Severe myoclonic epilepsy in infancy is one of the most severe epilepsies affecting the infants and deserves to be recognized as soon as possible in order to manage it appropriately. However, the diagnosis is not easy and every infant who presents with long and repeated febrile convulsions before the end of the first year of life must be carefully followed because he is at risk for this epilepsy. Up to now, no antiepileptic drug has allowed controlling the seizures completely and almost all the childern have an abnormal psychomotor development and cognitive impairment at the adult age. In the last years, the genetic origin of this epilepsy has been demonstrated, most of the patients being carriers of a *de novo* mutation in the SCN1A gene, but not all. Currently, many studies aim to discover either the other mutations that could be responsible or the function of the known mutations.

Historical Perspectives

Severe myoclonic epilepsy in infants (SMEI) was first defined in 1982[14] and recognized as a syndrome in the most recent international classification of the epilepsies.[9] Since 1982, about 445 cases have been published in the literature. Most cases are reported from Southern Europe and Japan, but descriptions also come from other regions.[3,26,30] The name of the syndrome was used in the first description to underscore the ictal and interictal, myoclonic component, which allowed differentiating this syndrome from the Lennox-Gastaut syndrome. In the latter, the ictal hallmarks are occurring by generalized tonic seizures, mainly during sleep, and atypical absences. Later, it appeared that myoclonus could be absent in some patients. Seizures were polymorphic, and it was more difficult to find an appropriate semiologic designation.[1] For this reason the Commission on International Classification has proposed using the eponym “Dravet syndrome.”[9] Since 2000, because of the discovery of a mutation in the sodium channel gene *SCN1A* in some patients,[8] this syndrome has been the target of a number of genetic studies that have given new insights to its pathophysiology.

Definition

Severe myoclonic epilepsy in infants is characterized by febrile and afebrile, generalized and unilateral clonic or tonic–clonic seizures that occur in the first year of life in an otherwise normal infant. Later there is with myoclonus, atypical absences, and partial seizures. All seizure types are resistant to antiepileptic drugs. Developmental delay becomes apparent within the second year of life and is followed by definite cognitive impairment and personality changes. The disorder has been categorized among “epilepsies and syndromes undetermined as to whether they are focal or generalized” because the syndrome shows both generalized and localized seizure types and electroencephalographic (EEG) paroxysms.[9] In the most recent proposal it is placed among the “epileptogenic encephalopathies.”[15]

Many children have been reported with a similar picture but without myclonus, and this condition has been designated as “borderline SMEI” (SMEIB).[33] These patients can have different EEG features but have the same course and outcome as patients with myclonus, and they can be included in the same syndrome. Recent genetic studies have demonstrated of *SCN1A* mutations in SMEIB patients but with differences in the type and the site of these mutations.

Epidemiology

SMEI is a rare condition. In the patient population of the Centre Saint-Paul, SMEI was diagnosed in 63 of 6,300 patients (1%) between 1970 and 1990. Hurst[26] estimated an incidence of at least 1 case in 40,000 children <7 years of age in the general population, and Yakoub et al.[50] gave a slightly higher figure (1/20,000 or 1/30,000). In children with seizure onset in the first year of life, the proportion varies from 3%[2] to 5%.[50] These findings show that this syndrome deserves to be recognized in infants with early convulsions. Mild male predominance has been reported.[13]

Etiology and Basic Mechanisms

SMEI shares some characteristics with the idiopathic epilepsies (genetic predisposition, photosensitivity, generalized seizures, and generalized spikes-and-waves on EEG), but they are also associated with features of localization-related epilepsies (focal seizures, focal EEG anomalies, cognitive impairment). Moreover, the course of the disease—progressive during the first stage and always severe—could suggest a metabolic disease. However, none has been identified.

Until recently, magnetic resonance imaging (MRI) was said to be normal, even when repeated some years after the onset. However, in 2005, new data were published by Siegler et al.,[40] who performed the first systematic neuroimaging study with repeated MRI at different ages. They found hippocampal sclerosis (HS) in 10 of 14 patients with SMEI. In 6 of them, HS was not present on the first MRI, performed during the first 2 years in 5 patients and at 11 years in 1 patient, but developed later, between 14 months and 16 years. In the other 4 children, the first examination was not performed before the age of 4 years. In the last 4 children, MRI, performed between 6 and 17 years, remained normal. Because all the patients had a history of

numerous hemiconvulsions and generalized tonic–clonic seizures (GTCS) during the first year, these results support the hypothesis that HS is a consequence of prolonged febrile seizures, even if it is unclear why 4 of the patients did not show HS.

Neuropathologic findings reported by Renier and Renkawek[37] from an autopsied case included cerebellar microdysgenesis, irregular lamination of cerebral cortex, and threefold spinal cord canals. There are no other neuropathologic studies.

A mitochondrial cytopathy was suspected in three patients who presented with an extremely severe picture.[5,6,16] However, according to Dravet et al.[13] and Giovanardi-Rossi et al.[20] no structural or histochemical abnormality was present in the biopsy samples from muscles in respectively five and nine patients.

A family history of epilepsy or febrile seizures is often present, ranging from 25% to 71%.[13] Five families have been reported with two affected siblings in each.[13,33,47]

Monozygotic twins have been reported by Fujiwara et al.,[17] Musumeci et al.,[31] and Ohki et al.[35] Recently, several publications described SMEI cases in the syndrome of generalized epilepsy with febrile seizures plus (GEFS+).[41,42,47] Thus, a genetic etiology could be suspected and was confirmed by the recent discovery of a de novo mutation in the sodium channel gene *SCN1A*.[8] Several publications have reported analogous findings in a high proportion of patients with SMEI but not in all. The percentage varies from 35% among 93 patients,[32] to 62% among 76 patients[19] (in part already published in the Nabbout et al. study[32]), to 71.4% among 12 patients,[44] to 82.7% among 29 patients.[36] Only two studies reported a *GABRG2* mutation,[25,28] which was not found by Madia et al.,[29] in 53 patients without the *SCN1A* mutation. Different mutation types were reported (truncating, missense, nonsense) in different sites of the gene. Correlations of phenotypes to genotypes were variable in different studies. Mutations were observed also in SMEIB,[18] but truncating mutations were largely predominant in the typical form.

Clinical Presentation

Initially, prolonged, generalized, or unilateral clonic seizures are typically but not always triggered by fever. In some patients, isolated episodes of focal myoclonic jerking are noted by parents. Shortly thereafter, seizures also appear without fever. These convulsive seizures tend to be long (>20 minutes), recur in clusters in the same day, and evolve to status epilepticus. Their lateralization is variable, from one side to the other, either in different episodes or even in the same episode (alternating seizures). Generalized or erratic myoclonus, or both, appear between the ages of 1 and 4 years in typical cases. Jerks are usually mild, and falling is infrequent.

Other seizure types are observed during the course of the disease. Atypical absences accompanied by myoclonus occur in 40% of patients, often as absence status associated with convulsive seizures. The status consists of impaired consciousness, variable in intensity, with fragmentary and segmental, erratic myoclonias of low amplitude involving the limbs and the face, sometimes associated with a slight increase in muscular tone. According to the degree of altered consciousness, patients can or cannot react to stimuli, and have simple activities interrupted by short episodes of complete loss of contact and staring. Convulsive seizures can either initiate, occur during, or terminate the status. The EEG is characterized by diffuse slowing, intermixed with focal and diffuse spikes, sharp waves, and spike-wave discharge, of higher voltage in the frontal areas and the vertex, with random correspondence between spikes and myoclonias. Simple partial motor seizures or complex partial seizures, with prominent vegetative symptoms, occur in 46% of children observed as a complex partial status in one case.[48] Without EEG video recordings it is often difficult to differentiate between atypical absences and complex partial seizures. Generalized tonic seizures are exceptional but can be observed in the later stage of the disease. Other clinical paroxysmal events are described by parents, but we do not know if they are epileptic seizures.

Psychomotor delay becomes progressively evident. After children have started walking and producing first words at a normal age, they develop an unsteady gait for an unusually long time, and language skills are delayed, if acquired at all. After the age of 2 years, children become hyperkinetic, with recalcitrant behavior and major learning problems. About 60% of children have an ataxic gait, and 20% show mild pyramidal signs. Interictal EEGs are usually normal at the beginning. However, postictal recordings show asymmetry after unilateral seizures, and a photoparoxysmal response is evident before the age of 2 years in 20% of patients (Fig. 1). Interictal generalized spike-and-wave (SW) complexes appear within the second year of life in most children and can be frequent or infrequent, and only slightly activated by sleep. They are associated with focal and multifocal abnormalities in the majority of cases. Background activity is also usually normal at the beginning. Myoclonus is easily demonstrated by polygraphic recordings, accompanied by generalized SW or polySW when generalized, and without detectable EEG changes if erratic (Figs. 1 and 2).

Neuroimaging does not show any definite abnormality at the onset.[13]

Treatment and Outcome

Typically, the course of SMEI is characterized by three phases, as emphasized by Lambarri San Martin et al.[27] The first phase ("febrile phase" according to these authors) covers the first year, with onset of seizures in a normal infant, often febrile or related to infectious episodes and vaccinations. The second phase ("catastrophic phase") extends from the second to the fourth year, with explosion of frequent and various types of seizures, myoclonus, status epilepticus, psychomotor delay, behavioral disturbances, neurologic signs, and EEG worsening. After 4 years ("sequelae phase"), progressive improvement is observed with decreased seizures and EEG discharges, slow cognitive improvement, and attenuation of the neurologic signs.

However, other periods of worsening are not actually excluded. Although results of medical treatment are in general disappointing, valproic acid (VPA) and benzodiazepines are preferable to other drugs at the very beginning. The first seizures should be treated vigorously, whether, febrile or not, to avoid development of status with its deleterious consequences. Rectal diazepam is the drug of choice and can be used by parents and caretakers. Phenobarbital (PB) can be necessary in case of status. Phenytoin does not offer any advantage and may produce more severe side effects than PB. Continuous oral treatment by VPA should be given when febrile seizures are long and repeated, and when afebrile seizures and myoclonic jerks occur.[38] Among the newer antiepileptic drugs, topiramate is the most promising and should be used as soon as VPA resistance appears.[10] In case of repeated status, stiripentol is the best choice, combined with VPA and clobazam.[7,46] Other options are possible, such as bromides[13] and ketogenic diet.[2,3] Ethosuximide may be helpful in reducing myoclonus and atypical absences. In older patients (third phase), vigabatrin has given promising results, reducing convulsive seizures in patients in whom myoclonus was not a prominent symptom.[23] Conversely, severe worsening of convulsive seizures and myoclonus has been observed with add-on carbamazepine and

P.2339

lamotrigine, and these should be avoided.[21,48] Particular attention should be given to avoiding intercurrent infections and to prevent the occurrence of status epilepticus because any febrile episode may be complicated by convulsive status.

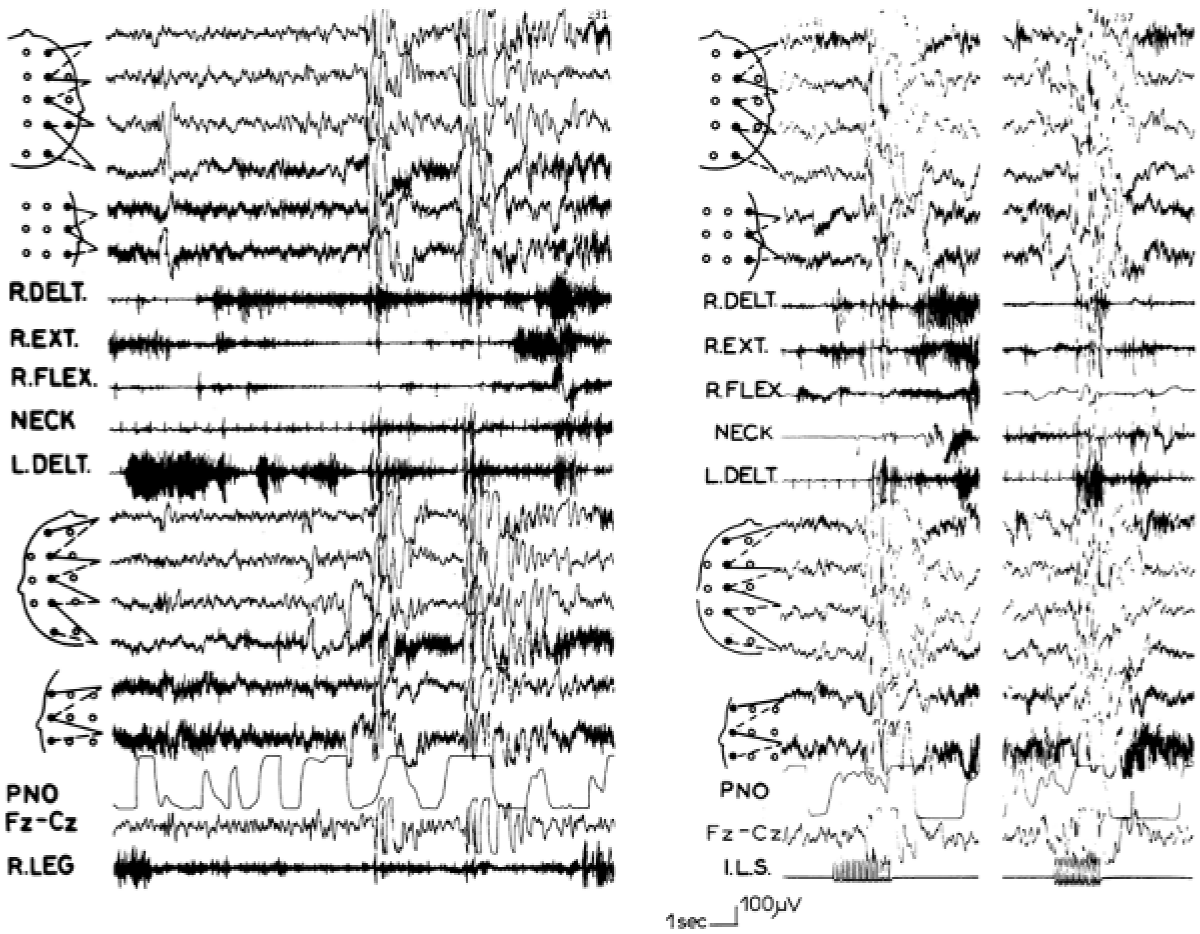

FIGURE 1. Boy, age 1 year, 8 months. **Left:** Polygraphic recording of spontaneous myoclonic attacks is accompanied by generalized spike-and-wave complexes. **Right:** Electroclinical findings of intermittent light stimulation (ILS)–induced generalized myoclonus are similar to those of the spontaneous attacks. L. DELT., left deltoid; R. LEG, extensor of the right leg; R. DELT., right deltoid; R. EXT., extensors of the right wrist; R. FLEX., flexors of the right wrist; PNO, pneumogram.

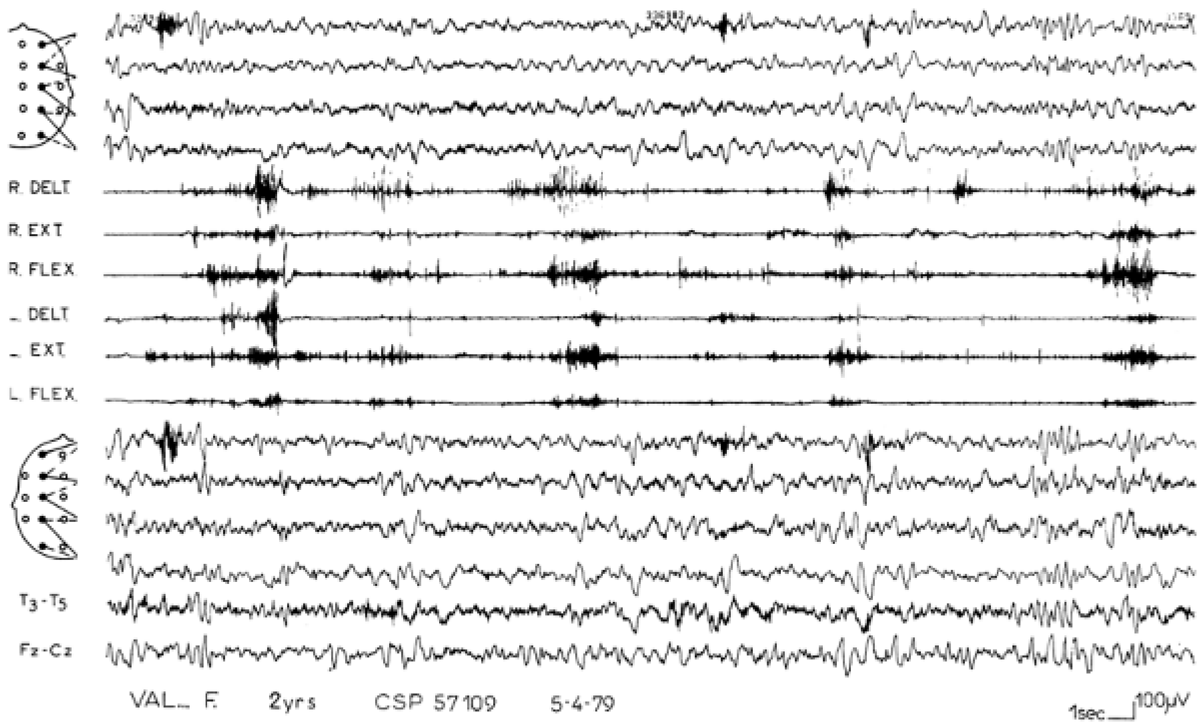

FIGURE 2. Girl, age 2 years. Polygraphic recording of segmental myoclonus at rest and during muscular contraction. Myoclonic potentials are not accompanied by time-locked paroxysmal electroencephalographic abnormalities. L. DELT., left deltoid; L. EXT., extensor of the left wrist; L. FLEX., flexor of the left wrist; R. DELT., right deltoid; R. EXT., extensors of the right wrist; R. FLEX., flexors of the right wrist.

Peculiar features are remarkable temperature, sensitivity and photosensitivity. Seizures can be triggered by slight variations in the body temperature of only few degrees (e. g., going from 36.5°C to 37.5°C) without associated infection, sometimes related to external temperature or physical efforts. In Japan, hot baths are a frequent triggering factor.[45] Other triggering factors are variations in the environmental light, eye closure, and pattern fixation leading to self-stimulation.

Long-Term Prognosis

Follow-up in the series by Dravet et al.[13] varied from 2 years, 6 months to 33 years, 8 months (median, 11 years, 6 months). Long-term outcome was always unfavorable. Convulsive seizures persist, with a tendency to be localized at night. They are described as generalized but often have a localized onset, proved by ictal video-EEG recordings. The course of myoclonus is variable. It may persist, more or less attenuated, disappears, or occur only just before a convulsive seizure. Complex partial seizures usually no longer occur after the first years but the age of disappearance is not homogeneous.[13,35] Atypical absences and absence status also tend to cease. Electroencephalographic findings may vary by age from one patient to another. Generalized SWs tend to disappear. Focal abnormalities, often localized in the central areas, are activated during sleep. Background activity can deteriorate during the course of the disease, mainly when convulsive seizures are frequent, especially between the ages of 5 to 10 years, and then return almost to normal. Temperature sensitivity decreases. Photosensitivity and pattern sensitivity can be constant during the course or occur inconsistently. All patients are cognitively impaired, with 50% of those 10 years and older having severe retardation. The mental impairment constitutes itself progressively during the first 4 to 6 years and then remains more or less equal without further deterioration. A single neuropsychological study was conducted in Marseille, France,[4,49] on 20 patients aged from 11 months to 16 years, with a follow-up of >3 years in 10 cases. Cognitive and behavioral difficulties were always present at varying degrees. Neuropsychological deficits involved all skills, with motor, linguistic and visual abilities being most affected. Behavior was

marked by hyperactivity, psychotic type of relationships, and some autistic traits. The appearance of neuropsychological disorders seemed to be related to the severity of epilepsy during the first 2 years of life.

The mortality rate is very high, around 15% in our most recent series.[13] Several other authors have also reported this high incidence of early deaths.[11,33,34] Causes of death are various, and include drowning, accident, status epilepticus with hepatic or multiorgan failure, severe infection, and sudden unexpected death.

In adulthood, these patients present as dependent persons with mental disabilities, with poor language, poor fine motor function, generalized slowness, sometimes autistic features, and rarely aggressiveness or other psychiatric features. They have few or no school skills, are unable to work, and live in specialized institutions or with their family. However, we underline that therapeutic possibilities have strongly increased with the use of new and more efficacious drugs and strategies. We can hope to see a better outcome for these patients due to these improvements.

Differential Diagnosis

The first seizures must be differentiated from febrile convulsions. Long duration and clustering of attacks despite treatment should lead one to suspect SMEI. Appearance of myoclonus, established by EEG and electromyographic recordings, and photosensitivity are typical. However, in some children with a similar outcome, myoclonus is a minor feature or is absent.[43] Differentiation from benign myoclonic epilepsy is quite easy and is based on three major features: (a) onset with brief generalized myoclonic attacks, (b) which represent the only ictal manifestation in a normal child, (c) with generalized SWs on the EEG.[12] In the rare patients having benign myoclonic epilepsy with febrile seizures, these seizures are always simple and infrequent. The differences between SMEI and Lennox-Gastaut syndrome are clear enough (see Chapter 241). On the contrary, more difficulty arises in differentiating SMEI from myoclonic-astatic epilepsy (MAE),[22,24] a syndrome category in which some children are first seen with early-onset generalized convulsive seizures triggered by fever.

Although this onset is very similar to that of SMEI, it is not the most common in MAE, and the course is different, with myoclonic-astatic seizures (drop attacks) becoming a major feature with absence of any focal clinical or EEG manifestation. The long-term outcome is variable. Some of the affected children remain intractable and have a severe cognitive impairment, but others improve and become seizure free. Another condition that must be ruled out is a progressive myoclonic epilepsy resulting from metabolic disorders, mainly the neuronal ceroid lipofuscinoses. The absence of visual disturbances and of abnormalities of the fundus coupled with negative results of relevant laboratory investigations eliminate this diagnosis. The last differential diagnosis is with a cryptogenic focal epilepsy, which may have the same onset, with febrile seizures rapidly associated with focal seizures. However, these patients do not present atypical absences and myoclonic jerks in the later course, and their EEG shows focal abnormalities that remain localized in the same area. Moreover, this diagnostic is very improbable when the hemiclonic seizures are alternating.[39]

Summary and Conclusions

Severe myoclonic epilepsy in infants is characterized by febrile and afebrile generalized and unilateral clonic or tonic-clonic seizures that occur in the first year of life in an otherwise normal infant and are later associated with myoclonus, atypical absences, and partial seizures. All seizure types are resistant to antiepileptic drugs. Developmental delay becomes apparent within the second year of life and is followed by definite cognitive impairment and personality disorders. Some cases do not present with all the features and are described as borderline or atypical forms. In the most recent proposal it is placed among the “epileptogenic encephalopathies."

In more than 60% of patients in the most recent studies, mutations in the sodium channel gene SCN1A have been found. In more than 60% of patients in the most recent studies, different mutations types were reported in different sites of the gene. Correlations of phenotypes to genotypes are not well established.

Initial prolonged, generalized, or unilateral clonic seizures are typically but not always triggered by fever, and seizures also appear without fever. They tend to evolve into status epilepticus. They are generalized or lateralized (alternating seizures). Later on, myoclonic seizures, atypical absences, absence status, simple partial motor seizures or complex partial seizures, with prominent vegetative symptoms, are observed. Interictal erratic myoclonus also appears between the ages of 1 and 4 years in typical cases. Psychomotor delay and behavioral disturbances become progressively evident, often associated with ataxia and pyramidal signs. Interictal EEGs are usually normal at the beginning. Later on, generalized spike-and-wave discharges associated with focal and multifocal abnormalities appear in the majority of cases, and photosensitivity is frequently observed. Neuroimaging does not show any definite abnormality at onset.

Typically, three phases characterize the course of the disease: the “febrile phase" (first year), the “catastrophic phase" (from the second to the fourth year), and the “sequelae phase" (after 4 years) with decrease in seizures and EEG discharges, slow cognitive acquisitions, and attenuation of the neurologic signs, other periods of worsening being not actually excluded. Triggering seizure effect of temperature variations persists all over the life, whereas photosensitivity is fluctuating.

Treatment is disappointing. Valproate, benzodiazepines, topiramate and stiripentol are the most useful antiepileptic drugs. Carbamazepine and lamotrigine should be avoided during the first phases. Particular attention must be given to avoiding intercurrent infections and to vigorously treating the febrile seizures to prevent the occurrence of status epilepticus (rectal and intravenous diazepam).

In published series, long-term prognosis was always unfavorable, and no adult patient became seizure free. All patients were cognitively impaired, with 50% of those 10 years and older having severe retardation. The mental impairment remained more or less static without further deterioration after the age of four. Mortality rates are very high, around 15%, ofen due to sudden unexpected death. Differential diagnosis mainly includes febrile seizures, myoclonic astatic epilepsy, progressive myoclonus epilepsies, cryptogenic focal epilepsies.

Dravet syndrome should be recognized in infants with early convulsions because it affects 3% to 5% of children seizures in the first year of life. Early diagnosis could allow improved management and, perhaps, a less severe prognosis.

Chapter 231
Idiopathic Myoclonic Epilepsy in Infancy

Charlotte Dravet

Federico Vigevano

Introduction

The syndrome of benign myoclonic epilepsy in infancy (BMEI) was not clearly identified before its first description in seven infants in 1981.[10] These authors defined it as the occurrence of myoclonic seizures (MS) without other seizure types, except rare simple febrile seizures (FS), in the first 3 years of life in otherwise normal infants. These myoclonic seizures were easily controlled and remitted during childhood. Psychomotor development remained normal, and no severe psychological consequences were observed. Many other cases have been published since. BMEI was classified among the generalized idiopathic epilepsies in the 1989 international classification.[4] Some authors have described cases with reflex myoclonic seizures, triggered by noise or contact, and have proposed to distinguish two separate entities, the second one being named "reflex myoclonic epilepsy in infancy."[24] We do not think this distinction is necessary,[11] and we will describe all cases as BMEI.

As of 2006, there were 155 cases published in the literature, of which 123 corresponded to the classical description and 32 were reported as "reflex BMEI" (for a review, see Auvin et al.[2] and Dravet and Bureau[11]). The 22 cases reported by Darra et al.[6] are not counted because it is not known how many were already included in other reports. In the first description, onset was before 3 years of age, whereas in subsequent reports, some cases had a later onset, up to 4 years 8 months.[17] This means that the same type of epilepsy may appear at different ages but tends to be more frequent in some periods.[18] The adjective "benign" is considered problematic, because some patients do not have an actually benign evolution, particularly from the neuropsychological point of view.[2,22] For this reason, the name "myoclonic epilepsy in infancy" has been proposed, but it is ambiguous. This BMEI is idiopathic, and to distinguish this syndrome from other myoclonic epilepsies, we propose replacing the *benign* by *idiopathic.* Thus, the condition should be termed "idiopathic myoclonic epilepsy in infancy (IMEI)," but, in this chapter, we continue to use BMEI, which is the designation best known to epileptologists.

In this chapter, the numbers reported without reference citation are taken from the extensive review of the literature by Dravet and Bureau,[11] supplemented by the paper of Auvin et al.[2]

General Considerations

Epidemiology

According to the few available epidemiologic data, BMEI seems to represent <1% of all epilepsies[20] (unpublished data from the Centre Saint-Paul, 1999), 2% of all idiopathic generalized epilepsies (unpublished data from the Centre Saint-Paul, 1997), and around 2% of epilepsies that begin in the first 3 years of life.[5]

Gender Distribution

There is a prevalence of male patients, with a male-to-female ratio of 2:1.

Genetics

The genetics of BMEI are unknown. Cases are rare, and no family cases of BMEI have been described. A family history of epilepsy or FS is present in 50.5% of cases. Epilepsy types found in relatives are difficult to assess. In one case, the mother presented with juvenile myoclonic epilepsy (JME).[6] In another case, the mother had a myoclonic-astatic epilepsy (EMAS). In the case described by Arzimanoglou et al.,[1] the proband was the second of two brothers, and the oldest was affected by typical EMAS. A similar situation was reported in 2006 by Darra et al.[6]

Personal History

Most patients do not have any relevant history prior to the onset of the myoclonic seizures. Only two (1.9%) had an associated disease: Down syndrome[13] and hyperinsulinic diabetes.[3] However, the occurrence of FS is not uncommon (28%). They are always simple, usually rare (one or two), and are observed before the onset of myclonus and before initiation of treatment. In one patient, two isolated nocturnal orofacial seizures occurred 6 months before appearance of myoclonic seizures.[6]

Clinical and Electroencephalographic Manifestations

The age at onset is usually between 4 months and 3 years; earlier onset is uncommon. Rarely, later onset, between 3 and 5 years, is reported.[17,18]

Initially, the myoclonic seizures are brief, often rare, and involve the upper limbs and the head, rarely the lower limbs. In infants, they may be barely noticeable, and the parents sometimes have difficulty determining their exact onset and their frequency. They often speak of “spasms” or “head nodding.” Later, the frequency increases.

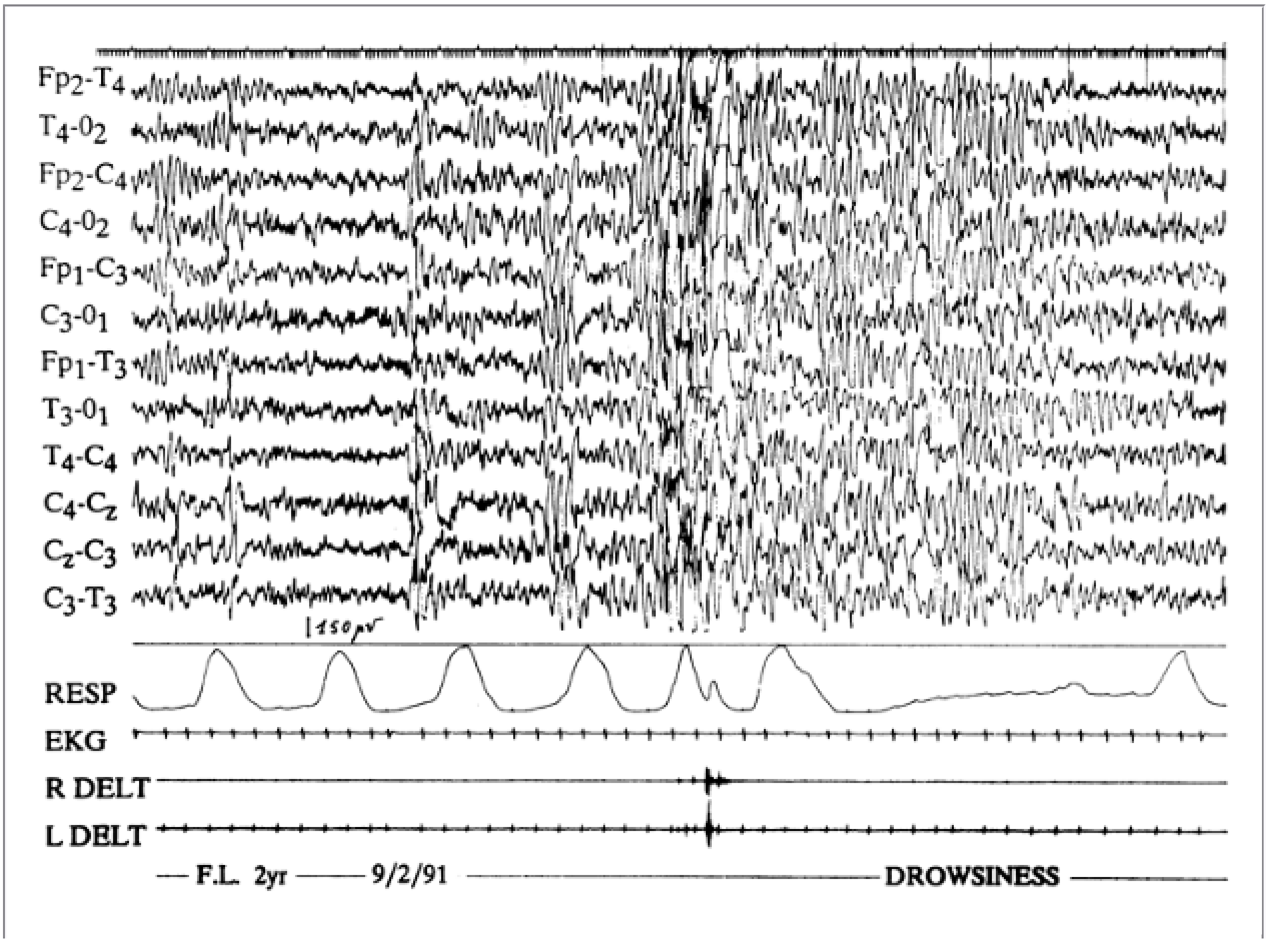

FIGURE 1. Infant with benign myoclonic epilepsy. A spontaneous massive myoclonic jerk was recorded during drowsiness. The ictal EEG shows a brief discharge of generalized spike-wave and polyspike-wave complexes. EKG, electrocardiogram; L DELT, left deltoid; R DELT, right deltoid; RESP, respiration.

Video-electroencephalographic (EEG) and polygraphic recordings have facilitated precise analysis of these seizures. They are more or less massive myoclonic jerks, involving the axis of the body and the limbs, provoking a head drop and an upward-outward movement of the upper limbs, with

flexion of the lower limbs, and sometimes a rolling of the eyes. Their intensity varies from one child to another and from one attack to another in the same child. The most severe forms cause a sudden projection of objects held in the hands and sometimes a fall. The mildest forms provoke only brief forward movement of the head or even a simple closure of the eyes. As a rule, seizures are very brief (1–3 seconds), although they may be longer, especially in older children, consisting of pseudo-rhythmically repeated jerks lasting no more than 5 to 10 seconds. They occur several times a day at irregular and unpredictable times. Unlike infantile spasms, they do not occur in long series. They are not activated by awakening, but rather by drowsiness, except in some cases. In some patients, they can be triggered by intermittent photic stimulation (IPS). In patients with the reflex BMEI, myclonus is triggered by a sudden noise, more often by a sudden contact. The state of consciousness is difficult to assess in isolated seizures. Only when seizures are repeated is there slight impairment of consciousness without interruption of activity. In reflex myoclonic seizures, the myoclonus is elicitable both in wakefulness and in sleep, with a threshold lower in stage I and increasing gradually during the slower stages.[24] No rapid eye movement (REM) sleep has been recorded and tested in patient with reflex myoclonic seizures.

As development continues normally, parents and pediatricians tend not to consider these movements as pathologic events.

When an EEG is performed, it can be normal during the awake state if no myoclonic fits are recorded.

However, myoclonias are always associated with an EEG discharge. Polygraphic recordings demonstrate that myclonic are accompanied by a discharge of fast generalized spike-waves (SW) or polyspike-waves (PSW) at >3 Hz, lasting for the same time as the myoclonia (Figs. 1 and 2). This discharge is more or less regular and can start in the two frontal areas and the vertex. Myoclonias are brief (1–3 seconds) and usually isolated. Each myoclonic jerk may be followed by a brief loss of time. Sometimes, after the attack, there is a voluntary movement, visible as a normal muscular contraction. In only one patient did we observe the association of myclonus in the deltoid muscle with pure atonia in the neck muscles. During drowsiness, there is enhancement of the myclonic jerks; they usually, but not always, disappear during slow sleep. The myoclonic seizures triggered by tactile and acoustic stimuli have the same characteristics (Fig. 2). Ricci et al.[24] noted that the initial manifestation generally, but not always, consisted of a blink, followed 40 to 80 msec later by the first myoclonic arm jerk. After a myoclonic attack, there was a refractory period, lasting 20 to 30 seconds to 1 to 2 minutes, during which sudden stimuli did not provoke attacks, even when the startle reaction was easily elicitable. IPS can also provoke myoclonic seizures.

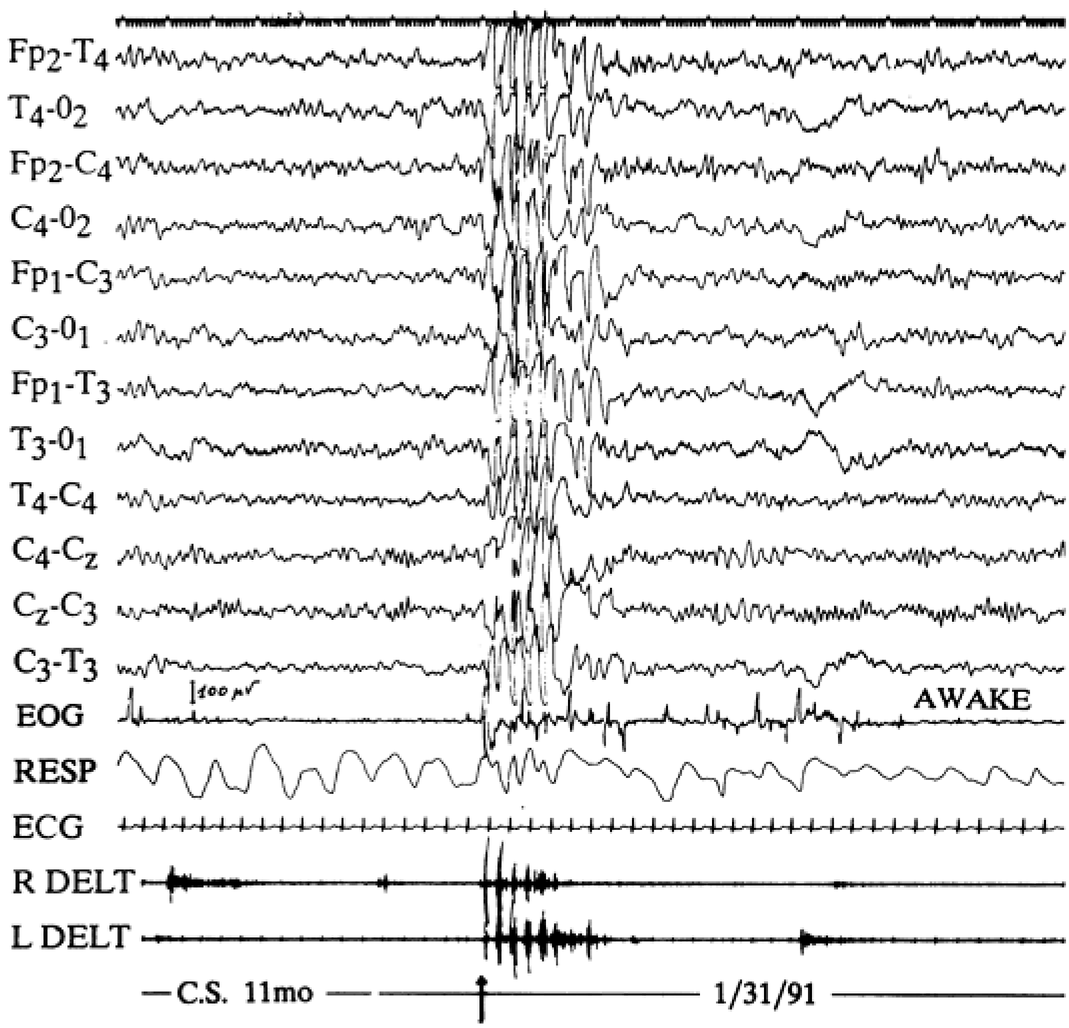

FIGURE 2. Patient affected by reflex benign myoclonic epilepsy in infancy. A sudden noise (*arrow*) triggers a brief cluster of myoclonic jerks; ictal electroencephalogram consists of generalized spike-and-wave complexes. ECG, electrocardiogram; L DELT, left deltoid; R DELT, right deltoid; RESP, respiration.

The interictal EEG is normal. Spontaneous SW discharges are rare; some slow waves may be found over the central areas. Darra et al.[6] described rhythmic, 4- to 5-Hz theta activity over the rolandic regions and the vertex in 4 of 22 children. IPS does not provoke SW without concomitant myclonus at the onset. Nap sleep recordings have shown a normal organization of sleep; generalized SW discharges may occur during REM sleep.

Evolution and Treatment

No other type of seizure is observed in children with BMEI, even if they are left untreated (for up to 8.5 years in one of our patients). In particular absence or tonic seizures do not

P.2345

occur. Clinical examination is normal. Interictal myoclonus was described only by Giovanardi-Rossi et al.,[17] in 6 patients. In reviewing our patients, we found mild interictal myoclonus in 2 patients, revealed by polygraphic recordings. Many patients were not investigated, but when computed tomography (CT) scan and magnetic resonance imaging (MRI) were performed, they were normal (46 patients).

The outcome seems to depend on an early diagnosis and treatment. Myoclonic jerks are easily controlled by valproate (VPA), and the child may then develop normally. If left untreated, patients continues to experience myoclonic attacks, and this may lead to impaired psychomotor development and behavioral disturbances.

The therapeutic modalities have been reported in 131 patients. Monotherapy was used in 109 patients (104 with VPA), polytherapy in 15, and no therapy in 7. Ninety-nine (95.2%) became seizure free on monotherapy. All of the others became seizure free using, usually including VPA and one benzodiazepine, rarely phenobarbital (PB), ethosuximide (ESM), or lamotrigine (LTG). Only in 1 patient did myoclonic seizures persist in spite of various drug combinations and even one ketogenic diet.[23] Finally, 7 patients, 4 of whom presented with reflex seizures, did not receive any treatment and became seizure free spontaneously. On the whole, 125 (95.4%) became seizure free. The study of Darra et al.[6] confirmed these findings, the control of myoclonic seizures having been achieved in all 22 patients.

These data support the VPA as the drug of first choice in BMEI. Treatment must be monitored using plasma drug levels, because irregular intake can lead to relapse and falsely mimic drug-resistant epilepsy. Lin et al.[19] gave a well-detailed account of treatment in their patients. They also underscored the necessity of monitoring and of using high doses at the onset (30–40 mg/kg) to obtain levels >100 mg/L at 3 hours after the morning intake in some patients. The daily dose was reduced to usual therapeutic plasma levels (50–100 mg/L) after seizures were controlled.

Long-Term Outcome and Prognosis

The length of follow-up is known in 112 cases, from 9 months to 27 years, and ≥5 years in 85.

In all these cases, myoclonic seizures disappeared. Their duration is known in 69 cases. In most patients they lasted <1 year. The longest duration (6 years 4 months) was observed only in the first publication, before recognition of the syndrome and its treatment.[13] When duration of follow-up is longer, the number of patients who have other seizure types after the end of the myoclonic seizures increases. Excluding FS, there were 17 reported among the 112 cases with known follow-up (15.2%). They were rare generalized tonic–clonic seizures (GTCS) in 12 patients, without associated myoclonic seizures. It is interesting that only 2 patients with BMEI evolved to juvenile myoclonic epilepsy (JME) at 9 and 12 years, respectively, with seizures well controlled by VPA.[2] Two other patients presented absences, respectively, at 10 and 11 years.[23] They were described as "petit mal" in the first patient and as absences with marked eyelid myoclonia in the second. The last patient, with reflex BMEI, had complex partial motor seizures from 6 years on, with normal EEG, with good response to the combination of carbamazepine and PB.[2] In a series of 22 patients,[6] 4 presented occasional isolated seizures after the age of 5 years: 1 spontaneous GTCS, 1 IPS-induced massive myoclonic seizures, 1 IPS-induced GTCS, and 1 television-induced GTCS.

The EEG outcome is known for 88 patients. EEGs remained abnormal after myoclonic seizures have disappeared, with generalized SW, sometimes focal without clinical correlate (frontal, frontocentral, frontoparietal, frontotemporal),

P.2346

but they became normal later in the majority of patients. It is interesting to note that photosensitivity can appear after the disappearance of myoclonic seizures, as reported by several authors, and can persist for many years after cessation of myoclonic seizures even to adult ages. In once older patients, photo sensitivity is only an EEG response without clinical correlate. Darra et al.[6] confirmed the persistence of photosensitivity. They reported one case with association of generalized SW and typical rolandic spikes, the latter persisting at 9 years, several years after seizure remission and withdrawal of treatment.

These findings affirm the usual good prognosis of BMEI. Attacks provoked by noise or contact were more easily controlled than spontaneous ones. Conversely, photosensitivity was more difficult to control and persisted several years after cessation of seizures.

On the whole, psychological outcome is favorable, and most patients are normal. Outcome is known in 96 cases. Seventy-nine (82.3%) were normal, of whom 56 were age 5 years or older. Twelve (12.5%) presented with mild retardation and attended specialized schools, but none was institutionalized. Five patients (5.2%) had cognitive deficits and personality disturbances. One of them had Down syndrome and strong photosensitivity, and another had myoclonic seizures until age 5 years, with sensitivity to IPS and eye closure.

The psychological outcome of cases reported by Darra et al.[12] was also favorable, and 77% had normal cognitive skills at follow-up.

One recent study[22] analyzed of the neuropsychological and behavioral outcomes in seven patients affected by BMEI, with an average follow-up of 6 years 9 months (range: 4 years 9 months–9 years 2 months). The mean full-scale intelligence quotient of the group was 74, with a significantly higher verbal IQ score in all but one patient. Five were within normal limits, one had slight mental retardation, and one had moderate retardation. All but one also had attention-deficit disorder. The authors underlined the young age at onset of the disease in the patients who had neuropsychological deficits.

In our opinion, the psychological outcome partly depends on an early diagnosis, allowing appropriate treatment and reassurance of the family for the future. The early occurrence of epilepsy often generates great anxiety and leads to wrong educational attitudes. There are, however, also other factors related either to an associated pathology or to an abnormal family structure and a disturbed mother/infant relationship. Finally, it cannot be excluded that the biologic process that causes the myoclonic attacks also interferes with the development of cognitive functions when it occurs in a very immature brain.

Differential Diagnosis

Differential diagnosis must be made with respect to the other epileptic and nonepileptic manifestations that appear in the first years of life. These include *benign nonepileptic myoclonus* described by Lombroso and Fejerman.[21] In this condition, both ictal and interictal EEG patterns are always normal, and the ictal manifestation is not a true myoclonus, but rather a movement similar to a shiver.

When myoclonic seizures start in the first year of life, the other diagnosis that comes to mind is that of *cryptogenic infantile spasms* (IS). IS are clinically different from benign myoclonias: They are more intense, and they involve a strong flexion (or extension) of the whole body, which is never observed in BMEI. In addition isolated, sporadic spasms are always associated with serial spasms in the same infant, and long serial spasms are more likely with awakening. Polygraphic recordings of IS show a typical pattern of a brief tonic contraction, well described by Fusco and Vigevano,[15] only rarely a prolonged myoclonia. The ictal EEG is not a fast, generalized PSW. It is variable, accompanied by a sudden flattening with or without superimposed fast rhythms, or a large slow wave followed by a flattening, or even no visible change. The occurrence of IS is associated with behavioral changes, poor quality of contact, and psychomotor delay leading to arrest and regression. Interictal EEGs are always abnormal, demonstrating either hypsarrhythmia or modified hypsarrhythmia, or focal abnormalities; they never show the isolated or brief bursts of bilateral synchronous SW as in BMEI.

In the first year of life, *severe myoclonic epilepsy of infancy* (see Chapter 230) might be considered, but it always starts with long and repeated febrile and afebrile convulsive seizures. Exceptionally, they can be immediately preceded by myoclonic attacks, more often focal.[12] They are drug resistant and associated with other seizure types. Psychomotor development becomes delayed during the second year of life with behavioral disturbances.

When myoclonic seizures begin after the end of the first year of life, the diagnosis of a *cryptogenic Lennox-Gastaut syndrome* (LGS) may come to mind. In LGS (see Chapter 241), seizures are typically tonic, leading to sudden falls and injuries, and atypical absences, sometimes associated with atonic seizures. Myoclonic seizures are rare. The ictal EEG shows either a recruiting rhythm, a flattening, or a high slow wave followed by runs of low-voltage rapid rhythms. Interictal awake EEGs are characterized by bursts of diffuse slow SW, and sleep EEGs by PSW and diffuse, high-voltage, rapid rhythms. When these EEG features are not present at the very beginning, the diagnosis is based on the rapid association of different types of seizures such as atypical absences and axial tonic seizures, constant impairment of behavior and learning, and lack of efficacy of antiepileptic drugs.

If myoclonic seizures remain isolated or are associated with GTCS, the diagnosis *of epilepsy with myoclonic astatic seizures* (EMAS) (see Chapter 232) must be entertained, although the onset of myoclonic astatic seizures in this syndrome is rare before the age of 3 years.[8] There are two essential differences. The first one is the clinical aspect of the seizures, which associate myoclonic jerks without fall and myoclonic-atonic or pure atonic seizures leading to violent drop attacks. In BMEI, only rarely do the myoclonic seizures provoke falls on the ground. In EMAS, the myoclonic seizures are combined with other seizure types, such as repeated GTCS, atypical absences, and minor epileptic status with stupor, which are never observed in BMEI. The second difference lies in EEG features. SW and PSW are more numerous, often interictal, and grouped in long bursts with an irregular frequency. They are activated by sleep where polyspikes can predominate. The typical theta rhythm over the centroparietal areas described in the seminal Doose's study[8] is not always present. Other differential criteria appear during the following months, including pharmacoresistance and slowing down of psychomotor delay. Some cases included by Doose,[8] however, should probably be classified as BMEI. In the same way, the group studied by Delgado-Escueta et al.[7] under the name of early childhood myoclonic epilepsy (ECME) seems to include cases of both EMAS and BMEI. On the other hand, some relationship between the two syndromes is strongly suspected (see later discussion).

A recent study[23] emphasized the relationship between BMEI and the syndrome of *eyelid myoclonias with absence* because the authors observed eyelid myoclonias with myoclonic seizures in three children. One of them later, at 10 years of age, had this seizure type. Other authors have not observed this evolution.

Finally, one should consider other epilepsies beginning in the first 3 years of life in which myoclonias are the main seizure type and which have a variable prognosis. They are heterogeneous: There is a combination of other types of seizures,

P.2347

constant presence of EEG focal abnormalities, previous delayed psychomotor development, poor response to drugs, and uncertain prognosis.[9,11] Most probably those are cases of symptomatic myoclonic epilepsies. We also mention the *autosomal-recessive benign myoclonic epilepsy of infancy* described in a single family,[27,28] in which myoclonic seizures were associated with GTCS persisting in adulthood. The locus was mapped to chromosome 16p13 in this family.

