early trials, the minimum effective daily dose was found to be 200 mg/day,[29] with 400 mg/day being the most effective dose in intent-to-treat analyses.[8,29] Doses from 600 to 1,000 mg/day conferred no additional benefit but increased the rate of adverse effects.[8,29,84] Later clinical trials featured a slower titration rate[41,43] or lower target dose.[43,119] Good results from these later studies have led to recommendations for an adjunctive-therapy initial target dose for adults of 200 to 400 mg/day, achieved by weekly 25- to 50-mg/day upward dose titration. Nearly all patients in these studies had TPM added to enzyme-inducing drugs; in their absence, lower doses of TPM may result in similar serum levels.

Partial-onset Seizures in Children: Adjunctive Therapy

A multicenter, double-blind, randomized, placebo-controlled trial demonstrated the efficacy of adjunctive TPM in children between 1 and 16 years with refractory partial-onset seizures with or without secondary generalization.[27] An 8-week baseline was followed by a 16-week double-blind treatment phase (8-week titration period followed by an 8-week stabilization period) with a weight-based target dose of 6 mg/kg/day. Forty-one TPM-treated and 45 placebo-treated children aged 2 to 16 years completed treatment. For partial-onset seizures, the median percent reduction from baseline in the average monthly seizure rate in the TPM-treated group was 33% compared to 11% in the placebo group ($p = 0.034$).[27]

Partial and Generalized-onset Seizures: Monotherapy

Four monotherapy trials have been conducted.[32,33,34,35] In the first, adult outpatients with refractory partial-onset seizures were converted gradually from one or two standard drugs to either 100 mg/day or 1,000 mg/day TPM.[94] Stopping rules for patient safety were used, such as a doubling of the baseline seizure frequency. Success, defined as conversion without invoking a stopping rule, was more common with the high dose, and 13% of the high-dose patients but no low-dose patients became seizure free.

Two randomized, controlled multicenter trials with a similar design explored lower TPM dosages in recently diagnosed epilepsy in children and adults.[5,33] As in most new-onset trials, patients with both partial-onset seizures and generalized-onset tonic–clonic seizures were included. In the first trial, 252 patients 3 years of age or older with epilepsy for <3 years took either a low dose (25 mg/day if weight <50 kg, 50 mg/day if weight >50 kg) or a high dose (200 mg if weight <50 kg, 500 mg if weight >50 kg).[33] Patients were either on no medication at baseline (56%) or on one drug, which was withdrawn within 6 weeks. Although the primary end-point, time to second seizure, was not statistically significant between these doses, when the time to first seizure was added as a covariate, the high dose proved superior ($p = 0.01$). Fifty-four percent of high-dose and 39% of low-dose patients were seizure free during the 6-month trial ($p = 0.02$). In the second multinational study, patients 6 years of age or older with untreated epilepsy for <3 months took either 50 mg/day or 400 mg/day.[5] The primary end-point, time to first seizure, favored the high dose. Seizure-free rates at 12 months were 76% and 59% for the high and low doses, respectively ($p = 0.001$).[5]

Lower doses, 100 and 200 mg/day, were used in a fourth study of new-onset seizures.[85] For each patient, physicians were given their choice of either valproate 1,200 mg/day or carbamazepine 600 mg/day as the active control agent. Patients were then randomized to TPM 100 mg/day, TPM 200 mg/day, or the control drug. Seizure control was statistically equal among all patient groups. As expected, physicians usually chose valproate for suspected generalized-onset seizures and carbamazepine for suspected partial-onset seizures, but in both groups the TPM efficacy was equal to that of the control agent. Because 100 mg/day TPM proved just as effective as 200 mg/day, the authors suggested 100 mg/day as an initial target dose for patients with new-onset seizures. In the subset of pediatric partial-onset seizure patients, the time to first seizure was similar for patients in the TPM, carbamazepine, or valproate arms, as were the proportions of seizure-free patients during the last 6 months of treatment.[115]

Generalized Tonic–Clonic Seizures of Nonfocal Origin

The efficacy of TPM for children and adults with uncontrolled generalized tonic–clonic (GTC) seizures of nonfocal origin was examined in a double-blind, placebo-controlled, multicenter study.[14] Patients had to be at least 4 years old, have had at least three GTC seizures during an 8-week baseline phase, have EEG findings consistent with generalized epilepsy, and be taking no more than two standard AEDs. Patients were randomized to either TPM or placebo adjunctive treatment, titrated to target dosages of 6 mg/kg/day over 8 weeks, and maintained at that dose for 12 weeks.