Diagnostic Evaluation

The diagnostic workup is simple. It requires a good clinical description and repeated polygraphic video-EEG recordings to demonstrate the presence of myoclonic seizures with generalized SW discharges, either spontaneous or facilitated by drowsiness, noise, contact, or IPS. A sleep recording shows slight activation of discharges without change in morphology, without appearance of rapid rhythms and focal abnormalities. Neuroimaging can be useful to confirm the absence of brain lesions but is not mandatory when the symptomatology is typical. Neuropsychological assessment is more useful to check psychomotor development and follow its evolution. Biologic investigations may be necessary in cases where associated symptoms suggest another disease.

Management

Treatment of choice is VPA monotherapy, which must be prescribed as soon as possible. The use of solution is preferable to that of syrup because it is better tolerated by the infant. Plasma levels must be monitored carefully. A dose of 30 mg/kg divided three times a day is usually sufficient, but higher doses are necessary in some patients.[18] VPA is also effective against possible febrile seizures. If myoclonias are not completely controlled by VPA, the addition of either a benzodiazepine (clobazam or nitrazepam) or ESM can be considered, and the diagnosis must be reviewed. Treatment should be continued for 3 to 4 years if it is well tolerated. In cases of purely reflex seizures, drug therapy may be avoided. When used, seizures can usually be stopped early, except in cases of photosensitivity. The occurrence of a GTCS at adolescence can require another brief period of treatment. The medical treatment must be associated with psychological help to the family, who may be extremely anxious and need to be reassured concerning the good prognosis of this epilepsy.

In practice, the diagnosis of BMEI should be restricted to patients fulfilling the following criteria:

- Brief myoclonic seizures, spontaneous or provoked by noise or contact
- Onset between 4 months and 3 years

- Previously normal infant, often with a family history of epilepsy or FS
- Not associated with other seizure types, except rare simple FS
- In the EEG:
  - Generalized fast SW and PSW during myoclonic seizures
  - Rare interictal SW when awake
  - SW enhanced by drowsiness and slow sleep, sometimes by IPS
  - Normal background
  - Absence of focal discharges
- Good response to VPA monotherapy

In patients with this typical picture, treatment given without delay leads to a good clinical outcome in terms of seizures and cognitive function. In cases with less typical features, particularly in the presence of focal EEG discharges, the diagnosis remains uncertain until a long remission is observed.[26] When the onset is later than 3 years, the diagnosis may be the same.[18]

Nosology

This syndrome belongs to the group of idiopathic generalized epilepsies.[4] It seems to be the infantile equivalent of JME. Auvin et al.[2] reported the first two cases in whom the two syndromes were observed successively, and Darra et al.[6] reported a single case of a mother affected by JME. Delgado-Escueta et al.[7] did not find cases of JME in their study of 24 affected family members with ECME, although they found 76% with other types of idiopathic generalized epilepsies. The relationship with EMAS should be investigated as suggested by the case reported by Arzimanoglou et al.[1] and Darra et al.[6] Moreover, Doose[8] mentioned the case of a patient with EMAS who had two children. The first was affected by EMAS and the second by BMEI.

The last problem is that of the terminology this syndrome. In 1981, it was legitimate to name it "benign" because of the constant disappearance of seizures and the usually good psychological outcome. Today, how benign it is questionable, in light of the definition given by the ILAE Commission report[14] "a benign epilepsy syndrome is a syndrome characterized by epileptic seizures that are easily treated, or require no treatment, and remit without sequelae." It is now established that a small proportion of patients with BMEI have other seizures later (15.2%) or are not psychologically normal (17.7%) after remission of epilepsy. Whether the cognitive and personality disorders described in rare patients are the sequelae of their epilepsy is difficult to establish, however, given the early age of onset. In some patients, the syndrome can be associated with another conditions, as is accepted in other idiopathic and benign epilepsies, such as the benign epilepsy with centrotemporal spikes.[16,25]

We had the opportunity to read the paper by Zuberi et al.[29] only after the end of our work and have not included their six cases in our analysis.

Summary and Conclusions

In this chapter we have used the name "benign myoclonic epilepsy in infancy" (BMEI), and the terminology is discussed because it has recently been proposed as a substitute for "isdiopathic myoclonic epilepsy in infancy."

BMEI epilepsy is defined as the occurrence of myoclonic seizures (MS) without other seizure types, except rare simple febrile seizures (FS), in the first 3 years of life in otherwise normal infants. These myoclonic seizures are easily controlled by a simple treatment and remit during childhood. The psychomotor development remains normal, and no severe psychological consequences are observed. Some patients present with a reflex form, in which the myoclonic seizures are usually triggered by noise or contact.

BMEI was classified among the generalized idiopathic epilepsies in the 1989 international classification. It seems to represent <1% of all epilepsies and around 2% of epilepsies that begin in the first 3 years of life. Genetics is unknown. A family history of epilepsy or FS is present in 50.5% of cases. Juvenile myoclonic epilepsy (JME) and epilepsy with myoclonic astatic seizures (EMAS) were reported in four families.

Age at onset is usually between 4 months and 3 years, exceptionally between 3 and 5 years.

The myoclonic seizures consist of very brief shock-like seizures, affecting mainly the upper limbs and the head, isolated or grouped in short clusters, accompanied by a generalized spike-wave discharge of the same duration in the EEG.

P.2348

Interictal EEG discharges are rare, more often during drowsiness and sleep. An extensive clinical and EEG description of the myoclonic seizures is given.

The outcome seems to depend on early diagnosis and treatment. Myoclonic seizures are easily controlled by valproate (VPA) alone, and the child may then develop normally. If left untreated, the patient continues to experience myoclonic attacks, and this may lead to impaired psychomotor development and behavioral disturbances. On the whole, 95.4% of the patients reported in the literature became seizure free. However, the use of high doses of VPA and the monitoring of the plasma levels are necesssary at the onset. After seizures are controlled, the dosage can be reduced. In the reflex form, pharmacological treatment can be avoided.

Other types of idiopathic generalized seizures can occur after the disappearance of the myoclonic seizures (15.2% of the published patients) and these respond well to treatment. In two patients BMEI evolved to JME, well controlled by VPA. One patient, after a reflex BMEI, had complex partial motor seizures with a normal EEG.

On the whole, psychological outcome is favorable, and about 80% of the patients are normal. The others have slight to moderate mental retardation. Attention-deficit disorders are also described.

Differential diagnosis includes non-epileptic benign myoclonus of infancy, infantile spasms, severe myoclonic epilepsy in infancy (Dravet syndrome), and epilepsy with myoclonic astatic seizures.

Chapter 232

Epilepsy with Myoclonic Astatic Seizures

Olivier Dulac

Anna Kaminska

Introduction

Epilepsy with myoclonic–astatic seizures (EMAS) is a recently identified type of idiopathic, potentially severe epilepsy. It is characterized by a combination of seizures, including drop attacks, and psychomotor deterioration beginning in early childhood. These features are similar to those of Lennox-Gastaut syndrome, and the syndrome's nosologic limits, particularly with regard to the Lennox-Gastaut syndrome, are still not clearly determined. A "myoclonic variant of Lennox-Gastaut syndrome" has even been reported that most likely corresponds to one subtype of EMAS. Epilepsy with myoclonic–astatic seizures was identified on the basis of two distinct approaches by two different schools of epileptology: German researchers in Kiel identified genetic predisposition as an etiologic factor in severe pediatric epilepsy at the same time that researchers in Marseille were developing the concept of epilepsy syndromes.[5] A clear definition therefore needs to be established distinguishing EMAS from both the Lennox-Gastaut syndrome and other kinds of myoclonic epilepsy occurring in childhood.[8]

In this chapter, we describe the development of EMAS as a syndrome, delineate it nosologically, describe the specific pattern of cognitive and motor dysfunction, define the therapeutic strategy, and describe the present pathophysiologic hypo- theses.

Historical Perspectives

To understand the apparent contradictions that have paved the way for the identification of EMAS, one has to consider two major schools of epileptology following parallel pathways. The German school—Janz and Christian for adults[9] and Doose and coworkers for children—was making considerable effort to clarify the genetic basis of epilepsy.[7] Careful neurophysiologic analysis played a major role, particularly for children. Doose established a correlations between several electroencephalographic (EEG) patterns and familial antecedents of epilepsy, namely theta rhythms, generalized spike waves, spontaneous or triggered by hyperventilation, and photosensitivity (for a review, see Doose[6]). This allowed him to identify epilepsy conditions affecting early childhood that were thought to be due to genetic predisposition with polygenic inheritance. He called this group, in which myoclonic seizures causing drop attacks were a predominating feature, "centrencephalic myoclonic–astatic petit mal."[7] The main practical interest in the recognition of this group was to show that children with severe epilepsy involving the whole brain and producing drop attacks and cognitive deterioration did not all have Lennox-Gastaut syndrome, and thus some kind of brain lesion, but they could have genetically inherited epilepsy in an undamaged brain.

Patients within "centrencephalic myoclonic–astatic petit mal (CMAPM)" exhibited a range of different types of seizures: tonic–clonic, myoclonic, myoclonic–astatic, tonic, absence, and various types of epilepsy status, mainly myoclonic and absence. However, within this group, Doose distinguished various patterns correlated with different courses[5]:

- Patients who exhibit only generalized myoclonic seizures as the sole seizure type usually have good outcome.

- Patients with clonic seizures from the first year of life experience a severe course and the occurrence of long-lasting clonic status epilepticus contrasting with very few or even no spike waves on EEG.
- Poor outcome is also the case for patients who develop frequent tonic seizures in sleep and for those who have episodes of myoclonic status and develop dementia. Such cases usually begin after the second year of life.
- However, other patients, beginning after 2 years of age, may completely recover, even if they have experienced tonic seizures and daily drop attacks for weeks and their EEG shows a very active spike and wave pattern.

Therefore, although CMAPM features myoclonic seizures and generalized spike-waves, which are assumed to express genetic predisposition, it is completely heterogeneous in terms of clinical presentation, EEG characteristics, and outcome. It is thus not a syndrome, but an etiologic concept of difficult-to-treat generalized epilepsies resulting from genetic predisposi-tion.

In the meantime, the Marseille school developed the concept of epilepsy syndromes following the observation that patients with epilepsy have a variable course ranging from full recovery to pharmacoresistance with major impact on cognitive and motor functions, and that this variability is not related solely to age of onset, seizure type, interictal EEG, or etiology. Indeed, etiology is identified in only one fourth of patients, and the variability also affects both patients without identifiable etiology and those with a given etiology. The type of seizure is not linked to etiology or the course because a given seizure type may occur in epilepsies with the most benign as well as those with the most severe outcome. Children with epilepsy usually exhibit several types of epileptic seizures, and therefore it is not possible to distinguish the various types of epilepsy according to seizure types only. In addition, the neurologic condition prior to onset of seizures, the age of onset, and the interictal clinical and EEG phenomena also vary greatly. However, there are groups of patients that have similar age of onset, seizure types, interictal EEG pattern, and course. These characteristics form the basics of epilepsy syndromes. This concept appeared soon after the clinical introduction of EEG. It became possible to distinguish between two major EEG patterns of generalized spike waves, respectively “petit mal” and “petit mal variant” patterns, which were correlated with different seizure types and distinct courses. In addition, the “hypsarrhythmic” EEG

pattern was linked to infantile spasms. This approach to the separation of various epilepsy patterns with distinct courses was then systematized in Marseille. In Lennox-Gastaut syndrome, drop attacks result from tonic seizures or atypical absences, whereas myoclonic seizures are rare. Therefore, it differs from conditions that include mainly myoclonic seizures. When myoclonic epilepsy has begun in infancy without any identifiable cause, two groups with respectively severe (Dravet syndrome) and benign courses could be distinguished. In the last decade of the twentieth century, it became clear that these two conditions were included in Doose's “centrencephalic myoclonic–astatic petit mal.”

In addition, in some patients, “centrencephalic myoclonic–astatic petit mal” starts later in life, after the age of 2 years, in which severe myoclonic seizures cause the patient to fall, as in Lennox-Gastaut syndrome. Indeed, that can be difficult to distinguish this from Lennox-Gastaut syndrome. Patients with Lennox-Gastaut syndrome and EMAS share age of onset (early school age, various kinds of seizures including absences and drop attacks), generalized spike waves, and a major impact on cognitive functions. Thus, the usual understanding, expressed by Aicardi, was that there is a range from Lennox-Gastaut syndrome to myoclonic epilepsy, with myoclonic–astatic epilepsy between these two extremes.[1] This concept of a continuum was similar to that of the Montreal school regarding idiopathic generalized epilepsy (e. g., Berkovic et al.[3]). However, the concept of a continuum was inconsistent with the idea that one condition was genetically determined, whereas the other resulted from a brain lesion. Some difference should therefore exist. The difficulty in making reliable and reproducible distinctions lies to in the fact that the number of characteristics to be taken in account challenges our ability to identify possible differences. By applying a special mathematical method called “multiple correspondence analysis,”[10] it proved possible to recognize reproducible differences. This method can identify within a group of items belonging to a population those clusters of individuals that differ from the rest of the population for specific items and identify these items.[2] This method was applied to patients with various types of generalized seizures and various patterns of generalized spike waves, including either 3-Hz spike waves (SW) or slow spike waves (SSW), negative brain imaging, and first seizures between 1 and 10 years of age; two groups could be distinguished:

One group had onset between 5 and 7 years of age had mainly tonic and absence seizures together with SSW, and the course was unfavorable. There was an excess of focal EEG abnormalities. The sex ratio in this group was equal. This is the usual pattern of the Lennox-Gastaut syndrome.

The other group began slightly earlier, between 2 and 5 years of age, with tonic–clonic seizures before the occurrence of myoclonic–astatic seizures and 3-Hz SW. There was an excess of boys. The course was favorable in a majority after 2 or 3 years, although one third had recorded tonic seizures, a feature previously not mentioned in patients who recover. However, in a sizeable proportion, vibratory tonic and absence seizures and long-lasting myoclonic status occurred and the course was unfavorable: Following the disappearance of myoclonic status, clusters of vibratory tonic seizures at the end of night sleep and slow spike waves persisted for years together with major cognitive impact.

Definitions

Epilepsy with myoclonic–astatic seizures is defined by the combination of myoclonic–astatic seizures and other kinds of generalized seizures, including tonic–clonic, myoclonic, and eventually tonic seizures, absences and erratic myoclonus, and generalized spike-waves beginning in early childhood, between 2 and 5 years of age. The outcome ranges from complete recovery to intractable epilepsy persisting after the end of the second decade and consisting of tonic seizures in sleep with dramatic deterioration of cognitive and motor functions. This syndrome is not related to any brain lesion, but rather to genetic predisposition combined with brain maturational features.

Epidemiology

The epidemiology is not known because this condition has long been confused with Lennox-Gastaut syndrome. It is likely that the incidence is at least in the same range as that of Lennox-Gastaut syndrome if not higher.

Etiology and Basic Mechanisms

Although the etiology is unknown, familial studies suggest that some genetic predisposition is at work. However, the variable course has no explanation, and the search for gene mutations has been negative.[13] The only differences between favorable and unfavorable cases have been with regard to gender, with a poorer prognosis for boys than girls, and the age of onset, with poorer prognosis in case of late onset.[10]

Mechanism of Intractability and Cognitive Difficulties

The clinical presentation and course mentioned earlier are characteristic and result from the combination of two groups of factors:

- Generalized tonic–clonic seizures, myoclonus, and bursts of 3-Hz generalized SW seem to be determined mainly by genetic predisposition to idiopathic generalized epilepsy thought to involve the thalamocortical circuits. The rhythmicity in this model is generated by the thalamic reticular nuclei and the cortical contribution mainly involving the rolandic strip, generating myoclonus.
- Tonic seizures, atypical absences, and slow spike-waves suggest epileptogenicity-related and age-related hyperexcitability, and therefore a relation to brain maturation, which involves mainly both frontal lobes at that age. Irregular and slow spike-waves probably result from secondary bilateral synchrony involving both frontal lobes through the corpus callosum.

The pattern in patients with early onset but unfavorable course is consistent at onset with the pattern of the first group (genetic). In terms of the course of the disorder, it is consistent with the second group (maturation of frontal lobes) in the course of the disorder.

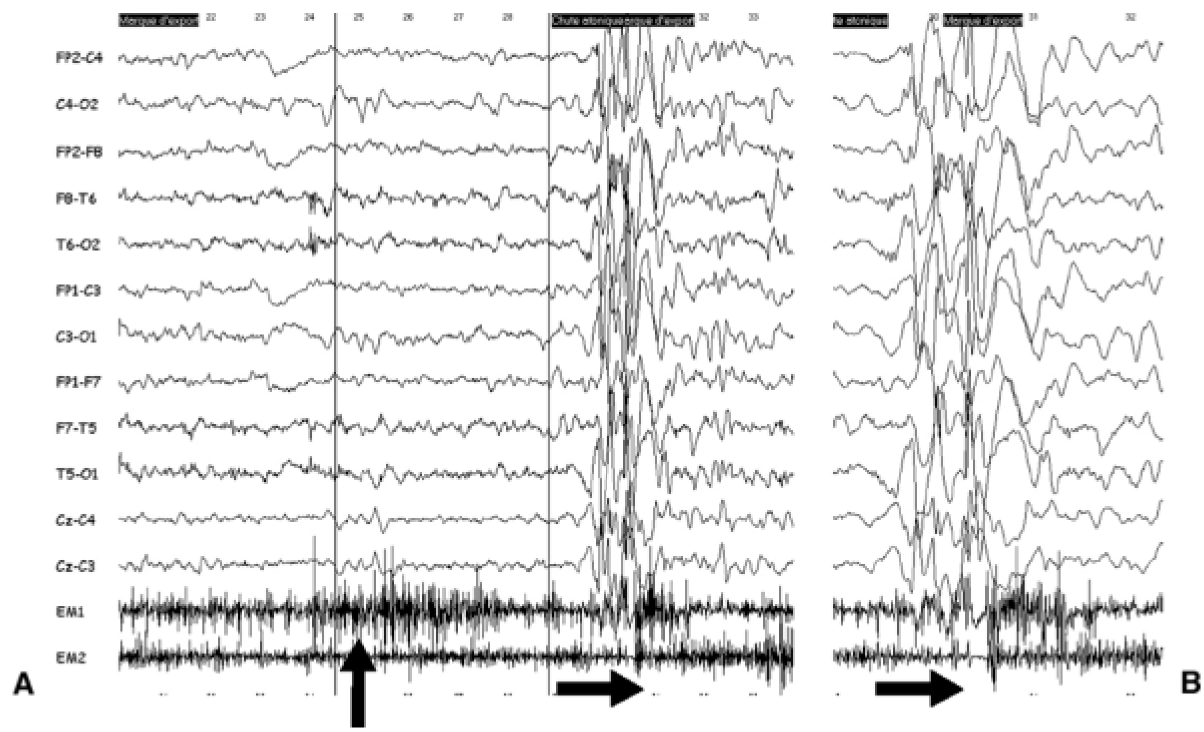

FIGURE 1. Polygraphy in a 3-year-old boy with drop attacks due to epilepsy with myoclonic–astatic seizures (EMAS). Notice that the jerk indicated by the arrow coincides with the spike and precedes the disappearance of muscle tone that coincides with the slow wave, which explains why the child is unable to protect his face from the injury. **A:** 15 mm/s; **B:** 30 mm/s.

The relative contribution of these two factors determines the severity of the condition: The combination of both epileptogenic factors could explain the long-lasting episodes of myoclonic status with drowsiness. The interaction of two distinct paroxysmal activities, respectively rhythmic at 3 Hz and irregular and slow at 2 Hz, could generate the apparently chaotic, irregular, and asynchronous spike and slow-wave activity and replace massive myoclonus by erratic myoclonus. The predominance of the latter in the perioral and tongue areas and in distal parts of the upper limbs is consistent with involvement of pyramidal pathways, because these areas are those mainly represented in the rolandic strip. In addition, the combination

P.2351

of two epileptogenic factors could also generate pharmacoresistance.

This formulation also clarifies similarities with Lennox-Gastaut syndrome, because in the latter, there is a combination of some cortical lesion with the same age-related hyperexcitability involving frontal maturation, ensuring pharmacoresistance. Therefore, in Lennox-Gastaut syndrome, pharmacoresistance would result from the combination of two etiologic factors— focal cortical lesion and maturation—whereas in unfavorable cases of EMAS, it would result from the combination of genetic predisposition with maturation. Because one factor is shared by Lennox-Gastaut syndrome and EMAS, the clinical and EEG patterns have similarities that have generated long-lasting confusion. Finally, in favorable cases of EMAS, the contribution of maturation factors would be milder, explaining the neater clinical pattern and lack of pharmacoresistance.

Neuropsychological findings are also consistent with this understanding of pathophysiology: Major features are dysarthria and apraxia, in addition to the ataxia that is often linked to myoclonus. Dysarthria and apraxia both involve areas of the cortex that are adjacent to the rolandic strip. Cases with unfavorable outcome exhibit in addition slowness and attention deficit, which are eventually additional features of frontal lobe dysfunction. The latter is shared with Lennox-Gastaut syndrome.

What Is the Precise Nature of the Genetic Predisposition?

The identification of a specific genetic predisposition to Dravet syndrome may open another way to understand the difference between favorable and unfavorable cases because a specific monogenic predisposition might apply only to unfavorable cases of EMAS.[4] The slightly lower incidence of familial antecedents of epilepsy in unfavorable cases would be consistent with this hypothesis. However, it is also consistent with the hypothesis previously mentioned of a combination of genetic and maturational features. In the case of Dravet syndrome, the characteristic pattern in patients with the mutation in *SCNA1* can be recognized from the beginning of the disorder because they exhibit unilateral clonic seizures. The only way to answer the questions thus opened on the neurobiologic basis of the various aspects of EMAS is through extensive search of the molecular predisposition in this disorder combined with very precise phenotyping. To date, however, such search has been negative.[13]

Clinical Presentation

Seizures

Myoclonic–astatic epilepsy begins between 2 and 5 years of age in a previously healthy child, usually with repeat tonic–clonic seizures that may repeat on the same day. Febrile seizures may have occurred, but this is not the rule.

Within a few days or weeks, the patient starts to have falling episodes due to myoclonic seizures. These drop attacks may be very severe, causing face injuries.

At this point, the child exhibits tonic–clonic, clonic, absence, myoclonic flexor, and atonic, and myoclonic–astatic seizures. The child becomes hyperkinetic and inattentive.

Pattern of Cognitive and Motor Dysfunction

The main findings in patients who are mildly affected are ataxia together with abnormal fine movements due to dyspraxia, and speech difficulties. Many patients suffer from attention deficit disorder with hyperkinesia that may persist for many months after the last seizure has occurred. Patients who undergo prolonged episodes of myoclonic status develop dementia.[11]

Diagnostic Evaluation

Electroencephalographic Findings

At onset, the interictal EEG shows slowing of the background activity, and generalized spike-waves increase when the patient is falling asleep (Fig. 1). When drop attacks have occurred, videopolygraphic recording shows different mechanisms underlying the falling: myoclonic flexor seizures, atonic seizures, and particularly myoclonic–atonic seizures, which are very particular because they combine myoclonic and atonic components (Fig. 1).[14]

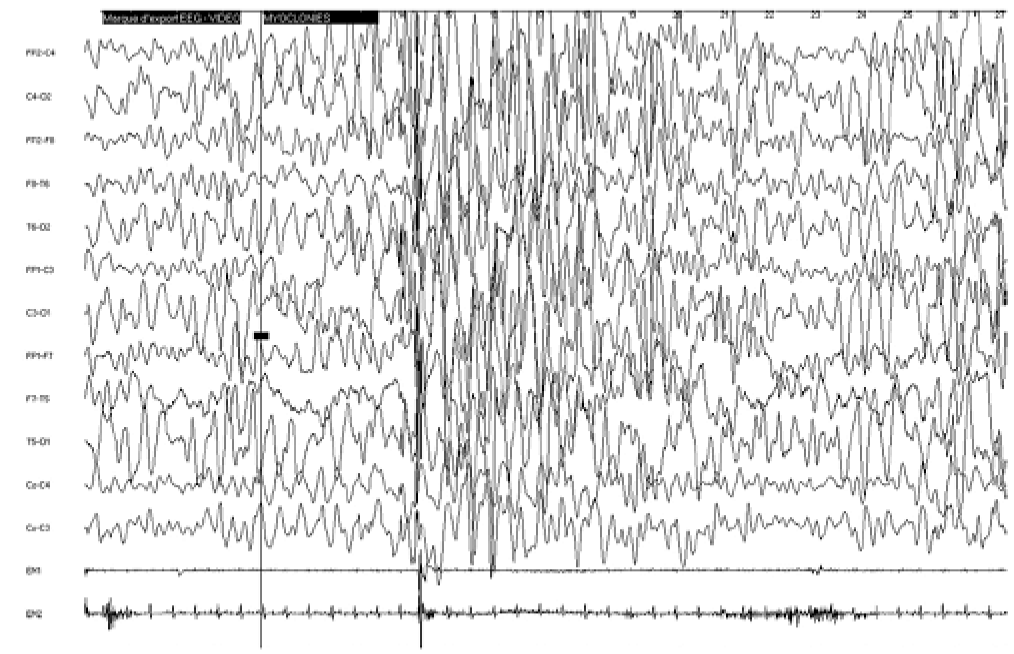

FIGURE 2. Myoclonic status. 1 cm = 100 µV, 15 mm/s; lack of physiologic rhythms, high-amplitude slow waves, and spike waves. Segmentary myoclonus.

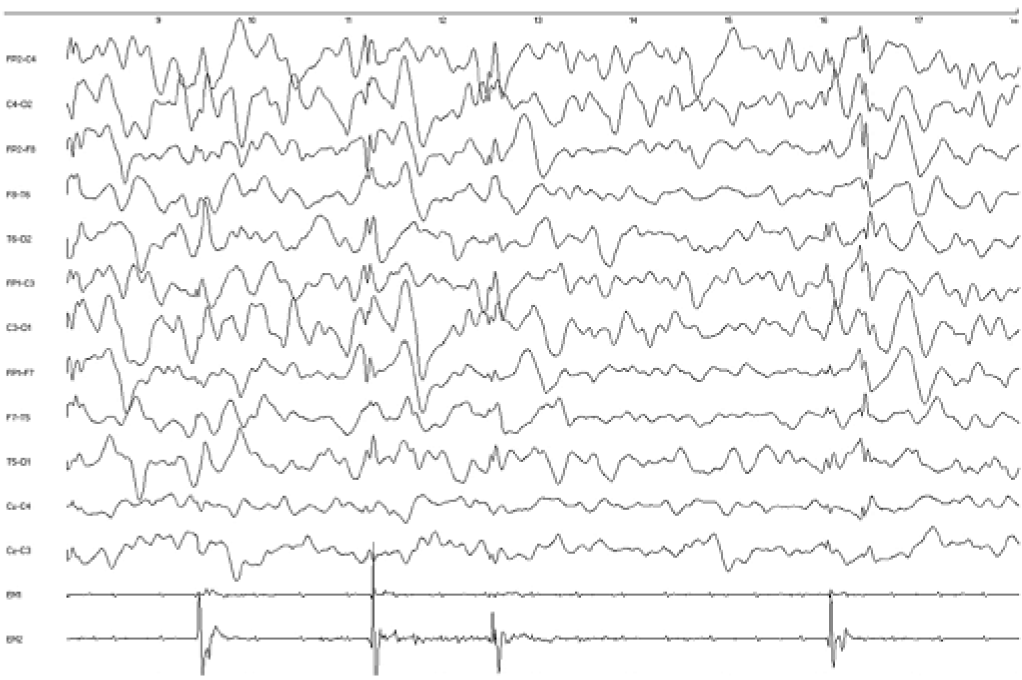

FIGURE 3. Myoclonic status. 1 cm = 200 µV, 1 cm = 30 mm; slow waves with multifocal spikes correlated with erratic myoclonus. Note that the spike activity is very mild.

Therefore, the combination of video-EEG and simultaneous recording of the surface EMG is most useful in this situation. It makes it possible to show that the drop attacks are due to the

patient being thrown forward and losing the ability to protect himself or herself with the upper limbs. This is the cause of severe injury to the face.

Neuroimaging and Other Laboratory Examinations

Neuroimaging is by definition negative, including in those cases with unfavorable outcome. Other laboratory investigations are also negative.

Differential Diagnosis

At this early stage, there are a few diagnostic issues. Some patients exhibit occasional partial seizures in addition to the generalized tonic–clonic seizures. They are distinct from partial seizures of focal epilepsy because they do not appear as repeated and stereotyped with an interictal EEG focus, as would be the case in focal epilepsy. The distinction is of major importance for the choice of medication. At onset of the disease, it is more dangerous to miss EMAS than to miss partial epilepsy, because the risk of iatrogenic worsening mainly concerns EMAS. On the other hand, the EEG may exhibit major slowing of the background activity, suggesting acute brain damage instead of epilepsy. Again, the physician treating a 2- to 5-year old child who starts having generalized tonic–clonic seizures should always consider the possibility of EMAS because it is highly treatable and, if overlooked, may destroy brain functions.

Treatment and Outcome

The Risk for Worsening

One characteristic of this disorder is drug-induced worsening, which has been reported by a number of research groups, including situations before the nosologic characteristics were identified (for review, see Perucca et al.[16]). Carbamazepine was long considered as the drug of first choice for children with epilepsy. It is now clearly established that this drug aggravates EMAS. It is difficult to give the incidence of aggravation due to the lack of controlled data, but Kaminska et al. found in their series that this occurred in more than half of the cases.[10]

The same applies to phenytoin, although this is less often administered to children. It is, however, an excellent drug for the treatment of status epilepticus, and it is then tempting to switch from the intravenous to the oral formulation.

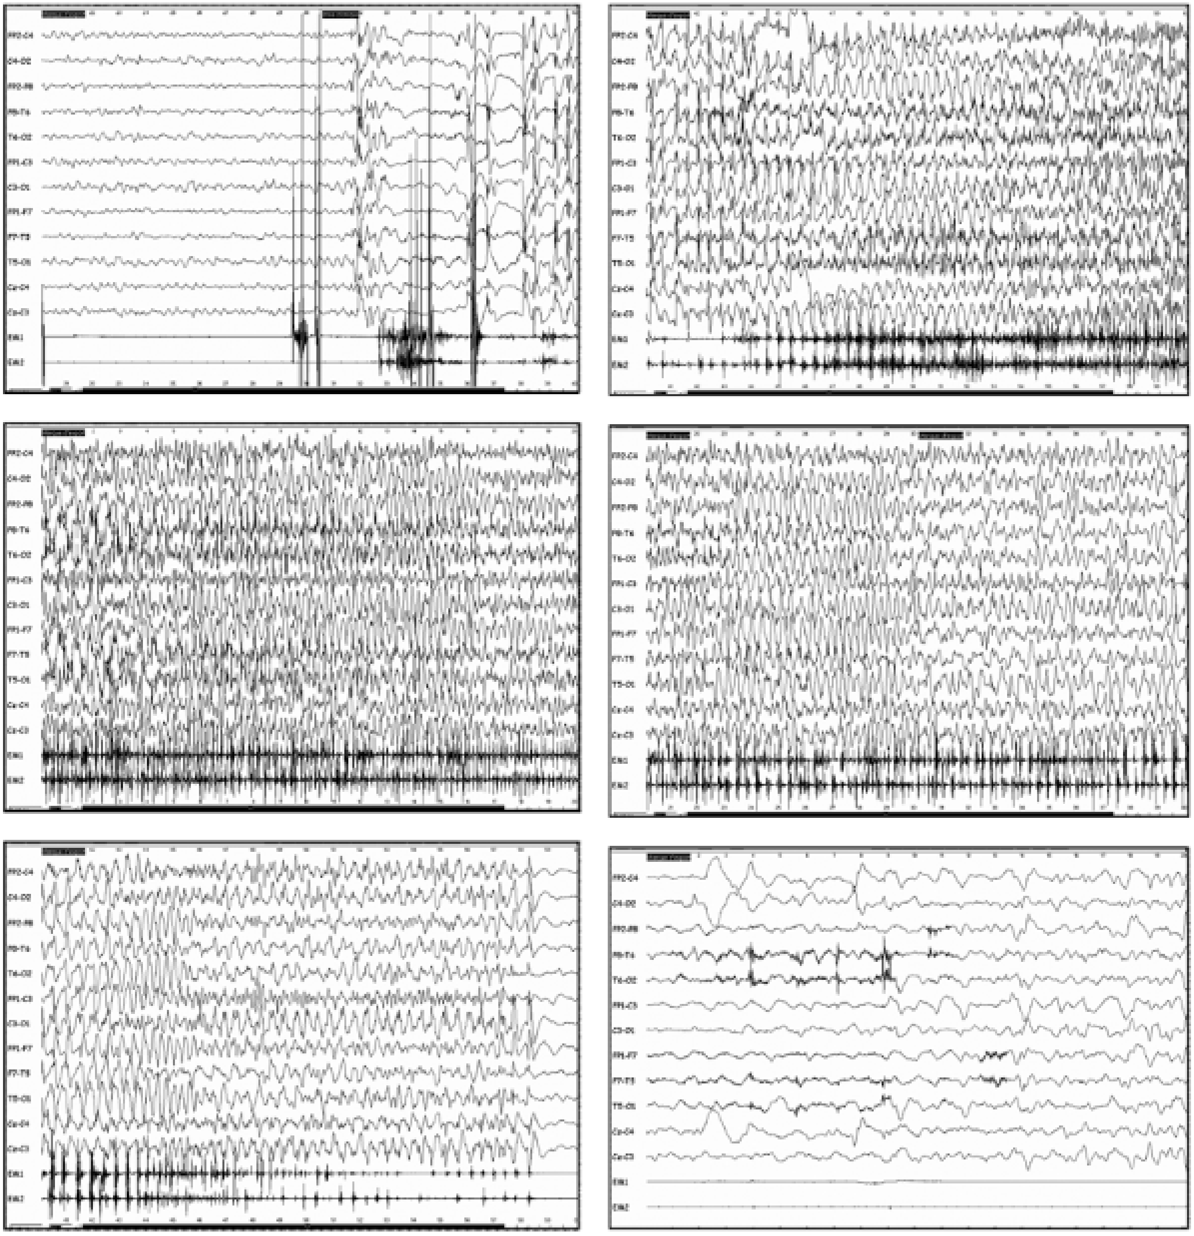

FIGURE 4. Myoclonic–tonic–clonic seizure. 1 cm = 200 µV, 1 cm = 30 mm. Note the complexity of the pattern compared to a classic tonic–clonic seizure observed in adolescence or adulthood, and the major postictal slowing.

Vigabatrin is also likely to worsen the condition.[12] Although the use of this drug has been restricted due to its potential retinal toxicity, it is very helpful for infants and children with pharmacoresistant epilepsies.

The risk related to the administration of phenobarbital is not as clear. However, given the high incidence of absence seizures in this type of epilepsy and the ability of phenobarbital to precipitate nonconvulsive status epilepticus, this compound clearly represents a theoretical risk for aggravation.

Benefits From Therapy

Valproate has some effect on tonic–clonic, absence, and myoclonic seizures. Ethosuximide is helpful for absences and myoclonic seizures. Benzodiazepines are indicated for the treatment of status epilepticus, but the benefit of long-term everyday administration is less clear for two reasons: These compounds may increase the incidence of tonic seizures or even precipitate tonic status epilepticus, and the chronic administration of the compound may reduce the potential of these compounds to interrupt status epilepticus. In addition, withdrawing benzodiazepines following chronic administration may be challenging because of progressive dependence; it needs to be done over several months. The introduction of lamotrigine has led to a revolution in the treatment of EMAS, with more than three fourths of patients experiencing >75% decrease in seizure frequency and many stopping seizures altogether.[10] Topiramate was effective, reducing seizure frequency by half in more than half of the cases.[18] Levetiracetam seems promising, provided moderate doses are administered at onset, but wider experience is required before it can be advised early in the course of the disorder.

In practice, the occurrence of a first tonic–clonic seizure in a 2- to 5-year-old child requires an EEG, in contrast to later age ranges. Slow basic activity, and even more so the presence of spike waves, indicates the need for administration of valproate. The occurrence of further seizures indicates the addition of lamotrigine. Although the epilepsy may prove intractable for months and could encourage dropping this therapy in favor of less appropriate compounds, seizure frequency tends to decrease progressively. The ketogenic diet is useful in this context, particularly in cases of recent worsening of seizure frequency.[15] Steroids may be useful in cases of frequent absence seizures or myoclonic status.

Long-Term Prognosis

The course is variable, with total recovery within a few months to 3 years in most cases, although behavioral abnormalities improve only slowly. A number of patients develop myoclonic status in which the child is drowsy with erratic myoclonus involving the mouth and tongue, the hands, and eventually the rest of the body. The EEG shows high-amplitude polymorphic delta slow waves, with rare and erratic spikes. Other kinds of motor seizures appear mainly at the end of the night, between 5 AM and 7 AM, in clusters consisting of axial hypertonia with a rapid clonic, vibratory component (Figs. 2,3,4). When unrecognized this status may last several weeks. The term status itself may not be appropriate because the long duration of this kind of seizure activity is also seen in epileptic encephalopathy. Following this episode of epileptic encephalopathy, erratic myoclonus disappears and consciousness improves, but the patient has lost cognitive abilities and become very slow in thoughts and behavior. The long-term unfavorable course is characterized by the persistence of clusters of vibratory tonic seizures at the end of night sleep many years later, even by the beginning of the third decade.

Mental retardation and persisting seizures are the two major features that prevent the patients from normal social integration (p <0.001).[10] The major factors for developing mental retardation are lack of familial antecedents and presence of short 3-Hz SW bursts, as shown with univariate analysis of electroclinical variables. Logistic regression analysis added the presence of tonic and absence seizures at onset as major risk factors (p = 0.01). On follow-up, univariate analysis showed that the main factors were duration of epilepsy >3 years (p <0.001), presence of vibratory tonic seizures (p <0.001), and myoclonic status epilepticus (p = 0.02). Factors relating to poor school performance in children with epilepsy were shown to include behavior problems, early onset, and polytherapy.[17] Although these children have onset of epilepsy after age 2 years, they have the two other risk factors.

Summary And Conclusions

Severe, generalized cryptogenic epilepsies comprise a particularly important model for understanding the respective roles of the three major categories of factors predisposing to epilepsy in childhood: (a) cortical lesions, (b) genetic predisposition, and (c) maturation of the brain. They also contribute to the understanding of factors of intractability in this age range. In addition, they make it possible to apply a mathematical method—multiple correspondence analysis—that is particularly useful in distinguishing discrete groups of patients with epilepsy that may appear as a continuum to the clinician, even though they result from distinct etiologic factors and thus from distinct neurobiologic mechanisms. This has made it possible to confirm mathematically the existence of EMAS as an epilepsy syndrome distinct from Lennox-Gastaut syndrome. The impression of a continuum is given by the combination of several factors in some patients. In addition, recent findings concerning the genetic predisposition to epilepsy suggest that genetic predisposition is heterogeneous due to several monogenic conditions, and thus this heterogeneity also contributes to the impression of a continuum. In addition, modulating genetic factors yet to be identified could also increase the clinical variability and thus the impression of a continuum.

Chapter 233

Hemiconvulsion-Hemiplegia-Epilepsy Syndrome

Alexis Arzimanoglou

Charlotte Dravet

Patrick Chauvel

Introduction

Hemiconvulsion-hemiplegia-epilepsy (HHE), described by Gastaut et al.[17] in 1957, was not considered as a syndromic entity in the 1989 International League Against Epilepsy (ILAE) classification of epilepsies and epilepsy syndromes. Indeed, one could argue that the initial episode of a prolonged unilateral convulsion can be classified as a unique episode of a motor partial status, with hemiplegia as the main sequela. The later development of focal seizures can be considered, and consequently classified, as a form of partial symptomatic epilepsy. In 2001, HHE was introduced as a syndrome in the published report of the ILAE Task Force on Classification and Terminology.[12] In fact, it is *the stereotyped sequence of events* (hemiconvulsions followed by hemiplegia and leading to a focal epilepsy) that makes HHE "a complex of signs and symptoms that defines a unique epilepsy condition," that is, a syndrome.

As mentioned, taken separately each of its components cannot be considered as an identifiable syndrome because they can be classified into other categories. However, as for progressive myoclonic epilepsies, maintaining HHE as a syndrome is still useful because of the unique characteristics of the condition and their importance when dealing with complex issues and concepts such as secondary epileptogenesis, role of febrile convulsions, and neuroprotection.

Historical Perspectives and Definitions

The sequence of prolonged hemiconvulsions (the term *unilateral status* could be used to differentiate them from focal status restricted to a body segment) immediately followed by hemiplegia and, secondarily, focal epileptic seizures was identified by Pierre Marie[26] in 1885 within the setting of infantile infectious disorders and described by Gowers in 1886 as "posthemiplegic epilepsy."[18] Similar descriptions advocated a vascular[13] or "acute encephalitic"[7] etiology.

In 1957, Gastaut et al.[17] grouped cases of hemiplegia in childhood following convulsions due to various causes (excluding cases of preexisting brain damage) and were the first to use the term HHE. In their series of 150 patients, they found that >80% of cases of chronic epilepsy occurred after a free interval of <1 year and 50% of cases of "psychomotor" epilepsy after >3 years. Partial seizures were considered to be of temporal origin. Further studies[8,9,33,34] have demonstrated that the initial episode may be observed in various situations and that the subsequent partial epilepsy can be temporal, extratemporal, or multifocal.

The term hemiconvulsion-hemiplegia (HH) is often used to describe the initial stage of the syndrome. It is considered as appearing in a child without antecedents, usually before the age of 4 years. Using current ILAE classification criteria for the definition of syndromes, one cannot consider HH as an epilepsy syndrome, because it corresponds to a unique paroxysmal episode.

The incidence of HHE has declined considerably over the last 20 years. Between 1967 and 1978 the number of

HHE cases in the district of Geneva decreased from 7.7 to 1.64 per 10,000 children (Beaumanoir, cited by Roger et al.[35]). A *PubMed* search reveals that the most recent publication of a series on HHE dates back in 1988[21]; it reported on computed tomography (CT) and electroencephalogram (EEG) abnormalities in 25 children with post-hemiconvulsive hemiplegia hospitalized between 1968 and 1980. Since 1995 not more than ten small series or isolated case reports have been published. It is expected that it would be difficult for isolated cases to be accepted for publication. The lack of published large series, however, probably reflects the dramatic improvement in the acute treatment of prolonged seizures in young children. As a consequence, some children who experienced HH avoid motor sequelae and late-onset epilepsy, whereas others do not develop the full HHE clinical picture and are considered as focal epilepsies with antecedents of an acute, usually febrile, convulsive episode.

Age at Onset

The HH initial episode has its peak of incidence during the first 2 years of life; 60% to 85% of the cases occur between 5 months and 2 years of age, with only few patients who are 4 years or older.[3,36] In approximately three fourths of patients, the HH episode evolves to the secondary appearance of partial epilepsy. The average interval from the prolonged initial convulsion to chronic epilepsy was 1 to 2 years, with 85% of the epilepsies having started within 3 years in one study.[3] However, this series was biased in favor of the early onset of complex partial seizures, and these often occur 5 to 10 years after the initial episode.

Clinical Presentation and Diagnostic Evaluation

The first stage of the syndrome, *hemiconvulsion*, constitutes a particular form of status epilepticus corresponding to the *unilateral seizures* described by Gastaut et al.[15] As stated in the previous edition of this book and by Arzimanoglou et al.,[6] this type of seizure deserves to be distinguished because it occurs frequently in infants and young children, diffuses to the whole of the affected side and can last 30 minutes or more (up >24 hours if untreated). In children, most of the long-lasting hemiconvulsions, particularly in the presence of fever, are the initial

P.2356

epileptic manifestations,[2,3,30] which explains the impossibility of prevention. Recognition of this type of seizure by general practitioners, pediatricians, and nurses is of primary importance because in most of the cases the outcome is favorable,[27,39] provided treatment is administered early in the course of the seizure. The seizure is predominantly of the clonic type, with saccadic adversion of head and eyes to one side and unilateral, more or less rhythmic jerks of the limb muscles (with contralateral involvement), variable degree of impairment of consciousness, and autonomic symptoms (cyanosis, hyersalivation, respiratory dysfunction) of variable severity.

The ictal discharge consists of rhythmic (2–3/s) bilateral slow waves, with higher amplitude on the hemisphere contralateral to the clinical seizure. On this side they are intermingled with recruiting rhythms of 10 cycles/s, which predominate posteriorly (Fig. 1). Ictal EEG is variable because of changes in shape, frequency, and topography of the slow and fast components. Pseudorhythmic Spike-waves (SWs) contralateral to the clinical seizure, periodically interrupted by electrodecremental events of 1 to 2 seconds' duration, also may occur. Polygraphic recordings do not demonstrate any consistent relationship between muscle jerks and spikes. Spontaneous seizure termination is brisk, with a brief extinction of all rhythms followed by delta waves of higher amplitude on the ictally engaged hemisphere alternating with short periods of suppression. On the opposite side, physiologic rhythms progressively reappear. At this time the hemiplegia is noted. When the seizure is stopped by intravenous diazepam, arrest of muscle jerks is immediate. The ictal discharge progressively vanishes, persisting longer on the ictally engaged hemisphere. Postictal asymmetry is obvious, with abundant drug-induced rapid rhythms invading the contralateral hemisphere.[8]

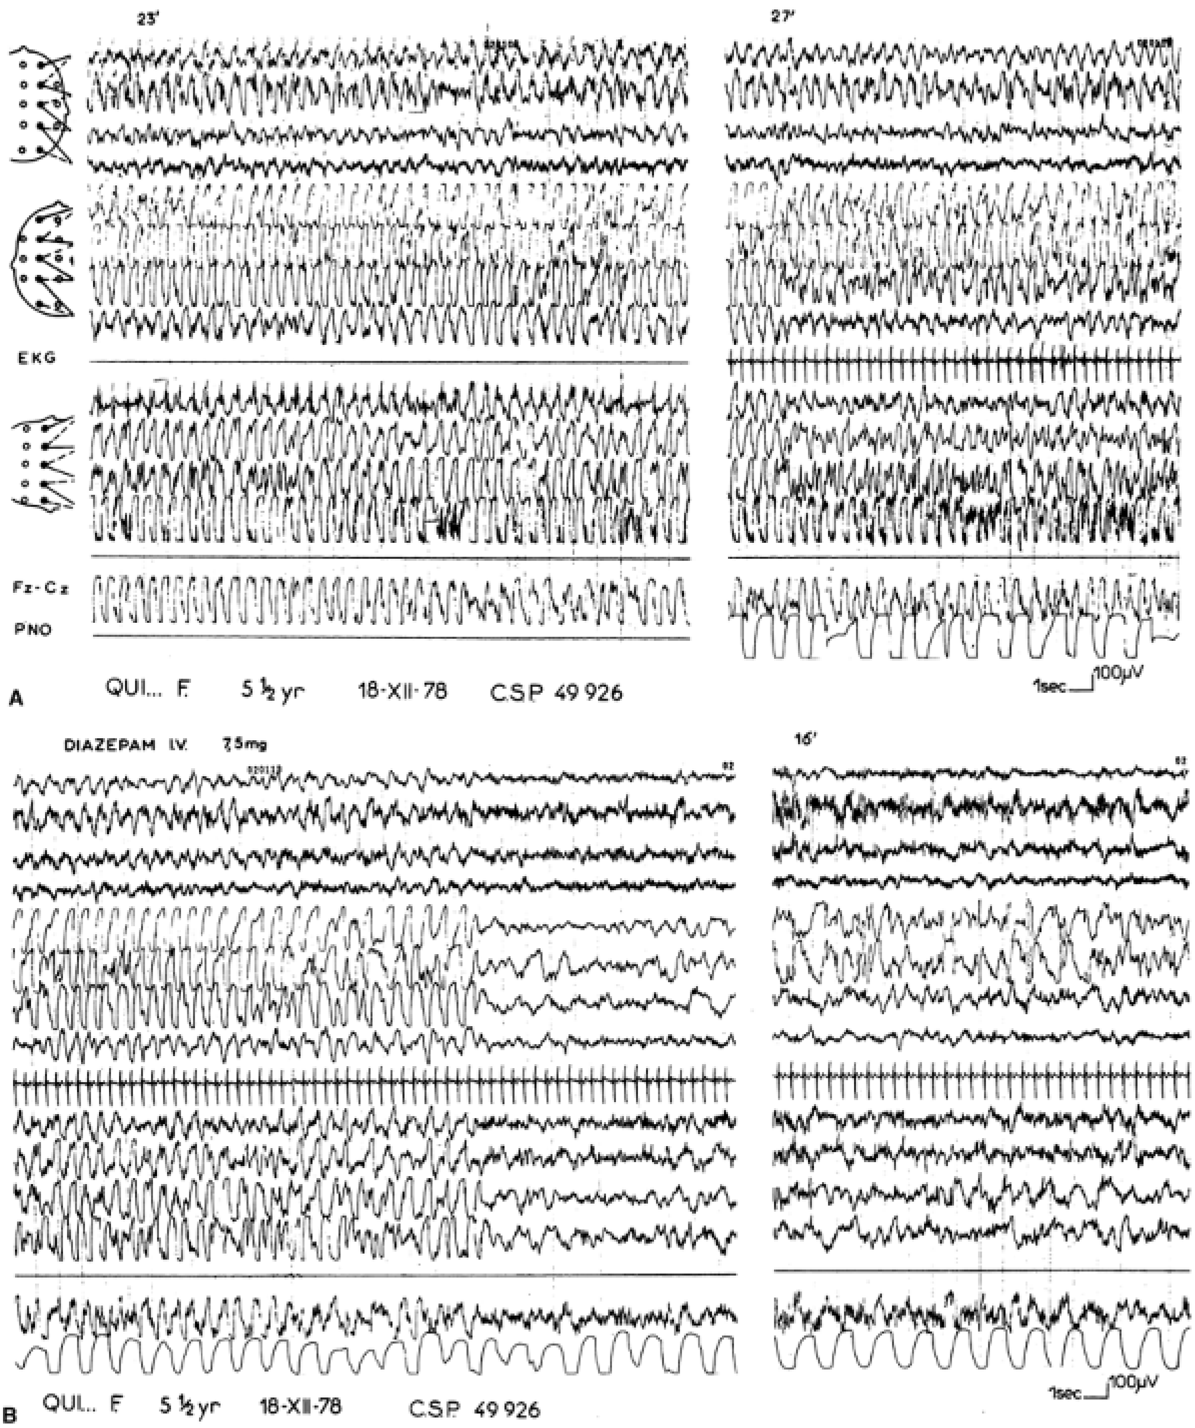

FIGURE 1. Right hemiclonic seizure in course in a 5-year-old boy afflicted with this type of seizure since the age of 3 years. **A:** Recordings 23 and 27 minutes after seizure onset. On the left hemisphere, high-amplitude rhythmic slow waves with superimposed small spikes; on the right hemisphere, rhythmic slow waves over the frontocentral area, with superimposed myoclonic jerks recorded from scalp electrodes. Tachycardia and slight irregularities in respiration. **B:** End of the seizure following intravenous injection of 7.5 mg of diazepam. On the left hemisphere, rhythmic slow waves stop abruptly; 16 minutes later, SW appear over the frontal area. On the right hemisphere, slow waves are replaced at the end of the seizure by fast rhythms caused by diazepam. Respiration becomes more regular. EKG, electrocardiogram; PNO, pneumogram.

The second stage of the syndrome, *hemiplegia*, immediately follows the prolonged convulsive episode. It is initially flaccid and fairly massive but tends to become spastic and less marked as time passes. The minimum duration of the hemiplegia is arbitrarily set at <7 days, to separate it from the more common postictal or Todd paralysis. In 20% of the cases of Gastaut et al., the hemiplegia was not permanent and disappeared within 1 to 12 months. In our experience,[6] some degree of spasticity, increased deep tendon reflexes, and pyramidal tract signs persist, even when the paralysis clears. The hemiplegia is usually predominant in the arm, but the face is constantly involved, an important sign that differentiates an acquired hemiplegia from a congenital one in cases of early onset.

The third component of HHE is *focal epilepsy*. The average interval from initial convulsions to chronic epilepsy is 1 to 4 years,[17] with 85% of the epilepsies having started within 3 years of the first hemiconvulsive episode in one study.[3] Vivaldi,[43] in his series of 45 cases, reported a range of 1 month to 9 years after the acute episode. Approximately two thirds of the late seizures are focal seizures with alteration of consciousness.[36,43] Focal seizures without alteration of consciousness, mainly clonic motor seizures, occur in approximately 30% of the patients; secondarily generalized seizures are reported in 20% and other episodes of status in approximately 10%.[36] Gastaut et al. considered that the epilepsy is always made of focal seizures originating from the temporal lobe (previously called "psychomotor seizures").

In an attempt to further characterize the types of epilepsy within the setting of HHE syndrome, Chauvel and Dravet[8] analyzed a series of 37 adult patients investigated in Sainte-Anne Hospital in Paris for surgical therapy. They were selected based on having a history of convulsions in infancy or early childhood, immediately followed by a hemideficit, and after a free interval (ranging from 1 month to 19 years; mean 5.6 years), having developed epilepsy. They had all underwent a stereotactic neuroradiologic investigation as part of the epilepsy surgery evaluation. The age of HH syndrome ranged from 1 month to 9 years. Only 19% presented the initial episode after the age of 3 years. The majority of the patients had several seizure types, whereas only 9 (24%) had one type of seizure. All the patients presented focal seizures, but 3 of them also had "absences" and seizures generalized at onset. The epileptogenic zone was considered unifocal in 29 and multifocal in 8. In the unifocal group, a striking predominance of suprasylvian localizations was found as compared to the pure temporal lobe epilepsies (5 patients). In 14 of those 29 (nearly 50%) the epileptogenic zone included the frontocentral and parietocentral regions; prefrontal epilepsies were rare, and no pure occipital epilepsy was reported. In the multifocal group, a predominant involvement of the parietal lobe was noticed (7 of 8 patients). These results clearly show that epilepsy in HHE is not always of temporal origin, as initially suggested by some authors.

Diagnostic evaluation following the initial acute episode mainly consists in identifying the cause or triggering event responsible (see the later section on the etiology of HHE). Immediately after the HH episode, CT scan may evidence swelling and edema of the hemisphere involved in the epileptic discharge. Later, a rather characteristic uniform hemiatrophy with midline displacement is observed. This evolution was initially reported using pneumoencephalography[2,17,20] or CT scan.[16,21] Case reports including magnetic resonance imaging (MRI) investigation confirmed this pattern.[14] Morimoto et al.'s case[29] showed a unilateral swelling and damaged cortex and subcortical white matter with a high-intensity signal in T2-weighted images at day 17 from status, followed, on day 25 and day 36 neuroimaging, by a severe hemispheric atrophy. Kawada et al.[22] reported a similar evolution, with atrophy being detected from day 15. Follow-up reports on the evolution of hemiatrophy are lacking, but in our experience it remains relatively stable (Fig. 2).

To our knowledge, the longitudinal evolution of interictal EEG abnormalities during the free interval period has not been studied in detail. In the Sainte-Anne series,[8] when the patients were seen for intractable epilepsy, interictal EEG showed multifocal spikes and sharp waves, as well as generalized and bilateral slow waves, in 56% of 37 patients. Widespread interictal abnormalities were more frequently encountered in the symptomatic category (see later discussion) of HHE patients. Even when radiologic studies suggested a strictly unilateral pathology, the distribution of EEG slow waves frequently suggested a more extended lesion (especially in the contralateral hemisphere), and interictal spiking frequently suggested multiple epileptogenic zones.[8]

Etiology

Prolonged clonic convulsions with a marked unilateral predominance usually occur in the course of a febrile disease. A number of acute cerebral disorders have been occasionally related to the occurrence of the syndrome (meningitis, subdural effusions, head trauma, etc.). In many cases no cause is obvious (*idiopathic hemiconvulsion-hemiplegia* according to Roger et al.[33]), and such cases may represent only prolonged (complicated) febrile convulsions that do not otherwise differ from common febrile convulsions. In such cases the seizure activity itself could be responsible for the appearance of new lesions occurring in a previously normal brain. As Aicardi and Chevrie[3,4] pointed out, "febrile, cryptogenic status epilepticus is only the most severe expression of idiopathic febrile convulsions and differs from the common brief, benign seizures in severity, not in nature." They proposed that "epilepsy and neurological sequelae might be the direct consequence of seizures *per se*." In the same way, Lennox-Buchtal[25] insisted that in cases in which febrile convulsions were focal and prolonged there was a definite risk for mental and neurologic sequelae as well as for subsequent development of epilepsy. The two preceding

P.2357

P.2358

studies stressed the importance of prompt treatment of febrile convulsions to prevent their sequelae. Furthermore, they stressed the importance of prevention with prophylactic treatment of febrile status in children at risk.

Alternatively, the presence of a preexisting asymptomatic lesion, of perinatal or prenatal origin, may be responsible in a number of cases (*symptomatic hemiconvulsion-hemiplegia* according to Roger et al.[33]) for the initiation or localization of the seizure. The prolonged seizure would then produce or contribute to the development of irreversible brain damage with resultant partial epilepsy.[3,4,5,25,35,37]

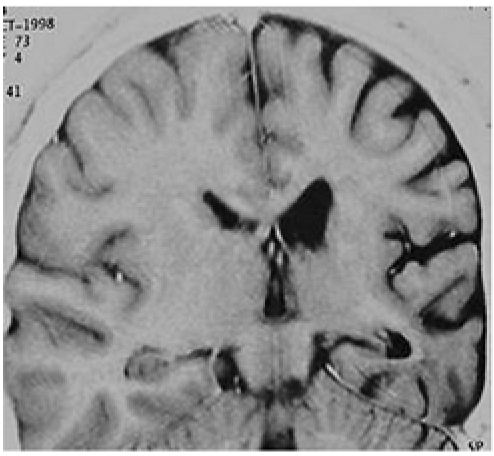

FIGURE 2. Magnetic resonance imaging (MRI) scan of a patient with hemiconvulsion-hemiplegia syndrome. The left hemisphere is diffusely atrophic with ventricular dilation and cortical atrophy. The MRI picture corresponds to the neuropathologic aspect known as hemiatrophia cerebri. It differs from the localized atrophy observed in congenital hemiplegias resulting from arterial occlusion, and it is seen only with acquired post-convulsive hemiplegia. (Reproduced from Arzimanoglou A, Guerrini R, Aicardi J. Epilepsies characterized by partial seizures. In: *Aicardi's Epilepsy in Children*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2004, with permission.)

The difference between "idiopathic" and "symptomatic" forms is not always easy to establish. As for "probably symptomatic" focal epilepsies, one could expect that showing some of the related lesions (particularly those due to a migration disorder) depends on the quality and capacity of the means of investigation. Particularly for cases investigated only by pneumoencephalography, CT scan, or early-generation MRI machines, a minor lesion would be difficult to detect. The combination of an "idiopathic" febrile seizure and a potentially epileptogenic lesion would then favor the prolonged character of the convulsive episode and the development of a "symptomatic" HHE syndrome.

The role of long-lasting febrile convulsions, as part of a hemiconvulsion-hemiplegia episode, in the genesis of hippocampal sclerosis and consequent mesial temporal lobe epilepsy also remains disputed. A statistical association is well demonstrated,[32] and there are strong arguments in favor of an etiologic relationship,[19] although the presence or absence of other contributing factors is not clearly established.[5,38,41]

Pathophysiology

The pathophysiologic mechanisms involved are not clearly elucidated. They most probably involve issues related to the pathophysiology of complicated febrile seizures (genetic factors, the triggering or predisposing role of a preexisting lesion, etc.), the duration of the initial event, the cortical structures involved in the propagation of the initial seizure, and the epileptogenicity of the brain lesions resulting from the initial event.

Chauvel and Dravet[8] recently reviewed the hypotheses on the pathogenesis of the syndrome. They underscored that radiologic studies appear to establish a sequential relation between early repetitive seizures, brain edema, cortical and subcortical atrophy. and, in a good proportion of the cases, chronic epilepsy. For that reason, pathogenesis of the HHE syndrome is of special interest, relating directly to major controversies in the pathogenesis of brain damage in human epilepsy. The principal arguments in this controversy center around two extreme positions: On one hand, it is argued that hypoxic damage (diffuse or selective) would be the result of deficient blood supply (directly by mechanical distortion of the brain at birth, or vascular thrombosis; indirectly by arterial or venous thrombosis of infectious origin[42] or secondary to brain edema); on the other hand, as emphasized by Meldrum and Corsellis,[28]

> insults such as a severe infection or a head injury may well be important factors in some cases, but the most sinister event commonly found to have occurred in epileptic patients with "hypoxic" brain damage is the onset of fits in infancy or in childhood.

The existence of a predisposing genetic factor has been discussed.[31] A high incidence of family history of febrile convulsions is frequently present. Tanaka and colleagues reported ictal and postictal single photon emission computed tomography (SPECT) findings in a 5-month-old boy.[41] When the SPECT was realized during left-sided hemiconvulsions and during the third day after partial status, diffuse hyperperfusion was revealed in the right hemisphere. On the seventh and tenth days after status, diffuse hypoperfusion was exhibited in the right hemisphere. Striking neuroimaging findings suggestive of diffuse cytotoxic edema confined to one hemisphere, including extensive diffusion-weighted imaging abnormalities, were reported by Freeman et al.[14] following early MRI screening. Japanese authors discussed the possible role played by hypercytokinemia[44] and elevated level of interleukin-6 in the cerebrospinal fluid,[23] whereas Scantlebury et al.[37] reported two patients for whom the HHE syndrome could be attributed to the factor V Leiden mutation.

Management

The incidence of hemiconvulsion-hemiplegia-epilepsy syndrome has declined considerably in countries in which emergency care is highly developed.[5,8,35]

Most cases of fever and prolonged convulsions occur during the first 18 months of life. The most important factor is the prompt recognition and early vigorous treatment of prolonged infantile seizures of whatever origin, especially of febrile convulsions. This seems to be the only way to reduce the incidence of postconvulsive hemiplegia and late-onset partial epilepsy. Symptomatic therapy of the acute convulsive episode uses mainly benzodiazepines, particularly diazepam. It can be easily administered by either venous or rectal route. The usual dose is 0.5 to 1 mg/kg given as a single dose. The dose may be repeated after 10 to 20 minutes. Clonazepam, midazolam, or lorazepam may also be used. Antithermic drugs are used in combination. According to the eventual causal agent, additional anti-infectious therapy is required. Prophylactic treatment of febrile convulsions is necessary after HH, but it does not prevent later epilepsy. The outcome of the HH syndrome has become less severe, and subsequent epilepsy seems to be less frequent in idiopathic cases.

In the complete form of the syndrome, partial seizures of temporal or extratemporal origin should be treated like any other type of focal symptomatic epilepsy, using antiepileptic drugs. Surgical treatment is an alternative. However, epilepsies due to extended brain damage may prove difficult to handle surgically. The possibility for a limited cortectomy will usually need an invasive presurgical evaluation performed by a group specialized in epilepsy surgery. Of the 37 patients explored in Sainte-Anne,[8] it was estimated that surgery was possible in only 20. Following surgery, 9 patients (45%) became seizure free or experienced <1 seizure per year; three patients (15%)

showed a significant reduction (40%) in seizure frequency, and no change was obtained in 7 patients (35%). One patient died during a postoperative status.

Hemispherectomy (total, subtotal, or "functional") may be another surgical alternative, particularly when limited cortectomy is not feasible. Delalande et al.[10] included 7 children with HHE syndrome in a series of 53 patients submitted to hemispherotomy. Indications and clinical outcomes of hemispherectomy for epilepsy of various etiologies have been recently reviewed.[11]

Kwan et al.[24] reported on 4-year follow-up in three children who underwent callosotomy. All patients experienced a significant reduction of "generalized tonic seizures," whereas partial seizures of the sensory type were unchanged.

Summary and Conclusions

Hemiconvulsion-hemiplegia-epilepsy syndrome can be considered as a unique epilepsy condition because of the stereotyped sequence of events that characterize it. Onset is in the form of an isolated episode of motor partial status (unilateral status) followed by hemiplegia. The seizure is predominantly of the clonic type, with saccadic adversion of head and eyes to one side and unilateral, more or less rhythmic jerks of the limb muscles (with contralateral involvement), variable degree of impairment of consciousness, and autonomic symptoms (cyanosis, hyersalivation, respiratory dysfunction) of variable severity. Hemiplegia, immediately follows the prolonged convulsive episode. It is initially flaccid and fairly massive but tends to become spastic and less marked as time passes. After a free interval the patient will develop focal seizures and neuroimaging will evidence a rather characteristic cerebral hemiatrophy. The complete sequence of event defines HHE. The HH initial episode has its peak of incidence during the first two years of life. The average interval from the prolonged initial convulsion to chronic epilepsy is one to three years. Diagnostic evaluation, following the initial acute episode, mainly consists in identifying the cause or triggering event responsible. The pathophysiological mechanisms involved are not clearly elucidated.

The most important factor that can influence long-term outcome is the prompt recognition and early vigorous treatment of prolonged infantile seizures of whatever origin, especially of febrile convulsions. This seems to be the only way to reduce the incidence of post convulsive hemiplegia and late onset partial epilepsy. In the complete form of the syndrome, partial seizures of temporal or extratemporal origin should be treated as any other type of focal symptomatic epilepsy.

Hemiconvulsion-hemiplegia-epilepsy syndrome is a form of focal epilepsy, more often symptomatic. It is the stereotyped sequence of events that justifies its recognition as a syndromic entity. The HH initial prolonged episode has its peak during the first two years of life and may or may not be related to fever. After a free interval of usually not more than 2 to 3 years approximately three fourths of the children will develop a focal epilepsy, temporal, extratemporal or multifocal.

Vigorous and early treatment of the initial episode, usually with rectal administration of a benzodiazepine, is the most appropriate way to reduce neurological sequelae. The incidence of HHE syndrome has declined considerably in countries in which emergency care is highly developed.

Chapter 234

Myoclonic Status in Nonprogressive Encephalopathy

Bernardo Dalla Bernardina

Introduction

Despite the existence in the literature of proof of the possible occurrence in infants and young children of an absence status with myoclonias of variable severity and duration called by various names, such as "minor epileptic status," "minor motor status," "myoclonic status," "obtundation with myoclonias," "nonconvulsive states with ataxia," "myoclonic state with impaired consciousness," "myoclonic status in symptomatic cases of myoclonic astatic epilepsy," and so on,[1,2,3,6,9,10,24,27,28,32,36,38,42] reports documenting the existence of an epileptic syndrome characterized by the recurrence of long-lasting or subcontinuous myoclonic status in children with a nonprogressive encephalopathy are relatively rare.[7,11,13,15,16,18,19,20,21,25,33] In fact a very similar electroclinical picture has been described in children with Angelman syndrome,[8,25,33,34,35,37,39,41,43,45,47,52] in some children with 4p- syndrome,[44,46,53] and in some children with Rett syndrome,[17] but very few authors have stressed how, in these cases, the electroclinical picture was typically that of "myoclonic status in nonprogressive encephalopathy,"[15,16,17,18,19,22,40,44] a syndromic entity recently proposed by the ILAE Task Force on Classification and Terminology[41] in its category "syndromes in development."

Definitions

The syndrome is characterized by the recurrence of long-lasting myoclonic status, that is often difficult to recognize and frequently refractory to different treatments, in children with a nonprogressive encephalopathy of variable etiology.

Epidemiology

The prevalence of this condition is unknown; it seems to be rare because the only three series available[7,11,17] account for a total of 96 cases. The true prevalence is probably higher than reported, considering that many similar cases can remain misdiagnosed particularly in the absence of polygraphic recordings. There appears to be a female predominance, with a male:female ratio of 1:2. Familial antecedents for epilepsy are present in about 15% of cases.

Etiology and Basic Mechanisms

A genetic disorder (4p- syndrome, Rett syndrome, and especially Angelman syndrome) is present in nearly half of the reported cases. In such cases, nonsignificant abnormalities are neuroradiologically detectable.

A history of prenatal anoxic injury is well documented in about 15% of the cases. In about half of these cases, the neuroradiologic investigation shows cortical atrophy of variable degree that maximally affects the frontal regions.

In about one third of cases, neuroradiologic investigations reveal brain developmental malformations such as unilateral or bilateral micropolygyria, complete or partial callosal agenesis, vermis hypoplasia, or bilateral hippocampal dysgenesis, in most cases probably genetically determined.[7,17]

In the remaining 10% of cases, the etiology is unknown, with normal neuroradiologic and other laboratory investigations.

In some of the genetic cases, as in Angelman syndrome and 4p- syndrome, hyperexcitability of the motor cortex might be related to reduced GABAergic inhibition. In pre and perinatal anoxic cases, a similar "localized" hyperexcitability could be induced by a circulatory disturbance in late pregnancy causing selective dysfunction in the motor cortex.[11]

Electroclinical Presentation

Neurological impairment, which may be severe, has been observed at onset in almost three fourths of the cases. There is axial hypotonia of variable degree associated with abnormal movements, presenting a picture of "ataxic" cerebral palsy of a dystonic dyskinetic syndrome, severe mental retardation and, in some cases, microcephaly with dysmorphisms.

In one fourth of the cases, the neurologic impairment at onset is less obvious, characterized only by delayed postural acquisitions and language skills.

Age at first seizure ranges between 1 month and 5 years, with a mean age of 10 months.

Onset of epilepsy in several cases has been characterized by a myoclonic status with very frequent daily or subcontinuous "absences" accompanied by periorbital and perioral myoclonias and rhythmic and arrhythmic jerks of distal muscles in nearly half of the cases. In other childern, the initial seizures are mostly partial motor, brief myoclonic absences, massive myoclonias, and, more rarely, generalized or unilateral clonic seizures. Massive startles frequently occur at rest and during drowsiness.

The average age at which myoclonic status is recognized is 14 months (range: 3 months–5 years). Because of severe mental retardation and continuous abnormal movements, both the paroxysmal attention disturbances ("absences") and the myoclonias can remain unrecognized for several months. Considering its insidious appearance, it is probable that the age of onset of the status, in many cases, may be significantly earlier than when it is recognized.

In many cases, the myoclonias are subcontinuous but asynchronous in different muscles, and their relationship to the paroxysmal electroencephalographic (EEG) activity is difficult to appreciate because they are arrhythmic and subtle and also

P.2362

because the paroxysmal nature of the EEG pattern is often difficult to recognize.

In some cases the myoclonias are more obvious, involving rhythmic contractions of both arms and orofacial muscles. In other cases, the myoclonias are followed by a brief silent period constituting a mixture of positive and negative phenomena. In others, negative myoclonus is predominant, continuously fragmenting the voluntary movements and inhibiting the maintenance of any fixed antigravitary postures.

Even when the child is awake, the EEG is characterized by slow and poorly reactive activity with paroxysmal abnormalities. These consist of relatively monomorphic subcontinuous delta-theta activity (3–6 c/s) that varies in amplitude and occurs asynchronously over the frontocentral regions. In addition, there are brief sequences of rhythmic delta waves with superimposed spikes constituting unusual spike and wave complexes.

When the myoclonias are rhythmic, synchronous on the two sides, and strictly related to the diffuse paroxysmal bursts, they constitute an ictal pattern similar to that of a brief myoclonic absence.

The myoclonias become easier to recognize when there is motor arrest, such as during absence or drowsiness when all other abnormal movements disappear.

During drowsiness and slow wave sleep, spikes and waves become continuous to the point that sleep spindles are not recognizable. During stages II and III of the following nocturnal cycles, the paroxysmal activation ceases and spindles are clearly represented. During slow wave sleep, the myoclonias vanish, reappearing briefly at arousal. During rapid eye movement (REM) sleep when the diffuse discharges disappear, there is continuous rhythmic theta activity involving mainly the vertex and rolandic regions. The same theta activity strictly related to myoclonias is transitorily observed during alerting.

Based on the electroclinical picture, three main subgroups can be recognized.

The *first group* consists of patients who show a mixed pattern of brief myoclonic absences and subcontinuous rhythmic positive jerks, eventually followed by a brief silent period related to subcontinuous delta-theta activity involving the central areas accompanied by brief sequences of rhythmic delta waves with superimposed spikes mainly involving the parieto-occipital regions and often elicited by eye closure.

In this group, the status can be recognized during the first year of life. These are events of variable duration recurring sporadically in about half of the cases, whereas they are more "chronic" (lasting for years) in about one fourth of the cases. No other types of seizures are observed except for rare unilateral or generalized seizures that often occur in the setting of a febrile illness.

This electroclinical picture has been observed mainly in children with Angelman syndrome and with 4p-syndrome.

As we have described previously,[16,17,18,19,22,23] and as confirmed by other authors,[7,25,33,40] we consider this electroclinical picture to be the earliest diagnostic indicator of Angelman syndrome. Many authors have, in fact, described a very similar status in cases of Angelman syndrome, but they didn't recognize the preeminent myoclonic character.[5,30,37,39,41,43,45,47,48]

The *second subgroup* is made up of patients showing a pattern characterized by the marked predominance of inhibitory phenomena mixed with a severe fragmented dystonic component and sudden irregular, fast, lightning-like jerks. In these cases, the status is often difficult to recognize because of the very severe mental impairment, which is present from onset, and the abundance of continuous polymorphic and coarse abnormal movements. The jerks are mostly erratic and are therefore difficult to distinguish from violent dyskinetic movements. Moreover, the EEG paroxysmal abnormalities consist of subcontinuous multifocal slow spike waves that predominate in the frontocentral regions but fluctuate in amplitude and extent, making it very difficult to correlate with the positive and negative myoclonias. The result is an epileptic status characterized by a complex dysregulated motor pattern inducing a peculiar "hyperkinetic complete motor inhibition."

Except for brief generalized tonic-clonic seizures sometimes in clusters, other types of seizures are very rare.

Patients showing this electroclinical picture are females affected by a nonprogressive encephalopathy of unknown etiology or by associated with a cortical malformation.[7,17]

The *third subgroup* is made up of children who have only mild neurologic impairment at onset. Initially they have partial motor seizures or brief myoclonic absences. More or less rapidly and more or less subtly, a progressive myoclonic status begins, characterized initially by a subcontinuous sequence of generalized spike-wave paroxysms related to the rhythmic myoclonias of face and limbs. With time, there is progressive deterioration of the electrical activity and a morphologic modification of the paroxysms to sharp theta wave type with very slow pseudorhythmic continuous spikes in the central regions and vertex. At the same time, motor function is progressively compromised and pyramidal signs and intention tremors appear. In addition, continuous myoclonic inhibitory phenomenon appears that sometimes can be recognized clinically and polygraphically only when postural tone is increased. Complete motor inhibition is invariably the result.

In one fourth of the cases, magnetic resonance imaging (MRI) shows a probable disturbance, in gyration such as focal bilateral micropolygyria. Some children have Rett syndrome.[7,17]

Partial motor seizures, predominantly tonic and only sometimes followed by generalization, are frequent even at long follow-up intervals, whereas other types of seizures are absent.

Differential Diagnosis

Because of the significant progressive increase of both neurological impairment and EEG paroxysmal abnormalities as well as worsening polymorphic myoclonic manifestations, the first and often most complex step is the need to exclude a progressive disease, particularly the late infantile form of neuronal ceroid-lipofuscinosis.[4,49,50] The absence of progressive visual impairment with persistence of normal visual evolved potentials (VEP) even when, as frequently observed, the somatosensory evoked potentials (SEP) are abnormal, there is an absence of a paroxysmal response to photic stimulation and there is persistence of recognizable spindles can help to suggest a correct diagnosis.

Neuropathologic and molecular genetic analyses are required to rule out a progressive disease, particularly neuronal ceroid-lipofuscinosis.

Another somewhat difficult differential diagnosis can be with the cases reported in the literature as having a "newborn continuous partial epilepsy,"[14] "early-onset progressive encephalopathy with migrant continuous myoclonus,"[29] or "migrating partial seizures of early infancy"[12,31,51] because many of these can present, soon after onset, long-lasting status characterized by continuous discharges of diffuse spikes and waves accompanied by bilateral asynchronous myoclonias with obtundation and drooling.

Treatment and Outcome

In children showing the first electroclinical picture, the status frequently lasts for years refractory to treatment, and even benzodiazepines and adrenocorticotropic hormone generally have only a transitory effect. Nevertheless, in many cases ethosuximide plus valproic acid and levetiracetam leads to a significant improvement, and as the status resolves the clinical picture

improves dramatically. Continuous disabling jerks are reduced and some children become able to walk. In about one third of cases, even if the status disappears, intention myoclonus becomes predominant, constituting the picture described by Guerrini et al.[33,35,36] as cortical myoclonus.

In children with the second electroclinical picture, the long-term prognosis is always unfavorable. The status is refractory to different therapies and permanent in evolution, with definitive aposturality and severe mental deficit. Some patients die in long-lasting motor status.

The third electroclinical pattern is a pharmacoresistant progressive epilepsy not associated with a progressive disease. The neurologic impairment increases dramatically over a few years: In one third of the cases, cortical-subcortical and cerebellar atrophy becomes recognizable on MRI.

Summary and Conclusions

This particular type of symptomatic myoclonic epilepsy, characterized essentially by the recurrence of long-lasting atypical status associated with an impaired attention and continuous polymorphic jerks mixed with other complex abnormal movements in infants suffering from a nonprogressive encephalopathy, constitutes a unique syndromic entity.

Although this condition is difficult to diagnose clinically, it can be easily recognized by polygraphic recordings, which show rhythmic discharges of diffuse slow spike-waves accompanied by more or less rhythmic asynchronous myoclonias that are continuous during wakefulness and, in many cases, persist during sleep.

It is probable that becuase it is not routine to perform polygraphic recordings in clinical practice, the frequency of this condition has been underestimated.

This status is invariably accompanied by concomitant worsening of the child's neurological condition. The etiology can be varied, and is probably mainly malformative and genetic.

Electroclinical analysis makes it possible to distinguish three subsets of the disorder that have important diagnostic and prognostic significance. The first is characterized by the association of absences, subcontinuous jerks, at times rhythmic or arrhythmic and mainly positive, brief myoclonic absences, and hypnagogic startles. These suggest a diagnosis of Angelman syndrome or the up-syndrome.

The second affects mainly females and is characterized by the association of absence status and continuous rhythmic myoclonus, mainly negative, mixed with sudden, uncontrolled continuous dyskinetic movements leading to a clinical picture of hyperkinetic aposturality, generally sustained by a cortical malformation.

The third is characterized by continuous spike activity over the rolandic regions that persists throughout life accompanied by bilateral rhythmic myoclonias followed by an inhibitory phenomenon leading to a progressive neuromotor deterioration. This presents as a form of myoclonic progressive epilepsy in the absence of a progressive disease. In these cases, cortical dysplasia involving the motor area is frequently recognized.

Chapter 235

Overview: Syndromes of Late Childhood and Adolescence

Jean Aicardi

Introduction

The incidence of epilepsy declines after the first few years of life but remains higher than in adults.[21] Greater maturity of the brain is associated with an increasing frequency of the classic types of seizures, such as generalized tonic–clonic, absence, and simple or complex partial seizures, and with a decreased incidence of the seizure types characteristic of infancy, such as infantile spasms, atypical absences, and febrile convulsions. Although lesional epilepsies of various causes can begin in this age range, a remarkable feature of many of the epilepsies of late childhood and adolescence is their occurrence in a previously normal child without neurologic or neurodevelopmental defects. Even more remarkable is the fact that a significant proportion of the epilepsies of late childhood and preadolescence tend to be self-limited and disappear after a few years without any detectable sequelae, and several such epilepsy syndromes with variable degree of benignity are described in the following chapters.

Such benign or favorable courses reflect the nonlesional nature of many of the epilepsies of this age, which are mainly determined by genetic factors.[14,16,32] Familial grouping of cases is well recognized, but there is still considerable uncertainty regarding the modes of inheritance of various types and the identification and localization of the responsible genes. Several monogenic syndromes have been described, but in most epilepsies of childhood and adolescence, only a few loci or genes have been characterized, and multigenic determination is considered probable. Even clinically homogeneous syndromes such as juvenile myoclonic epilepsy are genetically heterogeneous, and the current trend is to think in terms of susceptibility genes rather than of direct causation. This applies, for instance, to juvenile myoclonic epilepsy[23] and even more clearly to the syndrome of generalized epilepsy with febrile seizures plus (GEFS+), for which at least three genes have been identified,[17] and probably to other epilepsies.[32]

Two major groups of nonlesional, probably genetically determined, epilepsies are recognized: (a) the idiopathic generalized and (b) the benign partial epilepsies. The first group includes epilepsies with primary generalized tonic–clonic convulsions and several forms of myoclonic and absence epilepsies. The most common types in childhood and adolescence are childhood absence epilepsy (Chapter 239) and juvenile myoclonic epilepsy (Chapter 244). Absence epilepsy appears to be a clinically heterogeneous syndrome, and several distinct syndromes of absence epilepsy exist, whose recognition is probably important for prognostic purposes.[27] Childhood absence epilepsy has an excellent outcome, whereas juvenile absence epilepsy[34] and absences associated with juvenile myoclonic epilepsy are likely to persist into adult life. The exact nosologic place of some rare syndromes, such as eyelid myoclonia with absences[4] and absences with prominent perioral myoclonus between absence and myoclonic epilepsies, is not definitely determined. Juvenile myoclonic epilepsy is a common and well-defined syndrome in adolescents. The characteristic myoclonus on awakening easily goes unrecognized, and the diagnosis is often missed, so that the correct prognosis and treatment might not be given.[9,23] Juvenile myoclonic epilepsy, idiopathic grand mal epilepsies, and juvenile absence epilepsy may represent a spectrum of related syndromes (sometimes termed primary generalized epilepsies) with some types presenting only tonic–clonic seizures (awakening grand mal) and others with associated juvenile absences. It is not clear whether these different clinical presentations form different electroclinical and/or genetic entities or more likely belong to what is basically a single condition due to a common predisposition with specific factors determining the seizure expression, so that the group might be better termed primary generalized epilepsy.[30] Despite these different clinical aspects, the epilepsies in this group are benign in terms of neurodevelopment but tend to be persistent and not to remit for many years. They may even be lifelong, thus requiring continuous treatment.

The second group of partial idiopathic epilepsies has proved to be one of the most common types of epilepsy in older children. *Benign rolandic epilepsy* (Chapter 236), first described in the 1960s,[24] has been extensively studied.[5] The charactristic nocturnal sensorimotor facial seizures of short duration occurring in healthy children has now become familiar to neurologists and is easily recognized, even though the paroxysmal electroencephalogram (EEG) abnormalities may be more variable than initially thought.[34] The virtually complete benign nature of the syndrome has been repeatedly confirmed, although exceptional cases of an identical clinical syndrome in association with focal opercular lesions are on record.[3] However, recent studies have shown that disturbances of language and of other cognitive and behavioral functions may often be found, usually to a mild degree.[11,12] Long- term follow-up studies are necessary to assess the significance of these findings.

Cases closely related to benign rolandic epilepsy but with unusual features have received recent attention, and different aspects have been described. Opercular status epilepticus applies to rare cases with dysarthria, drooling, and pseudobulbar features lasting days to weeks, which might be considered as status of benign rolandic epilepsy, as confirmed by EEG recording.[8,11] Atypical benign partial epilepsy[1,20] is marked by the appearance of atonic seizures following a period of typical facial seizures, associated with intense spike-wave activity in slow sleep, and may wrongly suggest the diagnosis of Lennox-Gastaut syndrome. Electrical status epilepticus of slow sleep (ESES) is defined mainly by the EEG features and clinically by cognitive and behavioral deterioration. It is a heterogeneous group of patients, with approximately half of the cases having lesional causes.[18,19] The Landau-Kleffner syndrome (Chapter 242) often shares the EEG features of ESES and is clinically characterized by prominent language disturbances.[7,10] The very delineation of these syndromes is not entirely clear, and their relationship to benign rolandic epilepsy, which is

suggested by the interictal EEG findings and the ultimate remission of epilepsy, is not straightforward because some cases may be due to brain lesions and the reasons for the different clinical expression and course are obscure. The mechanism of epileptic encephalopathy outlined here is probably an important causal factor.

Benign childhood epilepsy with occipital paroxysms (Chapters 237 and 238) is a second form of idiopathic focal epilepsy. Its clinical presentation is variable. Most commonly it presents in young children with infrequent nocturnal seizures, vomiting, loss of consciousness, and eye deviation. Most seizures are brief, but some may last several hours, with prominent autonomic manifestations, and they may simulate abdominal emergencies.[26] Visual symptoms are more common in older children, mainly in the form of transient loss of vision. Striking EEG abnormalities include continuous spike-wave complexes arrested by eye opening. Less typical abnormalities may be more common, however, in the form of spikes over the posterior part of the head. The course is consistently benign. Similarities and sometimes coexistence between rolandic and occipital epilepsy have suggested the concept of benign seizure susceptibility syndrome. Other syndromes, such as epilepsy with evoked parietal spikes and benign psychomotor epilepsy, have not been validated.

New syndromes of partial nonlesional epilepsies have been recently reported. Nocturnal frontal lobe epilepsy[2] presents with nocturnal seizures and is often misdiagnosed as sleep disorder (Chapter 249). It is transmitted as an autosomal-dominant trait and, in some families, has been shown to be due to mutations in the gene for α- and ß-nicotinic cholinergic receptors or of the γ-aminobutyric acid (GABA) receptor GABRG2.[17] No linkage to these loci was present in other families, however, indicating further genetic heterogeneity. Several distinct syndromes of dominant partial epilepsy are now recognized. They include benign multifocal partial epilepsy,[2] benign rolandic epilepsy with pseudobulbar features,[31] and benign dominant mesial and lateral temporal lobe epilepsies,[6] which may not be rare but have not been recognized before adolescence (Chapter 248).

The benign couse and even the nonlesional nature of some of the newly described partial epilepsy syndromes are difficult to establish because similar cases can be of lesional origin. In general, the use of the term *benign* should be reserved for those cases in which a favorable outcome of the epilepsy and normal neurodevelopment have been consistently found. The term is not synonymous with *idiopathic* or *genetic* because cases belonging to the latter categories may have a severe outcome.

Seizures of lesional origin in children and adolescents may have quite variable manifestations. Late cases of the Lennox-Gastaut syndrome (Chapter 241) and even of epileptic spasms may appear. Well-defined complex partial seizures tend to become increasingly frequent as the patients grow older. The causes of lesional seizures in this age range differ from those found in adults. Developmental brain abnormalities are still common.[18] Cases of mesial temporal lobe epilepsy (Chapter 247) with typical temporal lobe seizures and evidence of hippocampal sclerosis on neuroimaging begin to appear in the latter part of the period. In younger children, cortical dysplasia and related migration abnormalities tend to predominate. They can involve any part of the brain, which explains the greater frequency of extratemporal epilepsies in children than in adults. Frontal lobe seizures are especially common and may be difficult to distinguish both from temporal lobe seizures and from pseudoseizures. In many frontal lobe seizures, consciousness is preserved despite unresponsiveness of the child and complex movements and attitudes.[5] Tumors are rare as a cause of seizures in children and adolescents. A majority are developmental tumors, commonly associated with neighboring dysplasias (developmental neuroepithelial tumors and gangliogliomas). Their diagnosis by neuroimaging has been reviewed.[29] A rare but important form of partial lesional epilepsy is Rasmussen syndrome (Chapter 243), a progressive inflammatory brain disorder of unknown origin that often causes epilepsia partialis continua and a progressive neurologic deficit requiring surgical therapy.

Summary And Conclusions

An important proportion of the epilepsies of childhood and adolescence are of idiopathic origin and relatively benign. Overtreatment should be avoided in these cases, and some epileptologists believe that drug treatment is unnecessary when the outcome can be firmly predicted. Intractable lesional epilepsies may be medically intractable and amenable to surgical therapy. However, the majority of the epilepsies with onset in late childhood and adolescence respond well to antiepileptic agents and are compatible with a reasonably normal quality of life in the cases in which no definitive remission is to be expected.

Chapter 236

Benign Childhood Epilepsy with Centrotemporal Spikes

Natalio Fejerman

Introduction

The recognition that some epilepsies in children have focal clinical manifestations and unilateral electroencephalographic (EEG) discharges with benign evolution has been one of the most interesting contributions to pediatric epileptology in the last 50 years.

The concept of idiopathic and benign focal epilepsies of childhood is relevant not only from the theoretical point of view, but also as a practical tool, because the term implies both absence of structural brain lesions and a genetic predisposition associated with age-dependent seizures. Benign childhood epilepsy with centrotemporal spikes (BCECTS) is the most frequent of the benign focal epilepsies of childhood and represents 15% to 25% of epilepsy syndromes in children <15 years of age. In addition, it is the most frequent epilepsy syndrome in school-age children.[25,101,125]

Historical Perspectives

Yvette Gastaut was the first to state, in 1952, that "pre-rolandic spikes" could be "functional" instead of an indicator of a cortical lesion.[48] In 1958, Bancaud et al.[6] and Nayrac and Beaussart[91] reported the first series of patients, emphasizing that rolandic or pre-rolandic spikes or spike-waves constituted EEG features that were typical of childhood, and that should not induce "neurosurgical behaviors," although they did not describe a clear electroclinical correlation. In 1960, Gibbs and Gibbs[51] stated that prognosis was much better in children with centrotemporal spikes than in those with spikes in the anterior temporal regions. In the same year Faure and Loiseau[39] wrote of "Rolandic spike-waves without focal significance," referring to age of onset and sleep as a trigger of seizures, and to spontaneous electroclinical normalization in puberty. Clinical features of seizures were not defined, however, because they found generalized seizures in 13 of their 15 cases. In 1966, Trojaborg[114] published a longitudinal study in a cohort of 519 children with focal spike discharges. Two hundred and eighty of these patients had cerebral palsy. The main purpose of this work was a detailed analysis of the significance of acute sharp waves in the EEG and their correlation with brain lesions. The author recognized that one prognosis was good in children with centrotemporal spikes, but did not determine their clinical correlates. Also in 1966 the most important series of children with temporal lobe epilepsy was published.[97] Among the 100 children followed, 33 constituted a subgroup without pathologic history and with mean age of onset of seizures between 7 and 8 years. It is now easy to imagine that a significant proportion of these 33 children might have had the diagnosis of BCECTS.

One year later, two independent groups reported their series of patients with a peculiar form of epilepsy to be differentiated from other focal epilepsies, mainly from temporal lobe epilepsy. Loiseau et al.[78] presented 122 cases with onset of seizures at school age and rolandic sharp waves in the EEG. In 80% of their patients, seizures occurred during sleep and were frequently motor with predominant involvement of the face. Lombroso[81] provided a clear description of the seizures, emphasizing somatosensitive symptoms in tongue, oral mucosa, and gums, along with speech arrest, and proposed the term "sylvian seizures," recognizing also the particular focal EEG features. Both Loisseau et al. and Lombroso stressed the benign character of the condition in terms of the evolution of seizures and normalization of the EEG. In 1972, Blom et al.[13] reported a prevalence and follow-up study and proposed that the condition be named "benign epilepsy of children with centrotemporal EEG foci." Several long-term follow-up studies confirmed the good prognosis.[8,9,72,80] Atypical and not-so-benign evolutions have been reported in some patients.[1,40,43,44,46,54] This form of epilepsy is now called benign childhood epilepsy with centrotemporal spikes and is placed in the group of idiopathic localization-related (focal, local, partial) epilepsies in the International Classification of Epilepsies and Epileptic Syndromes.[21,36]

Definitions

The most common name besides BCECTS appearing in the literature referring to this condition is "benign rolandic epilepsy." The term "benign" has been questioned for other epilepsy syndromes because some epileptologists believe that benign implies a natural evolution to remission of seizures and EEG abnormalities even without treatment. In this sense, BCECTS conforms to the aforementioned concept, even if we must accept that there are exceptions to the rule.

Onset during childhood with hemifacial motor, seizures, speech arrest, and sialorrhea, occurring mostly during sleep, along with distinctive centrotemporal spikes in the EEG are well-defined features that allow a prompt diagnosis and assure a good prognosis, although subsets of atypical cases with slight compromise of neurological functions are increasingly being reported.[102,120,122]

Epidemiology

Benign childhood epilepsy with centrotemporal spikes accounts for between 15% and 25% of all epileptic syndromes in children between the ages 4 and 12 years.[19,25,101,121] Its annual incidence has been reported to be between 7.1 and 21 per 100,000 in children <15 years of age.[56] Because nocturnal seizures can be overlooked in diagnosis, this disorder may be even more common than generally suspected. There is a slight male predominance.[82]

The prevalence of epilepsy is much higher among close relatives of children with BCECTS than in a matched control

P.2370

group.[17] In one study, 15% of siblings had seizures and rolandic spikes, 19% of siblings had rolandic spikes without attacks, and 11% of the parents had had childhood seizures that had disappeared by adulthood.[57]

In an epidemiologic study of epilepsy in a cohort of 440 consecutive children, benign rolandic epilepsy of childhood accounted for 8% of patients (neonatal seizures were excluded from the analysis).[67]

Etiology and Basic Mechanisms

The high incidence of a positive family history for epilepsy and focal EEG abnormalities indicates the importance of genetic factors in the etiology of BCECTS.[13,17,27,82] Most authors speak of an autosomal-dominant trait with variable penetrance.[17,57] This type of inheritance was also suggested by studies of monozygotic twins with rolandic discharges[64] and of HLA antigens and their haplotypes.[34] However, in another study of clinical and genetic aspects in children with benign focal sharp waves, including 134 probands with seizures (24% of which had typical rolandic seizures), the findings agreed with a multifactorial pathogenesis with "benign" focal epileptiform sharp waves.[32] Epileptic seizures appear in only 25% or less of individuals with this EEG trait.[82] Expression of the gene may be influenced by other genetic and environmental factors.[79] Linkage to chromosome 15q14 was found in 54 patients of 22 families with benign childhood epilepsy with centrotemporal spikes.[92] However, in a study of 70 families with BCECTS in Italy, the same linkage could not be found.[104] Approximately 10% of patients have a history of febrile seizures, and this also supports a genetic predisposition for febrile seizures expressed at earlier ages in children with BCECTS.[63,71]

A family with nine affected individuals in three generations was reported showing the features of rolandic epilepsy associated with oral and speech dyspraxia and cognitive impairment.[109] Similar seizures and the EEG phenotype of BCECTS were found in three children with de novo terminal deletions of the long arm of chromosome 1q, and the authors suggested that it could be a potential site for a candidate gene.[118]

Although the pathophysiology of BCECTS is unknown, and there is no associated structural lesion, the typical ictal clinical behavior and EEG discharge indicate a disturbance in the sylvian and rolandic areas.[37] Electrophysiologic studies, however, fail to demonstrate a discrete generator, and a large, shifting area of regional cortical dysfunction may be present. In some patients with BCECTS, the occurrence of generalized spike-wave EEG discharges, as well as focal spikes in other areas, suggests a relationship between BCECTS and the idiopathic generalized epilepsies, as well as with other idiopathic localization-related partial epilepsies.[73,82] Between 10% and 20% of patients with centrotemporal spikes may also have sharp slow wave complexes in other cortical locations.[100]

Combined recording of interictal spikes and somatosensory-evoked potentials led to the conclusion that in some patients multiple simultaneous neuronal populations are active within the central region.[7]

Magnetoencephalographic (MEG) analysis of generator sources and propagation of rolandic discharges in BCECTS using three-dimensional dipole localization suggested that rolandic discharges are generated through a mechanism similar to that of somatosensory-evoked responses.[86] A localization analysis of spontaneous magnetic brain activities also suggested the value of MEG for pathophysiologic studies.[65] Six children with bilateral centrotemporal synchronous discharges were studied using MEG and EEG with equivalent current dipole modeling. Results implied cortical epileptogenicity in bilateral perirolandic areas.[75] Interictal spikes were recorded in seven children during functional magnetic resonance imaging (fMRI) acquisition using a MR-compatible digital EEG system. Spike-related activation in the perisylvian central region was found in three of them.[14] High-resolution EEG and MEG and a realistic volume conductor model were used to study the spatiotemporal aspects of the sources of spikes in children with benign rolandic epilepsy. Results for EEG and MEG were different. Both high-resolution EEG and MEG revealed that in some cases there were multiple sources for spikes that were well separated in space and time, whereas in other cases only single-source activity was present.[61]

Recent papers considered BCECTS, Landau-Kleffner syndrome, and electrical status epilepticus in sleep as a spectrum of disorders with a common transient, age-dependent, nonlesional, genetically based epileptogenic abnormality, involving a perisylvian epileptic network. Halasz et al. refer to “mild to severe epileptic encephalopathy limited to the perisylvian network, where the cognitive impairment is caused by epileptic discharges interfering with cognitive development.”[55]

Clinical Presentation

We discuss the main clinical features of BCECTS, assuming that this is an idiopathic focal epilepsy that appears in children with normal neurological development, although this syndrome has also been reported in patients with nonevolutive brain lesions.[108]

1. BCECTS begins between 4 and 10 years of age in 90% of patients, and the median age of onset is approximately 7 years. There are no reports of BCECTS occurring during the first year of life or after age 15 years, and cases with seizure onset before the age of 2 years are extremely rare.[25,42]
2. BCECTS is seen more frequently in males, with a male-to-female ratio of 3:2.
3. Seizures are clearly related to sleep, whether during the night or the day. This is seen in 80% to 90% of patients. Seizures during waking hours are more likely to occur shortly after awakening,[82] although on many occasions, during the early morning the child wakes up with a seizure that really started during sleep. Seizure frequency is usually low, and around 10% of cases have only one seizure. In about 20% of the children, however, seizures are frequent and may even occur several times per day.[25] Most patients have a single type of seizure, but 20% to 25% of children experience more than one type.[79] Loiseau and Beaussart[77] described 35 signs or components of 275 seizures analyzed in 190 children with BCECTS. We can reduce this number to a small group of characteristic manifestations of seizures:
    a. *Orofacial motor signs*, especially tonic or clonic contractions of one side of the face, with predilection

for the labial commissure (contralateral to the centrotemporal spikes). There are also contractions of the tongue or jaw, guttural sounds, and drooling from hypersalivation and swallowing disturbance.

b. *Speech arrest,* most probably due to tonic contractions of pharyngeal and buccal muscles, constituting anarthric seizures. In fact, the patient cannot speak during the seizure because either he or she wakes up with hemifacial contractions or while awake opens his or her mouth with the intention to speak but stays blocked in that position.

c. *Somatosensory symptoms*, namely unilateral numbness or paresthesia of the tongue, lips, gums, and

cheek, are frequent, but sometimes have to be looked for in the context of recalling previous events.

d. The three mentioned groups of manifestations are related to an epileptic activation of lower rolandic motor and somatosensory areas. In terms of sialorrhea, it is not clear whether it corresponds to increased salivation, a swallowing disturbance, or both. In general, these seizures only last a few minutes. Although partial seizures are characteristic of this disorder, generalized seizures are not infrequently observed, particularly in younger children.[71,82] The initial event is often a nocturnal hemifacial convulsion, which may spread to the arm and the leg or may become secondarily generalized. It is highly probable that in these cases a focal seizure begins during sleep with a rapid generalization and loss of consciousness, which makes it difficult for the child to remember what happened. This is in line with the fact that almost all seizures that start while the person is awake are focal.