Eighty patients (3 to 59 years) were randomized to either TPM or placebo adjunctive therapy. The median baseline average monthly rate of GTC seizures was 5.0 in the TPM group and 4.5 in the placebo group. The mean TPM dosage during the stabilization period was 5.0 mg/kg/day. At the end of the 20-week double-blind phase, the median percent reduction from baseline in the average monthly GTC seizure rate was 57% for the TPM group compared with 9% for the placebo group ($p = 0.019$). A larger percentage of the TPM-treated patients experienced a ≥50% reduction in GTC seizures compared with the placebo-treated controls (56% vs. 20%; $p = 0.001$).

Lennox-Gastaut Syndrome

A multicenter, double-blind, placebo-controlled trial established TPM's efficacy as adjunctive therapy in patients with Lennox-Gastaut syndrome.[93] Patients had to have active drop attacks (either tonic or atonic seizures), a history of or active atypical absence seizures, and a prior EEG showing a slow spike-and-wave pattern, and be taking one to two concomitant AEDs. After a 4-week baseline, they were randomized to either TPM or placebo adjunctive therapy. TPM dosage was increased at weekly intervals over 3 weeks to 6 mg/kg/day and then maintained at that dose for 8 weeks.

Ninety-eight patients, aged 2 to 42 years (mean age 11), were randomized. The median monthly drop attack frequency during the baseline period was 90 in the TPM group and 98 in the placebo group; the median monthly frequency of all seizure types was 267 in the TPM group and 244 in the placebo group. The median average TPM dosage during the stabilization period was 5.8 mg/kg/day.[93]

Patients in the TPM group had a greater median percent reduction from baseline in drop attacks (15%) compared to the placebo group (–5%; $p = 0.041$). TPM-treated patients were nearly twice as likely to show an improvement in seizure severity as compared with controls (52% vs. 28%; $p = 0.040$) based on parental global evaluations.[93]

Infantile Spasms (West Syndrome)

At least eight open-label trials have examined efficacy in infantile spasms.[3,36,40,46,68,108,111,112] A pilot study of 11 patients with infantile spasms documented by 24-hour video-EEG utilized an initial dose of 25 mg TPM, followed by a "rapid-dose" titration schedule of 25-mg increments every 2 to 3 days over a 4-week period until either a maximal tolerated dose was reached, spasms were controlled, or a maximal dose of 24 mg/kg/day was achieved. Five patients (45%) became spasm free with absence of infantile spasms and hypsarrhythmia proven by repeat 24-hour video-EEG.[36] Seven of the 11 patients (64%) were able to achieve TPM monotherapy, while the others were able to reduce their intake of concomitant AEDs.[36]

In a retrospective study of TPM in patients with intractable epilepsy, four of seven infants with West syndrome became seizure free with TPM therapy.[108] Another study reported the efficacy of TPM in 13 infants with West syndrome as part of a multicenter study of 224 unselected patients with a variety of epilepsy types. Seven of the 13 (54%) West syndrome infants had a >50% reduction of their seizures and two (15%) became seizure free. Nine of the patients used TPM as initial monotherapy with doses up to 16 mg/kg/day.[46] An open-label, multicenter chart review study of 28 infants treated with TPM included eight infants with West syndrome. Almost all (seven of eight, 88%) of the patients with infantile spasms improved with TPM therapy and three patients were treated with TPM monotherapy.[112] An open, prospective, pragmatic study of TPM in 59 infants with epilepsy included 19 patients with West syndrome. Four of the six patients with cryptogenic West syndrome became seizure free after a median follow-up of 14 months. Among 13 patients with symptomatic West syndrome, four patients were classified as responders but only 1 of 13 (8%) became seizure free.[40] In contrast, one study of 18 patients with spasms (14 infantile, four late onset) found six responders but none seizure free.[68] A prospective open-label trial of TPM in 47 children (6 to 60 months old) with refractory epilepsy included nine patients with infantile spasms. Two of the nine patients became seizure free and another two experienced a >50% reduction in seizure frequency.[3] A retrospective review of TPM use in 13 children younger than 2 years old reported four infants with infantile spasms; following initiation of TPM therapy two became spasm free, one had a >75% reduction in spasms, and the other had no response to TPM.[111]