4. Behavioral and learning problems are less frequent than in other forms of childhood epilepsy.[58] It is often mentioned that children with BCECTS are free of neurological and psychological impairments.[45,46,71] In recent years, however, several reports based on meta-analyses of published series, retrospective analysis of patients, or prospective cohort studies have reported a higher incidence of learning and/or language difficulties in these children. In a study of 40 children with centrotemporal spikes with and without seizures compared with 40 healthy controls, patients were significantly impaired in IQ, visual perception, short-term memory, and psychiatric status. The deficits in IQ correlated more with frequency of EEG spikes than with the frequency of seizures.[122] Similar findings were reported in 19 children with this syndrome.[29] An increased frequency of rolandic spikes has been reported in children with attention deficit hyperactivity disorder.[59] One study found a consistent pattern of language dysfunction in 13 of 20 children with BCECTS, suggesting interictal dysfunction of the perisylvian language areas.[113] A longitudinal study of one boy with acquired epileptic dysgraphia was reported. Most probably, in this case, the acquired regression of graphomotor skills was associated with an increase in spike frequency as happens in cases with atypical evolution of this syndrome.[33] In a more recent report, written language skills were compared in 32 children with typical BCECTS with 36 controls. As a group, the patients with BCECTS performed significantly worse than controls in spelling, reading aloud, and reading comprehension, presented dyslexic-type errors, and frequently had below-average school performance.[102] Language assessment in 16 children with BCECTS also showed that the domains of expressive grammar and literacy skills were affected in a significant proportion of the cases.[89] A comprehensive study of neuropsychological and language profiles of 42 children with BCECTS selected using strict clinical and EEG criteria showed that the patients have normal intelligence and language ability, although a specific pattern of difficulties in memory and phonologic awareness was found. No correlation between EEG features and the aforementioned impairments was demonstrated.[94]

Atypical features in benign childhood epilepsy with centrotemporal spikes can be seen both clinically (daytime-only seizures, postictal Todd paresis, prolonged seizures, or even status epilepticus) and in EEG features (atypical spike morphology, unusual location, or abnormal background). In a retrospective case series, atypical clinical features were seen in 50% of patients and atypical electrographic features in 31%.[123] In a follow-up study of 74 children with typical rolandic epilepsy and 14 with atypical features, a significantly higher percentage of learning and behavioral disabilities was found in the second group.[120]

Several cases of partial status epilepticus have been reported. The manifestations include hemifacial seizures, dysarthria or anarthria, and persistent drooling.[20,43,44,52,66,106,107]

Diagnostic Evaluation

Electroencephalographic Findings

After recognition of typical clinical features, the cornerstone of the diagnosis of BCECTS lies in the characteristic interictal EEG pattern, which include the following features:

1. Background EEG activity is symmetric, well organized, and normally reactive during wakefulness, and the physiologic patterns of sleep are also normal.[25,26]
2. Interictal epileptic discharges and location of spikes are characterized as follows:
    a. *Characteristics of spikes*: Typical centrotemporal spikes (CTS) are located in centrotemporal or rolandic areas (Fig. 1). They are broad, diphasic, high-voltage (100–300 μV) sharp waves, with a transverse dipole, and they are often followed by a slow wave. The spikes may occur isolated or in clusters, with a rhythm of about 1.5 to 3 Hz.[79] Focal rhythmic slow activity is occasionally observed in the region in which the spikes are seen, especially when spikes are frequent.[87] They may be seen in only one hemisphere or independently on both sides of the head (Fig. 2).[37] The CTS tend to spread to adjacent regions. Several authors emphasized the characteristic dipole orientation in the EEG.[53,76,115] Two groups of patients have been found based on EEG findings (maximal negativity was registered in high- and low-central regions, but never in midtemporal regions): (a) a high-central-region group with more frequent hand involvement and (b) a low-central group with common orofacial symptoms.[70] The source distribution of benign rolandic spikes along and across the central sulcus was examined in 15 patients between 7 and 15 years of age. The equivalent current dipoles of the spikes measured by whole-head MEG were compared to the spike distributions detected by simultaneous scalp EEG. Rolandic spikes are consistent with by a precentral origin, assuming that the surface negative potential is continuous from the gyral to fissural cortices.[62]
    b. *Enhancement of discharges*: The centrotemporal spikes are not enhanced by eye opening or closure, hyperventilation, or photic stimulation. Moreover, hyperventilation sometimes reduces the frequency of rolandic spikes.[45,121] The discharge rate is increased in drowsiness and in all stages of sleep, and in about one third of children, the spikes appear only in sleep.[81] Sleep EEG organization is preserved.[23] In spite of their increasing frequency during sleep, the CTS show the same morphology as during wakefulness. A change in morphology, particularly the appearance of fast spikes or polyspikes, a marked increase in the slow component, or a brief depression of voltage, suggests an organic etiology even when the ictal features are suggestive of BCECTS.[25] There is no correlation between intensity of spike discharges in the EEG and

P.2372

frequency, length, or duration of clinical seizures.[72] In fact, extreme discrepancies between the rarity of seizures and the activity of the EEG foci are not uncommon, and clinical experience indicates that the EEG is often relatively unchanged, even with effective treatment.[5]

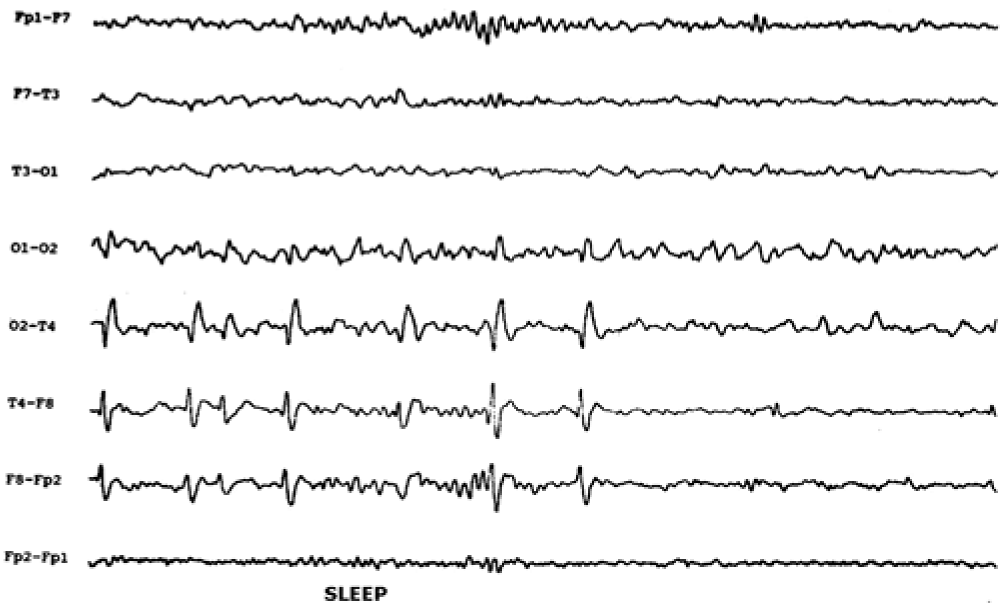

FIGURE 1. Sleep electroencephalogram (EEG) in a 6-year-old girl with typical seizures and right centrotemporal spikes.

c. *Spikes in other areas and spike-wave discharges*: Spike foci may coexist in other areas independent of their clinical correlation.[71,100] Generalized spike-wave discharges are rarely seen in the waking state but are not infrequent during drowsiness and sleep.[11,45] The real incidence of spike-wave discharges in children with BCECTS is not established; numbers vary between 7% and 65%.[25,27] One must be cautious in interpreting this because bursts of slow waves with spikes in drowsiness are seen in up to 20% of children between 3 and 6 years of age, especially those with history of febrile seizures.[2] We will see later that the coexistence of BCECTS with the Panayiotopoulos type of benign occipital epilepsy is not rare, whereas its association with absence epilepsy is exceptional.

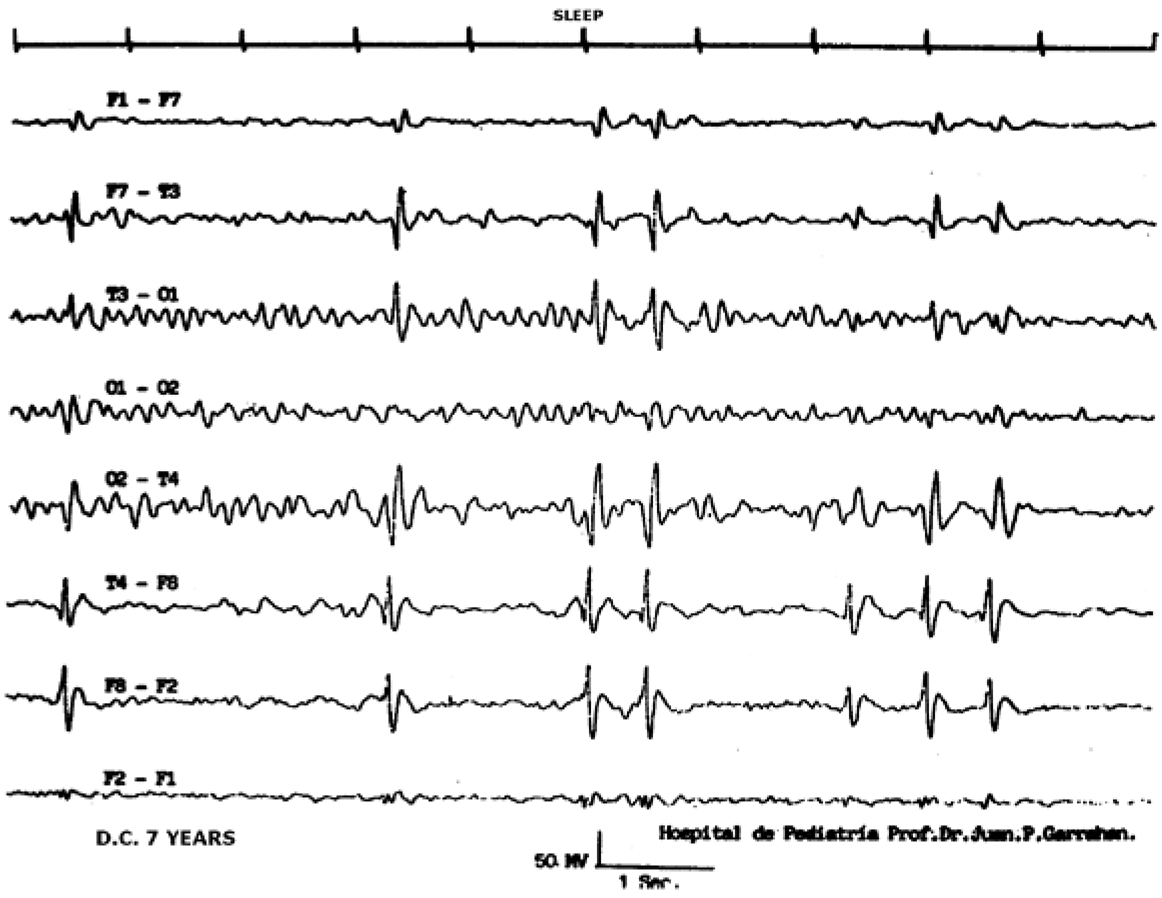

FIGURE 2. Sleep electroencephalo-gram (EEG) in a 7-year-old boy with typical seizures and bilateral centro- temporal spikes.

3. With regard to the frequency of discharges and the correlation with cognitive deficits, the association of more frequent discharges or multifocal paroxysms with complicated evolution in BCECTS is a debated subject.[25,85] It is clear, however, that the appearance of bilateral synchronies leading to continuous spikes and waves during sleep are frequently associated with severe cognitive and language impairment.[43] In a recent study of 20 children with benign partial epilepsies who were studied by combined EEG, MEG, and MRI, location of spikes was determined by dipole source estimates. There was a correlation

P.2373

between location of spikes and selective cognitive deficits, with left perisylvian spikes associated with poorer language test results in 11 cases, whereas 6 children with right perisylvian location performed within normal ranges in all parts of the tests.[124] In a small group of patients with status epilepticus in BCECTS, the finding of independent right and left seizures was considered a risk factor.[52]

4. EEG studies in large numbers of healthy children revealed centrotemporal spikes in 2.1% of 533 children between 6 and 15 years of age;[35] in 2.4% of 3,726 children between 6 and 13 years of age;[19] and in 3.5% of 1,057 children between 6 and 12 years of age.[95] Considering that in many of the cases the EEGs were performed in the waking state, we may assume that the actual figures should be higher. The fact is that in a vast majority of children with CTS, a genetically determined cortical excitability produces the EEG abnormalities, which in a few patients are associated with clinical seizures. It has been estimated that <25% of children with CTS have seizures.[82] The presence of CTS was also reported in children with Rett syndrome and fragile X syndrome and even in children with brain tumors.[69,90,93]

5. Reports in the literature on ictal EEGs in children with BCECTS are scarce and only deal with isolated cases.[3,26] The ictal pattern is generally characterized by a sequence of rhythmic spikes remaining quite monomorphic throughout the discharge. Lerman described a diurnal seizure with local decremental activity followed by dense spikes confined to the centrotemporal area during the tonic phase and with spike-waves during the clonic phase.[71]

Neuroimaging and Other Laboratory Examinations

When the clinical and EEG features are typical, the diagnosis is certain, and therefore neuroimaging in BCECTS has been regarded as superfluous by many authors.[5,71] However, several reports called attention to a higher percentage of brain abnormalities in children with typical BCECTS. Gelisse et al.[50] presented the case of a 10-year-old-boy with marked right hippocampal atrophy, although they concluded that the seizure disorder could not be ascribed to this abnormality. The same group reported computed tomography (CT) or MRI abnormalities in 10 of 71 consecutive patients with BCECTS, but the sample was most probably biased because 2 of the 5 children showing enlargement of the lateral ventricle had shunted hydrocephalus.[49] Hippocampal asymmetries and white matter abnormalities in MRI have been reported in 33% of 18 children with BCECTS, but the relationship was considered unclear.[83,84] On the other hand, because of a few cases that have presented the clinical and EEG phenotype of BCECTS in whom cortical dysplasia[3,40,110] and even brain tumors[111] were found, one might question whether an MRI study is indicated. Based on these findings and the evaluation of what happens in everyday practice, it is legitimate to obtain an MRI study to avoid the possibility of ignoring existing abnormalities.

Very few studies using positron emission tomography (PET) have been performed in children with BCECTS. De Saint-Martin et al.[30] reported a longitudinal study of a child with BCECTS using F-fluorodeoxyglucose (FDG) PET. They found a bilateral increase of glucose metabolism in the temporal opercular regions interictally during the "active" phase of the epilepsy. In 11 children with BCECTS studied with FDG-PET, no interictal side differences in glucose metabolism were demonstrated.[117]

Differential Diagnosis

Several series of children with BCECTS have included some patients with cerebral palsy.[13,72,82] Distinction between benign childhood epilepsy with centrotemporal spikes and more serious nonidiopathic epileptic conditions, such as mesial temporal lobe epilepsy, can usually be made easily on the basis of history and the unique dipole pattern of the centrotemporal spike. However, benign focal epileptiform discharges were found in 2 of 17 preadolescent children who eventually underwent anteromesial temporal resection for refractory temporal lobe epilepsy due to hippocampal sclerosis, and the authors suggested that it might not have been an incidental finding.[98] Because of their prevalence, fortuitous associations may be found between benign childhood epilepsy with centrotemporal spikes and nonprogressive brain lesions.[108] Isolated cases of children with BCECTS and unilateral opercular neuronal migration disorders have been published.[3,40,110] Cerebral tumors presenting as pseudo-benign partial epilepsy in childhood with centrotemporal spikes were reported in five patients.[111] Five children with a so-called "malignant rolandic-sylvian epilepsy" secondary to neuronal migration disorders and gliosis were reported as presenting similar clinical and EEG features of benign childhood epilepsy with centrotemporal spikes. The authors emphasized the role of MEG in the differential diagnosis.[96]

The pathophysiologic relationships that may exist between benign childhood epilepsy with centrotemporal spikes and other benign partial nonrolandic epilepsies can make differential diagnosis difficult. The coexistence of two types of benign partial epilepsies in children, namely Panayiotopoulos type of benign occipital epilepsy and BCECTS, has been reported, presenting either in sequence one after the other or at the same time,[18,22,99] although treatment and prognosis are the same.[73]

FIGURE 3. Sleep electroencephalogram (EEG) in a 7-year-old boy with a history of typical benign childhood epilepsy with centrotemporal spikes and onset of inhibitory seizures. Bilateral, almost continuous spike-wave discharges are seen.

Treatment and Outcome

In considering outcome in children with BCECTS, it is necessary to consider control of seizures on one hand and the incidence of neurological impairments, either transitory or persistent, on the other. Antiepileptic drug treatment is usually effective, although many authors believe that drug treatment is not necessary in the benign focal epilepsies of childhood.[25,47,100] Therefore, continuous treatment should be considered only in patients with frequent seizures and when the ictal events are disruptive to the patient or family. Carbamazepine was always the drug of choice. However, the use of benzodiazepines at night may be considered in those children who have seizures only during sleep. Benzodiazepine treatment for several weeks was also recommended.[28] In comparison with valproate and carbamazepine, clonazepam was found to be more effective in suppressing rolandic discharges after 4 weeks of treatment.[88] Sulthiame has been recommended in several reports.[31,71,74] In a double-blind, placebo-controlled study of 66 children with BCECTS, sulthiame was found to be remarkably effective in preventing seizures and was well tolerated.[105] A more recent report also showed the benefits of sulthiame.[38] Among new drugs, oxcarbazepine and levetiracetam showed good results.[10,116] Curiously enough, an ictal clinical and EEG study in one child suggested that voluntary protrusion of the tongue could stop seizures and EEG discharges.[119]

P.2374

A meta-analysis of outcome in 794 patients in 13 cohorts, concluded that early prediction of seizure outcome in a new patient cannot be given with certainty.[15] It was stated that the only predictor for a disease course in children with multiple seizures is onset before 3 years of age.[68]

In a prospective study of treatment in childhood epilepsy, it was concluded that 1 year of treatment can be recommended in children with benign childhood epilepsy with centrotemporal spikes.[16] In fact, once the decision to treat is made, it is not possible to make a firm recommendation regarding duration, but there is no need to wait for normalization of the EEG to stop medication. Relapse of seizures, however, may occur after premature withdrawal.[79]

If it is considered that there is risk of an atypical evolution due to worsening of the EEG, an increase in the number of seizures, the presence of inhibitory seizures, or evidence of neuropsychologic abnormalities, the following steps should be taken: First, stop the medication if it is carbamazepine, oxcarbazepine, phenytoin, or valproic acid, and then switch to a benzodiazepine, ethosuximide, or sulthiame. Two of our cases of BCECTS status only responded to treatment with steroids.[44] Sulthiame seems to be the drug of choice in patients presenting atypical evolution associated with secondary bilateral synchrony in the EEG.[41,43]

Long-Term Prognosis

In general, benign childhood epilepsy with centrotemporal spikes is associated with an excellent prognosis. Seizures are difficult to control in only a small number of cases.[9,12] The prognosis is favorable even in patients whose seizures are difficult to control as seizures almost always remit spontaneously in adolescence. In their investigation of 168 patients 7 to 30 years after cessation of epilepsy with centrotemporal spikes, Loiseau et al. reported that seizures persisted in only 3 cases after adulthood.[80] The seizures were all generalized tonic–clonic seizures. Two of the 3 had obviously isolated incidences. This incidence of generalized seizures in adults with a history of epilepsy with centrotemporal spikes in childhood is nevertheless higher than that of seizures in the general population.[80] Cognitive functions were evaluated in 23 adolescents and young adults in complete remission from BCECTS and showed no significant differences from controls. However, qualitative analysis suggested a different organizational pattern for cerebral language in adolescents and young adults in remission.[60]

The presence of atypical interictal epileptiform EEG patterns does not appear to alter prognosis.[11] However, atypical evolutions may cause doubt about the prognosis. For example, in the cases of benign atypical partial epilepsy described by Aicardi and Chevrie,[1] affected children showed partial or generalized atonic fits leading to multiple daily falls. These inhibitory attacks appeared in clusters that lasted for weeks, and the EEG showed continuous spikes-and-waves during slow wave sleep (Fig. 3). Status lasting days or weeks including motor facial seizures and anarthria with persistent drooling constitute other complications of this syndrome.[43,44] Both complications were still associated ultimately with a good prognosis. However, acquired epileptic aphasia and the syndrome of continuous spikes-and-waves during slow sleep have also been associated with BCECTS, and in these cases the risk of permanent language dysfunction or neurological abnormalities is clearly present.[40,43] EEG activity in these atypical evolutions seems to be a kind of secondary bilateral synchrony, but it is not understood why some children develop this EEG pattern. In some cases, certain antiepileptic drugs seemed to be responsible.[18,103,112]

Summary and Conclusions

Benign childhood epilepsy with centrotemporal spikes is an idiopathic childhood epilepsy characterized by well-defined

P.2375

electroclinical features, including brief hemifacial motor seizures, with sialorrhea and speech arrest, occurring more frequently during sleep, associated with centrotemporal spikes in the interictal EEG. It is the most frequent epilepsy syndrome in children between 4 and 12 years of age.

In general, BCECTS is associated with very good prognosis, with electroclinical normalization in puberty. There are rare cases (approximately 2%) with atypical evolutions leading to significant neuropsychologic impairments. This event should be recognized as early as possible.

Treatment is not always necessary. Common antiepileptic drugs can be used, but in the presence of atypical features such as increase in the number of seizures, onset of inhibitory seizures, continuous spike and waves during slow sleep in the EEG, and language or behavioral involvement, the best choice is benzodiazepines or sulthiame.

Chapter 237

Early-onset Benign Childhood Occipital Epilepsy (Panayiotopoulos Type)

Natalio Fejerman

Introduction

In the first edition of this book, only a few lines mentioned this condition under the heading of Childhood Epilepsy With Occipital Spikes and Other Benign Localization-Related Epilepsies.[33] At present, early-onset benign childhood occipital epilepsy (Panayiotopoulos type) (EOCOE) is not only a clearly recognized syndrome, but it also represents the second-most-frequent benign focal epilepsy syndrome in childhood after benign childhood epilepsy with centrotemporal spikes (BCECTS). The characteristic clinical features of this syndrome should be known not only by epileptologists and neurologists, but also by pediatricians. An early diagnosis would avoid undue interventions and concerns on account of its really benign outcome.

Historical Perspectives

In the International League Against Epilepsy (ILAE) classification of Epilepsy syndromes,[11] besides the well-known BCECTS, only childhood epilepsy with occipital paroxysms (CEOP), as described by Gastaut, is recognized.[29] In comparison with BCECTS, which has a prevalence of approximately 15% among children with epilepsy,[15,18,52] the Gastaut type of CEOP is rare, of uncertain boundaries, and often of unpredictable prognosis.[8] This condition is characterized by brief seizures with mainly visual symptoms such as elementary visual hallucinations, illusions, or amaurosis, followed by hemiclonic convulsions. Postictal migraine headaches occur in half of the patients. Age at onset is approximately 8 to 9 years. The electroencephalogram (EEG) shows occipital spike-wave paroxysms that attenuate or disappear when the eyes are open.[11,29,30,47]

In 1989, two significant papers of Panayiotopoulos based on an already long follow-up of his patients called attention to the particular cluster of symptoms present in what he called "benign nocturnal childhood occipital epilepsy."[49,50] He had already emphasized vomiting as an ictal symptom in epileptic seizures in children 1 year earlier.[48] Another peculiar clinical feature of EOCOE was the "cerebral insult–like" partial status epilepticus including autonomic symptoms.[38,57,64] To stress the variable phenotypes of benign focal epileptic syndromes in childhood, Panayiotopoulos and coworkers used the term "benign childhood seizure susceptibility syndromes."[51,52] After 1996, Fejerman and coworkers proposed naming this syndrome early-onset benign childhood occipital epilepsy (Panayiotopoulos type) as opposed to late-onset childhood occipital epilepsy (Gastaut type).[7,8,19,20,21,22] Three important series of children with this syndrome were published about this time.[25,37,45] Retrospective analysis of the clinical histories allowed the authors to study the variants of childhood epilepsies with occipital paroxysms and to recognize this early-onset variant. In the same year, the first prospective study of 66 children with EOCOE was published.[8] In 2001, the task force on Classification and Terminology of the ILAE published a proposed diagnostic scheme for people with epilepsy.[17] It adopted the names proposed by Fejerman including eponymic designations to emphasize the differences between the Gastaut type and the Panayiotopoulos type of childhood epilepsy with occipital paroxysms, keeping intentionally the term "benign" only for this early-onset form.[19,20] Thereafter, several authors preferred the eponymic term "Panayiotopoulos syndrome" (PS) to include patients with and without occipital spikes or occipital ictal origins.[3,8,13,14,16,26,27,28,36,42,54,56,59] Considering the emphasis given in recent years to the presence of autonomic seizures and autonomic status epilepticus in this condition, that occipital EEG abnormalities are not found in a certain proportion of the cases, and that there is no clear documentation of an occipital origin of seizures, we agree that the name PS might be more appropriate. As a practical measure, we will continue to refer to EOCOE as PS in this chapter.

Definitions

Types of seizures, age of onset, normal neurologic status of patients, and spontaneous evolution allow us to define the PS as a benign, age-related focal epilepsy syndrome occurring in early and mid-childhood. The analysis of several large series of published cases and our own present series clearly demonstrates the significant frequency of PS, which is seen about one third as often as BCECTS.

Epidemiology

PS is seen only in children, with a peak incidence between 4 and 5 years of age. Given that the official recognition of EOCOE or PS took place only in 2001, it is very difficult to find epidemiologic studies in a childhood population that include PS among the diagnoses. Additionally, most studies are based more on seizure types than syndromes. One study included a mix of seizures and syndromes for the recognition of epilepsies in 440 consecutive pediatric patients. Thirty-six (8%) of the cases were diagnosed as benign rolandic epilepsy of childhood and 8 cases (2%) as benign occipital epilepsy of childhood. We may assume that this last group was underevaluated, and we do not know how many of the cases corresponded to PS.[39] A cohort of 407 children with their first unprovoked seizure was followed for a mean of 9.4 years, and distribution of epilepsy syndromes was reported: Of 114 children with localization-related

P.2380

epilepsy syndromes, 26 were idiopathic, 24 were rolandic, and only 2 were occipital.[60] Another study of a population-based, active-prevalence cohort in children <16 years of age was able to classify syndromes in 235 (96%) of the 245 patients followed for many years. However, no specific data about PS were included in any of these three studies because they were based on the 1989 ILAE Classification.[61] Therefore, one has to credit the everyday experience of active epileptologists caring for children, who have become aware of this condition in the last few years:[3]

- Oguni et al. 1999: Among 649 children with localization-related epilepsy selected from their database, 62 met the criteria for diagnosis of PS.
- Kivity et al. 2000: A file review of patients with occipital EEG paroxysms disclosed 72 children with typical PS.
- Caraballo et al. 2000: A prospective study selected 66 patients with PS with strict criteria for inclusion.
- Lada et al. 2003: A retrospective analysis of clinical and EEG records included 1,340 children with focal seizures; 43 who had PS and >2 years since they were seizure free were followed-up.
- Caraballo and Fejerman 2005: The addition of new cases after the 66 reported in 2000 provided a total of 156 children with typical PS who were followed prospecti-vely.
- Panayiotopoulos 2005: In an ongoing hospital-based, prospective study at the end of 3 years, 228 children aged 1 through 14 years with one or more seizures had one or more EEGs. Fourteen of them (6.1%) had Panayiotopoulos syndrome.[54]

Etiology and Basic Mechanisms

As an idiopathic epilepsy syndrome, PS is by definition not associated with remote symptomatic or acute symptomatic etiology. Most likely, it is genetically determined, although neither a gene nor a chromosomal locus has been found in PS. Linkage with chromosome 15 has been reported in BCECTS,[43] although in another study this locus was not found.[58] One affected sibling with PS was reported in one series,[25] and two pairs of affected siblings were seen in each of two other series.[8,42] Three siblings were reported in 1987 as having benign occipital epilepsy as described by Gastaut, although the paper indicates that the three siblings showed seizures starting at ages 4 and 5 years, and the clinical features were quite compatible with PS.[40]

There is a high prevalence of febrile seizures in children with PS, ranging from 16% to 45%.[8,13,14,25,45,64] A family history of epilepsy was found in 30.3% of the cases.[8] The finding of several children with PS who at the same time or later had rolandic seizures and centrotemporal spikes typical of BCECTS as well as siblings who had either rolandic epilepsy or PS speaks in favor of a genetic linkage of these two syndromes, perhaps expressed as a reversible functional derangement of the brains cortical maturation.[6,8,13,14,24,50,52,54,56] Basic mechanisms and pathophysiology of PS are largely unknown. Clinical findings indicate that there is a diffuse cortical hyperexcitability, which is related to maturation.[14,26,54] Even when the majority of cases show occipital spikes, a significant number of patients have spikes in other areas, and according to the mentioned reference of PS and BCECTS in the same children, spikes may appear in two areas at the same time or over the course of time.[6,13] In addition, the high frequency of ictal vomiting indicates that epileptic discharges are generated at various cortical locations. The same concept is valid for other autonomic manifestations. As we will see later, different cortical locations in patients with PS were also documented with magnetoencephalo-graphy.[36]

Table 1 Frequency of seizure types in children with Panayiotopoulos syndrome

Core clinical features

- Ictal emetic symptoms and other autonomic manifestations
- Deviation of the eyes
- Impairment of consciousness

Frequent types of seizures

- Unilateral clonic or tonic–clonic seizures
- Secondary generalized tonic–clonic seizures
- Encephalopathy-like status epilepticus (focal motor—unilateral or generalized—and autonomic)

Less frequent but not rare symptoms and signs

- Visual symptoms
- Migraine-like headaches
- Incontinence of urine and feces
- Syncope-like symptoms
- Other

Clinical Presentation

Panayiotopoulos syndrome occurs in children who are otherwise normal; it is not associated with neurodevelopmental problems. Although it has been described as starting as early as 1 year of age and as late as 14 years of age, the large majority of patients have their first seizure around the age of 4 to 5 years. Three fourths of patients have their first seizure between the ages of 3 and 6 years. It affects boys and girls almost equally. Seizures occur predominantly during sleep, and only in sleep in two thirds of patients. In seizures occurring while the patient is awake, onset may be inconspicuous with pallor, agitation, feeling sick, and vomiting. At this stage, the epileptic nature of the event can hardly be suspected in the absence of motor convulsive symptoms that, if present, may be rightly considered as secondary to an ongoing serious brain insult. It is only the normal postictal state of the child that should be reassuring.

The duration of the seizures is usually long, commonly >5 minutes, and in approximately 40% of the cases, >30 minutes, constituting then a focal or secondarily generalized status epilepticus. Three groups of symptoms are recognized, as shown in Table 1.

Core Clinical Features

Ictal Emetic Symptoms and Other Autonomic Manifestations

Ictal vomiting, which is considered to be exceptional in other epilepsies, occurs in approximately 80% of the cases with PS.[8,13,25,42,45,48,49,50,54,55] In one prospective study, vomiting was considered a criterion for inclusion, although we now know that vomiting is not present in 100% of the cases.[8] In nocturnal seizures, it is usually the first apparent symptom, whereas in seizures occurring while the patient is awake, other symptoms of the emetic spectrum such as nausea or retching may appear along with or before vomiting.[13]

Vomiting may occur repetitively or only once during the seizure.

Pallor is the most frequent autonomic manifestation. It occurs mainly at onset and commonly together with vomiting. In seizures starting while the patient is awake, pallor, nausea, and "feeling sick" are frequent symptoms.

Deviation of the Eyes

Unilateral deviation of the eyes is as common as vomiting and also occurs in approximately 80% of the patients.[8,25,45,48,49,54,56] The eye deviation may be brief or prolonged and is frequently accompanied by head deviation. It may be continuous or, less often, intermittent. Consciousness is often but not invariably impaired at this stage. It should be noted that exact details of this symptom are rarely witnessed because seizures occur mostly at night.

Impairment of Consciousness

Consciousness is usually intact at seizure onset but becomes impaired in 80% to 90% of cases as the seizure evolves. Impairment of consciousness may be mild or moderate, with the child retaining some ability to respond to verbal commands but often talking out of context. In seizures with motor components occurring during sleep, complete loss of consciousness may be seen, especially in all those that are prolonged into status. In diurnal seizures, clouding of consciousness usually starts after the appearance of autonomic and behavioral symptoms. Awareness may be preserved throughout the ictal state in 10% to 20% of the seizures.[25,45,46,50,54,56]

Frequent Features of Seizures

Unilateral Clonic or Tonic–Clonic Seizures

Unilateral clonic convulsions in face and extremities at onset or following vomiting and eye deviation are seen in 25% to 30% of the cases.[8,54,55]

Secondarily Generalized Tonic–Clonic Seizures

This type of seizure rarely appears at onset and usually follows seizures starting with focal motor manifestation. In one series of patients, this course was seen in nearly 40% of the cases.[8]

Status Epilepticus

This is usually nonconvulsive, lasts >30 minutes, and occurs in approximately 30% of cases in all series.[8,25,45,49,54,55,56] This “encephalopathy-like” form of status epilepticus may progress to hemiconvulsions. We will show under the heading of differential diagnosis how important it is to recognize PS when it may mimic other pathologies caused by true cerebral insult.

Less Frequent, but Not Rare, Symptoms

Visual Symptoms

Visual symptoms are typical of the Gastaut type of CEOP. However, in patients with PS, elementary visual hallucinations, illusions, and blindness were registered in <10% of children who were able to describe them.

Migraine-Like Headaches

These are rarely present, and in older children may sometimes cast doubt on a differential diagnosis with the Gastaut type of CEOP.

Incontinence of Urine and Feces

This may occur when consciousness is impaired.

The occurrence of syncope-like symptoms is another autonomic manifestation that has been emphasized more recently. Children becoming completely irresponsive and flaccid, often without convulsions, are not considered rare by many authors.[13,14,26,54,56]

Diagnostic Evaluation

Neuroimaging and Other Laboratory Examinations

By definition of an idiopathic epilepsy syndrome, neurologic and neuropsychological evaluations of children with PS are normal. Some of the initial symptoms may mislead the pediatrician regarding the nature of the condition, mainly when vomiting and other autonomic symptoms are present. Excessive laboratory examinations might then be undertaken. When syncope-like manifestations occur, cardiology consultation is required.

Brain imaging studies are normal. However, the spectacular nature of ictal features, and especially the frequency of status epilepticus, makes magnetic resonance imaging (MRI) necessary to rule out conditions that can provoke focal, unilateral, or generalized seizures.

Electroencephalographic Findings

The most useful laboratory test is EEG. Ictal EEG reports are rare because seizures are infrequent. The ictal discharge in PS is characterized by rhythmic monomorphic decelerating theta or delta activity that is markedly different from the episodic fast activity of visual seizures of the Gastaut type CEOP and starts either from the posterior[2,16,45,64,65] or frontal regions.[14,45] We recently registered an ictal EEG in a 4-year-old girl with a seizure consisting of vomiting, pallor, and loss of consciousness; rhythmic spike discharges could be seen starting in the right occipital region and propagating to frontal areas (Fig. 1).[4]

Because most patients with PS are first seen between ages 3 and 6 years, many of these EEGs are obtained during sleep. Sleep activates the appearance of occipital spikes in these children (Fig. 2).[8] Occipital spikes are bilateral and synchronous, often with voltage asymmetry, or unilateral. In awake EEGs, occipital paroxysms of high amplitude with sharp and slow-wave complexes that occur immediately after closing the eyes are often registered. These paroxysms are eliminated, or markedly attenuated, when the eyes are opened, a phenomenon due to fixation of sensitivity.[47,54,55] This phenomenon, which should be sought in every EEG laboratory, was considered pathognomonic of the Gastaut type of CEOP, but it is not. It has been reported not only in patients with PS, but also in patients with other conditions.[12,44]

Even when occipital spikes and spike-wave paroxysms are the main EEG feature, their absence does exclude the diagnosis of PS. It has been emphasized that extraoccipital spikes (centrotemporal, frontal, parietal) may also be found in children with PS.[14,45,52] Generalized spike and wave discharges are not seen in children with PS as frequently as they are in children

P.2382

with BCECTS.[18] Normal EEGs during sleep are exceptional according to a recent consensus report.[26]

FIGURE 1. A 4-year-old girl. Ictal EEG: The seizure started 5 seconds before the discharges seen in this sample, with rhythmic spikes in the right occipital area and propagated to frontal areas.

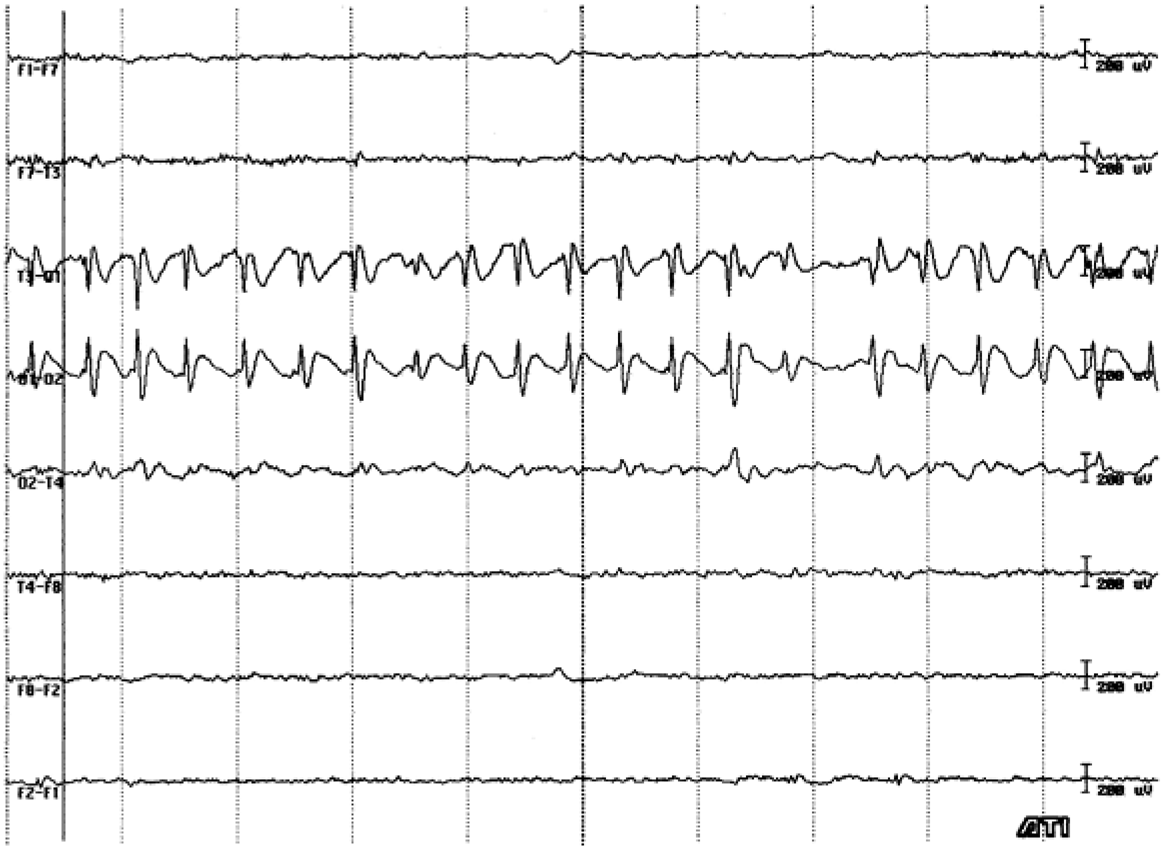

FIGURE 2. A 7-year-old boy. Left occipital spikes activated by sleep.

The evolution of EEG discharges in 76 children with PS was followed with repeated sleep EEG examinations. These showed that the occipital spike pattern was prevalent in the first few years of the diagnosis and later became associated with frontal or centrotemporal spikes.[46]

An interesting recent paper related to EEG in PS showed that a group of EEG technicians trained on the clinical features of PS were able to diagnose the condition in 14 children, and in 9 of the cases their information was crucial to achieving a diagnosis.[59]

In a recent study of eight children with PS, dipole analysis of the interictal spike discharges was performed. The various types of spikes observed in PS had similar and stable dipole locations. The dipoles showing high stability were located in the mesial occipital area and were accompanied by dipoles located in the rolandic area, suggesting a possible pathogenetic link between PS and BCECTS.[66]

Other Neurophysiologic Studies

In 13 children with PS who ranged in age from 3 to 14 years, the localizations of equivalent current dipoles (ECDs) of spike discharges by magnetoencephalography were examined. Eleven patients (84.6%) showed clustered ECDs in areas alongside the parietooccipital sulcus and/or the calcarine sulcus. Five of

the children who also presented rolandic seizures showed in addition clustered ECDs in rolandic areas.[36]

Studies of visual-evoked potentials (VEPs) were performed in 9 children with PS and 10 children with the Gastaut type of CEOP. High-amplitude VEP responses attributed to hyperexcitability of the occipital cortical structures were present in all 19 patients.[34]

Table 2 Differential diagnosis of Panayiotopoulos syndrome

With other neurologic conditions

- Encephalitis
- Acute toxic encephalopathy
- Acute disseminated encephalomyelitis (ADEM)
- Mitochondrial encephalopathy with lactic acidosis and stroke (MELAS)
- Acute cerebrovascular event
- Migraine (basilar artery migraine)
- Diseases of the autonomic nervous system

With other epilepsy syndromes

- With other idiopathic epilepsy syndromes
  - Childhood epilepsy with occipital paroxysms (Gastaut type)
  - Benign childhood epilepsy with centrotemporal spikes
  - Idiopathic photosensitive occipital epilepsy

- With symptomatic occipital epilepsies
  - Celiac disease, occipital calcifications, and epilepsy
  - Occipital epilepsy after neonatal hypoglycemia
  - Other symptomatic occipital epilepsies

Differential Diagnosis

Despite sound clinical-EEG manifestations, for many years Panayiotopoulos syndrome escaped recognition, for many reasons. Ictal vomiting is rarely considered as an ictal event. When this is associated with deteriorating level of consciousness followed by convulsions, encephalitis or other acute cerebral insults are the prevailing diagnoses at the acute stage. If the seizures are hemigeneralized, a more focal cerebral insult is always looked for. If the child is seen after complete recovery, atypical migraine, gastroenteritis, or a first seizure is a likely diagnosis. Table 2 lists the main differential diagnoses of PS. The presence of prolonged seizures in a previously healthy child inevitably leads to consideration of acute cerebral insults due to encephalitis; intoxication; acute disseminated encephalomyelitis; mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS); or acute cerebrovascular event. Complete recovery after ≥1 hours of seizures makes these diagnoses improbable, although, as stated before, brain imaging studies are usually obtained. Basilar or other infrequent forms of atypical migraine are among the main differential diagnoses in cases with prolonged or repeated vomiting with other autonomic symptoms. Both conditions may appear abruptly, and in both, full recovery is seen. Impaired consciousness does not rule out the diagnosis of migraine.[53] However, it is extremely rare for migraine to start with vomiting interrupting sleep in young children.

Syncope-like episodes with pallor, irresponsiveness, and flaccidity may lead to consideration of real syncopal attacks and to ask for cardiology examination. Of course, common syncope in children does not appear during sleep, but nausea, pallor, and sick feeling in an awake child can be the first symptoms of a syncopal attack.

Table 3 shows the differential diagnosis between PS and the Gastaut type of CEOP.

The mean age of onset of BCECTS is approximately 7 to 8 years of age, and its typical features differ clearly from those of PS. However, we will note later that it is not rare to see children presenting at the same time ictal symptoms of both syndromes. As for the idiopathic photosensitive occipital lobe epilepsy, its mean age of onset is around 11 years, and all ictal events are preceded by the exposure to photic stimulation, either intermittent lights or TV or computer game screens.[35] This condition is quite rare and less frequent than other reflex epilepsies secondary to visual stimuli.

Symptomatic occipital epilepsies may present clinical features similar to those of the idiopathic occipital epilepsies. The EEG may even show the occipital spike-and-wave discharges disappearing after eye opening that is so typical of the Gastaut type of CEOP but may also be seen in PS.[12,44] There are two particular conditions to consider in children with seizures manifested by visual symptomatology and occipital spikes or spike-waves. One is celiac disease with occipital calcifications and epilepsy. The majority of patients with this condition do not have overt symptoms of celiac disease. That is why, in the presence of occipital discharges and seizures, posterior cerebral calcifications have to be discarded. If they are present, specific studies for celiac disease are mandatory because in these children their epilepsy improves with a gluten-free diet.[1,32] Silent celiac disease was investigated in a study of 72 patients observed consecutively over a 5-year period with an initial diagnosis of idiopathic partial epilepsy. In the 47 children with BCECTS, specific antibodies were not found, but in 2 of the 25 cases with childhood partial epilepsy with occipital paroxysms (CEOP), the results were positive and later confirmed by jejunal biopsy.[41] This study did not attempt to distinguish between the Gastaut type and the Panayiotopoulos type of CEOP.

In a recent series of 12 patients, we showed a clear association between history of neonatal hypoglycemia and posterior cerebral lesions provoking seizures. Epileptic seizures in these children were usually well controlled by antiepileptic drugs (AEDs), but most of the cases presented intellectual impairment.[8]

Association of Panayiotopoulos Syndrome With Other Idiopathic Epilepsy Syndromes

Isolated cases with electroclinical features of BCECTS are occasionally found in children with idiopathic occipital epilepsies.[24,38,49,54] In 1998, idiopathic partial epilepsies with both rolandic and occipital spikes appearing were reported in ten patients. Five of them had first PS and after ≥2 years presented hemifacial motor seizures with anarthria typical of BCECTS. The other five patients presented anarthria and hemifacial contractions with sialorrhea and ictal vomiting with head deviation as typical seizures of PS and BCECTS in the same epoch and even in the same episodes.[6] This finding was later confirmed by another group of authors.[13]

Another small series of cases reporting the presence of two idiopathic epilepsy syndromes in the same children showed that absence epilepsy was associated with the Gastaut type of CEOP in five patients and with PS in one child.[10]

Table 3 Differential Diagnosis Between Panayiotopoulos Syndrome and Gastaut-Type Childhood Occipital Epilepsy

	Panayiotopoulos syndrome	Gastaut-type childhood occipital epilepsy
Prevalence among benign focal epilepsies in childhood (%)	27	3

Age at onset (yr)	1–14 (mean: 4–5)	3–16 (mean; 8–9)
Duration of seizures		
• <2 min	Exceptional	As a rule
• >5 min	As a rule	Rare
High seizure frequency	Rare	As a rule
Seizures during sleep	>2/3 of cases	<1/3 of cases
Features of seizures		
• Ictal vomiting	Frequent	Exceptional
• Deviation of the eyes	Frequent	Rare
• Impairment of consciousness	Frequent	Rare
• Visual hallucinations	Rare	As a rule
• Loss of vision	Exceptional	Frequent
• Autonomic disturbances	Not rare	Rare
• Postictal headache	Rare	Frequent
Seizures evolving into status	Frequent	Exceptional
Interictal electroencephalogram	Frequent occipital spikes; less frequent spikes in other areas.	Spike-wave occipital paroxysms reactive to eye opening
Prognosis		

• Remission within 1–3 yr from first seizure	As a rule	Rare
• Evolution into Continuous spike and waves during slow sleep	Rare (3 cases reported)	Rare (2 cases reported)
• Overall prognosis	Excellent	Uncertain

Treatment and Outcome

There is no consensus about treatment in PS. Because approximately one third of the patients only have one seizure, either

P.2384

brief or prolonged, many authors recommend not starting AED treatment.[14,56] However, it is not so easy for pediatric neurologists to advise parents after their child has had a prolonged seizure that there is no need to try to prevent further events using medication. Even when both authors of this chapter agree about the good outcome in patients without medication, one of us prefers to medicate after the first seizure when it was prolonged. Carbamazepine and valproic acid are the drugs of choice, and the latter is preferred when the EEG shows spike-and-wave discharges instead of spikes. At any rate, clear instructions should be given to parents on how to use rectal diazepam immediately after onset of a new seizure.

Long-Term Prognosis

Despite the high incidence of seizures evolving into status epilepticus, PS is a remarkably benign epilepsy syndrome.[8,14,54,56,62] One third of the patients have only a single seizure, and most of the cases present no more than two to five seizures. Remission usually occurs 1 or 2 years after the first seizure, and there are no comparable data on whether there is a significant difference in cases treated with AEDs.

FIGURE 3. A 5.5-year-old boy. Atypical evolution of Panayiotopoulos syndrome with frequent bilateral spike-wave discharges in sleep.

Regarding the risk of persistence of seizures or of developing other types of epilepsy in adult life, except for the personal experience of Dr. Panayiotopoulos, no series has reached a sufficient long-term follow-up to provide information.

A need for caution in reference to neuropsychological findings has recently been raised. A study of 22 children with PS showed that intellectual quotients were within normal limits, but selective dysfunctions were found relating to verbal and visual-spatial memory, visual-motor integration global abilities, reading and writing, and arithmetic ability.[31]

Atypical Evolutions in Patients with Panayiotopoulos Syndrome

As stated before, a number of cases presenting BCECTS after the onset of PS are well documented, and even one case with typical absence epilepsy following PS was recently reported. The concept is that even when these associations occur, long-term prognosis is almost always benign. We say “almost” because nothing is absolute in medicine. We showed three cases with typical features of PS that presented atypical evolutions quite like those described in BCECTS.[23] The three children started with inhibitory seizures and drops, atypical absences, and language and behavioral impairment associated with continuous spike-and-waves discharges in the sleep EEG (Fig. 3). They were well managed with appropriate changes in AEDs, but we do not know what the natural evolution of this complication would have been.[5,28] Moreover, ictal cardiorespiratory

P.2385

arrest was recently reported in a patient with PS,[63] an exception confirming the rule of very good long-term prognosis.

Summary and Conclusions

- Early-onset benign childhood occipital epilepsy (Panayi- otopoulos type), or Panayiotopoulos syndrome, is a clearly identifiable epilepsy syndrome that is second in frequency to benign childhood epilepsy with centrotemporal spikes among idiopathic focal epilepsies with onset in childhood.
- Vomiting and other autonomic ictal manifestations are very frequent and should call attention to the possibility of PS. The other frequent seizure features are eye deviation and impairment of consciousness.
- Approximately one third of patients present prolonged seizures evolving into status; one third of children have only one seizure.
- Sleep EEG shows occipital spikes in a majority of patients, although spikes in other areas can also be seen in more than one third of patients.
- There is no clear understanding of the mechanisms of vomiting and other autonomic ictal features and their association with interictal epileptiform discharges in the EEGs of these children.
- Prognosis is excellent despite prolonged seizures or the rare event of atypical evolutions with continuous spike-and-waves during slow sleep and its clinical correlations.
- Future research should clarify the not rare association between PS and BCECTS, perhaps based on a finding of genetic linkage explaining the different phenotypic expressions within a wider group of benign focal epilepsies in infancy and childhood.

Chapter 238

Late-onset Childhood Occipital Epilepsy (Gastaut Type)

Giuseppe Gobbi

Renzo Guerrini

Salvatore Grosso

Introduction

Occipital epilepsies commonly start in childhood or adolescence and include two etiologic groups: Symptomatic and idiopathic epilepsies. Symptomatic occipital epilepsies may be caused by brain malformations (focal cortical dysplasia, polymicrogyria, subcortical band heterotopia, periventricular heterotopia), metabolic disorders (Lafora disease, juvenile neuronal ceroid lipofuscinosis, mitochondrial disorders such as MERRF [syndrome of myoclonus epilepsy and ragged red fibers] and MELAS [syndrome of mitochondrial encephalopathy, lactic acidosis, and strokelike episodes]), and occipital bilateral calcifications (often associated with celiac disease).[95] Among the idiopathic group, the new classification system of the International League Against Epilepsy (ILAE) Task Force[30] recognizes three epilepsy syndromes: (a) the early-onset benign childhood occipital epilepsy (Panayiotopoulos type), (b) the late-onset childhood occipital epilepsy (Gastaut type), and (c) the idiopathic photosensitive occipital lobe epilepsy. The latter is included among the reflex epilepsies.