Severe Myoclonic Epilepsy of Infancy (Dravet Syndrome)

Four studies have examined TPM's efficacy for children with severe myoclonic epilepsy in infancy (SMEI).[18,40,68,78] One prospective multicenter open label add-on study in 18 patients (2 to 21 years, mean 9 years) with SMEI used a starting TPM dose of 0.5 to 1 mg/kg/day, with 2-week increments of 1 to 3 mg/kg/day up to a maximum of 12 mg/kg/day. Three patients (16.7%) became seizure free and ten patients (55.5%) had a >50% reduction in seizures (mean 11.9 months with range of 2 to 24 months). No patient experienced seizure worsening.[18] A second SMEI trial examined effectiveness in 18 patients with SMEI using a starting dose of 1 mg/kg/day, increasing every 1 to 2 weeks with a maximum dose of 6 to 8 mg/kg/day. Three patients (16.7%) became seizure free, and ten (55.6%) had a >50% reduction in seizure frequency (mean 10.5 months with range of 6 to 18 months).[78] A smaller study found that three of five SMEI patients responded to TPM therapy.[68] An open, prospective, pragmatic study of TPM in 59 infants with epilepsy included six patients with SMEI. Only two of the six SMEI patients responded and none became seizure free.[40]

Other Epilepsy Syndromes

There are small studies suggesting that TPM is effective for juvenile myoclonic epilepsy,[13,105] absence epilepsy,[20] Doose syndrome,[68] and progressive myoclonic epilepsies.[6]

Long-term and Open-label Treatment

Among 214 adults with refractory partial-onset seizures who elected to take TPM after completion of blinded, controlled trials, 64% continued for another 30 months. Of the one third converted to monotherapy, 28 (13% of the 214) were seizure free for at least the last 3 months.[91] In an analysis of 131 adults and children who had completed studies of refractory primary generalized tonic–clonic seizures, 63% had a 50% decrease in seizure frequency during a mean follow-up period of 387 days and 16% were seizure free for the past 6 months.[69]

For the 83 children with partial-onset seizures, with or without secondary generalization, who continued long-term open-label TPM therapy after the double-blind trial phase, the mean TPM dosage was 9 mg/kg/day.

Seizure frequency over the last 3 months of therapy was reduced by ≥50% in 57% of children; 14% of children were seizure free for ≥6 months at the last visit.[88] In the open-label extension phase of the Lennox-Gastaut trial, 97 patients received a mean TPM dose of 11 mg/kg/day for a mean duration of 539 days (range, 44 to 1,225 days); at the last clinic visit, drop attacks were reduced by ≥50% in 55% of patients; 15% of patients had no drop attacks for ≥6 months.[37]

However, these trials were response conditional, enrolling only successful completers of randomized trials. Prospective open-label series may be more predictive of results in clinical practice. Among 292 adults with refractory seizures treated with adjunctive TPM and followed for a mean of 2.2 years (84 to 804 days), mean reductions of >50% in both partial and generalized-onset seizures were observed, and 10% were seizure free for at least 6 months.[1] Discontinuations were more often due to adverse effects (32%) than to lack of efficacy (19%), a pattern typical for TPM treatment.[1,15,58,107] In a 6-month Canadian multicenter study of 209 adults given TPM as adjunctive therapy, patients experienced a 41% median seizure frequency reduction during the final 8 weeks, with 10% becoming seizure free and with improvements in quality-of-life measurements.[7] Long-term retention rates of 30% to 50% for 3 to 4 years have been reported from three large open-label series,[39,41,43] suggesting that a satisfactory effect is sustained for many patients.

Most patients in open-label series were considered refractory; insufficient data are available on the long-term outcome

P.1667

of new-onset epilepsy patients treated with TPM as the first drug.

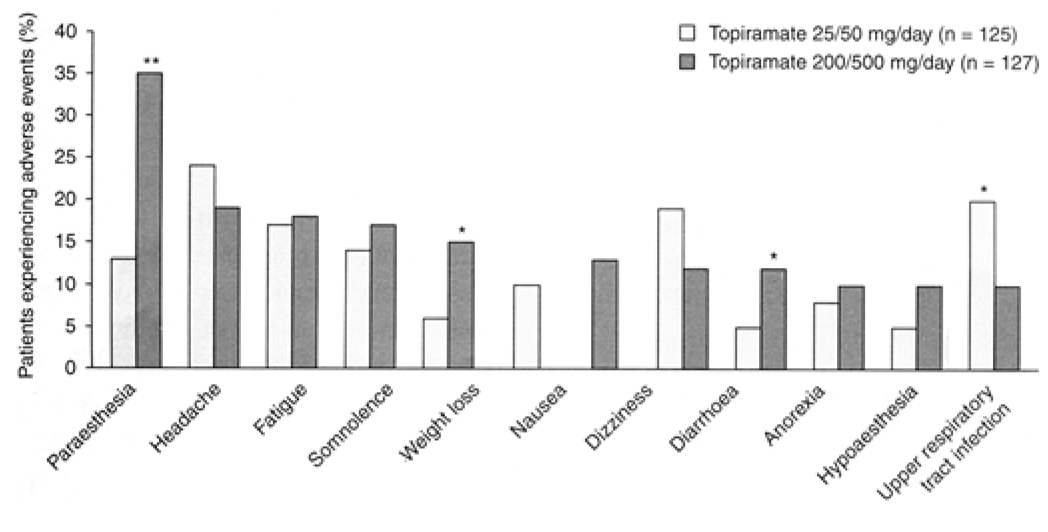

FIGURE 3. Adverse effects at low doses (25/50 mg/day) and high doses (400/500 mg/day) in monotherapy. (Reproduced with permission from Waugh J, Goa KL. Topiramate as monotherapy in newly diagnosed epilepsy. *CNS Drugs*. 2003;17(13):985–992.)

Adverse Effects

During short-term controlled clinical trials of adjunctive therapy, 11% to 28% of patients had TPM discontinued because of adverse effects.[86] Monotherapy is better tolerated (Fig. 3). Cognitive problems, paresthesias, anorexia, and decreases in serum bicarbonate are dose related. Effects seen mostly during dose initiation and unrelated to final dose include dizziness, somnolence, fatigue, and ataxia.[61,103] Gastrointestinal symptoms, renal stones, and psychiatric effects are dose related in some reports. FIGURE 3 relates dose to adverse effects in a monotherapy study. Serious adverse effects are rare.

Dose-related Adverse Effects

Cognitive Effects

The most salient adverse effects, and the ones most likely to limit therapy, are effects on cognition.[15,107] Cognitive effects are in part qualitatively different from those typically seen with other antiepilepsy drugs, tending to affect language function in particular.[62,65,109] In the early, high-dose, rapid-titration, adjunctive-therapy clinical trials, cognitive effects were prominent.[86,103] "Thinking abnormal" was reported in 13% to 33% and "concentration impaired" in 15% to 25%; these effects were dose dependent. In contrast, only 5% of patients in a 200-mg target dose adjunctive therapy trial with slow upward titration of 25 to 50 mg/week experienced "concentration/attention difficulty."[43] Two studies compared the effect of adding either TPM or valproate to carbamazepine using a cautious dosing strategy.[4,66] In the first, patients taking TPM did worse on two tests of verbal memory, but not on eight other cognitive tests,[4] and differences diminished with continuing therapy. Short-term verbal memory was the only one of 17 variables worse among the TPM group in the second study.[66] Among patients with new-onset seizures treated with monotherapy carbamazepine 600 mg/day, valproate 1,250 mg/day, or TPM 100 or 200 mg/day, no cognitive side effect exceeded 8% in any group, though valproate was slightly better tolerated.[85]