The late-onset childhood occipital epilepsy–Gastaut type (LOCOE-Gastaut type) is the topic of this chapter, while the early-onset benign childhood occipital epilepsy (Panayiotopoulos type) and the idiopathic photosensitive occipital lobe epilepsy are described in Chapters 237 and 257.

Historical Perspectives

Benign occipital epilepsy was first described by Gastaut.[35] It was considered an epilepsy syndrome with a typical clinical history and interictal electroencephalographic (EEG) pattern. The existence of an idiopathic/cryptogenic benign childhood occipital epilepsy was already evident in the first reports of Gastaut in 1950[34] and Gibbs and Gibbs in 1952.[42] Further observations corroborated the identification of "benign occipital epilepsy,"[10,25,68,93] but discussions about a new "benign migraine-epilepsy syndrome" developed among authors.[1,16,71,78,90,94] The controversy regarding whether the origin of this syndrome was epileptic or migrainous was resolved by Gastaut,[35,36] who critically reviewed the four children reported by Camfield et al.[16] and concluded that their benign occipital epilepsy constituted "a primary and independent epileptic disorder." Gastaut[36] and Gastaut and Zifkin[39] considered both visual ictal symptoms and the interictal occipital spikes and waves that appeared upon closing the eyes as the main clinical and EEG signs of the benign childhood epilepsy with occipital paroxysms (CEOP). However, it was already known that occipital foci in young children might also be a sign of a "maturational" factor in a variety of cerebral dysfunctions.[63] In fact, occipital lobe epileptogenesis with occipital spikes may occur in genetically predisposed children with visual defects at a critical stage of development.[67,73] Reactive occipital spikes have been reported in children without epileptic seizures[2,11,60,76] as well as in patients having cryptogenic or symptomatic occipital epilepsies[2,23,27,36,41,51,76,98] and those having occipital epilepsies associated with progressive disorders.[29,49,50,74,89,91] Finally, visual symptoms and reactive occipital paroxysms may be absent in CEOP.[41,54] These data cast some doubt on the existence of a true benign and idiopathic occipital epilepsy as defined, using the clinical and EEG criteria proposed by Gastaut.[35] Among patients with occipital epilepsy and occipital EEG abnormalities suppressed by eye opening, a series emerged with "nonlesional" epilepsy, remarkable age-dependent seizure onset, familial predisposition, and benign evolution.[6,23,98] According to these criteria, CEOP was included in the ILAE classification[21] as an idiopathic form having the clinical and EEG findings suggested by Gastaut,[35,36] but with an uncertain long-term prognosis. More recently, Panayiotopoulos[80,81] described a form of CEOP characterized by early onset, nocturnal seizures with tonic deviation of the eyes, and vomiting,[80,81] which has an excellent prognosis with seizure remission occurring within 1 to 2 years. On that basis, Caraballo et al.[17] proposed designating this early-onset CEOP as "Panayiotopoulos-type benign childhood occipital epilepsy," and "Gastaut type of benign childhood occipital epilepsy" the occipital epilepsy described by Gastaut.

Finally, the latest diagnostic scheme for people with epilepsy proposed by the ILAE Task Force on Classification and Terminology[30] recognized this syndrome as "late-onset childhood occipital epilepsy–Gastaut type."

Definition

LOCOE-Gastaut type is an age-related, possibly genetically determined, epilepsy syndrome, with onset ranging from 4 to 13.2 years, and with a peak of incidence at 8 years. Girls and boys are equally affected.[85]

Epileptic seizures are characterized by brief, frequent, diurnal visual hallucinations; blindness; or both. Although commonly preserved, the consciousness is mainly impaired when seizure progresses toward a hemiclonic or generalized convulsion or automatism. In 25% to 50% of cases, visual seizures are followed by pulsating headache, associated with nausea and vomiting in about 10% of patients.

Interictal EEG features consist of high-voltage spikes-and-wave complexes or sharp waves recurring rhythmically in the occipital and posterior temporal areas of one or both hemispheres, but only when the patient's eyes are closed. Fixation-off sensitivity is typical. Ictal EEG is characterized by the sudden appearance of an occipital discharge consisting of fast activity and/or spikes, which may spread to the central or temporal regions.[85]

Since both clinical and EEG findings do not exclude a symptomatic epilepsy, neurophysiologic, neuropsychological, neuroimaging, and laboratory assessment are always indicated. At

present, no definite statement on prognosis is possible,[21] even though it seems to be relatively benign, especially using rigid criteria of selection.[99]

Epidemiology

LOCOE-Gastaut type is a rare condition with a probable prevalence of 0.2% to 0.9% of all epilepsies, and 2% to 7% of benign childhood partial seizures. On average, LOCOE-Gastaut type is considered five times less frequent than Panayiotopoulos type.[85] Higher figures have been reported by Gokcay et al.,[52] who observed ten patients with LOCOE-Gastaut type among 29 cases presenting with idiopathic occipital epilepsies. A slightly higher frequency of LOCOE-Gastaut type than the Panayiotopoulos type has also been found by Tsai et al.,[99] which was attributed to the inclusion of patients with migrainous headache with focal occipital paroxysms and the exclusion of patients with adversive seizure and EEG foci beyond the occipital area.

Etiology and Pathophysiology

Gastaut[36,37] stressed the presence of genetic or functional factors, such as a predisposition to epilepsy and febrile convulsions, in 36.6% to 47% of the cases. However, patients with lesional epilepsy related to premature birth, mild perinatal distress, and HHE (hemiconvulsion-hemiplegia-epilepsy) syndrome were also included in LOCOE-Gastaut type.[36,37,41] A thalamocortical mechanism, similar to the reticulocortical mechanism of idiopathic generalized epilepsies[46] but limited to a localized thalamocortical area, was hypothesized.[34] According to the concept of "idiopathic" epilepsy, symptomatic cases are no longer included in this group of patients.

A role of genetic factors as part of the etiology is still presumed, and the recognition of familial cases strongly suggests this hypothesis. A family history of epilepsy varying from 33% to 43% in patients with occipital epilepsy has been reported by several authors.[6,60,98] Kuzniecky and Rosenblatt[65] suggested "an autosomal dominant pattern for the EEG abnormalities with age-dependent expression and variable penetrance of the seizure disorder." Nagendran et al.[75] reported a family in which two siblings had visual seizures and occipital paroxysms, and another presented with centrotemporal spikes on the EEG. Moreover, there may be an association between idiopathic generalized epilepsies and LOCOE-Gastaut type. In fact, generalized spike-wave discharges in addition to occipital epileptiform activity were noted in this group of patients.[36] In turn, in idiopathic generalized epilepsies there may be focal activity, which is typically frontal but may also occur in posterior areas.[77] Caraballo et al.[18] reported the occurrence of childhood absence epilepsy in 5 out of 35 children with LOCOE-Gastaut type. Patients with both types of epilepsy have also been reported by Sofue et al.[92] and by Grosso et al.,[53] respectively. Typical absences have mainly been found in patients with LOCOE-Gastaut type (14% of patients) rather than in the much larger group with the Panayiotopoulos type (0.6%). Therefore, it has been suggested that childhood absence epilepsy may have a closer genetic relationship to LOCOE-Gastaut type than to the Panayiotopoulos type.[18]

From a pathogenetic point of view, mechanisms underlying LOCOE-Gastaut type remain to be established. The primary visual cortex (VI or Brodmann area 17) represents the site where elementary visual hallucinations are generated. Simple visual symptoms can also be evoked by stimulation of extra-striate and prestriate (Brodmann areas 18 and 19) cortical regions. The stimulation of the latter areas can also provoke visual illusions. Recently, it has been confirmed that both the mesial and lateral occipital lobe may be involved in generating elementary visual phenomena, and that there is a wide semiologic overlapping of visual symptoms between seizures originating from these occipital areas.[15] In fact, mesial foci rapidly spread to the lateral occipital region and vice versa.[20] Occipital epileptogenic activity spreads extensively to the adjacent neocortex and to limbic structures through the projections from the occipital cortex to lateral and mesial temporal areas.[15]

In particular, reciprocal connections between temporal neocortex and the primary visual cortex have recently been confirmed.[3,62] Complex visual seizures have been considered to represent seizure spread to the temporal lobe. Blume et al.[15] suggested that structured visual phenomena require the involvement of both neocortical and limbic regions. This is consistent with the clinical occurrence of initial occipital symptoms followed by structured visual hallucinations and other temporal lobe findings.[5,102] Actually, the role of the temporal lobe in determining visual symptoms appears to be more complex. Indeed, it should be remembered that simple visual phenomena have also occasionally been reported in temporal (lateral or medial) epilepsy. Motor phenomena of both lateral and mesial occipital epileptogenesis may be explained by their access to supra-Sylvian or to brainstem motor regions.[15]

The pathophysiologic mechanisms leading to postictal headache remain also to be clarified. Migraine is considered a paroxysmal and unique neurovascular disorder.[101] According to Goadsby,[47] migraine is a disorder of sensory dysmodulation that involves the trigeminovascular system and central nervous system modulation of the pain-producing structures of the cranial structures. A multitude of factors able to increase neuronal and network hyperexcitability may trigger migraine attack. Thus, it is possible that an occipital ictal discharge triggers a genuine migraine headache through trigeminovascular or brainstem mechanisms.[84] It has been pointed out that postictal migraine headache occurs in predisposed children with impaired or labile cerebrovascular autoregulation. On that basis, occipital ictal activity may result in a persistence of vasodilation in the posterior territory of cerebral and basilar arteries with subsequent plasma extravasation and neuropeptide release.[101]

Clinical Presentation

The mean age at onset ranges from 3 to 4 to 13 to 16 years.[85,99] Gastaut and Zifkin[41] reported an upper age at onset of 19 years.

The main clinical findings of LOCOE are represented by *visual seizures*. Usually, they occur in the daytime, but are not invariably present. In some instances, triggering or facilitation stimuli have been reported: Extinction of light,[69,79] passage from light to darkness or vice versa,[8,37] and darkness.[86] In some teenage girls, seizures seem to occur with menstruation.[37,41] *Elementary visual hallucinations* are brief (5 to 20 seconds, rarely more than 3 minutes or even 15 to 20 minutes) seizures, which usually occur as an initial ictal symptom, and may represent the only seizure type (30% of the patients)[64,84] or be associated with other occipital symptoms such as illusions of ocular movements, tonic deviation of the eyes, and eyelid fluttering. This type of seizure may also be prolonged, especially when visual symptoms are followed by autonomic-migrainous postictal symptoms, and may progress to hemiconvulsions or generalized tonic–clonic seizures. *Positive elementary visual hallucinations* may consist of perception of white flashes or colored (bright red, yellow, blue, and green are prominent) unformed or formed phenomena, usually circular, commonly appearing in the periphery of a hemifield, evolving into multicolored circular patterns that multiply and enlarge during seizure progression, flashing or static, with a possible horizontal movement toward

P.2389

the other side.[84] Sometimes the patient may turn his or her head and eyes to look at them.[64] In each patient elementary visual hallucinations have a stereotypic appearance regarding morphology, colors, location, and movement. *Negative elementary visual seizures*[6,36,37] are the second most common seizure type. They consist of a sudden ictal blurred vision or amaurosis, lasting up to 5 minutes. Ictal amaurosis may be the sole event in a patient who, during other seizures, has visual hallucinations without blindness. Blindness may involve the whole visual field or be confined to a part of it (quadrantanopia, hemianopia). Hemianopia may be both ictal and postictal. The elementary visual seizures in nontreated patients may be frequent, up to several per day or week. Responsiveness is commonly preserved. Loss of consciousness usually occurs at the onset of other ictal manifestations following visual hallucinations or amaurosis, such as eye deviation or convulsions.[85]

Complex visual hallucinations and visual illusions are rare in LOCOE-Gastaut type patients, occurring in <10% of the patients. *Complex visual hallucinations* represent the progress of elementary visual seizures, and consist of hallucinations of animals, people, or scenes, or of numerals or letters, stationary or moving. In complex hallucinations an evident emotional component, such as elements from memory, unfulfilled wishes, or intense affects related to them, which is lacking in simple hallucinations, is experienced by the patient. *Ictal visual illusions* may be simple with alteration in perception of objects, such as micropsia/macropsia (dysmegalopsia), dyschromatopsia, achromatopsia, metamorphopsia, plagiopsia, kinetopsia, and teichopsia, or may be complex, such as palinopsia, teleopsia, macroproxiopia, and microtlepsia.[6,36,37,38,39,41,78,81] *Sensory hallucinations of ocular movements and pain* without detectable motion usually occur with progression of ictal elementary visual hallucinations

Nonvisual ictal seizures with occipital lobe origin may also be present in

P.2390

the context of the clinical picture. *Adversive seizures with contralateral eye deviation*, often associated with head turning, is the most common nonvisual symptom. Kivity et al.[64] reported that 79% of patients with visual symptoms experienced adversive manifestations, either independently, as a separate entity that preceded or followed the visual symptoms by weeks or months or even years, or as a part of the same event. In the latter, usually they start after visual hallucinations or occur while hallucinations persist. More often these events are severe with impairment of consciousness and may evolve into secondary generalizations or hemiconvulsions with or without secondary generalization. *Forced eyelid closure and eyelid blinking* occur in approximately 10% of LOCOE patients.[84,85] They may precede by months the onset of elementary visual hallucinations (personal observations). Other nonvisual seizures may occur as a result of seizure propagation. Visual symptoms may be followed by *hemiclonic* (44%), *complex partial* (19%), or *generalized tonic–clonic seizures* (8%).[34,35,36,37,38,39,40,41] *Partial status epilepticus* is rare.[64] Contrary to what occurs in symptomatic occipital epilepsies, progression to hemiclonic seizures is more frequent than to complex partial seizures,[24,98] and symptoms related to the temporal lobe are more evocative of a symptomatic cause.[85] *Ictal vomiting* is rare in LOCOE-Gastaut type.[32]

Rarely, *migraine-type headache* with photophobia, nausea, and vomiting with or without impairment of consciousness preceded the seizures,[2] sometimes by several hours.[41,69] Some patients may have headache during their seizures at the same time as visual symptoms.[66] It is unclear whether these were migraine-triggered seizures or migrainelike ictal symptoms. Undoubtedly, headache as an ictal event is rare.[85] By contrast, *postictal headache* is common and observed in 30% to 50% of LOCOE-Gastaut type patients. Headache is bilateral, throbbing, and often associated with nausea and vomiting, photophobia and phonophobia, and sometimes obfuscation of consciousness.[36,37,78,98] Postictal headache may be indistinguishable from migraine, especially when it follows a simple visual seizure, which may be considered as the presenting visual event of migraine with aura attack.[41] Duration ranges from 30 minutes to several hours, and appears to be proportional to the duration and severity of the preceding seizures. Postictal headache may also be present in the cases of symptomatic occipital seizures.[85]

Finally, an association between LOCOE-Gastaut type and *typical absences* has been reported. In these patients typical absences appeared at the same time as visual seizures or after 1 year. All patients had typical occipital paroxysms and a 3-Hz generalized spike-wave on the EEG.[18,53,92] *Febrile convulsions* have been reported in 14% of the patients as well.[85]

Diagnostic Evaluation

Interictal EEG

EEG shows normal background activity[6] and typical occipital dysphasic spike-and-wave complexes, spikes, or sharp-wave paroxysms of high voltage (200 to 300 μV) with a strong negative peak followed by a small-amplitude positive peak and a negative slow wave.[35,36,37,38,39] The occipital spike component has been found to be usually higher in amplitude than the negative slow waves, often exceeding 100 μV, with a duration <70 msec.[96] Occipital paroxysms are rhythmic at a frequency of 1 to 4 Hz in bursts or sequences.[36,37,81] In 5% of cases, occipital paroxysms consist of rhythmic posterior slow waves.[41] Distribution of paroxysmal abnormalities is over the occipital and posterior temporal regions of one hemisphere or over both hemispheres, synchronously or independently. When bilateral, the spikes are frequently asymmetric.[81] Topographic mapping may show the focus mainly at the occipital area mostly spreading to the parietal or temporal area. No superficial dipole field was noted by the voltage mapping of scalp EEG.[99] Other independent epileptiform discharges may be found, in addition to occipital spikes.[99] Photic stimulation does not usually affect occipital paroxysms[36,37,82] but may occasionally have an inhibitory effect.[66,82] Activation during hyperventilation has occasionally been reported.[60,66,98] Discharges are usually, but not invariably, increased during non–rapid eye movement (REM) sleep.[6,41] In some patients, discharges appear only during sleep.[66] Usually, occipital spikes disappear upon eye opening and reappear 1 to 20 seconds after eye closure.[35,36,37] Panayiotopoulos[79] and Lugaresi et al.[69] found that occipital spikes are also activated by darkness, and that in darkness they were suppressed by fixation on a very small light source (fixation-off sensitive spikes). This would indicate that the abolition of central vision (macular vision) is responsible for the appearance of occipital paroxysms.[79] The absence of the typical EEG paroxysms does not exclude the diagnosis[41,55,81,96] if the other clinical and EEG criteria are present. Moreover, occipital spikes may often occur only between the ages of 3 and 5 years.[61] Occipital paroxysms may remain in the same location during follow-up or may shift from side to side, and they sometimes may be replaced by, or associated with, bilateral rolandic spikes.[43,45,54,55,82,98] Spikes and seizures usually disappear simultaneously,[6] but epileptiform EEG abnormalities may outlast seizures.[37,54,80,96]

Although the normal background and the suppression of occipital paroxysmal discharges operated by eye opening were considered to be distinctive and characteristic of LOCOE-Gastaut type,[40,60,95] further studies showed that these features were not very specific, since they may also be observed in symptomatic epilepsies[49,50,56] and in epilepsies with undefined complex partial seizures.[70]

Ictal EEG

Electroencephalographic seizure patterns do not differ from those of other occipital epilepsies.[6] In general, in the case of brief seizures there are ictal discharges localized in one or both occipital areas and characterized by rapid spikes that slow progressively.[6,36,37] Panayiotopoulos[81,84,85] observed that in complex visual seizures the discharges are slower than in simple ones, and that ictal EEG anomalies during amaurosis are represented by pseudoperiodic slow waves and spikes, which are different from those observed during visual hallucinations. Brief seizures recorded during sleep show disappearance of interictal occipital discharges, followed by repetitive spikes of about 10 Hz that sometimes spread to the parietal region.

Other Neurophysiologic Investigations

Visual-evoked potentials (VEPs) and somatosensory-evoked potentials (SEPs) had a higher amplitude in the involved hemisphere.[41,87] Gokcay et al.[52] also reported that P100 potential amplitude values of LOCOE-Gastaut type patients were significantly higher than those recorded in healthy subjects and mostly attributed to hyperexcitability of the occipital cortical structures.

Neuroimaging and Other Laboratory Examinations

Neuroimaging is normal by definition. However, since both clinical and EEG findings do not exclude a symptomatic epilepsy[2] with unfavorable outcome, especially at the onset of the disorder,[48,51] further diagnostic investigation is needed, including neuroimaging, especially with high resolution, visual field assessment, and full laboratory evaluation (see Differential Diagnosis section).

Neuropsychological Assessment

Neuropsychological assessment could be important in children for diagnostic purposes, as well as early detection of possible cognitive disturbances accompanying nonidiopathic forms. However, to our knowledge, apart three reported cases with evolution to continuous spike-wave during sleep (CSWS) and cognitive deterioration,[31,97] any data available are on the neuropsychological profile in patients with LOCOE-Gastaut type. The few studies addressing that topic included patients presenting with both early- and late-onset childhood occipital epilepsy.[19] Since the occipital lobes are mainly involved in both low-level and high-level visual processing, including object identification and localization and face recognition, it is possible that any interictal dysfunction of occipital circuitries may have visuoperceptual difficulties as a clinical counterpart. In fact, lower performance in visuoperceptual tasks, attention, memory, and verbal functions were reported in idiopathic childhood occipital epilepsy,[58] even though studies that compared the neuropsychological outcome of patients with idiopathic childhood epilepsy with occipital paroxysms with normal controls revealed no significant differences in basic neuropsychological functions. However, a cognitive profile with relatively better verbal than performance abilities, a high incidence of scholastic disabilities, and the presence of psychiatric disturbances in the form of anxiety and depressive disorders was found in a cohort of patients with idiopathic occipital epilepsy.[19]

Differential Diagnosis

LOCOE-Gastaut type has to be differentiated from the Panayiotopoulos-type childhood-onset epilepsy, photosensitive idiopathic occipital epilepsy, symptomatic occipital epilepsies (including malformations of cortical development), temporal epilepsies, idiopathic generalized epilepsy, and migraine.

Concerning the Panayiotopoulos-type childhood-onset epilepsy, cardinal differences are age at onset of seizures, higher frequency, shorter duration, and daily occurrence of seizures. Ictal vomiting is commonly lacking, even though it may sometimes occur after visual symptoms.[33,99]

In the case of photosensitive idiopathic occipital epilepsy, age at onset is around the fourth year of life with visual symptoms consisting of either blurred vision or ictal amaurosis followed by secondary tonic–clonic generalization. Seizures are typically triggered by televisions or less often by video games. Interictal EEG shows occipital paroxysms activated by intermittent photic stimulation. Ictal EEG is characterized by spike-and-wave occipital paroxysms spreading to the temporal areas.[57,82,83,84,85]

Symptomatic occipital epilepsies often imitate LOCOE-Gastaut type. In fact, although Gastaut and Zifkin[41] stated that the ictal symptoms are different in idiopathic and in symptomatic occipital lobe epilepsy, seizure semiology analysis cannot invariably help to distinguish between different forms of occipital lobe epilepsy.[84,85,100] Therefore, clinical examination; neurophysiologic investigations; neuroimaging studies, including high-resolution magnetic resonance imaging (MRI) for the detection of subtle lesions; and neuropsychological assessment are needed for a correct etiologic diagnosis. Interictal EEG in symptomatic forms may show focal or diffuse abnormal background activity,[98] occipital polymorphous delta activity,[41] and prolonged bursts of sharp waves in temporo-occipital regions,[23] frequently associated with secondary generalization, occipital bursts of fast activity,[48] or multifocal spikes that are semiologically different from those of benign childhood epilepsy with centrotemporal spikes. The interictal abnormalities are enhanced during sleep and often show morphologic modification into rapid rhythms or polyspikes and waves.[51] Sleep interictal EEG is especially useful in the differential diagnosis of some symptomatic cases in whom the clinical and waking EEG features resemble those of a LOCOE-Gastaut type at the beginning of disease[44,51,76] but in whom progressive severity becomes apparent after a benign onset (Fig. 1). In this "malignant variant," occipital polyspikes or rapid rhythms during sleep are the only early warning sign.[48,51] Brain mapping of the occipital spikes in LOCOE-Gastaut type shows the spike maximum in the occipital area, while in symptomatic occipital lobe epilepsy it is located away from the occipital pole, often in the temporo-occipital or the parieto-occipital areas.[72] Clinical and EEG findings in the different forms of occipital epilepsy are summarized in Table 1.

Finally, among the symptomatic occipital epilepsy causes should be considered celiac disease[49,50] Lafora disease[89]; neuroaxonal dystrophy with myoclonus epilepsy; mitochondrial diseases, such as MELAS and MERRF[4,29,91]; and metabolic disorders such as hyperglycemia,[59] in which occipital lobe seizures and EEG abnormalities may be present in the early stages, before other clinical features are present; and hypercalcemia, nonketotic hyperglycinemia, hypoglycemia (in neonatal age), and glycogenosis.

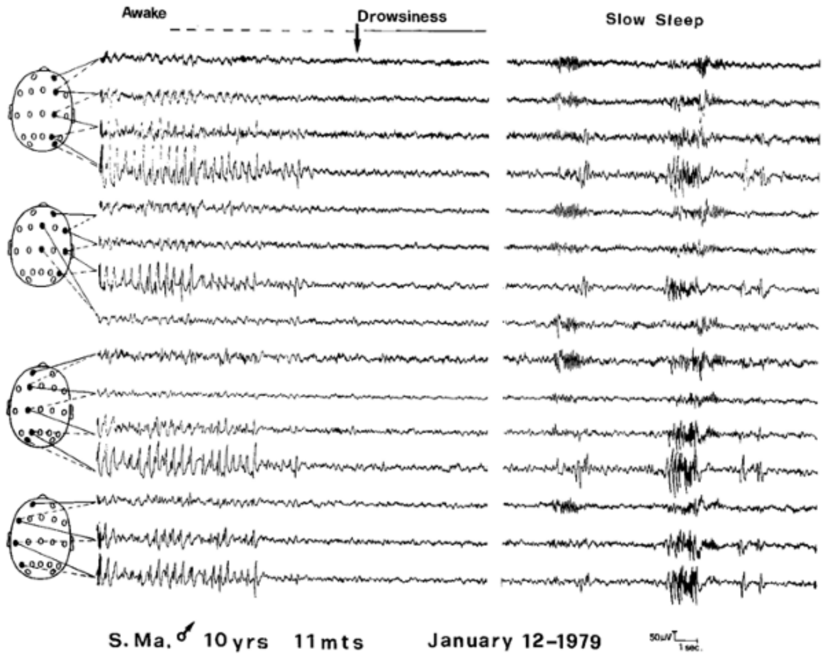

FIGURE 1. Patient with cryptogenic occipital epilepsy and severe evolution, 5 months after the epilepsy onset. **Left** (awake to drowsiness): Rhythmic bilateral occipital spikes and waves disappear in drowsiness. **Right:** Bilateral occipital polyspikes and rapid rhythms appear during slow sleep instead of occipital spikes and waves.

Childhood epilepsies with posterior temporal seizure onset[28,41,66] and complex partial seizures accompanied by

P.2391

illusions or hallucinations, followed by motor ictal phenomena, also have to be assessed. The so-called "concentric changes of visual field" seizures, which consist of continuous progressive restriction of the visual field, referred to as "tunnel vision" by patients and often associated with emotional distress, are strictly related to either the hippocampus or the temporolateral neocortex.[12] In these cases ictal and interictal EEG abnormalities are usually localized over the temporal, central, and posterior frontal region.

There may be diagnostic confusion between idiopathic occipital epilepsy and idiopathic generalized epilepsy. In fact, in idiopathic occipital epilepsies of childhood there may be generalized spike-wave discharges, and, conversely, EEG of idiopathic generalized epilepsies may show focal activity, which typically occurs in the frontal regions but may also occur in posterior areas. Moreover, patients with absences or even myoclonus may report brief "blacking out" of vision, mimicking a simple visual seizure. Distinction is possible through careful electroclinical analysis.[96]

Differential diagnosis between migraine with aura, basilar migraine, and LOCOE-Gastaut type should not be difficult if all of their components are present and properly evaluated.[85] In general, the age at onset of basilar migraine is during adolescence.[7,9,13] The persistent occipital abnormalities of LOCOE-Gastaut type have rarely been reported in cases of basilar migraine.[16,78,90,94] However, elementary visual seizures followed by headache and vomiting may be especially confusing. In fact, classic distinctive criteria, suggesting that in migraine the prodrome is usually longer than 5 minutes, as opposed to the very brief epileptic aura,[26] have proved to be unreliable.[14,56,57] On the other hand, visual auras, when of epileptic origin, are multicolored with circular or spherical patterns, as opposed to the predominantly black-and-white linear pattern of migraine attacks,[83] and are followed by eye deviation and lateralized or generalized convulsions, and there are no brainstem or cerebellar symptoms.[98] Eventually, postictal EEG commonly return quickly to the pre-ictal state, in contrast to the prolonged postcritical EEG abnormalities of migrainous attacks.[6]

Treatment and Outcome

Unlike other benign childhood partial epilepsies that may not need treatment, LOCOE-Gastaut type should be treated because seizures, although brief and mild, are frequent with

P.2392

P.2393

possible secondary generalization, and the active period is variable. Most of the available data on treatment are based on studies performed when the distinction between early- and late-onset variants had not yet been defined, and the results reported could therefore be biased. In prospective studies of patients with strictly defined diagnoses, carbamazepine was able to control visual seizures.[84,85,100] It may be possible that delaying appropriate medication may adversely affect prognosis. Antiepileptic drugs do not necessarily normalize EEGs, and the epileptiform abnormalities may persist for a few years after the cessation of seizures and withdrawal of drugs.[36,54] Clusters of seizures do not seem to be influenced by antiepileptic drugs. Clobazam seems to control the seizures and spikes and waves after a few days in some difficult cases.[41,66]

Table 1 Clinical and EEG findings differentiating the idiopathic and symptomatic occipital epilepsies

Occipital epilepsies	Age at onset of occipital seizures, y	Main seizure patterns	Photoparoxysmal response	Photically induced occipital seizures	Interictal EEG findings	Outcome	References
EOBCOE- Panayiotopoulos type	2–14, peaks 4–5	Sleep-related—tonic eye deviation, unresponsiveness, vomiting	Never reported	Never reported	Normal background, occipital S or SW reactive to eye	Remission within 1–2y, before 12 y	90,91
LOCOE-Gastaut type	3–16, mean 8	Diurnal visual seizures, followed by postictal headache and often by CPS or hemiclonic seizures	Never reported	Never reported	Normal background, occipital S or SW reactive to eye	Seizures persisting into late adolescence	40,41
Idiopathic photosensitive occipital lobe epilepsy	5–17, peak at about 15	Visual symptoms, epigastric discomfort, headache, version, vomiting	Constant posterior, generalized, or both	Constant	Normal background, occipital S or SW reactive to eye opening	Good in most patients; seizures may persist with wide photosensitivity range	50,79
Symptomatic/cryptogenic epilepsy (unspecific etiology)	Variable	Varies with suprasylvian/intrasylvian spread	Not infrequent: posterior	Sporadic	Usually abnormal background, S or SW reactive or not to eye opening evolving in to rapid rhythm or pSW during sleep	Variable, with progressive occipital lobe severity (malignant variant)	56,60
Special conditions that may be associated with recurrent occipital seizures:							
Occipital lobe epilepsy (with and without occipital calcifications) and occipital lobe epilepsy with occipital calcifications (without celiac disease)	2–14	Visual and versive first; tonic, atypical/atonic absences if worsening	Not infrequent: posterior	Not infrequent	Normal or abnormal background, occipital S or SW reactive or not to eye opening, in celiac disease	Variable: favorable, or steady orprogressive severity	5,54,55
Lafora disease	6–19, peak at about 11	Visual, clonic, GTC, myoclonus	Almost constant: occipital, generalized, or both	Sporadic	Normal or abnormal background, occipital and generalized S and pSW	Progressive myoclonus, epilepsy, and mental deterioration	106
Hyperglycemia	Adulthood	Visual and versive	Never reported	Never reported	Normal or abnormal background, occipital slow waves	Drug-resistant if glucose levels abnormal	61

Among patients who had been treated, drugs were successfully withdrawn before the age of 16 in 33% of cases. According to Panayiotopoulos,[85] slow reduction of medication 2 to 3 years after the last visual or other minor or major seizure may be advisable, but if visual seizures reappear, treatment should be restored. However, a relapse at drug withdrawal is possible even after a 2-year seizure-free period,[54] and long-lasting spontaneous remission is not guaranteed. The duration of the active phase may be difficult to predict, and consequently optimal duration of treatment is hard to assess.

Long-term Prognosis

Prognosis of LOCOE is not firmly established. Prognosis variability may depend on the selection criteria of the patients. In the early series of Gastaut, seizures were completely controlled by medication in only 60% of cases.[36,41] Beaumanoir reported seizure control before the age of 13 years, whereas Gastaut found 19 years to be the upper limit.[10] Patients initially classified as having idiopathic epilepsy but with a less favorable course turned out to have minor lesions on high-resolution MRI, which had not been detected in earlier neuroimaging studies.[72] When strict inclusion criteria such as normal neurologic examination and normal imaging studies are fulfilled, most patients have a favorable outcome.[99] Brain mapping seems to be valuable predictor of seizure outcome.[72]

Summary and Conclusions

In general, occipital epilepsies constitute a rare condition, but it is common opinion that they are probably underestimated because, especially at the onset, they may emulate other epilepsies since the visual hallucinations, which are the most important symptom for diagnosis, may lack or may be difficult to elicit on history, especially from younger children. The typical EEG abnormalities may also be absent, and if the no-visual seizures are the predominating ictal event, a different localization-related epilepsy may be supposed.

The usual clinical picture of LOCOE-Gastaut type is a normal child within the typical age range having either short visual seizures or eye-adversive seizures accompanied by visual ictal phenomena, which may be followed by hemi- or generalized convulsions. Elementary visual seizures are frequent, up to more than one per day. In about 50% of the patients, ictal hallucinations are followed by unilateral and pulsating headache, and in 10% of the cases they are associated with nausea and vomiting, making visual seizures indistinguishable from migraine with aura or basilar migraine attacks. Even though specific studies are needed to draw definite conclusions, these patients might be at risk for lower intellectual performance, scholastic disabilities, and psychiatric disorders. In particular, specific deficits in the visuoperceptual domain might occur.

LOCOE-Gastaut type has to be differentiated from the Panayiotopoulos-type childhood-onset epilepsy, photosensitive idiopathic occipital epilepsy, symptomatic occipital epilepsies, temporal epilepsies, idiopathic generalized epilepsy, and migraine. Especially important differential diagnoses are symptomatic occipital epilepsies. The following features should be considered as indications of a symptomatic or cryptogenic origin: Neuropsychological and neuroradiologic abnormalities, brief (>30 minutes) and persistent frequent partial seizures that may be associated with an alteration of consciousness, polymorphous seizures, abnormal background EEG activity, focal slowing, multiple spike foci, secondary generalization, and a change in the morphology of paroxysmal abnormalities during sleep.[6,22,51,61,88,98] A full neurophysiologic, neuropsychological, neuroimaging, and laboratory assessment is invariably mandatory in all patients with occipital epilepsy.

Prognosis and outcome of LOCOE-Gastaut type is not more firmly established than in other benign idiopathic epilepsies. This variability may depend on the selection criteria of the patients. When strict inclusion criteria are fulfilled, most patients have a favorable outcome. Because of prognosis uncertainty; seizures, though brief and mild, are frequent with possible secondary generalization; and the active period is variable, LOCOE-Gastaut type should be early treated. It may also be possible that delaying appropriate medication may adversely affect prognosis. Carbamazepine seems able to control visual seizures.

Chapter 239

Childhood and Juvenile Absence Epilepsies

Edouard Hirsch

Pierre Thomas

Chrysostomos P. Panayiotopoulos

Introduction

Typical Absences: The Symptoms

Typical absences (TAs) are epileptic seizures manifested by impairment of consciousness and 2.5- to 4-Hz generalized spike-and-slow-wave discharges[47,85,187] (see Chapter 49). Impairment of consciousness may be mild (requiring special testing)[1,7,27,112,122,161,162,199,205,206,208] or severe and may be associated with other clinical manifestations, such as automatisms,[184] regional or widespread myoclonia (rhythmic or random), and autonomic disturbances.[46] Furthermore, the electroencephalographic (EEG) discharge may be brief or long, continuous or fragmented, with multiple or single spikes that are consistently associated or not associated with the slow wave. The intradischarge frequency may be relatively constant or vary.[161]

Thus, the term *typical absences* does not refer to a stereotyped symptom, but to a cluster of clinico-EEG manifestations that may be syndrome related. It should be appreciated that like any other physical symptoms in medicine, a detailed study of the manifestations of TAs is a prerequisite for a meaningful syndrome-related diagnosis. The clinico-EEG manifestations of absences have been best described in the eminent video-EEG studies by Penry et al.[185] and Stefan et al.,[211] but it is only recently that an attempt has been made for their syndrome-related characterization with video-EEG analysis.[108,109,158,159,160,161,170,171,172] It has been shown that some of the manifestations of TA may be more specifically related to an epileptic syndrome than others, but no single symptom is sufficient to define an epileptic syndrome.[173]

Epileptic Syndromes with Typical Absences

An epileptic syndrome, by definition, requires the nonfortuitous clustering of many symptoms and signs.[48]

Four epileptic syndromes with TAs have been recognized by the International League Against Epilepsy (ILAE)[48]: Childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), juvenile myoclonic epilepsy (JME), and myoclonic absence epilepsy (MAE). The first three (CAE, JAE, JME) are considered as part of idiopathic generalized epilepsies (IGEs), whereas the fourth (MAE) is categorized among the symptomatic or cryptogenic generalized epilepsies.

There may be more epileptic syndromes with TAs, such as eyelid myoclonia with absences (EMA), perioral myoclonia with absences, and others awaiting further studies and confirmation.[166,168,171,177,178] Furthermore, idiopathic generalized tonic–clonic seizures on awakening are often associated with mild absences.[175] Many of these syndromes are different in presentation, severity, and prognosis. Children with CAE in their majority will remit, those with MAE are affected by or may develop mental and behavioral problems, and those with JME in their midteens may develop lifelong myoclonic jerks and generalized tonic–clonic seizures (GTCSs). Other patients may have subtle clinical manifestations during the typical 3-Hz spike-and-wave discharges of which they are not aware (phantom absences); often they seek medical consultation only after a generalized tonic–clonic seizure develops, probably a long time after the onset of absences.

Some investigators[11,21,23,24,25,26,117,192,193] have proposed that all these disorders, not only idiopathic (for which some theoretical justification may exist) but also those whereby the seizures arise from known brain damage, constitute a neurobiologic continuum.

Historical Perspectives

This topic has been discussed in detail elsewhere.[66,67,116,125,127,134,135,139,194] According to Temkin,[216] the first description of absences was made in 1705 by Poupart. Tissot in 1770[217] described a girl with absences "*avec un très léger mouvement dans les yeux*" associated with frequent GTCSs. The term *epileptic absences* was first used by Calmeil[35] in his doctoral thesis of 1824. The term of *petit mal* was introduced by Esquirol in 1815.[73] Gowers in 1881[97] gave the most accurate description of absence seizures "without conspicuous convulsions," and Hughlings Jackson in 1879[115] discussed the differences between absences and complex partial seizures. Absences also have been described on clinical grounds, without EEG, by Friedmann.[83] Although he believed that these absences were not epileptic, he gave an excellent description of the attacks and a long-term favorable prognosis. Sauer[204] originated the term *pyknolepsy* (from the Greek *pyknos* indicating closely packed, dense, aggregated). Adie.[2] based on his own observations but mainly, as he admitted, on those of Friedmann,[83] Heilbronner,[106] and Stier,[212] defined pyknolepsy in the most admirable way as follows:

> "A disease with an explosive onset between the ages of 4 and 12 years, of frequent short, very slight, monotonous minor epileptiform seizures of uniform severity, which recur almost daily for weeks, months or years, and which are uninfluenced by anti-epileptic remedies, do not impede normal and psychical development, and ultimately cease spontaneously never to return. At most the eyeballs may roll upwards, the lids may flicker and the arms may be raised by a feeble tonic spasm. Clonic movements, however slight, obvious vasomotor disturbances, palpitations and lassitude or confusion after the attacks, are equivocal symptoms strongly suggestive of oncoming grave epilepsy, and for the present they should be considered as foreign to the more favourable disease."

The electroclinical characteristics of absences were described by Gibbs.[94,95] The petit mal triad of Lennox,[126,127] which was misused and misunderstood, was finally clarified by the ILAE[47] with the differentiation of typical and atypical absences.

The present ILAE distinction[48] between CAE and JAE is mainly based on the pioneer work of Doose et al.[61] and Janz.[116] Doose et al.,[61] in a study of 149 children with absences, found three different groups with emphasis at the age of onset: (a) an absence epilepsy of early onset from birth to 4 years of age, (b) CAE (pyknolepsy) with onset at 4 to 8 years of age, and (c) JAE with onset before puberty and with absences occurring in clusters (cycloleptic) or sporadically (spanioleptic). Janz[116] emphasized the significance of the frequency of the absences in a comparative study of 505 pyknoleptic and 197 nonpyknoleptic cases and confirmed Doose's conclusions regarding differences of age at onset and sex.[116,118,119]

Tassinari et al.,[215] by describing myoclonic absences, and Jeavons,[121] by describing eyelid myoclonia with absences, were probably the first authors to report absences starting in childhood but having different characteristics and prognoses than in CAE.

Definitions

Childhood Absence Epilepsy

According to the international classification of epilepsies,[48] CAE represents an idiopathic generalized epilepsy defined as follows: Pyknolepsy occurs in children of school age (peak manifestation age 6 to 7 years), with a strong genetic predisposition in otherwise normal children. It appears more frequently in girls than in boys. It is characterized by very frequent (several to many per day) absences. The EEG reveals bilateral, synchronous symmetric spike-waves, usually 3 Hz, on a normal background activity (Fig. 1). During adolescence, generalized tonic–clonic seizures often develop. Otherwise, absences may remit or, more rarely, persist as the only seizure type.

This brief definition of the ILAE Commission[48] mainly based on retrospective studies was a source of confusion. Thus, many authors make the arbitrary interpretation that CAE is any type of epilepsy with onset of absences in childhood. Therefore, epidemiology, genetics, age at onset, clinical manifestations, other types of seizures, long-term prognosis, and treatment do not accurately reflect the syndrome of CAE. A more precise definition of childhood absence epilepsy has been recently proposed by the ILAE Task Force on Classification defining inclusion and exclusion criteria.[140] It takes into account several important diagnostic points, such as the degree of impairment of consciousness, the morphology of spike-wave discharges, and the place of generalized tonic–clonic seizures. Clear exclusion criteria were also proposed[140]: Eyelid myoclonia (which is predominantly myoclonic and has minimal consciousness impairment) and TAs consistently provoked by specific stimuli. The same applies for multiple spikes (more than three spikes per wave) that also indicate a bad prognosis and coexistent myoclonic jerks or GTCSs.[160]

The following definition may better represent CAE (Table 1):

> Childhood absence epilepsy is an age-related idiopathic generalized epilepsy, which occurs in otherwise normal children, more frequently girls, with a strong genetic predisposition. Age of onset is between 4 and 10 years of age, with a peak at 5 to 7 years. Absences are frequent, tens to hundreds per day. Their duration varies from 4 to 20 seconds, though most of them last around 10 seconds. Clinically, there is abrupt and severe impairment (loss) of consciousness, with cessation of voluntary activity, which is not restored during the ictus. The eyes spontaneously open; overbreathing, speech, and other voluntary activity stop within the first 3 seconds from the onset of the discharge. Automatisms are frequent but have no significance in the diagnosis. The eyes stare or move slowly, and random eyelid blinking (usually not sustained) may occur.
>
> Persistent eyelid myoclonia, rhythmic massive limb jerking, and single or arrhythmic myoclonic jerks of the head, trunk, or limbs are probably not compatible with childhood absence epilepsy. However, milder myoclonic elements, particularly at the onset of the seizure discharge, may be a feature of childhood absence epilepsy. Generalized tonic–clonic seizures and other types of seizures like myoclonic jerks should not be featured in childhood absence epilepsy. Visual (photic) and other sensory precipitation are most likely against a diagnosis of childhood absence epilepsy. Mild or no impairment of consciousness is not compatible with childhood absence epilepsy.
>
> The EEG has a normal background, with sometimes rhythmic posterior delta activity. Ictal discharges consist of generalized high-amplitude spike- and double (maximum occasional three spikes are allowed)-spike-and-slow-wave complexes. They are rhythmic at around 3 to 4 Hz (>2.5 Hz) with a gradual and regular (0.5 to 1 Hz) slowdown from the initial to the terminal phase of the discharge. The first 1 to 2 seconds of the onset of the discharge is usually fast and unreliable for these measurements. There are no marked variations in the relation of spike to the slow wave, no fluctuations in the intradischarge frequency, and certainly no fragmentations of the ictal discharges.
>
> Remission usually occurs before the age of 12 years but infrequent GTCSs may develop in adolescence.

Juvenile Absence Epilepsy

According to the Revised International Classification of Epilepsies and Epileptic Syndromes,[48] JAE is one of the age-related idiopathic generalized epilepsies. The following description is given:

> The absences of JAE are the same as in pyknolepsy, but absences with retropulsive movements are less common. Manifestation occurs around puberty. Seizure frequency is lower than in pyknolepsy, with absences occurring less frequently than every day, mostly sporadically. Association with GTCS is frequent, and GTCSs precede the absence manifestations more often than in childhood absence epilepsy, often occurring on awakening. Not infrequently, the patients also have myoclonic seizures. Response to therapy is excellent.

A similar but slightly more restrictive definition has been proposed by Panayiotopoulos.[166]

Epidemiology

Childhood Absence Epilepsy

The annual incidence of CAE is low and may vary from 1.9 to 8 per 100,000 children below the age of 16 years, and the prevalence is probably in the range of 2% to 10% of children with epileptic disorders.[23,30,133,200,201] A twofold preponderance in girls than boys may be a realistic estimate, although some studies have reported that boys and girls are equally affected.

Juvenile Absence Epilepsy

There are no population-based epidemiologic data on this syndrome. According to Janz,[118] JAE represented 10% of the age-related epilepsies with petit mal seizures.

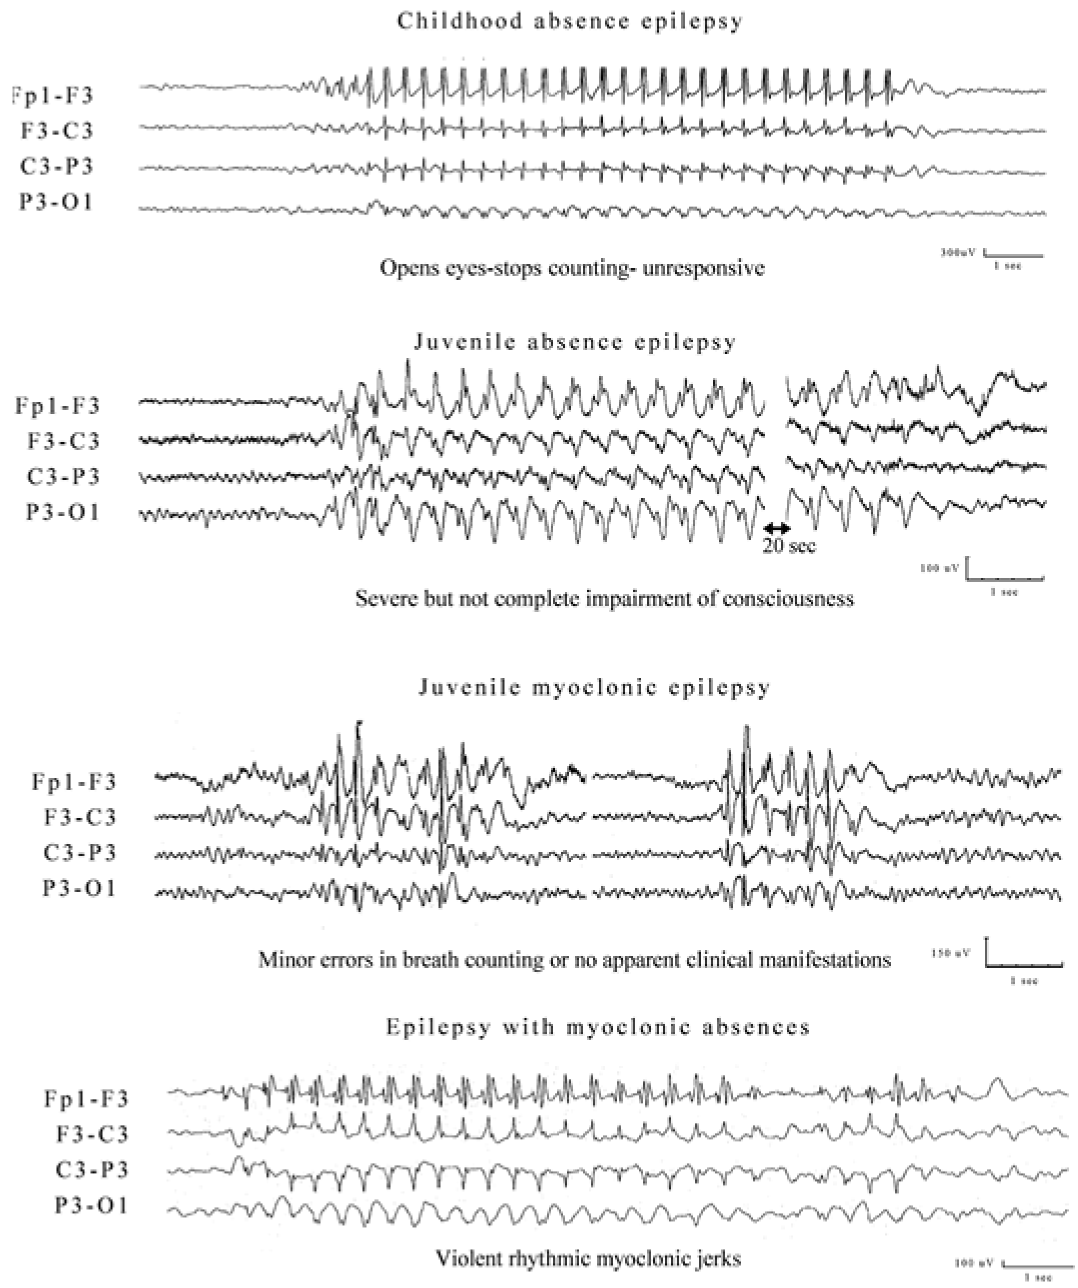

FIGURE 1. Video-electroencephalographic (EEG) recordings. **Upper:** This trace is from a 7-year-old girl with frequent daily typical absences (TAs). She stops overbreathing and counting within the first 3 seconds after onset of the EEG 3-Hz spike-and-slow-wave discharge, she is unresponsive, and she demonstrates features described in the text for CAE. Automatisms are seen in some of her seizures, but there is no eyelid or perioral or limb myoclonia. She is not photosensitive. Note the regularity and rhythmicity of the ictal paroxysm. **Upper middle:** This trace is from a 33-year-old woman who has experienced frequent daily absences that were highly resistant to treatment since 8 years of age. Ten long spontaneous absences were recorded during the 3-hour video-EEG session, but they were mainly provoked by overbreathing. She experiences severe impairment of consciousness, but she may recall events occurring toward the end of the ictus, usually keeps her eyes closed, and may restore counting during the discharge. The long ictal EEG is as rhythmic and regular as that of CAE. **Lower middle:** This image is from a 38-year-old woman with juvenile myoclonic epilepsy (JME). Note the brief fragmented discharges with "W's. Impairment of consciousness may be detected with breath counting (annotated

with numbers) where there is a significant delay in pronouncing the next number after a discharge. **Lower:** This trace is from an 11-month-old boy with mild developmental delay and a 1-month history of absences. In video-EEG these were manifested with 3-Hz rhythmic multiple spike-and-slow-waves with rhythmic myoclonic jerking of the head, body, and shoulders.

Table 1 Inclusion and Exclusion Criteria for Childhood Absence Epilepsy

INCLUSION CRITERIA FOR CHILDHOOD ABSENCE EPILEPSY

1. Age at onset between 4 and 10 years and a peak at 5–7 years
2. Normal neurologic state and development
3. Brief (4–20 seconds, exceptionally longer) and frequent (tens per day) absence seizures with abrupt and severe impairment (loss) of consciousness. Automatisms are frequent but have no significance in the diagnosis.
4. EEG ictal discharges of generalized high-amplitude spike- and double (maximum occasional three spikes are allowed) spike-and-slow-wave complexes. They are rhythmic at around 3 Hz with a gradual and regular slowdown from the initial to the terminal phase of the discharge. Their duration varies from 4 to 20 seconds.

EXCLUSION CRITERIA FOR CHILDHOOD ABSENCE EPILEPSY

The following may be incompatible with childhood absence epilepsy:

1. Other than typical absence seizures such as generalized tonic–clonics seizures or myoclonic jerks prior to or during the active stage of absences
2. Eyelid myoclonia, perioral myoclonia, rhythmic massive limb jerking, and single or arrhythmic myoclonic jerks of the head, trunk, or limbs. However, mild myoclonic elements of the eyes, eyebrows, and eyelids may be featured—particularly in the first 3 seconds of the absence seizure.
3. Mild or no impairment of consciousness during the 3- to 4-Hz discharges
4. Brief EEG 3- to 4-Hz spike-wave paroxysms of <4 seconds, multiple spikes (more than three), or ictal discharge fragmentations
5. Visual (photic) and other sensory precipitation of clinical seizures

From Loiseau P, Panayiotopoulos CP. Childhood absence epilepsy. In: Gilham S, ed. *Neurobase*. San Diego, CA: Arbor Publishing Corp.; 2000, with permission.

Etiology and Basic Mechanisms

According to Tissot,[217] "To produce epilepsy, two things are necessary: (i) a tendency for the brain to fall into spasm more readily than during health; (ii) a source of irritation that can precipitate this tendency." These two factors (genetic factor and acquired factor) exist with a very unequal significance in absences epilepsies.

Genetic Factors

Childhood Absences

Although CAE is genetically determined, the precise mode of inheritance and the genes involved remain largely unidentified.[9,10,84,154] A positive family history of epilepsy was found in 15% to 44% of cases.[20,53,59,62,63,108,127,205] Ascertainment of family history of epilepsy has to be considered: When keeping only epilepsy in parents and siblings, the frequency decreases from 42.6% to 20.7%.[111] In two series, epilepsy in first-degree relatives was found in 17% of CAE.[36,137] These seizures are TAs and GTCSs. In studies on twins, 84% of monozygotic twins had 3-Hz spike-waves, and TA developed in 75% of pairs and dizygotic twins 16 times less often.[127] An Australian study of epilepsy in twins confirmed that in concordant pairs, twins developed a similar syndrome.[26] Bianchi et al.[28] found that in 24 families with a CAE proband, there was a high concordance (33.3%) for the same clinical form in first-degrees relatives, while febrile convulsions (46.7%) and GTCSs (30%) were more common in distant relatives. Epilepsy risk in children of patients with CAE would be 6.8%.[17]

Currently, various chromosomal loci have been identified in families with absences of childhood onset (not necessarily equated with CAE). Linkage to chromosome 1 was found in families with absences starting in childhood and the later development of myoclonic jerks and GTCSs, as in JME.[58] Linkage analysis in five generations of a family in which affected patients had childhood absences and GTCSs provided evidence of a locus on chromosome 8q24.[58,81] The candidate region for this locus, designated ECA 1, has been refined, but a gene remains to be identified. According to the criteria proposed in this chapter, neither of these groups is CAE. There are also reports implicating chromosome 5q31.1 and 19p13.2.[52] Furthermore, there is now evidence available to suggest that mutations in genes encoding GABA receptors[145] or brain-expressed voltage-dependent calcium channels[44] may underlie CAE. Marini et al.[145] found $GABA_A$ receptor γ-2 subunit gene mutations on chromosome 5 in a large family with CAE and febrile seizures (including febrile seizures plus and other seizure phenotypes). This gene mutation segregated with febrile seizures and CAE, and also occurred in individuals with the other phenotypes. The clinical and molecular data suggested that the $GABA_A$ receptor subunit mutation alone could account for the febrile seizure phenotype, but an interaction of this gene with another gene or genes was required for the childhood absence phenotype in this family. Linkage analysis for a putative second gene contributing to the childhood absence phenotype suggested possible loci on chromosomes 10, 13, 14, and 15. Chen et al.[44] found 68 variations, including 12 missense mutations in the calcium channel *CACNA1H* gene in CAE patients. The identified missense mutations occurred in the highly conserved residues of the T-type calcium channel gene.

Juvenile Absences

A family history of epilepsy is frequent, and identical twins who both have the syndrome have been reported.[26] Obeid[156] reported that in a Saudi Arabian population where consanguineous marriages are frequent and can be found in 47% of the families of patients with JME,[152] this was only true for 1 out of 14 JAE families. This could indicate that a recessive gene is important in JME but not JAE. In the clinical genetic study of families with idiopathic generalized epilepsy,[146] phenotypic concordance within families of JAE was 10%, which was low compared to families of other IGE syndromes. Because 31% of JAE relatives had CAE but only 2.5% had JME, the authors suggested that CAE and JAE share a close genetic relation, whereas JME may be a more distinct entity. There are several reports of mutation of the CACNA1 A *α*-1 subunit of the CaV2.1 Ca2+ channel, or the CACNB4 *β*-4 subunit, with the phenotype of absence seizures with ataxia,[72,114] which does not fit in any of the known absence epilepsies. The paper of Escayg et al.[72] comprises an observation of a mutation in a family with an identical locus in CACNB4 as in the *lethargic* mouse mutant but which resulted in a quite different human phenotype. Findings with the genetically well-defined series of mouse mutants with absences can probably not be easily transferred to human epilepsies.

Acquired Factors

As concordance in monozygotic twins is not 100%, nongenetic factors are likely.[26] Perinatal complications, postnatal head trauma, and cerebral inflammatory disease were found in the

case histories of 7% to 30% of patients,[146,225] and only 3.9% in the Janz series.[118] However, these cerebral aggressions are very common in children and were not risk factors in a population-based case-control study.[196] A history of febrile convulsions is frequent: 20% to 23% of cases.[196,205] More than a risk factor, febrile convulsions are probably the first manifestation of an epileptic diathesis.[196] This is in accordance with results of studies on the phenotype of families with "febrile convulsions plus" related or not to mutations of voltage-dependant sodium channel gene mutations (SCN1A or SCN1B). In such families, tonic–clonic, tonic, and absence seizures have been reported.[14,128]

Pathology and Structural Brain Imaging

Autopsy[147,148] and magnetic resonance imaging (MRI)[225] studies found microdysgenesis and other cerebral structural changes in some patients with CAE. Meencke and Janz[148] reviewed autopsy findings in CAE and confirmed their previous reports on microdysgenesis[147] with the frontal lobe more severely affected. Using quantitative MRI, Woermann et al.[225] found that patients with idiopathic generalized epilepsy had significantly larger cortical gray matter volumes than control subjects. Abnormalities of the regional distribution of cerebral gray and subcortical matter were frequent in other patients with IGE but only in 1 out of 10 patients with childhood absence epilepsy. However, all cases of Meenke[149] had frequent absences from childhood to adulthood and GTCSs, which would not conform to a strict diagnosis of the syndrome of CAE. Similar may be the single patient with abnormal MRI of Woermann et al.[225] Recently, thalamic atrophy was demonstrated, using optimized voxel-based morphometry in a series of absence epilepsy patients. Bilateral thalamic atrophy may be either a result of damage from seizures (as in hippocampal sclerosis) in this group of patients with difficult to treat absences or a reflection of a primary underlying pathology as the cause of absence seizures.[41]

Basic Mechanisms

Current thinking about the pathogenesis of absence seizures dates to the landmark experiments of Jasper and Drooglever-Fortuyn.[120] They demonstrated that 3 c/s stimulation of the midline and intralaminar nuclei of the thalamus in cats could produce bilaterally synchronous spike-wave discharges in the cortical EEG of those animals. Over the next 50 years, a debate ensued in the literature as to which was pre-eminent in controlling synchronous spike-wave discharge that characterized absence seizures: The cortex, the thalamus, or both. With the advent of number of animal models of generalized absence seizures, this controversy has been at least partially resolved.[210] Moreover, the availability of these models has advanced our understanding of the basic mechanisms of absence seizures. The unifying hypothesis coming from animal data and in vitro neurophysiologic data will be briefly summarized in this chapter.

Animal Models of Generalized Absence Seizures

A valid animal model of generalized absence seizures should reflect the clinical and pharmacologic characteristics of this disorder.[42,113,144,155] The criteria for animal models of absence seizures are EEG findings and behavior analogous to human absence epilepsy; reproducibility; predictability; ability to standardize and quantitate; attenuation or blockage by ethosuximide, trimethadione, valproic acid, and benzodiazepines; appropriate ontogeny; exacerbation by γ-aminobutyric acid (GABA)-ergic drugs; blockage by $GABA_B$ antagonists; spike-wave discharges that originate in the thalamus, cortex, or both; and hippocampus silent during seizure activity. There are two main genetic models of absence seizures in rats: WAG/Rij[46] and GAERS (genetic absence epilepsy rats from Strasbourg).[56] A number of other well-characterized genetic mouse models of absence seizures are reported. However, these models manifest a variety of neurologic abnormalities and in some cases other seizures types besides absence epilepsy. Several pharmacologic models of generalized absence seizures are described (γ-hydroxybutyrate [GHB], pentylenetetrazol, penicillin, etc.). These pharmacologic models are all electrographic models because bilaterally synchronous spike-wave discharges are observed.

Unifying Hypothesis

The animal data suggest that three interacting neuropharmacologic forces within the context of the thalamocortical circuitry are involved in the pathogenesis of absence seizures: (a) postsynaptic events required for the occurrence of generalized absence seizures are glutamate-mediated excitatory postsynaptic potentials (EPSPs) followed by $GABA_A$- and $GABA_B$-mediated inhibition that triggers a low-threshold calcium current in nuclear reticularis thalamus neurons; (b) the overall setpoint of thalamic and cortical excitability is modulated by means of ascending cholinergic pathways that project to the thalamus and noradrenergic and dopaminergic neurons projecting to the cortical end of the thalamocortical loop; and (c) presynaptic $GABA_B$ and GHB receptors may contribute to the regulation of thalamocortical rhythmicity by means of precise control of excitation and inhibition through modulation of GABA and glutamate release within the involved thalamocortical circuitry.

Genetic Identifiers of Animal Models of Absence Epilepsy

Studies have uncovered the causative genes for absencelike mice models. Tottering and leaner mice have defects in the calcium channel *α* subunit, lethargic mouse in the calcium channel *β*-4 gene, and stargazer and waggler mice in the calcium channel *γ* subunit gene. These mice mutants show some characteristics of absence epilepsy; however, all affected mice show some degree of cerebellar degeneration, which is quite different from human absence epilepsy.[110] Attempts to identify the genetic defects in calcium channel genes that underlie human absence epilepsy have so far failed.[201] Similar mutations of P/Q-type voltage-gated calcium channel CaV2.1 have been reported in a family with autosomal dominant transmission of absences and episodic ataxia.[114] Genetic studies in GAERS suggest a polygenic mode of inheritance of the EEG phenotype with at least three gene loci on chromosomes 4, 7, and 8.[197]

Clinical Presentation

Childhood Absences

The age at onset of CAE is classically between 4 and 8 years, with a peak at 6 to 7 years, although some investigators have suggested a much wider range reflecting differences in definition criteria. For example, Janz et al.,[118] using frequency of absences as a selection criterion, found that pyknoleptic absences first occur at 3 to 16 years of age, with a peak at 7.5 years. Girls are affected twice as frequently as boys.

The description of Gowers[97] probably best describes the clinical manifestations of TA in CAE:

> "Transient loss of consciousness without conspicuous convulsions. A patient stops for a moment whatever he or she is doing, very often turns pale, may drop what ever is in the hand…. There may be a slight stoop forward, or a slight quivering of the eyelids…. The attack usually lasts only a few seconds. The return of the consciousness may be sudden and the patient after the momentary lapse, may
>
> P.2402
>
> be in just the same state as before the attack, may even continue a sentence or action which was commenced before it came on, and suspended during the occurrence."

The absences of CAE are easily precipitated by hyperven-tilation,[34] which may be used during clinical examination for observation. They are easily studied with EEG because untreated children with CAE invariably manifest clinical absences with 3-Hz generalized spike and slow waves during well-performed overbreathing.

A typical case of CAE is of a girl with normal intelligence and development who at the age of 6 years started having absences with severe impairment of consciousness. They were brief, lasting around 8 seconds, and occurred many times (tens or hundred) per day. The EEG, as nearly always with CAE, demonstrated 3-Hz regular spike-and-slow-wave generalized discharges that were mainly provoked by hyperventilation.[33] Video-EEG confirmed exclusion and inclusion criteria for CAE. There was no evidence of photosensitivity.

Cessation of seizures was achieved by administration of sodium valproate, but because of body weight increase this was changed to ethosuximide, which also successfully controlled her absences. Two years later, ethosuximide was gradually withdrawn. At 21 years of age, she is well, attends college, and plans to start a family.

Juvenile Absence Epilepsy

Age of onset is mostly in the range of 7 to 17 years with a peak at 10 to 12 years.[69,174,227,228] The seizure frequency is lower than in pyknolepsy, with clinical absences occurring less frequently than every day, mostly sporadically. The same types of absence occur as in CAE, but absences with retropulsive movements are less common. In one video-based study,[160,161] language functions in JAE absences were less rapidly abolished, consciousness was less severely impaired, and hyperventilation stopped later than in CAE. Spontaneous eye opening was rare, and simple absences were more common. However, this study is based on only three cases of JAE and is therefore not necessarily representative.

The majority of patients also have GTCSs, but it may be that the diagnosis is often missed if absences are the only seizure type. If the patients also have GTCSs, their manifestation precedes that of the absences more often than in CAE. Most frequently, they belong to the awakening type. Association with myoclonic seizures of the type seen in JME is more common than in CAE, probably in the order of 15% to 20%.

Diagnostic Evaluation

Electroencephalographic Findings

Childhood Absence Epilepsy

Video-EEG studies showed that CAE demonstrates the following ictal symptoms[108]:

1. The impairment of consciousness is severe. There is no verbal or other response to commands, and recollection of verbal ictal events is lost.
2. The eyes are open, overbreathing stops, and speech discontinues within 3 seconds after the onset of the discharge.
3. Automatisms occur in two thirds of the seizures but are not stereotyped. The same patient may have simple and complex absences. Automatisms may be evoked by passive movements. Automatisms in absences indicate severe impairment of consciousness and do not occur in patients with mild impairment of cognition, even if the discharges last for more than 8 seconds.
4. Rhythmic blinking at 3 Hz is an infrequent, unsustained feature. The eyes may stare, but they also may move during the ictus, particularly if the child is loudly called by name.
5. Retropulsive movements of the eyes and head, which characterize eyelid myoclonia with absences, are not a usual clinical feature of CAE but may occur at the onset of the absence.
6. The duration of absences in CAE is shorter than in JAE (mean 12.4 and 16.3 seconds, respectively).

The clinical manifestations of CAE are associated with the following EEG features:

1. The interictal EEG is normal or shows rhythmic posterior delta activity. Occasionally, centrotemporal or occipital spikes may be seen.
2. The ictal EEG shows generalized, spike- or double-spike (no more than three spikes are seen)-and-slow-wave complexes at 3 Hz (no less than 2.7 Hz and no more than 4 Hz at the initial phase of the discharge with gradual and smooth decline in frequency from the initial to the terminal phase). The discharge is regular, with well-formed spikes that retain a constant relationship with the slow waves. The duration is usually around 10 to 12 seconds, no less than 4 seconds, and no more than 20 seconds (Fig. 1).

Partial seizures, myoclonic jerks, GTCSs, and other more bizarre fits have been described with absences starting in childhood (not necessarily CAE).[14,75] GTCSs occurring before the onset of TAs should not be accepted in CAE.

Juvenile Absence Epilepsy

In the EEG, the background activity is usually normal. The characteristic feature of the interictal and ictal EEG is generalized symmetric spike-and-waves discharge with frontal accentuation. The spike-and-waves frequency is usually faster than 3 Hz (3.5 to 4 Hz), the first complex of a group sometimes being even faster.[220] Often, the slow wave is preceded by two or three spikes. The above-mentioned preliminary study of Panayiotopoulos et al.[160] indicated that the ictal discharges may be longer in JAE (16.3 ± 7.1 seconds) than in CAE (12.4 ± 2.1 seconds) and in JME (6.6 ± 4.2 seconds). They were more regular than in JME but could show fragmentation unlike in CAE. In one study,[226] photosensitivity was less common than in other idiopathic generalized epilepsies, but this was not confirmed in the only other study.[220,229]

Neuroimaging

Functional imaging with positron emission tomography demonstrates normal cerebral glucose metabolism and benzodiazepine receptor density in absence epilepsies with diffuse hypermetabolism during 3-Hz spike-and-wave dis-charges.[71,188,198] There is no evidence of any interictal overall abnormality of opioid receptors, though typical absences have been found to displace 11 C-diprenorphine from the association areas of the neocortex. In contrast, binding of 11 C-flumazenil to cBZRs has been shown not to be affected by serial absences.[71] Functional MRI-EEG study of absences seizures in adult patients with JAE demonstrated bilateral activation of the thalamus and widespread deactivation of the cortex maximal in frontal regions.[6,124,199] Substraction interictal-ictal single photon emission computed tomography (SPECT) coregistered to MRI (SISCOM) was used to evaluate cerebral blood flow changes during the ictal and immediate postictal phase in

P.2403

four children with CAE.[153] The authors reported a widespread decrease of cerebral blood flow during ictal phase and an increase during post ictal phase. Those studies confirm in humans data observed in animal models, which suggest a crucial role of the thalamo-cortical loop and specific metabolic modifications during absence seizures.

Differential Diagnosis

The diagnosis of CAE may be difficult, even by specialists. Three child neurologists independently classified epilepsy syndromes in a cohort of children with newly diagnosed epilepsy and 7 of 74 CAEs were not diagnosed as such by one of the three.[18] In practical terms, a child suspected of typical absences should be asked to overbreathe for 3 minutes counting his or her breaths. Hyperventilation will provoke an absence in nearly all untreated children with CAE.[224] This procedure should preferably be videotaped for documentation of the clinical features.

CAE and JAE are epileptic syndromes that have to be distinguished from a variety of conditions such as nonepileptic manifestation (attention disturbance and daydreaming)[80] or focal epilepsies. Differential diagnosis of absence epilepsies from focal epilepsies should be easy, though alteration of consciousness and automatisms may be common in both. Temporomesial seizures could be characterized by staring and automatisms, reasons that in the past it was improperly called “pseudoabsences” or “temporal lobe absences.” However, in temporal mesial seizures, loss of consciousness is preceded by vegetative aura; seizure ending could be characterized by postictal signs (asthenia, aphasia). A main problem is “typical absence seizures” from frontopolar lobe origin that may also have concomitant more or less regular bilateral 3-Hz spike-wave discharges.[75,77,219] Focal motor components, asymmetric ictal discharges, or stable interictal frontal foci in the EEG may help in their differentiation. MRI may demonstrate frontal abnormalities[77] or subependymal gray matter heterotopia.[190] However, rare focal EEG abnormalities are possible in CAE.[16,141,231] Loss of consciousness of milder intensity is observed during atypical absences in Lennox-Gastaut syndrome. Lennox-Gastaut syndrome is characterized by the association of atypical absences with tonic and atonic seizures, runs of rapid spikes in non-REM sleep, and status epilepticus. Resistance to therapy and persistence of epilepsy are among the most frequent features. Mental retardation is a leading symptom, occurring on average in 90% of cases.

Other Epilepsies with Typical Absence Seizures Starting in Childhood or Early Adolescence

The differentiation of CAE from other IGEs with absences may be difficult without video-EEG comparisons (Fig. 2). Eyelid myoclonia with absences is the easiest of all to differentiate from CAE because of brief, mainly eyelid myoclonia; minor impairment of consciousness; EEG generalized discharges of predominantly polyspikes; and photosensitivity. Myoclonic absence epilepsy and absences with perioral myoclonia have clinically apparent myoclonic jerks, and EEG discharges usually show polyspikes. The major problem is with JAE and JME that may start with typical absence seizures long before the appearance of myoclonic jerks and GTCSs.

Juvenile Myoclonic Epilepsy (Janz Syndrome)

Absence seizures occur in one third of JME patients, but these are usually very mild, are often inconspicuous, and have different EEG patterns.[100,160,165,167] The main seizure type of JME is myoclonic jerks upon awakening, and these do not occur in CAE. The problem is when JME starts with absences prior to the onset of myoclonic jerks, but again, there are a number of clinico-EEG differences such as milder impairment of consciousness, frequent polyspikes, and fragmentations of the EEG discharges in JME.[160,207] Some authors consider these cases as CAE evolving or progressing to JME.[58,223] In our opinion, this is JME starting with absences in childhood. In the majority of these patients with JME starting with TAs in childhood, video-EEG studies would clearly differentiate them from the TAs of CAE.[160] However, there may be cases where their differentiation is difficult and JME will not be diagnosed until many years after with the appearance of myoclonic jerks and GTCSs.

Absence Epilepsy of Early Childhood

A syndrome of absence epilepsy of early childhood was proposed in the 1960s[61] and later,[8,29,38,40,55,57,65] that included a heterogenous group of patients, some of whom had CAE. It was characterized by an onset before the age of 5 years; possible occurrence, at the onset or later, of GTCSs and/or myoclonic-astatic seizures; irregular 2- to 3-Hz spike-and-waves discharges on the EEG; and often an unfavorable prognosis. Later, its heterogeneity was admitted.[64] Age at onset artificially covers various idiopathic generalized epilepsies with a polygenic inheritance. Absence epilepsies of early childhood include early-onset CAE and other absence epilepsies in which more important environmental factors explain the frequency of GTCSs and a less favorable outcome. The “intermediate petit mal” described by the Bologna school[142] probably corresponds to similar situations.

Myoclonic Absence Epilepsy

This syndrome described by Tassinari et al.[214,215] is also incorporated in the ILAE Classification[48] as a rare generalized cryptogenic/symptomatic absence epilepsy. Severe bilateral rhythmic clonic jerks, often associated with a tonic contraction, occur during the absence.[143] Awareness of the jerks may be maintained. Seizures occur many times a day. Other types of seizures are rare. Age of onset is around 7 years, and there is a male preponderance. Prognosis is not good because of resistance to therapy, mental deterioration, and possible evolution to other types of epilepsy such as Lennox-Gastaut syndrome.[215]

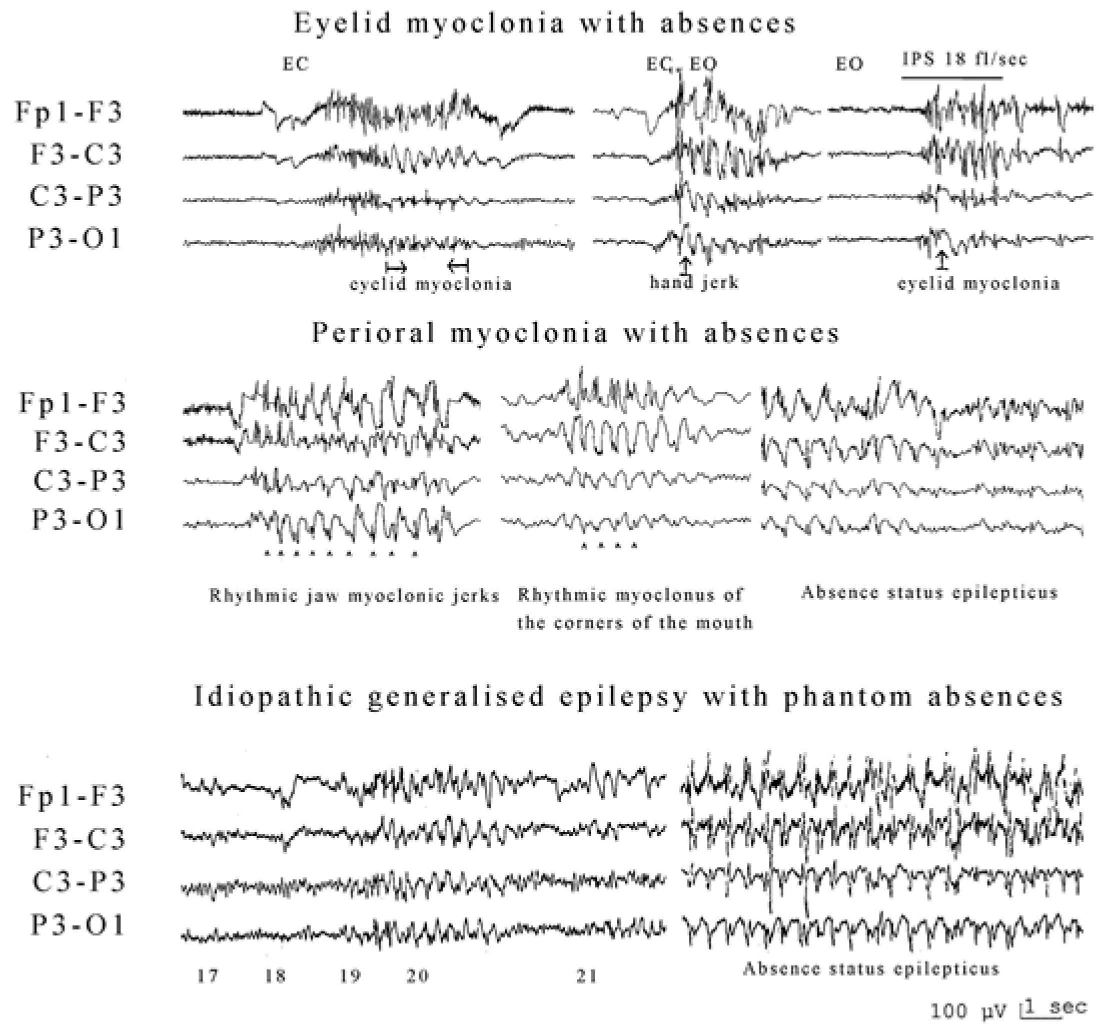

FIGURE 2. Video-electroencephalographic (EEG) recordings. **Upper left:** Brief ictal discharges consisting mainly of polyspikes and slow waves are induced after eye closure in a 32-year-old woman with eyelid myoclonia with absences (EMA). They are associated with eyelid myoclonus and occasionally mild impairment of consciousness. Similar abnormalities are seen in a 17-year-old girl on eye closure **(middle)** and intermittent photic stimulation **(right)**. In the latter case, mild myoclonic jerks of the hands also were seen. Details of these patients have been reported by Giannakodimos and Panayiotopoulos.[50] **Middle left:** Rhythmic jaw jerking (annotated with *arrows*) with mild impairment of consciousness were the characteristic clinical features during these brief discharges in an 18-year-old woman with intractable absences, generalized tonic–clonic seizures (GTCSs), jerks, and possible absence status. Similar EEG abnormalities associated with rhythmic contractions of the depressor anguli oris were recorded in a 37-year-old man with infrequent absence status followed by GTCSs **(middle)**. An episode of absence status with perioral myoclonia and cloudiness of consciousness ending in a GTCS was recorded via EEG in a 29-year-old woman with frequent absences and absence status with GTCSs **(right)**. Details of these patients have been reported by Panayiotopoulos et al.[102,103] **Lower right:** Phantom absences manifested with delays in counting during overbreathing (numbers) in a 17-year-old girl with a single GTCS at 17 years of age **(left)**. Similar brief and mild absences were recorded in another 56-year-old woman who also had two episodes of de novo absence status of late onset **(right)**. Details for these patients have been reported by Panayiotopoulos et al.[106]

Eyelid Myoclonia with Absences (Jeavons Syndrome)

The syndrome of eyelid myoclonia with absences was first described by Jeavons in 1977 as a form of photosensitive epilepsy[70,121] and was confirmed by other investi-gators.[12,13,15,55,79,90,91,96,99,103] Eyelid myoclonia with absences is frequently familial.[182] It is considered more a myoclonic than an absence syndrome.[177,213] The following definition was proposed by Panayiotopoulos[181]: Jeavons syndrome (eyelid myoclonia with absences) is an idiopathic epileptic syndrome manifested by frequent (pyknoleptic) seizures, consisting of eyelid myoclonia often associated with absences. Onset is usually in early childhood. The seizures are brief (3 to 6 seconds) and occur mainly after eye closure.[169,176,222] They consist of eyelid myoclonia, which persists throughout the attack with or without absences. Absences without eyelid myoclonia do not occur. The eyelid myoclonia consists of marked, rhythmic, and fast jerks of the eyelids, often associated with jerky upward deviation of the eyeballs and retropulsion of the head. There is probably an associated tonic component of the involved muscles. If the seizure is prolonged, impairment of consciousness occurs. The latter is mild or moderately severe

P.2404

without associated automatisms. Milder seizures of eyelid myoclonia without absences are common, particularly in adults and treated patients, and may occur without EEG accompaniments. All patients are highly photosensitive in childhood, but this declines with age. Infrequent GTCSs, either induced by lights or spontaneous, are probably inevitable in the long term and are likely to occur after sleep deprivation, fatigue, and alcohol indulgence. Myoclonic jerks of the limbs may occur, but are infrequent and random. The eyelid myoclonia of Jeavons syndrome is resistant to treatment and may be lifelong. However, clinical absences may become less frequent with age.

The EEG ictal manifestations consist mainly of generalized polyspike-waves at 3 to 6 Hz, which are more likely to occur after eye closure in an illuminated room. Total darkness abolishes the abnormalities related to eye closure. Photoparoxysmal responses are recorded from all untreated young patients.

Perioral Myoclonia with Absences

Panayiotopoulos et al.[168] reported that TAs associated with marked perioral myoclonia may constitute a new epilepsy syndrome defined as follows:

> Perioral myoclonus with absences is a syndrome of idiopathic generalized epilepsy with onset in childhood or adolescence, characterized by frequent typical absences with variable severity of impairment of consciousness and ictal localized rhythmic myoclonus of
>
> P.2405
>
> the perioral facial muscles (lip myoclonus) or occasionally of the masticatory muscles (jaw myoclonus). TA duration is usually brief, ranging from 2 to 10 seconds. Ictal EEG shows generalized discharges of spikes, more often irregular polyspikes and slow waves at 3 to 5 Hz. They are not associated with eye closure and photosensitivity. Perioral myoclonia with absences often associates with absence status.[5] GTCSs always occur either early or several years after the onset of TA; they are usually heralded by clusters of TAs or absence status and may be infrequent. The syndrome is lifelong and often resistant to medication. A family history of epilepsy is common.[181]

Lips and chin myoclonia are by themselves insufficient symptoms to justify a syndromic individualization, because of a possible moderate myoclonic component in CAE and JAE.[37,108] However, a unique combination of characteristic clinico-EEG features is likely in perioral myoclonia with absences.

Phantom Absences and Generalized Tonic-Clonic Seizures

Phantom absences is the term we have coined to denote TAs that are so mild that they are inconspicuous to the patient and imperceptible to the observer.[76,88,180] They have been known for many years as “subclinical or larval absences.”[1] The absences are simple, occasionally with eyelid blinking. They are common in patients with idiopathic generalized epilepsies but are often unrecognized. Based on patient information, the absences often start after patients' teen years. The absences were shown on video-EEG recordings with breath counting and consisted of brief (3 to 4 seconds) generalized discharges of 3- to 4-Hz spikes or multiple spike-and-slow-wave discharges, during which mild impairment of cognition manifested with consistent errors and discontinuation of breath counting. Absence status occurred, either in isolation or terminating in GTCSs.[209] In these patients GTCSs were consistently preceded by absence status. After recognition of this sequence, GTCSs were often preventable with rectal benzodiazepine, self-administered while in absence status. Long-term prognosis may be the same as in other syndromes of IGE with TAs and GTCSs. In view of the high incidence of absence status, patients should be advised to use rectal diazepam.

Symptomatic Absence Seizures

In genetically predisposed individuals, brain damage may precipitate TA occurrence, most often associated with neurologic signs and/or mental retardation. This category comprised 10% of patients with TA in a Swedish population-based study.[158] Ferrie et al.[77] made a list of diffuse and focal cerebral pathologies in which TAs have been reported. They are as follows, in alphabetic order: Arteriovenous malformations, autism, biochemical disturbances, brain tumors, cerebral abscess, congenital microcephaly, craniostenosis, Down syndrome, drugs/drug withdrawal, encephalitides, endocrine disturbances, head injury, hemiplegia, hydrocephalus, hypothalamic lesions,[152] juvenile Batten disease, mitochondrial encephalopathies, neonatal intracranial hemorrhage, precocious puberty, progressive myoclonic epilepsy, Sturge-Weber syndrome, subacute sclerosing panencephalitis, tuberculous meningitis, and tuberous sclerosis. Most of these reports are old and, hence, poorly documented, and one may wonder how many patients fitted with CAE characteristics. Subtentorial lesions[189,191] are noteworthy, because they may disturb the corticothalamic oscillatory networks. Prognosis is that of the underlying pathology. In most cases, the association is probably coincidental. However, cerebral pathology may modify the expression of genetic seizure susceptibility.[77] In these cases, the correct diagnosis is not CAE, but symptomatic absence epilepsy, with a less favorable outcome.

Treatment and Outcome

Childhood Absence Epilepsy

Childhood absence epilepsy needs treatment because absences are very frequent throughout the day and may adversely affect cognitive functioning.[32,68] However, clinicians should avoid overtreatment with antiepileptic drugs (AEDs), which may induce cognitive side effects. First-line drugs are ethosuximide, sodium valproate, and lamotrigine, alone or in combination.[78,164,195] Clonazepam, clobazam, and acetazol- amide are second-line drugs for CAE, sharing a similar risk of tolerance and adverse effects.[98,179] Amantadine could be effective in association as a third-line drug in pharmacoresistent absence epilepsies with few adverse events. Despite this clear-cut evidence of antiabsence drug efficacy, many children with typical absence seizures would still be treated with inappropriate drugs.[183] Sodium valproate controls absences in 75% of patients[22] and has the advantage also of controlling generalized tonic–clonic seizures (70%) and myoclonic jerks (75%), but may be undesirable for women. Rare cases of paradoxical aggravation in CAE with valproate have been reported; this might be related to a genetic heterogeneity of CAE.[129] Similarly, lamotrigine may control absences in possibly 50% to 60% and GTCSs in 50% to 60%, but may worsen myoclonic jerks; hypersensitivity immune reaction are possible.[49,50,82,89] Ethosuximide controls 70% of absences, but it is undesirable as monotherapy if other generalized seizures are at risk. Combination of any of these three drugs may be needed for resistant cases. Minute doses of lamotrigine added to sodium valproate may have a dramatic beneficial effect. Clonazepam, particularly in absences with myoclonic components, acetazolamide, and amantadine may be useful adjunctive drugs. Diones are no longer used.[186] Conversely, carbamazepine, vigabatrin, gabapentin, and tiagabine are contraindicated because of their proabsence effect.[39] Phenytoin and phenobarbital are contraindicated because of their usual inefficacy.[179,181] The place of topiramate, levetiracetam, and vagal nerve stimulation is still unknown.

Monotherapy with sodium valproate, ethosuximide, or lamotrigine should be the choice and should not be abandoned before making sure that the maximum tolerated dose has been achieved if smaller doses have failed. There are anecdotal reports whereby children may not respond to syrup of sodium valproate despite adequate levels, but seizures stop if this is replaced by tablets or microspheres of sodium valproate. If monotherapy fails or unacceptable adverse reactions appear, then replacement of one by the other is the alternative. The best possible combination is adding small, minute doses of lamotrigine to adequate doses of sodium valproate. Gradual withdrawal of medication is recommended in patients with CAE who are seizure free for 1 to 2 years and have a normalized EEG. EEG confirmation of the seizure-free state is needed during this withdrawal period.

Juvenile Absence Epilepsy

First-line drugs are sodium valproate and lamotrigine, alone or in combination. When there is concern about teratogenicity, lamotrigine can be given as first-line monotherapy,[82] although onset of action is much slower compared to

valproate.[49] There is at present no study specifically investigating the newer AEDs such as topiramate and levetiracetam in JAE. Carbamazepine and oxcarbazepine may aggravate the seizures of JAE.[87]

Long-term Prognosis

Childhood Absence Epilepsy

Most of the available evidence is inconclusive regarding evolution and prognosis of CAE. This is because of markedly different classification criteria in the relevant reports or of too-short follow-up periods. Most authors include in CAE any child with absences before the age of 10 years, which may not be CAE.[19,31,140,181] Retrospective studies in adults may lack accurate initial data. Patients must be followed beyond 18 or 20 years of age.[132,136,138] Our view is that CAE, if properly defined, has an excellent prognosis.

Prognosis of Typical Absence Seizures

At a time when no antiabsence drug existed, Adie[2] concluded that even if absence seizures in pyknolepsy persisted for a long time, they ultimately ceased, never to return. This is consistent with recent findings that absences of CAE, even if they may persist several years, finally disappear with age in more than 90% of cases.[132,136,138,202,203] In a Swedish population-based study, a 91% remission rate was found when patients with absence epilepsy had only absences.[105]

Typical absence seizures persist for a mean time of 6.6 years[53] and disappear between age 3 and 19 years, with a mean age of 10.5[107] or 14 years.[53] "The tendency for petit mal to cease is present at all ages and not just at puberty. In about a quarter of patients the attacks cease before the age of 15 and by the age of 30 years petit mal had ceased in about three quarters of the patients."[92,93] In this study, with a follow-up of about 5 years, only 3% of patients experienced TAs beyond 50 years of age. In another study,[130] of the 92 controlled patients, 89 were aged 20 or younger at the time of cessation of absence seizures.

Thus, TA persistence is rare, reported to occur in about 6% of patients.[157] In adults, attacks tend to be infrequent and milder, and occur with precipitating factors such as fatigue, sleep deprivation, and menstruation,[53,86,161,181] though in some cases absences may be very severe.[5]

Two favorable prognostic signs are age at onset of TAs and medication efficacy. In patients diagnosed early and followed beyond 20 years of age, TAs had disappeared in 95% and 90% of cases according to an age at onset of 8 or 10 years, respectively.[135,136] Their cessation soon after prescription of a convenient antiepileptic drug is considered as a favorable sign.[53,131]

Generalized Tonic–Clonic Seizures

However, cessation of absence seizures may not mean remission. This again depends on diagnostic inclusion and exclusion criteria. Considering all absences with onset in childhood as CAE, prognosis is uncertain and with great variations.[31,181] GTCSs may appear and patients may develop juvenile myoclonic epilepsy.[223] Absence seizures in these patients may persist, improve, or disappear.

It has been estimated that GTCSs occurs in 36% to 60% of patients with onset of TAs in childhood.[53,130] Most often, GTCSs occur 5 to 10 years after onset of TAs,[132] that is, mainly between 8 and 15 years of age,[43,60,130] and sometimes beyond 20 and even 30 years of age.[86] They have been considered as infrequent and easily controlled.

Different risk factors have been suggested, as follows:

- Age at onset of TAs: The later the onset of TAs, the higher the risk is for subsequent convulsive seizures.[20,43,51,54,102,127,130]
- Absence status, especially when absences occur late in the course of epilepsy,[60] but this may not be childhood absence epilepsy.[3,4,5,104]
- Sex: TAs are more frequent in girls and TAs + GTCSs are more frequent in boys.[157]
- EEG: Usually, clinical/EEG correlation is fair. However, the predictive value of the EEG is not absolute; spike-wave discharges may persist after clinical recovery, and conversely GTCSs may occur in spite of a normalized EEG.[105] When initial tracings show posterior delta rhythms, GTCSs rarely occur.[45,105,157] An abnormal background activity, multiple spikes,[74] and focal abnormalities are considered as unfavorable signs, but are likely to correspond to erroneous diagnoses.
- Therapy: With an early institution of effective therapy, GTCSs occurred in 30% of cases, and 68% after incorrect therapy.[20] GTCSs manifested in 85% of incorrectly treated patients.[60]

A change of CAE into epilepsy with focal seizures has been reported. It probably corresponds to erroneous diagnosis: Either TAs with automatisms or absence epilepsy other than CAE such as in febrile seizures plus.[123]

Complete Remission

A wide range of remission rates has been given: 78% to 33%. The reasons for this are as follows: (a) patients with absence epilepsies other than CAE were included; (b) patients' age at last clinic visit, with, for instance, inclusion of 82% of patients when beyond 18 years of age but only 65% in those beyond 20[60]; (c) follow-up duration, with relapse in 19% of patients who had been seizure free for 2 years or more; and (d) therapy[60]: With early and adequate therapy, 70% of patients were included, whereas 18% with an incorrect therapy were included.[20]

Social Prognosis

Social adaptation of patients having had CAE would be poor in one third of patients, even when in remission.[60,102,107,142] In childhood absence epilepsy, TAs are very frequent and the EEG shows brief discharges of bilateral spike-waves without apparent clinical impairment. Neuropsychological studies have documented cognitive dysfunctioning (reaction time tasks and sustained attention tests) during these discharges. “The transitory bursts of spike-wave activity represent the tip of an iceberg. Below the surface there may be a more or less continuously active pathophysiological process, which is reflected in impaired performance on tests of attention and in alterations in event-related brain potentials.”[150,151] Therefore, long-term sequelae of scholastic difficulties are not surprising. Furthermore, a psychomotor slowing beginning late in follow-up has been found in some patients with TAs persisting after the age of 30 to 61 years.[86] It was supposed to be multifactorial in origin.

Juvenile Absence Epilepsy

The response to therapy is good in spite of the frequent combination with GTCSs. Wolf and Inoue,[230] in their cross-sectional study of 229 adolescents and adults who had a diagnosis of absences and still were in treatment, reported that all were seizure free if they had only had absences (n = 21), and 87% were seizure free if there had not been more than ten GTCSs. If there were more GTCSs (which was the case in 123 patients), the response was still very good, but 24% were not seizure free. The response was better in JAE (85% seizure free) than in CAE (80%, p <0.02), and combination with myoclonic seizures did not affect the therapy prognosis. In these patients, the absences were mostly treated with ethosuximide, valproate, or both—and in some cases with mesuximide—and if necessary the doses were increased to the maximum the patients could tolerate. If GTCSs were present, these were often treated with an additional drug, especially with succinimide treatment for absences. In the study of Trinka et al.,[218] 40 (62%) of 64 JAE patients were seizure free for at least 2 years, which was almost similar to the seizure-free rate of CAE patients (56%).

Summary and Conclusions

Childhood absence epilepsy is an idiopathic generalized epilepsy that should not be equated with any type of absences first appearing in childhood. It may be as benign as the benign childhood partial seizures,[163] but further prospective studies must be conducted with strict clinico-EEG criteria of the classification. A better definition of CAE and related syndromes allows a better classification of patients with idiopathic absence epilepsies. However, 33% of patients are still difficult to classify.[101] This syndromic approach is necessary for the improvement of genetic and pharmacologic studies. Juvenile absence epilepsy is an idiopathic form of epilepsy that is probably lifelong. It is characterized by frequent absences with severe impairment of consciousness (imitating CAE) associated with GTCSs and occasionally with myoclonic jerks (imitating JME). Thus, the phenotypic manifestations of JAE are intermediate between CAE and JME. Whether this is also the case for their genotypes remains to be seen. Incidence, prevalence, long-term prognosis, genetics, and what is the most realistic treatment (which may be lifelong) need to be studied.

Epilepsy with Myoclonic Absences

Carlo Alberto Tassinari

Roberto Michelucci

Elena Gardella

Guido Rubboli

Introduction

Epilepsy with myoclonic absences (MAs) is an epileptic syndrome characterized clinically by absence seizures associated with rhythmic, bilateral myoclonic jerks of severe intensity. The diagnosis is based on clinical observation and ictal video-polygraphic recordings. Indeed, in video-polygraphic investigations (recording an electroencephalogram [EEG] and electromyogram [EMG] from upper limb muscles, such as deltoids), MAs are characterized by rhythmic, bilateral, synchronous, symmetric 3-Hz spike-wave (SW) discharge, as in typical absences, associated with EMG myoclonic bursts at 3 Hz, superimposed to a progressively increasing tonic contraction.

Demonstration of MA seizures is essential for the diagnosis; thus, epilepsy with MAs belongs to the group of epilepsy syndromes that is defined by a specific seizure type (as, for example, juvenile myoclonic epilepsy or myoclonic astatic epilepsy [Doose syndrome]). Indeed, since the early description of MAs,[13,15,16] it has been believed that this seizure type could characterize a distinct epileptic condition that could be identified and separated from other forms of generalized epilepsy, such as childhood absence epilepsy. The Commission on Classification and Terminology of the International League Against Epilepsy (ILAE) accepted this view, recognizing epilepsy with MAs as an autonomous syndromic entity that was included, in the 1989 ILAE Proposal for Revised Classification of Epilepsies and Epileptic Syndromes,[6] in the group of cryptogenic or symptomatic generalized epilepsies, due to an overall dismal and heterogeneous prognosis. On the other hand, in the more recent Proposed Diagnostic Scheme for People with Epileptic Seizures and with Epilepsy produced by the ILAE Task Force on Classification and Terminology,[9] it has been tentatively placed among idiopathic generalized epilepsies. Recent reviews on this epileptic condition by Bureau and Tassinari[2,3] and Tassinari et al.[21] acknowledged the existence of at least two forms of epilepsy with MAs: one with a more benign course, and eventually disappearance of seizures, in which MAs are the sole, or predominant, seizure type; and the other with MAs associated with other seizure types (particularly, frequent generalized tonic–clonic seizures) that bears a more severe prognosis, as compared to other idiopathic generalized epilepsies. Furthermore, cases with "atypical" features in which MAs were part of a clinical picture characterized by some degree of mental retardation, neurologic deficits (e.g., congenital hemiparesis), and chromosomopathy[7,8,11] have been reported.

Clinical Data

General Remarks

Epilepsy with MAs is a rare condition; in a selected population of epileptic patients attending the Centre St. Paul in Marseilles, it accounts for 0.5% to 1% of all epilepsies. There is a male preponderance (69%), at variance with childhood absence epilepsy in which females are more frequently affected. Etiologic factors reported in about 35% of cases are prematurity, perinatal damage, consanguinity, congenital hemiparesis, and chromosomopathy.[2,3] The evidence in some cases of associated chromosomal dysfunction has led to the hypothesis that abnormal expression of genes located in the affected chromosome segments may play a role in the pathogenesis of myoclonic absence epilepsy.[7,8] A genetic susceptibility, as demonstrated by a positive family history of epilepsies, has been observed in about 20% of cases.

The mean age of onset of MAs is 7 years, with a range between 11 months and 12.2 years. Reports describing cases with onset of MAs in the first year of life have been published in the last years.[1,14,19,22]

Myoclonic Absences

MAs are characterized by the following:

Impairment of consciousness, which can vary in intensity, ranging from a mild disruption of contact to a complete loss of consciousness. Sometimes the patients are aware of the jerks and may recall the words pronounced by the examiner during the seizures.

Motor manifestations, which consist of bilateral myoclonic jerks, often associated with a discrete tonic contraction that has been clearly documented in proximal upper limb muscles. The myoclonias mainly involve the muscles of the shoulders, arms, and legs; facial myoclonias, when present, are more evident around the chin and the mouth, whereas eyelid twitching is typically absent or rare. Due to concomitant tonic contraction, the jerking of the arms is accompanied by a progressive elevation of the upper extremities, giving rise to a quite constant and recognizable pattern. When the patient is standing, falling is uncommon. In some patients, asymmetric features, such as head and trunk deviation, may occur.

P.2414

Autonomic manifestations, which consist of an arrest of respiration and inconstant loss of urine.

MAs last for 10 to 60 seconds, and recur at a high frequency (many seizures per day), being often precipitated by hyperventilation or awakening. MAs may also be observed during the early stages of sleep. Episodes of MA status are distinctly rare.

Seizures Other Than Myoclonic Absences

MAs represent the only seizure type in about one third of patients. The remaining cases can suffer from other seizure types, which can appear before the onset of MAs or occur in association with MAs. They consist of generalized tonic–clonic seizures, absences, or epileptic falls.

Neurologic and Neuropsychologic Examination

Neurologic examination is normal, except in those cases with congenital hemiparesis. Mental retardation is present in about 45% of cases before the onset of MAs. During the course of MAs, mental retardation may worsen, or even appear, in patients previously normal, particularly in those patients with frequent tonic–clonic seizures associated with MAs. These data constitute a very significant difference for this subgroup of patients when compared with the cognitive status observed in childhood absence epilepsy.

Neurophysiologic Data

Interictal EEG

The interictal EEG shows a normal background activity in all cases. In one third of cases, bursts of generalized SWs or, more rarely, focal or multifocal SWs are present. It is noteworthy to point out that the sinusoidal posterior slow rhythm has never been observed, as reported in childhood absence epilepsy.