Generic terms in standard adverse-event dictionaries do not accurately convey the nature of TPM cognitive effects. Expressive language function may be impaired as well as verbal memory,[109] and a general slowing of cognitive processing may occur.[40,86] These effects often appear without sedation or mood change. There may be a mild dysnomia,[70] or just hesitation in verbal replies. Word fluency declines were seen in normal volunteers[62,67] and in patients with epilepsy.[109] Improvements in verbal fluency, working memory, and other frontal lobe–associated functions were seen in 19 patients withdrawn from TPM as polytherapy.[52] Word-finding difficulty may be more likely in patients with dominant-hemisphere seizure foci or pathology.[70]

Monotherapy reduces the probability of cognitive effects[5,33,94] (Fig. 3). In one trial, effects on concentration/attention occurred in 7% and on memory in 4% of patients assigned to 50 mg/day, and in 8% for each effect in patients assigned 400 mg/day.[5] The total incidence of at least one cognitive effect was 19% for the 50-mg/day group and 26% for the 400-mg/day group, but dose reduction was necessary in only 2% and 7%, respectively.[80]

Cognitive effects are not universally present; many patients are completely unaffected even at higher dosages: Group differences are strongly influenced by a subset of patients who are severely affected.[47,66] Patients with intellectual disabilities[51,104] and the elderly[44] do not appear to be more susceptible. Besides slowing titration rate and limiting dose, another effective strategy is concomitant medication reduction.[74] Physicians should question patients and families carefully about changes in cognitive functions after TPM initiation and after dose increases.

Effects Related to Carbonic Anhydrase Inhibition

Paresthesias, metabolic acidosis, and renal stones are associated with the inhibition of carbonic anhydrase isozymes II and IV.[21] Paresthesias are much more common in monotherapy, probably because of higher serum levels.[33,94] In migraine clinical trials, 35% of subjects had paresthesias at 50 mg/day and 49% at 200 mg/day.[110] Tingling or numbness involves hands and feet, or sometimes the whole body. Patients should be reassured that it is harmless and usually transient.

TPM often lowers serum bicarbonate levels. The manufacturer states that this is a dose-dependent effect, with 32% of adults taking 400 mg/day having levels below 20 mEq/L;[110] however, a lesser effect, an average decrease of 5.1 mEq/L (26.8 to 21.7), was reported in one study.[32] This effect is more prevalent in children.[110] Serum pH is ordinarily compensated and patients are asymptomatic. A clinically significant non–anion gap hyperchloremic acidosis could occur in some circumstances, including ketosis, renal or respiratory insufficiency, or status epilepticus. Serum bicarbonate should be measured at baseline, at the target dose, and after large dose increases.

P.1668

Weight Loss and Anorexia

Many patients taking topiramate lose weight, probably because of anorexia, but the extent and duration is variable. The average decrease in body weight is 4.6%, usually plateauing by 18 months of therapy,[86,92] but obese patients tend to lose more.[9] Weight loss is usually beneficial, though it sometimes limits therapy in thin people and those who cannot voluntarily increase caloric intake. In TPM placebo-controlled trials involving children, weight loss occurred in 9% of the TPM group versus 1% of the placebo group.[79]

Overdose

Overdoses produce drowsiness and lethargy, but serious toxic effects are rare.[59] Gastrointestinal decontamination reduces severity.[61] One fatal case was reported: An adult found dead in bed had taken an unknown amount; a postmortem serum blood level was 170 μg/mL.[56] At autopsy pulmonary and cerebral edema were present. Because TPM protein binding is low, 15%,[97] hemodialysis should remove it effectively, if clinically necessary.

Adverse Effects Not Definitely Related to Dose

Somnolence

Sleepiness during short-term clinical trials affected 15% to 35% of subjects,[29,41,84,106] but it is usually transient and does not limit therapy.[107]

Fatigue

Fatigue, or asthenia, is a common effect of many antiepilepsy drugs.[28] Among adults in adjunctive TPM clinical trials, fatigue was noted in 13% assigned to placebo, 15% in those assigned to 200 to 400 mg/day, and 30% in those assigned to 600 to 1,000 mg/day.[110] Fatigue was seen in 16% of children taking adjunctive TPM and 5% taking placebo.[110] An incidence of about 16% was unrelated to dose during monotherapy trials of 25 to 500 mg/day.[113]