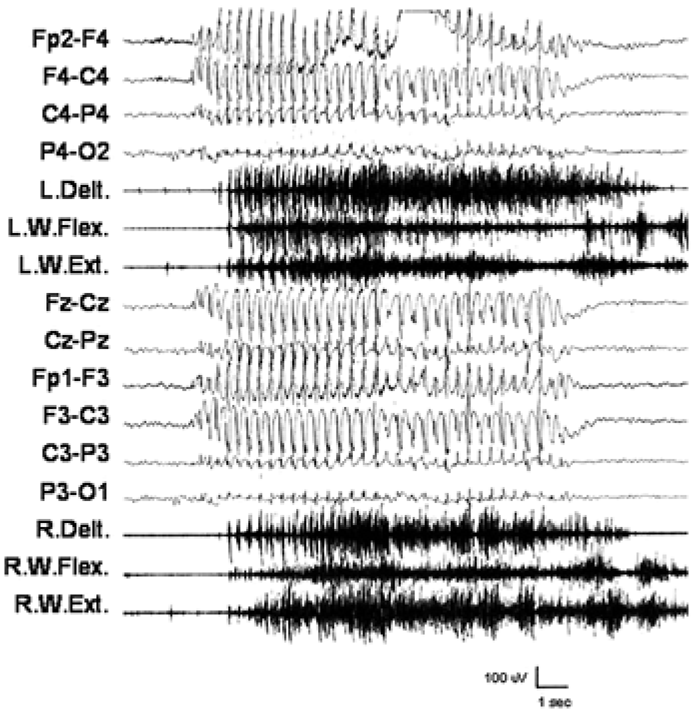

FIGURE 1. Spontaneous myoclonic absence. Electroencephalogram (EEG): Rhythmic spike-wave (SW) discharge at 3 Hz, bilateral, synchronous, and symmetric, as observed in typical absences. Electromyogram (EMG): Rhythmic myoclonia, at the same frequency of the SW, involving the upper extremities, and starting about 1.5 seconds after the onset of the EEG paroxysmal discharge, associated with a tonic contraction with progressively increasing intensity. Delt., deltoid; W.Flex., wrist flexor; W.Ext., wrist extensor; R., right; L., left.

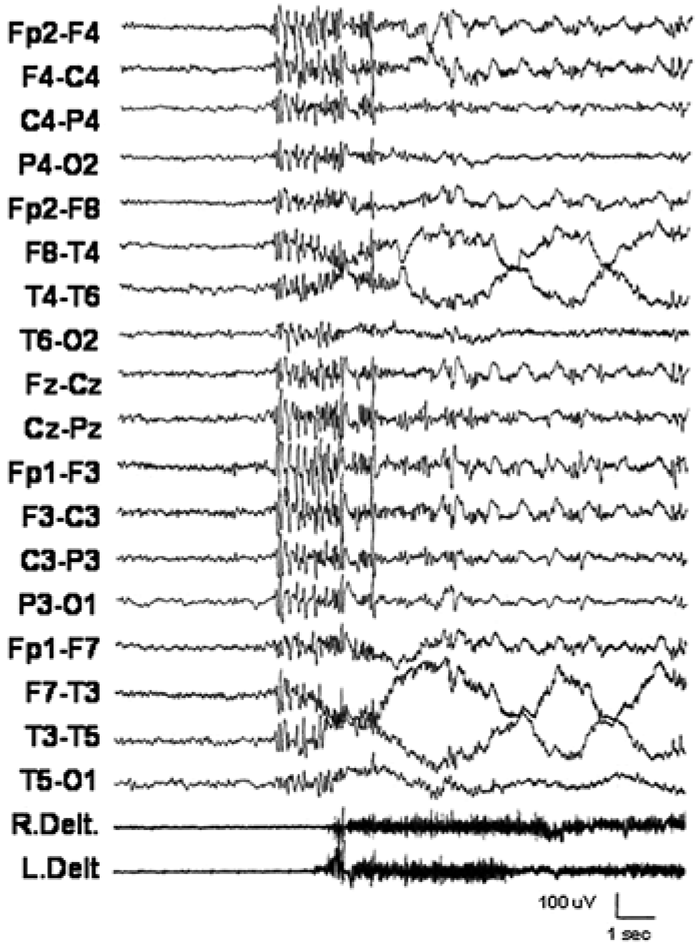

FIGURE 3. Tonic seizure during light sleep in a 45-year-old patient who started to suffer from myoclonic absences when she was 11 years old. Tonic muscular activity appears about 1 second after the onset of a rhythmic polyspike discharge. Delt., deltoid; R., right; L., left.

Ictal EEG

The ictal EEG consists of rhythmic SW discharges at 3 Hz, which are bilateral, synchronous, and symmetric, as observed in typical absences. The onset and the end of SWs are abrupt. Polygraphic (EEG-EMG) recording discloses the appearance of bilateral myoclonias, at the same frequency as the SW, which begin around 1 second after the onset of EEG paroxysmal discharges and are followed by a tonic contraction, maximal in the shoulder and deltoid muscles (Fig. 1). Original investigations by Tassinari et al.[16,17] by means of high-speed oscilloscopic analysis provided a detailed description of the relationships between the EEG SW and motor events, showing a strict and constant relation between the spike of the SW discharge and the myoclonia (Fig. 2). These studies emphasized the relationships between the positive transient encompassed in the SW complex,[24] which in MAs is of high amplitude and is followed on the EMG by a myoclonia with a latency of 15 to 40 msec for the more proximal muscles and of 50 to 70 msec for the more distal muscles. This myoclonia is itself followed by a brief silent period (60 to 120 msec), which breaks the tonic contraction. Recently, Gardella et al.[10] demonstrated that the first myoclonic jerks were restricted to the facial musculature, then spreading to the neck and upper limbs muscles. Back-average of the EEG activity triggered from the onset of the first myoclonia confirmed the correlation of the

myoclonic phenomenon with the positive transient of the SW complex.

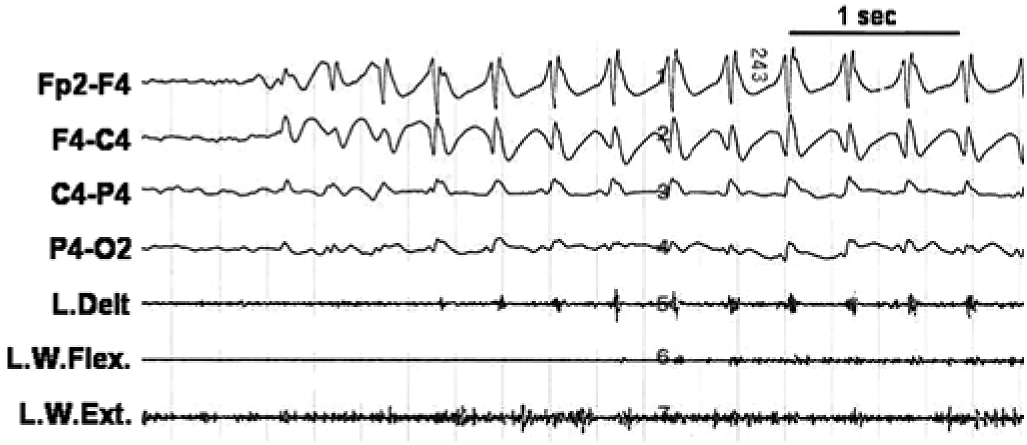

FIGURE 2. High-speed polygraphic recording of a myoclonic absence (MA) seizure, showing the relationship between the spike of the spike-wave (SW) complex and the myoclonic potential. The first three SW complexes are not associated with any evident myoclonic activity. Delt., deltoid; W.Flex., wrist flexor; W.Ext., wrist extensor; L., left.

Physiopathogenetic hypotheses on the peculiar muscular pattern that characterizes MA seizures admit that the tonic muscular contraction component that is superimposed on the myoclonic activity might be related to the involvement of secondary motor areas,[3] possibly in the frontomesial cortex.[12] Indeed, tonic contractions occur always in MAs, but after the appearance of few SW complexes, possibly suggesting a spread of paroxysmal activity to frontomesial areas. During the evolution, some cases may evolve to a “Lennox-Gastaut–like syndrome” with tonic seizures, particularly during wakefulness or light sleep, associated in the EEG with rhythmic polyspike waves (Fig. 3). In these patients, the disappearance of SW complexes might be observed, replaced by focal frontal spikes; although infrequently, a frontal partial status may occur that can be controlled by phenytoin administration.

Sleep EEG

Sleep organization is constantly normal and physiologic patterns are symmetrically present. During sleep the evolution of the SW discharges is similar, on the whole, to that observed in childhood absence epilepsy.[18] MAs may occur during stage I of sleep, awakening the subject. During stage II, SW discharges, of brief or long duration, are also observed, sometimes associated with bursts of myoclonias.

Evolution

Classical data on the evolution of MAs indicate that these are still present in about two thirds of the cases followed up for a mean period of 10 years, whereas they disappear in the remaining patients after a mean period of 5.5 years from the onset.[2,3,21] The two groups of patients differ in the frequency and type of associated seizures: in fact, patients with “refractory” MAs have a high incidence (80%) of associated seizures, mainly of generalized tonic–clonic and atonic types. On the contrary, patients with remitting MAs have a lower incidence (40%) of associated seizures, mainly of the absence type. The long duration of MAs is likely to be an important factor for the appearance of mental retardation, since intellectual functions are always preserved in children with rapid remission of MAs. In rare cases, the disappearance of MAs has been followed by the onset of other seizure types, namely absences with atypical SW discharges and clinical and subclinical tonic seizures, giving rise to a clinical picture similar to the Lennox-Gastaut syndrome.[19,20]

Diagnosis

The diagnosis of MAs mainly rests on the polygraphic demonstration of SW discharges at 3 Hz (as in typical absences) accompanied by rhythmic myoclonias. Therefore, polygraphic recording is mandatory when the clinical suspicion of MAs is raised. Since the anamnestic data may sometimes be misleading (asymmetric MAs may be misdiagnosed as partial motor seizures, MAs with mild myoclonias may be misdiagnosed as typical petit mal absences, etc.), we suggest that polygraphic recording should be performed also in patients with "drug-resistant" absence seizures and in cases with refractory "myoclonic" or "partial motor seizures."

Capovilla et al.[4] reported a group of patients with childhood absence epilepsy exhibiting absence seizures associated with mild myoclonic jerks, involving mainly the facial and neck muscles (eyebrows, nostrils, perioral region, chin, sternocleidomastoideus). Indeed, the electroclinical characteristics (particularly, benign course with excellent response to treatment, and possible drug withdrawal in the evolution, and mild myoclonia without a background of tonic contraction) differentiate this clinical picture from epilepsy with MAs. Moreover, myoclonic phenomena have also been described in children with early-onset typical absences (before age 2 to 3 years).[5]

Finally, MAs must be differentiated from absence seizures with more or less rhythmic myoclonias associated with 2.5–3 Hz irregular SWs observed in nonspecific diffuse epileptic encephalopathies.[20]

Treatment

Data on outcome suggest that the correct medical therapy for MAs consists of the associated use of valproic acid and ethosuximide at high doses, with serum plasma levels ranging from 80 to 130 µg/mL and 70 to 110 µg/mL, respectively. Recent studies found lamotrigine, particularly in combination with valproate, or in one case ethosuximide, to be useful when other measures had failed.[14,23] In individual cases, good seizure control was achieved by using a combination of phenobarbitone, valproic acid, and benzodiazepines. It must be pointed out that since epilepsy with MAs is a relatively rare condition, no comparative or controlled clinical trials have ever been performed; therefore, the only available data are of retrospective nature. In particular, the efficacy of more recent antiepileptic drugs that are currently used in the treatment of

refractory absences or in myoclonic epilepsies, such as levetiracetam, topiramate, and zonisamide, has not been adequately investigated in epilepsy with MAs. Finally, it should be mentioned that drugs such as carbamazepine or phenytoin (and possibly vigabatrin, gabapentin, tiagabine, and oxcarbazepine) might theoretically worsen MAs; however, as above mentioned, in patients who present with partial status, phenytoin may be useful to stop seizure activity.

Summary and Conclusions

The syndrome of epilepsy with MAs is a distinct form of childhood epilepsy characterized by a peculiar seizure type that identifies this epileptic condition. Recognition of MAs relies on direct clinical observation and polygraphic recording; in particular, the EEG-EMG ictal pattern bears specific features that allow differential diagnosis with other generalized seizure types. It can be stated that the demonstration of MAs is sufficient for the diagnosis. Regarding the natural history and prognosis of epilepsy with MAs, two forms may be identified: a form in which MAs are the sole or predominant seizure type and a form in which MAs are associated with other seizure types and particularly with numerous generalized tonic–clonic seizures; this latter form bears a poor prognosis in terms of seizure control and neuropsychological deterioration.

Acknowledgments

We thank Prof. G. Avanzini and Prof. S. Franceschetti from the Neurological Institute "C. Besta" in Milan for providing the case illustrated in FIGURE 1, and Mrs. C. Giardini for her help in the preparation of the manuscript.

Chapter 241

Lennox-Gastaut Syndrome

Pierre Genton

Charlotte Dravet

Introduction

Among childhood epilepsies, Lennox-Gastaut syndrome (LGS) is one of the most severe. It is characterized clinically by frequent seizures, including sudden falls, marked resistance to therapy, and progressive mental and behavioral disturbances. The syndrome is difficult to treat, even with the most recent antiepileptic drugs. Although the physiologic and pathogenic mechanisms of LGS are not fully understood, it has precise, well-defined clinical and neurophysiologic characteristics that restrict the diagnosis to a fairly homogenous, albeit rather uncommon entity. Historically, its main trait (i.e., the presence of diffuse slow spike-wave discharges), has led to overdiagnoses and confusion with other encephalopathic epilepsies; not all diffuse slow spikes-and-waves, not all epileptic drop attacks, and not all severe, polymorphic encephalopathic childhood-onset epilepsies are caused by LGS. Indeed, some cases previously diagnosed as LGS would nowadays be reclassified into other categories, like myoclonic astatic epilepsy or the Dravet syndrome.

LGS has many possible causes, and modern concepts have stressed the major part played in the genesis of LGS by secondary bilateral synchrony originating from the frontal cortex. In spite of its relative rarity, LGS has in recent years been the object of specific clinical trials evaluating the efficacy of newer antiepileptic agents, probably because it still represents the archetype of a recognizable, yet severe, intractable childhood epileptic encephalopathy.

Historical Perspective

Early authors had already noticed the poor prognosis of some types of childhood seizures (i.e., atypical absences, tonic seizures, and astatic seizures), when Gibbs in 1938[38] and then Gibbs et al.[39] in 1939 identified an electroencephalographic (EEG) pattern characterized by slow (about 2-Hz) spikes-and-waves. They called this the *petit mal variant* as opposed to the less severe *petit mal absence*, characterized by 3-Hz spikes-and-waves. Lennox in 1945[57] and Lennox and Davis in 1950[59] established the clinical correlates of this pattern and described a symptomatic triad comprising slow diffuse spikes-and-waves, mental deficiency, and three seizure types: Myoclonic jerks, atypical absences, and head drops or falls, the latter successively described as *akinetic seizures*, *astatic seizures*, and finally *drop attacks*.

The further studies by Sorel[80] and Doose et al.,[25] and the MD dissertation of Dravet, published by Gastaut et al.,[33] allowed precise characterization of the electroclinical features of the syndrome. Different denominations were used over the years (including such complex ones as *childhood epileptic encephalopathy with diffuse slow spike-waves*) until the consensual denomination of *Lennox-Gastaut syndrome* was proposed by Margaret Buchtal-Lennox in 1966, in tribute to both the initial work of Lennox[57,58] and the thorough clinical description performed by the Marseille school. Further investigations included the long-term studies of large series reported by Oller Daurella,[69] Gastaut et al.,[34] Loubier,[60] Ohtahara et al.,[68] Beaumanoir,[11] and Chevrie and Aicardi.[18] Of particular interest from a clinical, genetic, and therapeutic perspective is the progressive delineation of LGS from other encephalopathic epilepsies like myoclonic astatic epilepsy (the Doose syndrome), severe myoclonic epilepsy of infancy (the Dravet syndrome), the syndrome of continuous spikes-and-waves during slow-wave sleep, and specific encephalopathies like the Angelman syndrome.

Definitions

In the International Classification of Epilepsies and Epileptic Syndromes,[20] LGS is classified among the symptomatic or cryptogenic generalized epilepsies. It is defined by several criteria:

a. Onset during childhood
b. Coexistence of several seizure types, with mainly atypical absence, axial tonic, and atonic seizures; the presence of tonic seizures during sleep is a constant feature; other seizures (myoclonic, generalized tonic–clonic, focal) can occur
c. Diffuse slow spikes-and-waves and bursts of fast rhythms at 10 to 12 Hz during sleep
d. Permanent psychologic disturbances with psychomotor delay, personality disorders, or both

The seizure frequency is high, and episodes of status are not uncommon. In the EEG, focal and multifocal abnormalities can be associated with the diffuse slow spikes-and-waves. These electroclinical features may occur in a previously normal child, without pathologic antecedents and without signs of brain lesion, usually between the ages of 1 and 8 years, and constitute the cryptogenic form of LGS. They also can occur in a child with prior signs of brain damage, sometimes in the wake of another type of epilepsy, such as infantile spasms or focal epilepsy, and constitute the symptomatic forms of LGS. In the latter cases, the range of ages at onset may be wider (between 1 and 15 years, rarely more).

In the 2001 proposal of the ILAE,[29] LGS was classified among epileptic encephalopathies, a category of epilepsies *in which the epileptiform abnormalities may contribute to progressive dysfunction.*

Epidemiology

Epidemiologic data on LGS vary greatly. Different criteria were used in selecting cases. Some studies have included all forms of severe childhood epilepsies associated with slow spikes-and-waves on the EEG. Others have restricted the criteria to those defined above. Its frequency has thus been estimated to range

from 3% to 10.7% of all cases of childhood epilepsies.[4,11,34] In the population observed in the Centre St. Paul, which specializes in the treatment of severe epilepsies, the figure is 3.7% in the whole population (children and adults) and 6.6% in patients with onset before age 10 (personal data from a prospective registry of all newly referred epilepsy cases seen between 1986 and 1996). A study performed in metropolitan Atlanta, GA, found a prevalence of 4% among children aged <10.[84] Another study performed in Finland found a yearly incidence of 2 per 100,000 of “broadly defined” LGS among children aged 1 to 14 years.[47]

There is no particular geographic or ethnic distribution. Boys are slightly more often affected than girls.[60,61,68] A closer look at patient registries would probably show that the incidence has declined in recent years, due to stricter diagnostic criteria, leading to other specific diagnoses and to changes in the early treatment of severe childhood epilepsies that may have avoided the progression of symptomatic cases into the full-blown LGS. In our recent experience, the incidence of LGS has been comparable to that of myoclonic astatic epilepsy and the Dravet syndrome.

Etiology and Basic Mechanisms

LGS can be symptomatic or cryptogenic. Numerous etiologies can be found in the symptomatic forms[12]: Perinatal anoxic ischemia; antenatal or perinatal vascular accident; antenatal, perinatal, or postnatal cerebral and cerebromeningeal infection; HHE (hemiconvulsion-hemiplegia-epilepsy) syndrome; both diffuse and lateralized or even focal brain malformation and migration disorders; tuberous sclerosis, Down syndrome, hydrocephalus, head trauma, brain tumor and radiotherapy for brain tumor, and many others. There are numerous publications on uncommon etiologies, and a sample may be quoted here to underline the etiologic heterogeneity of this syndrome. LGS may, for instance, occur following chemo- and whole-brain radiotherapy for acute lymphocytic leukemia[63]; in an encephalitic form of neurocysticercosis[1]; or in common variable immunodeficiency with acute disseminated encephalomyelitis.[53]

In some cases, despite psychomotor retardation before the onset of seizures or of mild to moderate, nonspecific cerebral atrophy demonstrated by computed tomography (CT) and magnetic resonance imaging (MRI), there is no recognizable etiology. When epilepsy starts in the first year of life, it is often in the form of infantile spasms, followed by LGS. Otherwise, LGS can be preceded by focal seizures, or all the features of LGS may be manifesting at onset or soon thereafter. It must also be stressed that the typical features of LGS can be observed only transiently in some patients.[11] In the cryptogenic forms, there is no etiology by definition. However, "cryptogenicity" may depend on the amount of investigation, and this category may have shrunk since the availability of MRI. Some authors have been enticed to subdivide LGS patients in three categories: Symptomatic, noncryptogenic, and cryptogenic, the latter category referring to individuals with strict criteria of normal development, lack of dysmorphism, and normal MRI[41]: Using such criteria, these authors found no difference in seizure outcome between these etiologic categories.

The mechanisms underlying LGS are not well understood. In 1987, Theodore et al.[82] used positron emission tomography (PET) to investigate the cerebral metabolism of ten patients, and Chugani et al.[19] that of five, without considering the various etiologies. Their results appear too heterogeneous to be significant. Microscopic studies of samples obtained at autopsy and brain biopsy from 15 patients were reported by Roger and Gambarelli-Dubois.[75] Selective neuronal necrosis was observed in the neocortex, hippocampus, thalamus, and cerebellum, but in eight cases the necrosis was restricted to the cerebellum. Electron microscopic examination of biopsy material from eight patients showed that neuronal loss occurred mainly at postsynaptic sites. Quantitative analysis confirmed the rarefaction of cortical dendrites and synaptic contacts. In two cases studied by Renier,[73] there were a few swollen astrocytes around the neurons in the deeper cortical layers, poor dendritic arborization, and disturbed synaptic development of the pyramidal cells restricted to the inner cortical layers. He hypothesized that these findings were the origin and not the consequence of LGS, and were perhaps related to an autoimmune process. A virologic and immunologic approach was adopted by Smeraldi et al.,[79] but the results of their studies were not significant. Eeg-Olofsson[28] discussed the relationships between a genetic defective immune mechanism and the occurrence of LGS.

Genetic factors do not seem to play a major part in LGS, and no multiplex families with LGS have been reported. The frequency of cases with a family history of epilepsy ranges from 2.5%[18] to 28%.[60] Boniver et al.[16] noted that 48% of patients with cryptogenic LGS had a family history of either epilepsy or febrile convulsions, but their series may have included patients with myoclonic astatic epilepsy. Interestingly, no case of LGS has been reported in large generalized epilepsy with febrile seizures plus (GEFS+) families, which include patients with Dravet syndrome or myoclonic astatic epilepsy. Among genetically determined cortical brain malformations, LGS may occur in patients with micropolygyria and in those with the XLIS mutation, which causes subcortical band heterotopia in females and pachygyria in males. In the latter example, the occurrence of LGS seems to be correlated with the thickness of the band or severity of pachygyria.[42]

The neurophysiologic processes leading to the production of interictal EEG changes and seizures in LGS have received some attention. Processes related to those occurring in idiopathic generalized epilepsies play a limited part, since abnormal sleep patterns found in patients with cryptogenic LGS seem to originate outside the usual thalamocortical circuit.[88] Secondary bilateral synchrony (SBS), which is of cortical origin, appears to be at the origin of the apparently generalized EEG changes: In their study comparing myoclonic seizures found in LGS and in (truly idiopathic) myoclonic astatic epilepsy, Bonnani et al.[15] convincingly demonstrated propagation from a lateralized origin in LGS. There is no satisfactory explanation for the genesis of this abnormal tendency to SBS and related inhibition of function, but this phenomenon clearly plays a major part in the genesis of both seizures and cognitive impairment. The occurrence of the LGS at a crucial stage of neurodevelopment is of course a major factor of the learning difficulties and progressive retardation, and Blume[14] has hypothesized that the intensity of interictal and ictal discharges diverts the brain from normal developmental processes toward seizure control mechanisms.

In the light of recent data, LGS appears to be an acquired, nonspecific, age-dependent diffuse encephalopathy, occurring without specific familial predisposition, and the reason why it appears in either normal or brain-damaged patients is not known.[12] There is evidence of major focal factors, related to the frontal lobes, but these coexist with a predisposition to bilateral synchrony, which accounts for most of the clinical features. Until we know more, this epileptic encephalopathy should thus still be ranked among the “generalized” syndromes.

Clinical Presentation

The onset is before the age of 8, with a peak between 3 and 5 years. Onset after age 10 is unusual. In cryptogenic cases,[16] the first seizures can be myoclonic, atypical absences, or falls, sometimes repeated in status. Sometimes, an isolated

seizure—tonic, clonic, tonic–clonic, or even a unilateral seizure—has preceded the typical seizures by several months. Nocturnal tonic attacks are usually not observed at the very onset. Psychological and cognitive disturbances can be concomitant with the first seizures or can develop later, insidiously. Thus, it is not easy to make the diagnosis of LGS very quickly. The EEG features at onset can consist of either diffuse slow spikes-and-waves or only more or less diffuse slow waves. A single case study of nocturnal sleep at this stage has been published,[21] demonstrating the presence of bursts of low-voltage rapid rhythms evoking subclinical tonic seizures. When LGS follows infantile spasms, there are two possible modalities: Either infantile spasms are replaced by tonic seizures without a free interval, or infantile spasms disappear and both the EEG and the psychomotor development improve for some time before falls, atypical absences, and diffuse slow spikes-and-waves appear, accompanied by a new slowing of development. When LGS complicates other types of epilepsy, the diagnosis is marked by the onset of falls and behavioral/cognitive changes. Several authors have reported the occurrence of LGS in adolescents and young adults who previously had an idiopathic type of generalized epilepsy.[59,68,74]

Interictal Symptomatology

The neuropsychological and psychiatric symptoms consist of arrest or slowing of psychomotor development, apparent deterioration of cognitive abilities, and appearance of psychiatric conditions, the expression of which depends on age. The youngest children are seen with physical and intellectual instability, mood lability, inability to acquire new skills, and progressive disharmony. Older children exhibit slowness of ideation and expression; language deterioration resulting from motor dysfunction, particularly changes in muscular tone of the orolaryngopharyngeal area[10]; aggression; irritability; loss of social relationships; tendency to isolation; and sometimes psychotic outcome. Personality disorders are always present in the cryptogenic forms.[89] There are no neurologic signs that can be considered specific to LGS, apart from transient cerebellar, pyramidal, or extrapyramidal signs during prolonged status. However, in some patients the recurrent episodes of status are so long and so frequent that this semiology can become permanent after more than 10 years of evolution. Iatrogenic factors may contribute to neurologic deterioration.

On the EEG, the background can be disorganized, with diffuse slow waves, poor reactivity, and lack of topographic differentiation. Such disorganization can be permanent (67% of patients) or transient, appearing only during periods of worsening of seizures. Constant disorganization is a sign of poor prognosis. Hyperventilation can elicit slow spike-and-wave discharges with or without clinical correlates (atypical absences), whereas intermittent photic stimulation has no effect. Paroxysmal changes are frequent, with discharges of diffuse slow spikes-and-waves and slow polyspikes-and-waves. In 75% of children, they are associated with focal and multifocal changes (spikes, slow spikes, slow spikes-and-waves), with constant or variable focalization, frequently frontal or temporal. They are increased during slow sleep, when the diffuse slow spikes-and-waves become more synchronous and rhythmic, with prominent polyspikes. During sleep, specific bursts of fast rhythms appear (see below). The differentiation of sleep stages can be preserved or can be blurred[7] (Fig. 1).

Ictal Symptomatology

In order of decreasing specificity, LGS, a disorder associated with multiple seizure types, includes tonic seizures, atypical absences, atonic seizures, and other types. Both tonic and atonic seizures may cause falls.

Tonic seizures are the main feature of the syndrome and are reported in 74%[11,34] to 90%[60] of patients. They can be axial, axorhizomelic, or complete, and symmetric or markedly unilateral. They can occur while patients are awake or asleep. The neck and body are suddenly flexed, the shoulders and arms are raised in a semiflexed or extended position, the legs are extended, the facial muscles (sometimes only of the lower lip) contract, and the eyes roll up. Apnea and facial flushing are apparent. The victim may fall suddenly. Loss of consciousness does not always occur and is rarely the initial symptom. Return to normal consciousness always coincides with the end of the EEG discharge. Enuresis can occur. The pupils are usually dilated. When these seizures are short and involve only rolling of the eyes and respiratory changes (which is usually the case during sleep), they may remain unnoticed. When they last for more than 10 seconds, they can culminate in a tremor that affects the whole body (resulting in a "vibratory" seizure). In tonic–automatic seizures, described by Oller Daurella[70] in 72% of late-onset cases, there is a final phase of gestural, sometimes ambulatory automatisms. Slow-wave sleep facilitates the occurrence of tonic seizures. The EEG during tonic seizures (Fig. 2) consists of either a bilateral discharge of fast rhythms, predominantly in the anterior areas and at the vertex, or a flattening of the background, or a combination of these two patterns, sometimes preceded by generalized spikes-and-waves, followed by diffuse slow waves and slow spikes-and-waves, that last longer in patients with "tonic–automatic" seizures. There is no postictal silence. The fast discharges are particularly common during slow-wave sleep, when they can be nearly subclinical. Gibbs[38] inappropriately described this ictal pattern recorded during sleep as the *grand mal pattern*.

Atypical absences are observed in a vast majority of patients. Clinically, they are often difficult to diagnose: The onset and end are gradual, contact is impaired but not completely lost, a simple activity can be continued, eyelid myoclonus is not rhythmic, perioral myoclonus is frequent, and slow forward motion of the head caused by loss of tone, as well as drooling, is also frequent. In the EEG, atypical absences are associated with often irregular, more or less symmetric discharge of diffuse slow spikes-and-waves at 2 to 2.5 Hz (Fig. 3), or with a burst of rapid rhythms, or with a mixed pattern.

Atonic, myoclonic-atonic, and myoclonic seizures are not easy to differentiate by clinical observation alone. Most authors group these seizures with falls under the name of *akinetic* or *astatic* seizures,[32] or *drop attacks*. They may provoke a sudden fall, either of the head only or of the whole body, which may cause injuries. This is followed by an immediate recovery (there may, however, be loss of consciousness and progressive recovery in case of significant head concussion). The EEG correlates are polymorphous: Slow spikes-and-waves, slow polyspike-and-waves, and decremental events. The simultaneous video-EEG and polygraphic recordings allow an accurate characterization of the seizure type. They occur together in the same patient in 95% of cases.

Other seizure types, not specific for LGS, can be observed: Generalized tonic–clonic, generalized clonic, and focal seizures. Reflex seizures may be seen in some cases, like seizures provoked by eating[56] or, more commonly, in Down syndrome patients with LGS, in whom a "startle" reaction may trigger tonic seizures or atypical absences.[43]

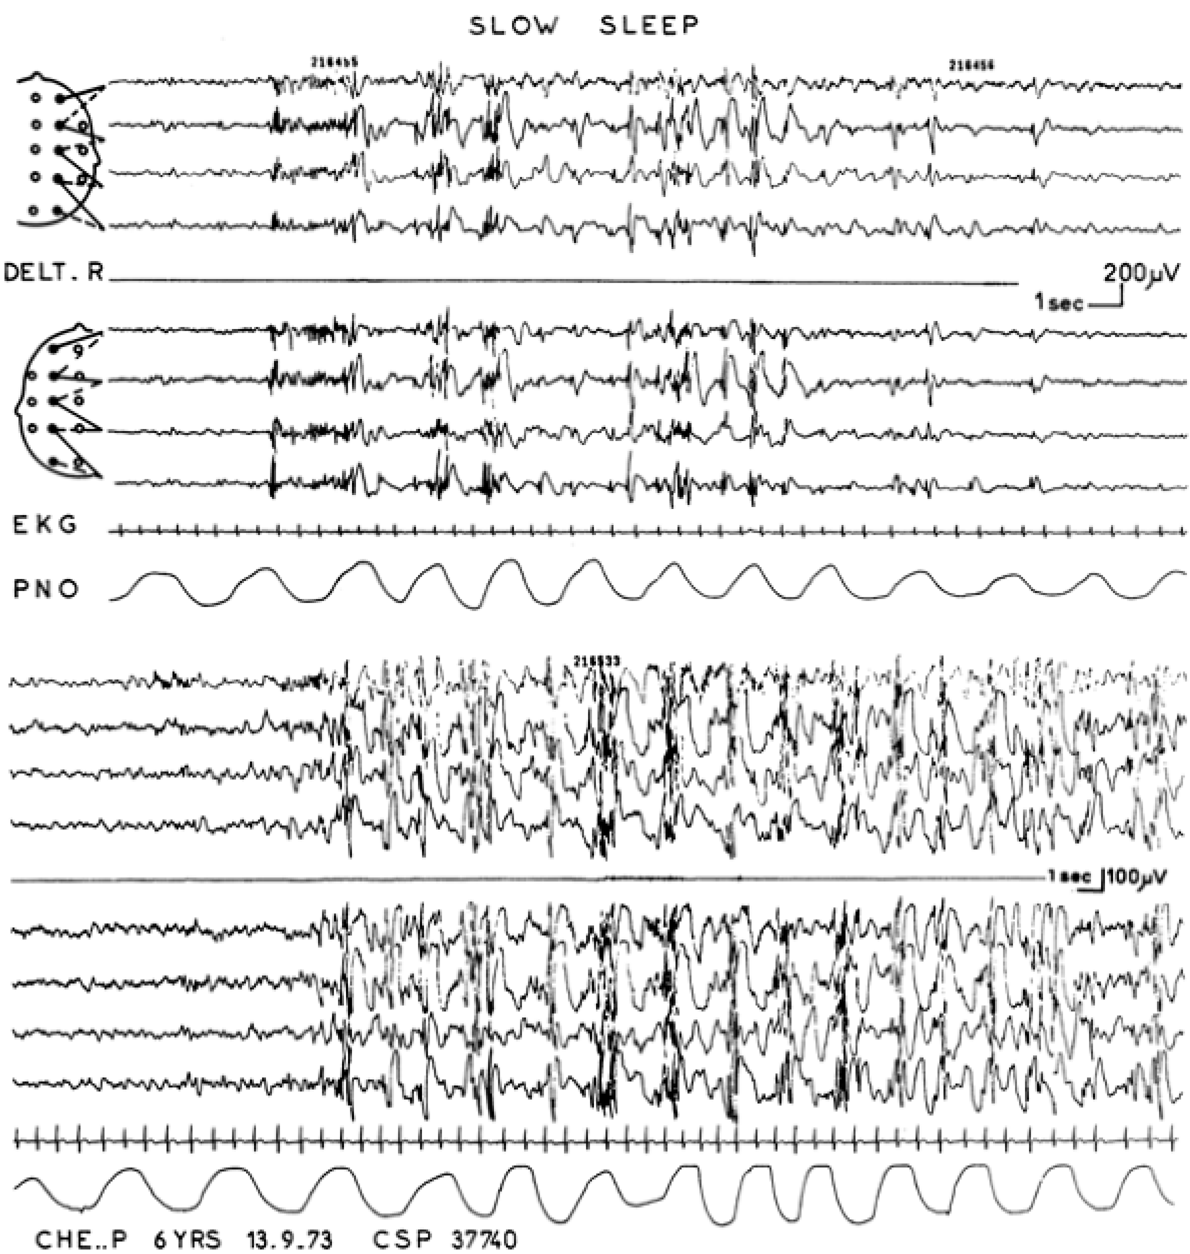

FIGURE 1. Electroencephalographic recording during sleep in cryptogenic Lennox-Gastaut syndrome. **Top:** Typical bursts of subclinical rapid rhythms, variable in amplitude and duration, recorded with decreased amplification. **Bottom:** Other runs of rapid rhythms recorded with the normal gain, accompanied by a slight change in respiration. DELT R, right deltoid; PNO, pneumogram.

All the seizure types occur as status in a majority of patients (54%,[60] 75%[11]). Status consists of periods of more or less profound obtundation/stupor, intermixed with serial tonic attacks, sometimes with myoclonic–atonic falls. When tonic attacks are predominant, they constitute a tonic status. The main characteristics of status episodes are their long duration

P.2420

(days to weeks), resistance to treatment, and tendency to occur repeatedly. During status, the EEG becomes almost hypsarrhythmic. It has been suggested that this represents only a temporary worsening of the usual interictal symptomatology.[11,26] The occurrence and frequency of nonconvulsive status is considered to contribute to the poor cognitive outcome of LGS.[48]

Clinical Variants

In the myoclonic variant of LGS, which represents 18% of the cases of Chevrie and Aicardi,[18] massive myoclonus and myoclonic–atonic attacks are the prominent seizure types. Tonic seizures are mainly nocturnal, and epileptic status is characterized by stupor and myoclonus. The awake EEG is not different from the typical form, but there are fewer runs of rapid rhythms during sleep. This myoclonic variant is cryptogenic in 64% of cases, and its mental prognosis is more favorable. Probably some of the patients reported to have “myoclonic LGS” in the literature actually had myoclonic astatic epilepsy.[24]

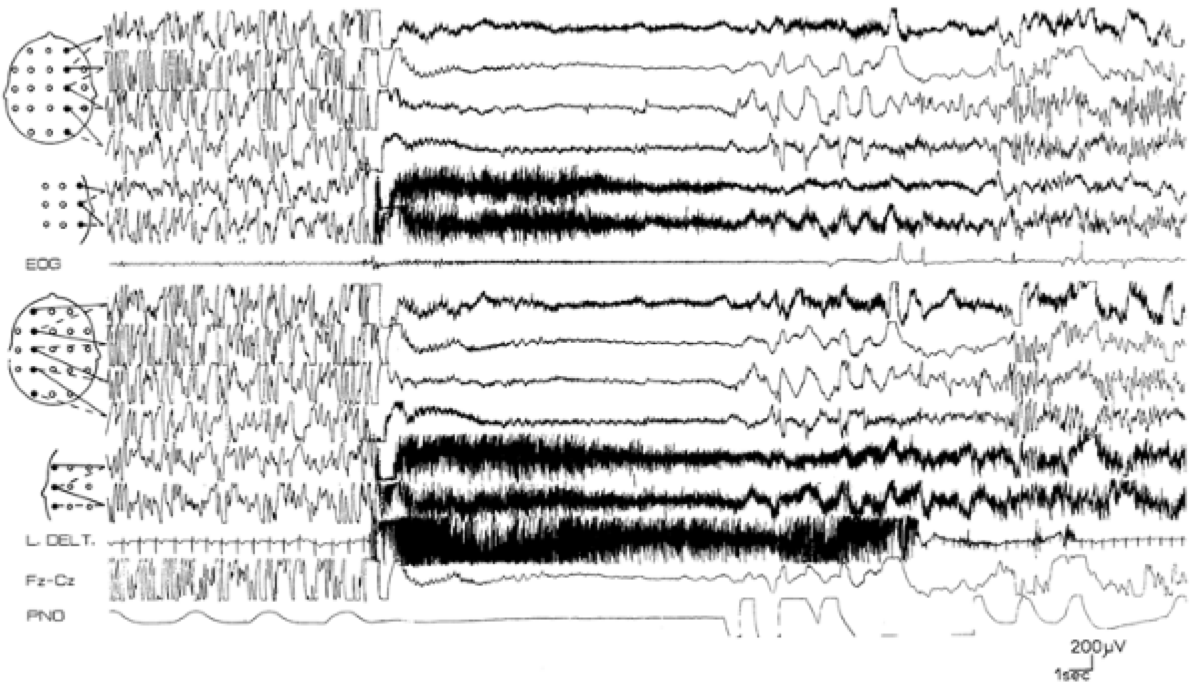

FIGURE 2. Awake recording of a tonic seizure in a boy with symptomatic Lennox-Gastaut syndrome. Interictal slow spikes-and-waves are abruptly interrupted by flattening, with superimposed rapid rhythms and muscular artifacts, for 15 seconds, followed by diffuse slow waves and then a burst of sharp waves. Polygraphy shows intense tonic contraction of the deltoid and apnea. (Note the decreased recording amplification used here.) EOG, oculogram; L DELT, left deltoid; PNO, pneumogram.

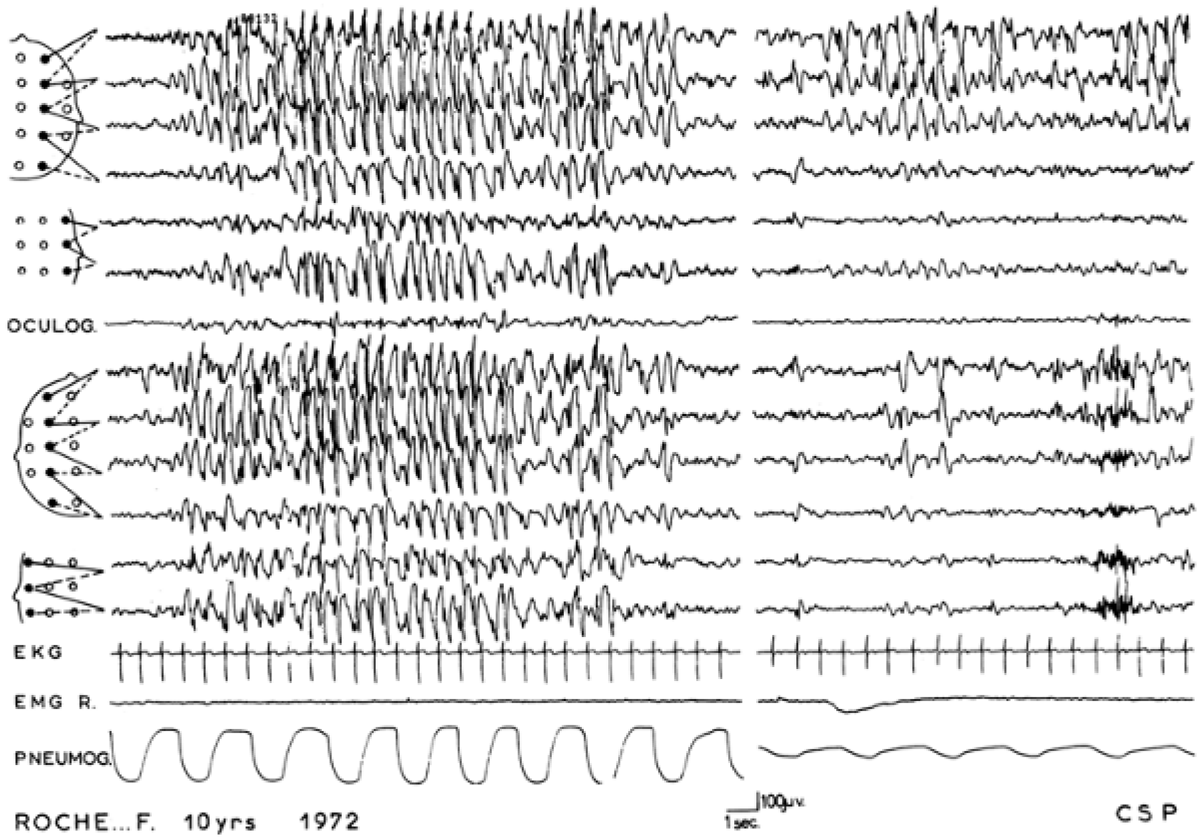

FIGURE 3. Left: Atypical absence with asymmetric, irregular, slow spikes-and-waves. **Right:** During slow sleep, one burst of frontal slow spikes-and-waves in the right hemisphere and a burst of rapid rhythms in the left hemisphere. In this girl, Lennox-Gastaut syndrome was preceded by partial seizures. EMG R, electromyogram of right deltoid.

Late-onset LGS has been studied by Oller Daurella,[69] Bauer et al.,[9] and Roger et al.[74] These authors have distinguished between LGS following idiopathic generalized epilepsy, LGS following partial epilepsy, and LGS appearing initially as the typical cryptogenic syndrome. The age of onset is usually between 10 and 20 years but in some cases was between 20 and 30 years. Patients with Down syndrome will usually initiate LGS with reflex seizures, between the ages of 8 and 12 years.[43] The clinical characteristics of late-onset LGS are the presence of tonic–automatic and generalized tonic–clonic seizures in addition to drop attacks and atypical absences. The psychologic features are mainly ideomotor slowness and psychotic change of personality. In the EEG, slow spikes-and-waves are often associated with fast spikes-and-waves.

P.2421

Diagnostic Evaluation

The diagnosis of LGS is based on electroclinical findings, which must be carefully collected. A precise description of seizures must be obtained so that atypical absences and nocturnal tonic seizures can be detected. A sleep EEG must be performed, and an afternoon sleep recording after partial sleep deprivation is usually sufficient. If the results are not informative, the EEG must be repeated, as the whole clinical and EEG picture can establish itself progressively over time. Given the subtle nature of atypical absences and sometimes of the atonic or tonic seizures, polygraphic recording with axial EMG leads is compulsory, and the importance of video-EEG monitoring has been stressed.[8] Simultaneous etiologic investigations (neurocognitive, fundus, MRI, biology) help distinguish symptomatic from cryptogenic cases.

Criteria for an early diagnosis were proposed by Boniver et al.[16] Existence of one or several seizures typical for the syndrome, presence of diffuse slow spikes-and-waves in the EEG, and cognitive impairment were considered major criteria; high frequency of seizures, drug resistance, and atypical seizures were considered minor criteria. The presence of at least two major criteria during the first 6 months of the epilepsy was strongly predictive of the diagnosis.

During the course of the disorder, the diagnosis rests on the demonstration of tonic seizures or subclinical runs of fast rhythms at 10 to 12 Hz during sleep, not on the presence of diffuse slow spikes-and-waves alone. Thus, at least one EEG must be recorded during sleep. The best way to confirm the diagnosis is to make a long video and polygraphic EEG recording with the patient awake and engaged in some activities, and again with the patient asleep (recording during an afternoon nap may be sufficient), so that interictal and ictal patterns can be studied. It is also necessary to follow the psychomotor and cognitive development of the child by the appropriate psychometric testing in order to react quickly to special educational needs.

Differential Diagnosis

Diffuse slow spikes-and-waves do not constitute a sufficient criterion for the diagnosis of LGS; they can appear secondarily during the course of other types of epilepsy,[59] as reported by Beaumanoir[11] in 38 of 103 patients seen with severe epilepsy resembling LGS. They can also be observed in cases of idiopathic generalized epilepsies modified by iatrogenic factors, and in other specific settings like the Angelman syndrome, which should be easily recognizable. A multiple seizure-type disorder with cognitive decline like the Dravet syndrome (severe myoclonic epilepsy in infancy) should not be confused with LGS, due to its own many specific diagnostic features. The main characteristics of encephalopathic epilepsies of childhood are summarized in Table 1.

The main nosologic and clinical problems involved in the differential diagnosis of LGS are different in cryptogenic and symptomatic forms, and depend partly on age at onset.

For cryptogenic LGS, the main differential diagnosis is myoclonic astatic epilepsy of early childhood (MAE, Doose syndrome), which has often been poorly separated from LGS, especially in patients with MAE and an unfavorable course, which may be associated with tonic seizures during sleep.[24] Contrary to LGS, MAE is a truly idiopathic type of epilepsy, with a strong genetic component. An in-depth clinical evaluation[52] has stressed the differential features of MAE, all of which are apparent within 1 year from seizure onset: A family history

of idiopathic epilepsy, earlier onset, fast spike-and-waves, and myoclonic and generalized tonic–clonic seizures are markers of a benign type of MAE with good outcome. Additionally, children with MAE may exhibit myoclonic status, vibratory tonic seizures, and marked slow components on the EEG, and may have a less favorable outcome. In this series, patients with a final diagnosis of LGS had atypical absences, no vibratory tonic seizures, no myoclonus, and a later age at onset, and all experienced mental degradation. Neurophysiology may also help in this differential diagnosis, with the evidence, on back-averaging studies of the EEG correlates of myoclonus, of SBS in the LGS versus a truly generalized aspect in MAE.[15]

Another condition has long been confused with LGS: Epilepsy with continuous spikes-and-waves during slow sleep (CSWS). Like LGS, CSWS, first described by Patry et al.,[71] can occur in children who were previously normal or already retarded, and in children with brain lesions or with normal MRI. It can succeed to partial or generalized epilepsy. It is characterized by atypical absences, drop attacks, mental deterioration, and diffuse slow spikes-and-waves in the EEG, especially pronounced during sleep. However, children with CSWS never have tonic seizures, either awake or during sleep, nor are runs of rapid rhythms or subclinical tonic seizures apparent in their sleep EEG. The typical sleep EEG pattern is one of continuous diffuse slow spikes-and-waves, which occupy at least 85% of slow sleep and are fragmented during rapid eye movement (REM) sleep. This pattern also occurs in children with acquired aphasia with auditory agnosia (Landau-Kleffner syndrome), which is not observed in patients with LGS. In CSWS, the epileptic seizures and EEG changes are strictly age related and always disappear at the latest during puberty.

Atypical benign partial epilepsy, described by Aicardi and Chevrie,[2] is difficult to diagnose at first, because it differs from CSWS only by its outcome and the absence of mental deterioration. It can be confused with LGS when electroclinical symptomatology worsens. At this stage, it is essential to look for factors that might explain these changes, such as inappropriate treatment or intercurrent disease, and to perform sleep EEG recordings to demonstrate the absence of tonic seizures and fast activities. This type of childhood epilepsy clearly overlaps with benign epilepsy with centrotemporal spikes and with CSWS. In the German-speaking area, the term of “pseudo-Lennox” syndrome is often used, even recommended, to describe such patients.[45]

There are severe focal epilepsies, usually of frontal lobe origin, in which seizures consist of sudden falls that resemble the drop attacks observed in the generalized epilepsies. However, in these disorders the electroclinical symptoms do not mimic those of LGS. In some cases, however, the diagnosis of focal epilepsy with SBS must be considered, to the point that the diagnosis may fluctuate between focal epilepsy with SBS and LGS at various moments during follow-up, as some age-dependent traits of LGS may disappear with maturation or may become less prominent due to medication.

Table 1 Distinctive Features of Encephalopathic Childhood Epilepsies

	Age at onset	First seizure	Other seizures	EEG changes	Mental outcome
LGS	2–8 yr	Variable	Falls Tonic, atonic Atypical absence Other (GTC, focal) Frequent status	Abnormal BA Slow SW 10–12 activities during sleep Multifocal changes	Abnormal
MAE	1–5 yr	Myoclonic, myoclonic astatic	Falls, GTC Myoclonic Atonic Obtundation state	Normal BA Centroparietal theta Generalized SW	Normal or abnormal
SME	<1 yr	Febrile clonic	Clonic, GTC, unilateral, Pseudogeneralized Myoclonic, absence, other	Normal BA at onset Multifocal Photosensitivity	Abnormal
ABPE	3–8 yr	Partial	Falls, focal Atypical absence neg. myoclonus	Normal BA Focal and diffuse	Normal

ABPE, atypical benign partial epilepsy; BA, background activity; GTC, generalized tonic–clonic; LGS, Lennox-Gastaut syndrome; MAE, myoclonic-astatic epilepsy; SME, severe myoclonic epilepsy; SW, spike-and-wave.