Effects on Mood

Depression was reported in 15% of participants in the first five controlled trials of adjunctive TPM, no more than with placebo.[103] In an open-label series, 11.9% of patients were described as having depression, hyperirritability, or aggressiveness.[15] In another survey 5% had depression and 5.7% irritability or aggressive behavior; these effects were more likely in patients with psychiatric histories.[50]

Idiosyncratic Reactions

Rare and potentially dangerous adverse events of topiramate include hyperchloremic, non–anion gap metabolic acidosis;[39] acute myopia and secondary angle closure glaucoma;[30] oligohidrosis and hyperthermia;[11] and hyperammonemia with or without encephalopathy.[16,57,60]

Teratogenicity

In teratology studies, TPM caused right-sided ectrodactyly (congenital absence of all or part of a digit), micromelia, and amelia in rats; increased embryo/fetal mortality in rabbits; and fetal malformations (primarily craniofacial defects) in mice.[76] These effects of TPM are similar to those reported with acetazolamide and other carbonic anhydrase inhibitors.[73,104]

Topiramate is rated by the U.S. Food and Drug Administration as Pregnancy Category C.[76] The Category C label means (a) animal reproduction studies have shown an adverse effect on the fetus, (b) there are no adequate and well-controlled studies in humans, and (c) the benefits from the use of the drug in pregnant women may be acceptable despite its potential risks.[2]

Drug Interactions

TPM is not an enzyme inducer and protein binding is low. Therefore, it has minimal effects on other drugs, although its metabolism is enhanced by enzyme-inducing agents. TPM is eliminated mainly by the kidneys, but these drugs increase the proportion metabolized by the liver from 20% to 50%.[31]

Effects of Topiramate on Other Antiepilepsy Drugs

In vitro, TPM has no effect on most cytochrome P450 isozymes,[12,110] and no effects on concomitant drug levels were detected in add-on clinical trials.[29,84] However, in one study, in three subjects with baseline phenytoin levels of 15 μg/mL or higher, phenytoin levels rose 30% to 50% when TPM 400 to 800 mg/day was added,[66] probably by inhibiting CYP2C19, the secondary enzyme for phenytoin metabolism.[95]

Effects on other antiepilepsy drugs are negligible.[12,96,110] Carbamazepine[96] and lamotrigine[22] levels are unaffected. TPM has little net influence on valproate clearance, but shifts the proportions of several valproate metabolic pathways,[65,69] the clinical significance of which is uncertain. An increase in a potentially toxic metabolite, 4-ene-valproate, has been proposed as a factor in the rare cases of hyperammonemic encephalopathy observed with combination TPM-valproate therapy.[45]

Effects of Topiramate on Oral Contraceptives

TPM at doses of 200 mg/day or more reduced serum levels of ethinyl estradiol derived from an oral contraceptive by 30%,[90] but in another series of women, TPM doses of 50, 100, and 200 mg/day had no significant effect.[25] This effect is less than that of carbamazepine, phenytoin, and phenobarbital, and unlike these agents, TPM does not lower progestin levels.[25] Nevertheless, women taking over 200 mg/day of TPM should take precautions. The absence of breakthrough bleeding is not a reliable sign of secure birth control, but its occurrence may suggest a need for a higher estrogen dose or a second method.

Effects of Topiramate on Other Drugs

In the presence of TPM, lithium, amitriptyline, and risperidone clearances increase and levels decrease slightly.[12] Metformin AUC increased by 25% in healthy volunteers given TPM.[110] When TPM is used as migraine prophylaxis, it has no pharmacokinetic effects upon concomitant propranolol, sumatriptan, or dihydroergotamine.[12]

Effects of Other Drugs on Topiramate

Both phenytoin and carbamazepine double the clearance of TPM[95,96] and thus reduce serum levels by about 50%. If these

P.1669

drugs are withdrawn, the TPM level will rise. Barbiturates may have a similar effect but have not been studied.

Role in Epilepsy Treatment

Indications

In the United States, TPM is indicated as adjunctive therapy for adults and children ages 2 to 16 years with partial-onset seizures or primary generalized tonic–clonic seizures and in patients 2 years of age and older with seizures associated with Lennox-Gastaut syndrome.[110] It is also indicated for the prophylaxis of migraine headache in adults.[110]

Dosing Recommendations

Topiramate is available in oral preparations either as a tablet (25-mg, 50-mg, 100-mg, and 200-mg strengths) or as a sprinkle capsule (15 mg and 25 mg).[76] There is no intravenous preparation commercially available.

Based on its clinical trials, TPM has been shown to be effective in a wide variety of seizure types (partial-onset seizures, generalized tonic–clonic seizures of nonfocal origin, drop attacks). Attention to the initial dose of TPM, subsequent titration rates, and the maintenance target dose are important to maximize tolerability and subsequently maximize effectiveness. In adults, initial TPM dosing ranges from 25 to 50 mg/day with subsequent weekly or every-2-week increments of 25 to 50 mg/day. For initial monotherapy, target doses as low as 100 mg/day may be effective. In an open-label naturalistic TPM monotherapy clinical trial involving 441 adults at 127 centers throughout Europe and the Middle East, the median final topiramate dose was 125 mg/day (range 25 to 700 mg/day).[44] As adjunctive therapy, TPM target doses range from 200 to 400 mg/day.

In children, initial TPM dosing ranges from 0.5 to 1 mg/kg/day with subsequent weekly increments of 0.5 to 1 mg/kg/day. In an open-label naturalistic TPM monotherapy clinical trial involving 114 children (<12 years old) at 127 centers throughout Europe and the Middle East, the median final topiramate dose was 3.3 mg/kg/day (range 1.3 to 13.0 mg/kg/day).[44] As adjunctive therapy, TPM target doses range from 6 to 9 mg/kg/day. Infants and some children may require significantly higher initial and target doses. Some infants and children benefit from TPM doses up to 50 mg/kg/day—particularly in the presence of a concomitant enzyme-inducing AED such as carbamazepine.

As with all AEDs, TPM should be titrated until there is a clear response (either seizure control without intolerable adverse events or persisting seizures with intolerable side effects). In patients showing some seizure reduction without intolerable adverse events, the dose of TPM can be further increased. If adverse experiences do occur, titration can be slowed; on the other hand, titration can be more rapid if the suppression of seizures is urgently needed. A small subset of patients (1% to 3%) appears unable to tolerate even the lowest doses of TPM.

Precautions

The manufacturer recommends measurement of baseline and periodic bicarbonate levels.[110] It is reasonable to do this at baseline, at the target dose, after large dose increases, and in circumstances predisposing to metabolic acidosis. Clinical judgment should guide whether dose reduction or alkali treatment is needed; minor decreases in bicarbonate require no action. No other routine laboratory testing is recommended.

Patients should be advised to seek medical care at once if blurred vision or severe unilateral eye pain occurs. The possibility of cognitive effects, renal stones and hyperthermia may be discussed at the time of TPM initiation.

Contraindications

The only absolute contraindication is hypersensitivity to components of the compound.

Summary and Conclusions

Topiramate, perhaps because of multiple modes of action on the central nervous system, is effective against many seizure types. Efficacy is best documented as monotherapy and adjunctive therapy against partial-onset seizures and generalized-onset tonic–clonic seizures, and against component seizure types of Lennox-Gastaut syndrome. Because of this broad spectrum, TPM is a reasonable therapeutic choice for new-onset seizures. It is particularly attractive for patients who may benefit from its antimigraine or anorectic qualities.

Pharmacokinetic characteristics are favorable, with good absorption, low protein binding, mostly renal elimination, few drug interactions, and a linear relationship between dose and serum level. Cognitive side effects occur in about one fourth of patients and may limit therapy. Renal stones occur in 0.5% to 1.5%. Rare side effects include reversible angle-closure glaucoma, oligohidrosis with hyperthermia, and hyperammonemia with or without encephalopathy.

For new-onset epilepsy in adults, 100 mg/day may suffice. With concomitant enzyme-inducing drugs, the target dose range is 200 to 400 mg/day. Some patients will benefit from, and tolerate, higher dosages. A slow titration rate of 25 to 50 mg/day at weekly intervals for adults, and of 1 mg/kg/day per week for children, will improve tolerability.