The concept of SBS was introduced by Jasper[51] and Tükel and Jasper.[85] SBS was described as bursts of high-amplitude, synchronous, slow spike-and-wave complexes, more or less symmetric over both hemispheres, caused by a unilateral epileptogenic lesion of the mesial surface of the frontal or temporal lobe. SBS is contrasted with *primary* bilateral synchrony, which is manifested by more rapid symmetric and synchronous spike-and-wave discharges over both hemispheres and is caused by a generalized epileptic process independent of any focal hemispheric lesion. Many authors have discussed this concept. Gastaut and Zifkin[35] and Blume[13] tried to establish the differences between epilepsy with SBS and LGS. According to the former, epilepsy with SBS begins later (mean age of onset, 10 years and 9 months); focal neurologic signs are much more frequent (hemiplegia in 30% vs. in 9% of those with LGS); obvious mental retardation is less frequent (35% vs. 87%); seizure frequency is lower; multiple seizure types are less often present in the same patient; partial seizures are more frequent; astatic seizures are less frequent; atypical absences are not observed; bursts of slow spikes-and-waves are more often asymmetric (50% vs. 23%); a constant, localized epileptic focus is seen in all cases of epilepsy with SBS versus a rather variable localized predominance of slow spikes-and-waves in LGS; and runs of rapid recruiting rhythms in slow sleep are less frequent (15% vs. 79%). The same EEG aspects were described by Niedermeyer et al.[65] in cases of severe head trauma associated with generalized tonic–clonic and complex partial seizures. Lesions are mainly frontal and temporal, and SBS can be the significant mechanism in such posttraumatic epilepsies. Epilepsy with SBS can be as severe as LGS. It is, however, important to recognize this situation, because surgery may be the treatment of choice in epilepsy with SBS— with either removal of the primary lesion when possible or callosotomy. Thorough functional imaging investigations can help determine the diagnosis and indication for surgery. Indeed, a study using ^{18}F-fluorodeoxyglucose (FDG)-PET in children with epileptic encephalopathies showed the absence of abnormal focal findings in five children with cryptogenic LGS, while focal changes were present in three fourths with an atypical LGS, and five sixths in LGS following infantile spasms.[30] It is clear that there is no tight border between LGS and epilepsy with SBS, especially in symptomatic, lesional cases.

Treatment

LGS is highly drug resistant. Classic antiepileptic drugs (AEDs) usually do not bring total seizure control, and the "gold standard" of monotherapy can seldom be applied.[12] Polytherapy, with a combination of drugs respectively active against the main seizure types, is the rule. A mixed seizure disorder with frequent attacks that requires polytherapy, like LGS, is a likely candidate for paradoxic aggravation of seizures,[37] and this phenomenon may escape attention due to the subtle character of seizures, to the unlikelihood of self-reporting, and to the spontaneously fluctuating course of the condition. Drugs that may aggravate typical absences are likely to increase atypical absences as well as myoclonic or astatic seizures. Specific aggravation has been described in LGS following the use of IV clo-nazepam, which may induce tonic status,[81] and following the use of gabapentin,[90] but these reports concern only the tip of the iceberg. Clinicians should thus remain acutely aware of the possibility of drug-induced aggravation in patients with LGS. Moreover, unwanted side effects of AED are more likely to occur in LGS, due to polytherapy and use of high daily doses, and they may be overlooked because of the spontaneous severity of the condition and the lack of adequate communication with the patient. Clinicians should also be aware of this. Recent considerations about treatment attitudes have stressed that individual risk–benefit considerations should apply.[77] Overtreatment is probably common, and may contribute in part to the unfavorable long-term evolution. Treatments used in LGS include classic MAE, recent MAE, and nonpharmacologic treatments like the ketogenic diet, vagus nerve stimulation, and surgery.

Among the classic AEDs, carbamazepine, valproate, and benzodiazepines are often used, mostly in combination. Despite their metabolic interactions, carbamazepine and valproate give interesting results when given in combination. Carbamazepine (like phenytoin) is effective against tonic seizures, but may increase absences, while valproate (like ethosuximide) is effective against atypical absences and myoclonic or atonic seizures, but has little effect on tonic seizures. Clobazam and nitrazepam have fewer side effects than clonazepam and may need to be prescribed alternatively because tolerance may occur. Nitrazepam, which has been recommended by the Marseille

P.2424

school in the treatment of LGS nearly 40 years ago, is seeming to enjoy a revival, with estimated responder rates above 50% and few side effects besides sedation and drooling.[49] Phenyt-oin can be used in adolescents and adults for the vibratory tonic and tonic–clonic attacks, and is often initiated during a tonic status.

Ethosuximide can also help control the atypical absences.

Among the newer AEDs, vigabatrin has not proved very useful. However, it is worth trying, and some good results have been reported in LGS associated with cortical dysplasia.[44] La-motrigine has proven efficacy in open studies[23,83] and in controlled trials,[64] apparently mostly when used in combination with valproate, which matches our own experience. Felbamate retains selective indications in LGS, with proven efficacy,[6] and a favorable effect on cognitive function and behavior[36]; its efficacy may be due in part to its combination with valproate.[78] Topiramate has been proven efficacious, especially against drop attacks, both in open-label, long-term studies[40] and in shorter controlled trials.[76] However, its efficacy is less prominent in LGS than in other epileptic encephalopathies like the Dravet syndrome.[62] There is a single study alluding to a possible positive effect of levetiracetam in LGS, especially against myoclonic and generalized tonic–clonic seizures, without effect, however, on tonic seizures.[22] Zonisamide has been used for more than 15 years in Japan, and is considered appropriate for use in LGS.[67] Among AEDs still in development, rufinamide has received an orphan drug designation in Europe for patients with LGS.[5]

The course of the disease is characterized by a succession of bad and better periods. During the better periods, only nocturnal seizures are observed, and patients are less handicapped in their daily life. But series of tonic seizures can occur suddenly, without obvious reason, particularly in the early morning. Even when epilepsy has improved, cognitive impairment and behavioral disturbances persist, requiring educational and psychological support. The degree of mental deficit is variable, from slight to profound. In cryptogenic cases, it increases with age and repetition of seizures, but it is less marked than in symptomatic cases.

One of the aims of treatment is to avoid episodes of status. Sometimes they are provoked by triggering factors, such as intercurrent illness, changes in drug regimen, and psychological stress.[26] In case of impending status, it is better not to change the treatment dramatically and not to hospitalize the patient in a nonspecialized unit. Rectal injections of diazepam or oral intake of a high dose of clobazam (30 to 40 mg) can stop serial attacks and avoid hospital admission. Overt status can be treated with IV benzodiazepines and/or phenytoin, sometimes with concomitant steroids, and with respiratory assistance if necessary. It must be noted that status is much less life threatening in LGS than in other types of epilepsies. Recovery is relatively swift. Steroids may be tried in children early in the course of the disease, as in infantile spasms.

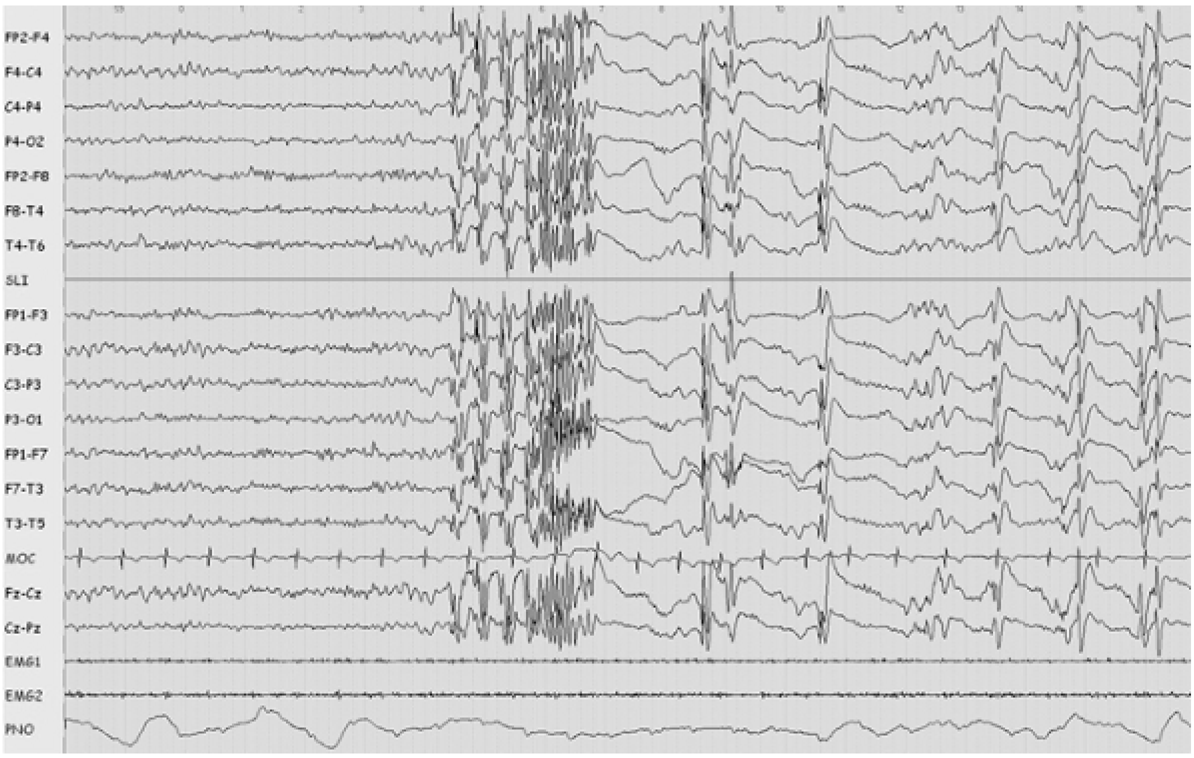

FIGURE 4. Sleep electroencephalogram (EEG) in a 48-year-old patient with cryptogenic Lennox-Gastaut syndrome since the age of 5. She lives in a home for the handicapped and has part-time sheltered employment. She still has several falls per month, atypical absences, and frequent nocturnal tonic seizures (usually several per night), with rare generalized tonic–clonic seizures. She receives a combination of valproate, felbamate, phenobarbital, and clobazam. Her waking EEG shows normal background *α* activity and is devoid of paroxysmal changes (not shown). During an afternoon sleep recording, there were few physiologic sleep transients and numerous high-amplitude bursts of fast activities, as well as suppressions and isolated spike-waves.

Other treatments have been used in LGS, without controlled trials. IV γ-globulins have been proposed,[17] as has thyrotropin-releasing hormone.[54] The ketogenic diet has been used, but not in controlled trials.

Surgical procedures are not often considered as treatment options. Callosotomy brought significant seizure relief to 31 of 48 (64.6%) patients with LGS,[55] but is reputedly less efficacious than in focal epilepsies with SBS. There are only isolated reports on successful lesional surgery in patients with focal brain pathology and LGS.[27] Conversely, vagal nerve stimulation (VNS) has been used quite extensively in LGS, and is considered well tolerated. A Dutch study showed marked cognitive improvement, which did not correlate with the modest effect on seizures (26.9% average seizure reduction).[3] This contrasts with the 52.2% seizure reduction observed in a U.S. study,[50] in which 3 of 13 patients reached a 90% reduction in seizure frequency. Indeed, the response may increase over time, with seizure reduction of 42% at 1 month, 58.2% at 3 months, and 57.9% at 6 months.[31] Stimulation procedures differing from VNS, especially deep brain stimulation, have been tried in selected patients,[88] apparently with some positive results against atypical absences and tonic seizures.[86,87] Modern recommendations are that the baseline treatment for LGS should rely on valproate, benzodiazepines, and either lamotrigine or to-piramate as second-line add-ons,[77] with the valproate + la-motrigine or valproate + topiramate probably representing the most logical, synergistic combinations. They carry their own risks, cumulating the potential side effects of either drug with the specific side effects of these combinations. According to a recent Cochrane review, none of the recent AED has shown spectacular power against LGS, and each case should be considered individually.[46] Indications for nonpharmacologic treatments should also be assessed individually. The multiplicity of therapeutic proposals does not really mask—and indeed, rather underlines—the relative impotency of medical intervention in LGS. Practical management is also a matter of common sense and restraint.

Long-term Prognosis

As stressed by all authors who have studied this syndrome, its long-term prognosis is unfavorable, and it is too soon to know whether it will be improved by recent advances in epilepsy treatment. Unfortunately, the availability of many new treatment options has not changed the global outlook for patients with LGS, in contrast with the apparently improved prognosis of MAE and Dravet syndrome.

Complete seizure-free recovery is rare: 13.7% of patients for Ohtahara et al.,[68] 6.7% for Gastaut et al.,[34] and none of the cryptogenic cases followed up for more than 15 years by Beaumanoir.[11] Among 72 patients followed over more than 10 years, 33% of the cryptogenic and 55% of the symptomatic cases had lost the characteristics of LGS, turning into nonspecific generalized symptomatic epilepsies, severe epilepsy with multiple independent spike foci, or localization-related epilepsies.[66] In another long-term study, with an average follow-up of 16 years, only 33% of 102 patients retained LGS.[91] Few studies have considered the epilepsy outcome in adulthood. Roger et al.[74] reported that only 47% of patients maintained a complete LGS profile in adulthood. Most had cryptogenic LGS with an onset before the age of 4 years. In 16%, generally those with symptomatic LGS, the syndrome as such disappeared, but an often severe, mostly unifocal epilepsy persisted, together with symptoms of frontal lobe dysfunctions. In 20%, seizures were rare, probably partial, but gross psychological disturbances were present. In 17%, epilepsy seemed to be nearly completely cured, with a normal or subnormal mental state. Rai et al.[72] reported on 17 patients institutionalized in an epilepsy center for a period of 16 years. The severity of epilepsy decreased even though the seizure types remained more or less unchanged. However, an attempt to reduce polytherapy failed, and a global improvement was observed only in three patients who had a relatively late onset of LGS between ages 5 and 10.

Mental deficiency is observed in 85% to 92% of patients. Major changes in behavior may occur at adolescence, with onset of violence, often directed against close family members. Frequently, but not consistently, patients become psychotic. Many patients are finally institutionalized, either in centers for epileptic patients or in homes for mentally handicapped people. Some children who are absolutely normal before the onset of cryptogenic LGS have a relatively good social outcome, with normal or near-normal schooling, and reach employment (often in a sheltered context) despite persisting seizures. The EEG features often attenuate with age, but some patients will retain

the full-blown LGS symptomatology, including the typical EEG traits, especially during sleep (Fig. 4), while awake EEGs may show only a slow background without slow spike-and-wave discharges.

Death is caused by intercurrent disease or accident, rarely by epilepsy itself. The mortality rate is difficult to assess: About 3% in the series of Gastaut et al.[34] with a mean follow-up of 8 years and 7 months, and 7% in that of Loubier[60] with a mean follow-up of 9 years and 9 months.

The main factors for a poor prognosis are the symptomatic nature of the syndrome, particularly after infantile spasms; early age at onset, before 3 years; high frequency of seizures; long duration of worsening periods; frequent status; and the presence of constantly slow background activity and multifocal localized abnormalities on the EEG.

Summary and Conclusions

Lennox-Gastaut syndrome is a well-defined epilepsy syndrome that can be easily recognized using a careful clinical and EEG approach and applying consensual diagnostic criteria. It is still overdiagnosed due to the prevalent concept that slow spike-waves and mental handicap is synonymous with LGS. It may be difficult to distinguish from myoclonic astatic epilepsy, and from epilepsies with secondary bilateral synchrony. It stands out among epileptic encephalopathies as a true syndrome, with multiple etiologies and a fairly homogenous presentation and prognosis. The multiplicity of therapeutic proposals does not really mask—and indeed, rather underlines—the relative impotency of medical intervention in LGS. Practical management is a matter of common sense and restraint. Here, as in other difficult-to-treat epilepsies, one shouldn't do anything just because not much can be done.

Chapter 242

Landau-Kleffner Syndrome and CSWS

Michael C. Smith

Charles E. Polkey

Introduction

Landau-Kleffner syndrome (LKS) and the syndrome of continuous spikes-and-waves during slow sleep (CSWS) were described independently and have been considered separate disorders. Both have been given distinct recognition by the Commission on Classification and Terminology of the International League Against Epilepsy[13] and by the World Health Organization in the International Classification of Diseases.[74] More recently, however, emphasis has been placed on the possibility that there may be common features in the pathophysiology of these two syndromes[15,25,27,28,41,43,62,71] and that LKS may actually be a subtype of CSWS.[25,43,46,62] A major symposium on this subject was held in Venice in 1993 and published in 1995.[8]

LKS and CSWS appear to represent points on a spectrum of functional age-related epilepsies ranging from the "benign" idiopathic localization-related childhood syndromes, such as benign childhood epilepsy with centrotemporal spikes (BECT), to full-blown continuous spikes-and-waves in slow sleep associated with behavioral disturbances.[62] They differ from the secondary generalized epilepsies, such as Lennox-Gastaut syndrome (LGS), in being a truly functional disturbance induced by age-related, self-limited paroxysmal activity.

Historical Perspectives

In 1957 Landau and Kleffner[37] reported six children with a syndrome of "acquired aphasia with a convulsive disorder." One of the children became aphasic and hemiplegic after a head injury, but the other five children's developmental aphasia was related to their convulsive disorder. These five children were presented in detail, with one added as an addendum. Landau and Kleffner described an aphasia that developed over days to months that then persisted from 2 weeks to several years. The associated seizures included grand mal, petit mal, and myoclonic seizures, and the paroxysmal abnormality was usually bilateral, most prominent over the temporal lobes.

They felt that although the relationship was not perfect, the severity of the paroxysmal disturbance on the electroencephalogram (EEG) did correspond to the severity of language disturbance. Landau and Kleffner noted that the seizures were easily controlled and the prognosis was generally good. They hypothesized that persistent convulsive discharge in brain tissue responsible for linguistic communication results in the functional ablation of these areas for normal language behavior. Their thesis was supported by the fact that these children did not have clouded consciousness like patients in petit mal status and had good performance on nonverbal intelligence tests.[37]

Since that time there have been over 350 published cases of acquired aphasia associated with a paroxysmal EEG.[4] The EEG abnormality is a predominantly bilateral posterior temporal spike or spike-and-wave discharge that is activated by slow-wave

P.2430

sleep. Most observers agree that the ultimate language outcome correlates with the age of onset of this epileptic disturbance, as well as its severity, bilateral anatomic location, and duration of the active phase.[15,28,41,62]

In 1971 Patry et al.[52] described "subclinical electrical status epilepticus" induced by sleep in children. They reported on six children who displayed seizures; cognitive decline, including language dysfunction; and severe paroxysmal EEG disturbance. The patients ranged in age from 7 to 12, four boys and two girls. There was a history of birth trauma in three, consanguinity in two, and epilepsy in the family of one. All displayed continuous spikes-and-waves in 85% of the non–rapid eye movement (REM) sleep record for an extended period of time. Seizures were described as atonic, generalized tonic–clonic, convulsive, clonic, and atypical absence. Five of the six children were mentally retarded and two failed to acquire language. The authors noted that the degree of mental retardation was related to the age of onset of the seizures and hypothesized that this syndrome represented a form of encephalopathy secondary to a focal or multifocal brain lesion. The activation of the paroxysmal activity during sleep, especially slow-wave sleep, was due to a particularly active synchronizing system during slow sleep.[52]

Tassinari et al. later retitled this syndrome electrical status epilepsy during sleep (ESES)[69] and then CSWS,[67] as a result of the criticism that clinical seizures were not seen during the spike-and-wave discharges. Tassinari et al. concluded that the persistent continuous spike-and-wave discharges over years were responsible for the complex and severe neurologic impairment.[67]

Definitions

LKS is a functional disorder of childhood usually described as having the following features: Acquired aphasia, paroxysmal EEG that is usually bitemporal, seizures that are easily treatable and self-limited, no demonstrable brain pathology that is sufficient to explain the behavioral symptomatology, and some degree of improvement when the epileptic condition resolves.[17,25,36,46,49,53,57]

Although these features are commonly cited in the literature, there are exceptions. The language disturbance is described as an acquired aphasia, but both these terms have been challenged. Rapin et al. argued that it is not an aphasia, but a verbal agnosia.[56] In fact, recent evidence suggests that it is an auditory agnosia.[49] Acquired aphasia implies a demonstrable age-appropriate language prior to onset of the CSWS. Early onset of the same process could prevent language function before any language is clearly demonstrable; however, a diagnosis of LKS would be impossible in this situation unless the aphasia is reversed by stopping the epileptic activity.

The paroxysmal EEG is commonly described as predominantly bitemporal and activated by sleep, especially slow-wave sleep. It usually becomes continuous in slow-wave sleep and persists for an extended period.[46] However, the paroxysmal disturbance may be interrupted by normal sleep EEG patterns, and eventually the epileptiform EEG disturbances disappear completely.[29] Furthermore, as will be discussed later, there is evidence to suggest that the primary epileptogenic region is unilateral.[46,49] Awake EEGs may be normal, even in the active phase of spike-and-wave during sleep. Seizures are not always seen, and when present may be quite subtle and not reported.[17,27,49]

Although there is no demonstrable brain pathology sufficient to explain the language dysfunction, multiple nonspecific structural abnormalities have been associated with LKS,[63] which presumably accounts for the epileptiform disturbances.

There is improvement in language function in all patients with the resolution of the active phase of spike-and-wave discharges; however, permanent sequelae in language function are usually seen, especially when there has been early onset of epileptic EEG activity[8,25,53,62] and when the epileptic activity is not eliminated before the critical period for language development is over.[44,49,57,58] LKS therefore represents an age-dependent functional disruption of language induced by a localized paroxysmal EEG disturbance.

CSWS is a functional disorder of childhood with the following features: Severe paroxysmal EEG disturbance, occupying at least 85% of sleep (sleep index 85%); seizures that may be severe but self-limited; behavioral deterioration, with or without premorbid developmental disturbances; no demonstrable brain pathology sufficient to explain the behavioral deterioration; and stabilization or improvement of behavior once the epileptiform EEG abnormalities resolve.[9,68]

These features are not invariably agreed upon. Although Tassinari et al.[68] have maintained that a sleep index of 85% is a necessary component of the diagnosis, the ILAE definition did not require it (ILAE 1989). There may be fluctuations, fragmentation, and variability in the continuity of the spike-and-wave discharges over time. Seizures are usually seen, but they may be subtle and go unreported.[9,68] Traditional antiepileptic drugs usually prevent the expression of the seizures but do not eliminate the paroxysmal EEG abnormality. Although behavioral deterioration is seen in all patients, it may not be as marked in those with previously abnormal development.[68]

Prior abnormal neurologic development is not uncommon in CSWS. Demonstrable brain pathology is seen, but it is insufficient to explain the deterioration of function. There is spontaneous resolution of the epileptiform discharges by the midteenage years with stabilization and often improvement of the neuropsychological and behavioral deterioration. However, significant permanent sequelae are seen in the majority of patients that appear to be related to the duration of the active phase of spike-and-wave activity.[9,53,73] CSWS, therefore, also appears to be an age-dependent disturbance of brain function, induced by a severe paroxysmal disturbance that resolves over time.

Epidemiology

The frequency of Landau-Kleffner syndrome cannot be accurately ascertained. Using the strict diagnostic criteria discussed earlier, LKS is a rare disorder. There have been over 350 published cases since 1957. There were 81 cases reported between 1957 and 1980, but 117 cases were reported between 1980 and 1990.[3] Dugas et al.[21] observed one new case per year in a Parisian psychiatric clinic. Males are affected more commonly than females, with a peak onset between 5 and 7 years of age.[10]

The frequency of CSWS is also unknown. Using the strict criteria of continuous spike-and-wave discharge during 85% of sleep associated with cognitive and behavioral decline, CSWS is a rare disorder. Between 1971 and 1984, Tassinari et al. reported 19 personal cases from the Centre St. Paul in Marseille and an additional 25 from the literature.[67] Since 1984, ten new cases have been seen at the Centre St. Paul, a rate of one to two per year.[68] Males are affected more commonly than females, with a peak onset between 5 and 7 years of age.[10]

Etiology and Basic Mechanisms

A convergence of evidence suggests that LKS and CSWS are due to a common pathophysiologic mechanism,[14,25,27,29,41,43,46,62,71] and a specific hypothesis has been proposed for LKS.[46,49] Both disorders develop during a period of cortical synaptogenesis when the basic functional circuitry is being established (age 1 to 8). Synaptogenesis involves an overabundant growth of axonal processes and synaptic contacts thought to be twice the number found in mature adults.[31,32,54,55] Neuronal activity or synaptic use is the major factor that determines which synapses will be strengthened and which will be pruned.[31,54] The environment, more than genetic programming, plays the crucial role in the establishment of permanent synaptic contacts. If a significant paroxysmal EEG disturbance is present during this age-dependent synaptogenesis, it acts to strengthen synaptic contacts that should have degenerated in order for the neuronal aggregates to mediate normal behavior.[49] In the case of LKS, the paroxysmal activity reinforces inappropriate contacts in the developing temporoparietal cortex, thus producing a permanent language dysfunction.[49] In addition, the disturbance must have a bilateral effect to prevent transfer of function to the contralateral homotopic cortex. In CSWS, the most prominent paroxysmal activity appears to be in the frontal area, which would disrupt higher cognitive and executive function and attention before producing language dysfunction. Because the functional disruptions induced by paroxysmal EEG activity can spread to involve a larger cortical area, the symptom complexes of LKS and CSWS tend to merge as the disease goes on, producing severe cognitive, behavioral, and social dysfunction, much like the child with severe autism.

This proposed underlying mechanism predicts that, if unsuccessfully treated, those children affected earlier in this period of synaptogenesis will suffer the most serious neuropsychological sequelae after the epileptiform disturbances remit. Several authors have reported this in their series.[8,23,57,58,70] The importance of overactive inhibition as well as overactive excitation in these syndromes has been recently highlighted. This combination results in coexistence of a lack of overt seizures at the same time as severe cognitive/language dysfunction—a hallmark of the epileptic encephalopathies.[27]

Multiple nonspecific pathologic abnormalities can be associated with these syndromes and, although insufficient to explain the behavioral deterioration, may be responsible for the epileptic disturbances. Common etiologies in CSWS include congenital hydrocephalus, periventricular, and diffuse atrophy.[7,20] The pathologic findings associated with LKS in the literature are similar to those seen in other partial epilepsies; they include encephalitis, vasculitis, subpial gliosis, cysticercosis, and neuronal migration disorders.[12] The biopsy material taken from the temporal pole, at a distance from the primary epileptic site, in one surgical series of 14 patients with LKS revealed a variety of pathologic abnormalities in 13.[63]

The mechanistic hypothesis presented here raises the question of whether other epilepsies might also induce progressive behavioral dysfunction. BECT and other idiopathic localization-related epilepsies involving frontal, temporal, parietal, and occipital lobes all could have deleterious effects on cortical development and function where the abnormality

is maximal. It may be that we cannot clinically detect the permanent sequelae because of the poor sensitivity of our testing.

Clinical Presentation

Landau-Kleffner Syndrome

LKS is an acquired epileptic aphasia or auditory agnosia, occurring in a previously normal child, in language function, in association with paroxysmal EEG abnormalities with or without clinically apparent seizures, and without a structural substrate sufficient to account for the behavioral deterioration. The disorder begins most commonly between the ages of 3 and 8 in children who have already developed age-appropriate speech. The onset may be subacute or stuttering and initially consists of a loss of verbal understanding (i.e., receptive disturbances predominate). Soon, however, speech output is affected and paraphasias and phonologic errors appear. In the most severe cases, the child becomes entirely mute and will fail to respond to even nonverbal sounds—such as the ring of a telephone, a knock on the door, or a dog barking—that were previously well attended to. Behavioral disorders such as hyperactivity and attention deficit are common. Rarely, there is progression to severe disinhibition and psychosis.[3,46,49]

Seizures vary in type, but most commonly are associated with eye blinking or brief ocular deviation, head drop, and minor automatisms with occasional secondary generalization. They bear a variable relationship to the language deficit, and, indeed, from 20% to 30% of patients do not exhibit behavioral seizures.[4] The seizures have a benign course, are readily responsive to antiepileptic drugs, and generally subside by the age of 15 years. The language disturbance, as a rule, has a much less satisfactory prognosis, although early on the symptoms may show marked fluctuation, and even complete recovery, within weeks or months of onset.[15] However, if the aphasia persists for more than 2 to 3 years, complete recovery is most unusual; such patients may expect a lifelong linguistic defect.[8,36,46,49,53,57]

A critical component of LKS is the presence of continuous 1.5- to 5-Hz spike-and-wave EEG discharges in slow sleep that fragment or disappear during REM sleep[29,41,42,46,49] (Fig. 1). It is this latter feature that links the two conditions under discussion and provides the impetus to seek clinical similarities. A distinctive feature of LKS, however, is that the spike-and-wave discharges predominate in the posterior temporal regions. Most patients do not show spike-and-wave activity for 85% or more of slow sleep at the time of study, and some may not show continuous spike-and-wave during sleep at all; however, it has been assumed that this condition was met at some point during the course of the disorder.[46] During the active phase, brief posterior temporal epileptiform discharges can also be seen during wakefulness on the routine EEG, which can be localized to one posterior temporal region. With the use of the methohexital suppression test,[47,64] intracarotid amobarbital, EEG dipole mapping, and magnetoencephalogram (MEG), it can be shown that most, if not all, children have a unilateral primary epileptogenic region.[39,46,49,51,65] This can involve either side, since the contralateral propagation of paroxysmal discharges creates bilateral dysfunction that disrupts normal language development, regardless of the side of origin.

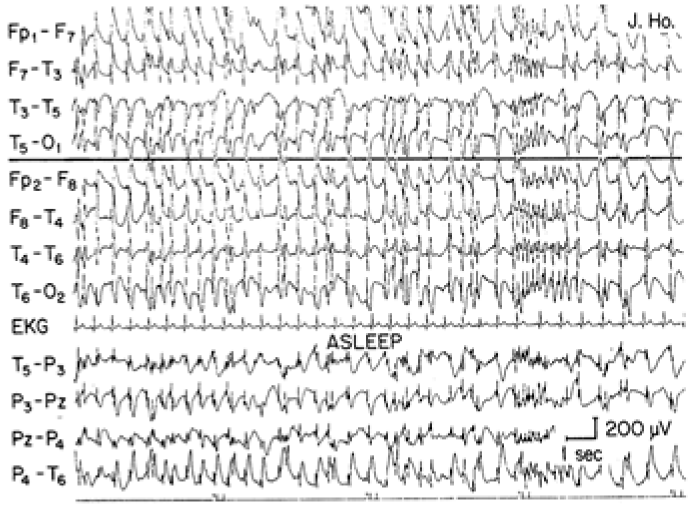

FIGURE 1. Electroencephalogram tracing taken during sleep in a patient with Landau-Kleffner syndrome prior to treatment. Such patterns may occupy 80% to 90% of the hours normally given to slow-wave sleep. The first four channels derive from the left hemisphere, the second four from the homotopic regions on the right. The lowest four channels show a transverse array, left to right, across the parietal region. Electrode designations are those of the standard "10 to 20" international system. (From Morrell F, Whisler WW, Smith MC, et al. Landau-Kleffner syndrome: treatment with subpial intracortical transection. *Brain.* 1995;118:1529–1546.)

Continuous Spikes-and-Waves during Slow Sleep

The EEG pattern of CSWS consists of bilateral generalized, 1.5- to 5-Hz spike-and-wave discharges strongly activated by sleep, being present for 85% to 90% of slow-wave sleep and interrupted during REM episodes or in the waking state. REM and wakefulness are characterized by focal or multifocal paroxysmal EEG activity, or by brief bursts of bilateral spike-and-wave discharges.[52] Focal spikes tend to be frontal.

Generally, the seizures associated with CSWS are focal motor or hemiclonic, partial motor, complex partial, absence, or secondarily generalized tonic–clonic. Tonic seizures do not occur. Although the seizures may be frequent, they are usually responsive to medical management and disappear entirely in the middle teens.[10,68]

Much more serious are the cognitive disturbances. These may include aphasias and apraxias, but generally embody widespread multisystem cognitive decline leading to substantial retardation and dementia.[9,68] Although the cognitive symptoms are highly correlated in time with the onset of CSWS, antiepileptic drugs do not improve them.

Tassinari et al.[68] have distinguished three groups of patients with CSWS based on clinical seizures. The first group suffers rare orofacial, generalized tonic–clonic, and myoclonic seizures in sleep. These patients resemble children with BECT. The second group suffers unilateral partial, generalized tonic–clonic, and absence seizures. The frequency of seizures in this group is greater, and seizures occur in wakefulness. The third group has unilateral partial and generalized tonic–clonic seizures in sleep and absence, absence status, and atonic seizures with falls in wakefulness.[68]

Table 1 Comparison of LKS versus CSWS[a]

	LKS	CSWS
Sex	**(Sex) 68% male**	**(Sex) 63% male**
Antecedent history	3% encephalopathy	31%; 36% cerebral palsy; 36% encephalopathy
FH epilepsy	3%	10%
Age of onset	Peak, 5–7; 5% after 9 years of age	Peak, 5–7; 20% after 9 years of age
First symptom	Seizure, 60%	Seizure, 80%
Second symptom	Neuropsychological, 40%	Neuropsychological, 40%
Seizure types	GTC seizure, 35%; unilateral, 26%; unilateral status, 6%	Unilateral, 50%; unilateral status, 6%; absence, GTC, CPS
During active phase of spike-and-wave	(-) atonic seizure, not significant ↑ seizure, clonic/unilateral, CPS	+ atonic seizure/with fall, significant ↑ in seizures, ↑ absence, ↑ atonic seizure, ↑ atypical absence
After active phase of spike-and-wave	19% rare seizure: 81% seizure free	16% rare seizure; 84% seizure free
Neuroimaging	13% abnormal	33% abnormal
Meet criteria for 85% spike-and-wave in sleep	<50%	78%

When reviewing the psychomotor development and neuropsychological disturbances, Tassinari et al.[68] distinguished two groups. The first has a normal development prior to the CSWS. During the active phase of epileptic discharge, there is a severe decrease in IQ, marked reduction in language function in the majority, severe disturbance of temporospatial orientation, and a marked behavioral disturbance in all. The behavioral disturbance includes reduced attention span, hyperactivity, aggressiveness, disinhibition, and difficulty in contact with the environment. The second group has pre-existing abnormalities of psychomotor development. These patients suffer deterioration of function and worsening of behavior, but this condition

is not as marked from pre-existing baseline as that of the first group. Long-term outcome in a CSWS patient is generally poor, with significant mental retardation common and frontal lobe syndrome and frontal lobe epilepsy described.[53,73]

Overlap between the Syndromes

A major problem in our understanding of this spectrum of age-related functional cognitive disorders induced by paroxysmal activity has been the low frequency of reported cases in a given institution. At the Venice colloquium,[6] case reports from an international group were analyzed, yielding 103 patients. Of this group, 71 best fit the syndrome of CSWS and 31 best fit that of LKS. One could not be classified. This substantial body of information allows a direct comparison of these two syndromes.[10] Not all the cases could be used in each reported analysis because of the insufficient or poorly described information. Nonetheless, these data confirm the significant overlap between these proposed separate syndromes (Table 1). The reported differences in clinical presentation, seizure type, and neurologic and behavioral sequelae appear to be due to the primary cortical area involved; the age of onset of epileptiform EEG abnormalities in relation to age-dependent synaptogenesis; severity of the continuous spikes-and-waves during sleep, as measured by the sleep index; and length of time the EEG abnormality persisted.[66] Because of the commonality of features and the more specific localization of the epileptogenic region in LKS, it might be considered a subtype of CSWS.[46]

Diagnostic Evaluation

In the evaluation of children with suspected LKS or CSWS, a careful developmental history is taken and physical and neurologic examinations are done. Documentation of premorbid language and of cognitive and behavioral performance is sought, including school testing and intelligence testing.[49]

All children with suspected LKS or CSWS should undergo careful neuropsychological testing by a specialist team experienced in both linguistic and nonlinguistic capacity. This testing allows one to judge whether there are specific deficits in cognitive function, as expected in LKS in the language domain, or whether there is frontal dysfunction, as expected in CSWS.

Laboratory testing includes structural and functional neuroimaging. Routine EEG is essential, and either closed-circuit television (CCTV)-EEG monitoring or ambulatory monitoring can be helpful.[3,46,49] More sophisticated investigations, which are of value for LKS when surgical treatment is considered, can include MEG,[39,51,65] computerized amplitude mapping of EEG, and intracranial EEG recordings, as reviewed by Morrell et al.[49]

In general, structural neuroimaging is usually normal in LKS but abnormal in CSWS, reflecting the prior neurologic insult.[49,68] The structural abnormalities reported in CSWS include unilateral atrophy, focal porencephaly, focal pachygyria, diffuse atrophy, congenital hydrocephalus, and minor white matter abnormalities. The abnormalities reported in LKS include focal pachygyria and mild diffuse atrophy.[7,10,20]

Functional neuroimaging has been reported in only a minority of patients with LKS and CSWS. An important point in interpreting these results is to know whether radionucleotide injection and scan was performed during the active phase of spike-and-wave and whether it was performed in the wake or asleep state. In general, if scans are performed in the wake state or after the period of active spike-and-wave activity, both single photon emission computed tomography (SPECT) and positron emission tomography with ^{18}F-fluorodeoxyglucose (FDG-PET) show an area of decreased blood flow or glucose utilization, whereas if they are done in sedated patients with induced continuous spikes-and-waves, they show a focal area of increased

P.2433

blood flow or glucose utilization.[41,49] Hirsch et al. reported increased glucose metabolism during the active phase of spike-and-wave during both the asleep and wake states in both disorders, though the area of increased metabolism was greater in sleep.[28] It is not noted whether the paroxysmal activity was present during the wake scan. The hypermetabolism was restricted to focal or regional cortical association areas and the type of neuropsychological impairment was in good agreement with the topography of this disturbance.[28,41] The pattern seen in both LKS and CSWS combined features of immature brain with superimposed focal abnormalities. The metabolic abnormalities of these two syndromes displayed significant overlap, suggesting that they represent two parts of the same spectrum of functional disorders of childhood.[28,41] Some patients who underwent FDG-PET scans after the active phase of spike-and-wave discharges had resolved showed persistent regions of hypometabolism in areas that previously showed hypermetabolism, documenting enduring metabolic change.[41]

EEG recordings in slow sleep are important in the diagnosis of LKS and CSWS, but, because of the short recording time, routine studies rarely record slow-wave sleep. Amitriptyline at a dose of 1 to 2 mg/kg and a prolonged recording of 3 hours significantly improves the chance of observing slow sleep. The Venice colloquium provided direct comparison of EEG data in LKS and CSWS[6] (see Table 1). During the active phase of spike-and-wave discharges, more patients with CSWS met the criteria of a sleep index of 85% than those with LKS. The average frequency of the spikes-and-waves was 2 Hz in each disorder. Sleep spindles were absent in 10% of patients, more commonly in the CSWS group than in the LKS group. If a patient had a frontal EEG spike focus, he or she was more likely to have a sleep index of 85% or greater, suggesting that intrinsic circuitry and dense callosal connections of the frontal lobe predispose to generalization during sleep. Patients could be divided into two groups, depending on the severity of the EEG abnormality. The first group had a sleep index of 85% or greater, frequently disrupted sleep spindles, only rare focal discharges during sleep, and bursts of spikes-and-waves in wakefulness. This EEG pattern was seen in 70% of patients with CSWS and in 40% of those with LKS. The second, less severely affected group, showed a sleep index between 50% and 80%, often recognizable sleep spindles, more frequent focal spiking during sleep, and absent or rare spike-and-wave discharges during wakefulness. This set of EEG findings was seen in 30% of the CSWS group and in 60% of the LKS group. These data support the significant overlap in EEG findings, although those with CSWS are more likely to have a severely affected EEG.[6] In addition, focal spikes tend to be frontal in CSWS and are temporoparietal in LKS.

Magnetoencephalography on a number of patients with LKS revealed a focus of slow waves and epileptiform activity in the posterior temporal area adjacent to the sylvian fissure, supporting an origin in the dorsal surface of the superior temporal gyrus[24,39,49,53,65] (Fig. 2). Computerized amplitude and polarity mapping has also been performed in a few patients with LKS and CSWS. In LKS, isolated unilateral spikes during the methohexital suppression test or the first spike in a burst of spikes-and-waves displays a tangential dipole with suprasylvian negativity and infrasylvian positivity, also indicating the origin to be in the dorsal surface of the superior temporal gyrus.[30,41] Amplitude mapping of spikes during wakefulness in three cases of CSWS showed two to be predominantly left frontal with temporal spread and one right frontal with frontal and temporal spread. The sleep spikes tended to have a more diffuse distribution.[24,62] Although the number of cases studied is small, they support differences in maximal cortical areas involved in these syndromes.

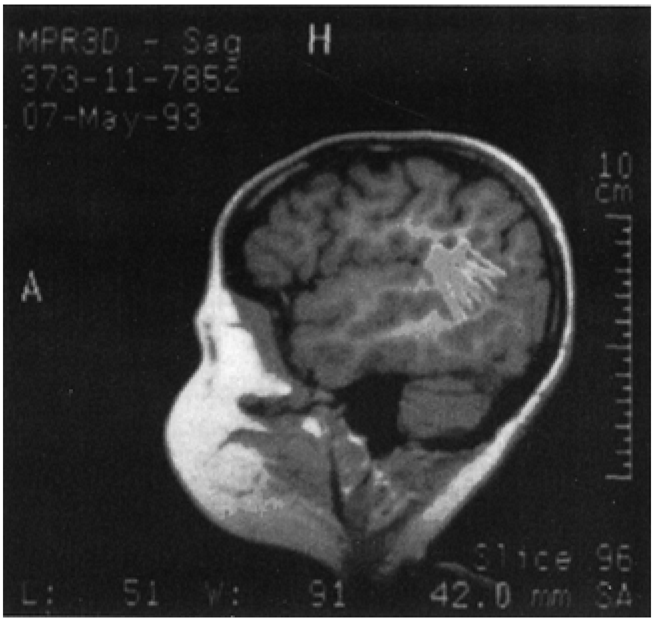

FIGURE 2. Magnetic resonance image (MRI) of another patient with Landau-Kleffner syndrome. In this example, the entire dipole, including its orientation, is displayed on the MRI. In (A) a sagittal section of the left sylvian region is shown. The dipolar orientation is perpendicular to the sylvian fissure and is angled in the anterior–posterior dimension, the suprasylvian projection being anterior to the intrasylvian one.

FIGURE 3. Electroencephalogram derived from implanted epidural electrodes in a 5-year-old child. The bilateral spike and spike-wave pattern is well seen. Electrodes were placed symmetrically over the sylvian fissure in each hemisphere. (From Morrell F, Whisler WW, Smith MC, et al. Landau-Kleffner syndrome: treatment with subpial intracortical transection. *Brain.* 1995;118:1529–1546.)

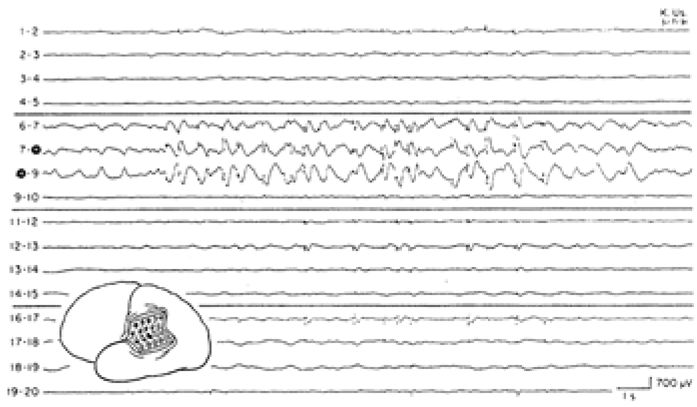

FIGURE 4. Electrocorticographic recordings derived from a pad of electrodes inserted between the lips of the surgically opened sylvian fissure. A vigorous epileptiform discharge was encountered at electrode number 8, whereas highly attenuated spikes were detected in adjacent electrodes of the pad. Electrode 8 lay directly on the dorsal surface of the superior temporal gyrus immediately posterior to the transverse gyrus of Heschl. (From Morrell F, Whisler WW, Smith MC, et al. Landau-Kleffner syndrome: treatment with subpial intracortical transection. *Brain.* 1995;118:1529–1546.)

A few children with LKS have undergone chronic intracranial electrode and intraoperative recordings in the course of surgical treatment.[33,49,59] These studies confirmed that the common paroxysmal abnormality is in the area of the posterior temporal lobe, often maximal on the superior temporal gyrus (Fig. 3). At times the epileptogenic region is confined within the sylvian fissure near the Heschl gyrus (Fig. 4).

Differential Diagnosis

The differential diagnosis between LKS and CSWS, whether or not the former is considered to be a subtype of the latter, is difficult (see Table 1). LKS tends to affect a slightly younger population, presenting first with language dysfunction and only later with other cognitive and behavioral deterioration. In CSWS the children affected tend to be slightly older, presenting with more global neuropsychological and behavioral deterioration before language dysfunction appears.[9] The severity of the seizures and

P.2434

EEG abnormality is not as pronounced in LKS as in CSWS. The spike-and-wave discharges are maximal in the centrotemporal and posterior head region in LKS and in the frontal head region in CSWS.[6]

The disorders most commonly confused with LKS and CSWS are pervasive developmental delay (PDD) and autism.[25,62,71] The most important distinguishing feature is the loss of previously achieved developmental milestones with LKS and CSWS. In contrast to LKS, children with PDD and autism display abnormal, nonverbal intelligence as well as language dysfunction. Children with early-onset and persistent CSWS may deteriorate more globally and begin to mimic autism. However, although PDD and autism may be associated with paroxysmal EEG abnormalities, they do not have the continuous spike-and-wave discharges during slow sleep of CSWS.

Mental retardation from a wide variety of causes can occasionally be misdiagnosed as LKS or CSWS. A careful history will usually document that motor developmental milestones were not met and suggest the child was affected from birth. The neurologic examination is often abnormal, demonstrating abnormalities in the motor and other systems. These children may also display EEG abnormalities reflecting the underlying cortical pathology; however, these abnormalities rarely meet criteria for continuous spikes-and-waves.[17]

Developmental dysphasia is another disorder that may mimic LKS. Children with this condition do not develop language skills in the usual time frame. They often have a normal neurologic examination and nonverbal intelligence. EEG abnormalities are uncommon, and a continuous spike-and-wave abnormality has not been described.[17] If a child presented with continuous spikes-and-waves in sleep and developmental dysphasia, early-onset LKS is possible.

Once seizures and EEG recordings have indicated the presence of an epileptic disorder, other epileptic syndromes must be considered. These include BECT; other idiopathic, localization-related epilepsies; and Lennox-Gastaut syndrome.[9] Although clear features distinguish LKS and CSWS from Lennox-Gastaut syndrome, there is an overlap with BECT and related disorders.

Classic CSWS and Lennox-Gastaut syndrome (see Chapter 241) share some common features. These include the presence of atypical absence and atonic seizures. The EEG of Lennox-Gastaut syndrome typically shows slow spikes-and-waves that may activate with sleep, but not to the extent of CSWS. In addition, the EEG of Lennox-Gastaut syndrome, but not CSWS or LKS, typically includes polyspikes-and-waves as well as bursts of rhythmic fast activity.[9,25,62,68] Finally, children with Lennox-Gastaut syndrome, but not with CSWS or LKS, display tonic seizures as a prominent component of their disorder.[25,62,68]

Although there are clear clinical differences in these syndromes, a common feature may be that severe epileptiform activity is responsible for progressive cognitive dysfunction. In CSWS and LKS, the paroxysmal abnormality is more restricted and time dependent, whereas in Lennox-Gastaut syndrome the epileptiform activity is multifocal, persistent, and secondary to central nervous system (CNS) injury that also contributes to cognitive disturbance that is not time dependent; this results in a chronic seizure disorder and permanent cognitive dysfunction.[9,68]

The idiopathic localization-related epilepsies (see Chapters 236, 237, and 238) are more difficult to distinguish pathophysiologically from LKS and CSWS but are readily separated clinically.[9,25,43,62,71] These disorders may have less of an effect on cognitive function because the active spike-and-wave activity is less severe, or because it involves different, more “silent” cortical areas. Aicardi and Chevrie[1] reported a syndrome that displayed active spike-and-wave discharges that became continuous with sleep. These children had no detectable cognitive or intellectual deterioration. However, the sleep index and the duration of the active phase of spike-and-wave were not documented.[7] Deonna et al.[19] had six similar cases, but documented increasing neuropsychological dysfunction at the time of EEG deterioration. Polypharmacy may have worsened the clinical status, and all of Deonna's cases improved with antiepileptic drug (AED) taper. It is probable that this syndrome is a subset of CSWS with an older onset and a shorter course of the active phase of continuous spikes-and-waves. It may also be that more careful neuropsychological testing would be able to detect cognitive deficits.[10]

Benign childhood epilepsy with centrotemporal spikes is easily distinguished from LKS by the absence of acquired aphasia; however, BECT may also be a subset of CSWS.[25,62] In Tassinari's clinical division into various subsets of CSWS, one type with orofacial and generalized tonic–clonic seizures in sleep mimics BECT. Absence seizures have been reported with BECT.[68] There are differences, however, in EEG manifestations. In CSWS, focal abnormalities predominate in the frontal areas, whereas in BECT they are maximal in the centrotemporal areas. There is a clear activation of epileptiform activity in BECT during sleep, at times becoming continuous spikes-and-waves; however, the sleep index never reaches 85%.[9,11,25,62] There was one reported case of BECT that worsened with the introduction of carbamazepine and reached a sleep index of 85%; clinical deterioration with atypical absence and falls resolved with withdrawal of the carbamazepine.[11] Mental retardation and a history of prior neurologic insult are commonly seen in CSWS but not in BECT. Family history of epilepsy is reported in 40% with BECT but in only 10% with CSWS.[9] Despite these clinical differences, it is probable that a child with early-onset and persistent BECT with a high sleep index would display cognitive or motoric deficits if carefully tested.

Treatment and Outcome

As previously noted, the clinical seizures in LKS and CSWS, as with the other idiopathic localization-related epilepsies, are, for the most part, not severe and are easy to control.[10,25,41,46,49,62]

The one important exception to this is in the subgroup of CSWS with daily atypical absences and drop attacks.[68] In this group, clinical seizures are severe and at times difficult to treat. The clinical seizures in both groups are self-limited, with only rare seizures in about 20% of both groups once the active phase

of spike-and-wave has resolved.[10] All available AEDs have been used individually and in combination for the treatment of LKS and CSWS. The Venice colloquium confirmed this and listed the medications used by participating investigators.[72] During the active phase of spike-and-wave, polytherapy was the rule, with only 9% of patients treated with monotherapy. Efficacy was difficult to judge, because in general, all AEDs were effective in treating the clinical seizures, but there was poor response of the paroxysmal EEG. There have been reports of carbamazepine causing a worsening of seizures, especially atypical absence and atonic falls.[11] In reviewing which AEDs, if any, were being used at the time of resolution of the CSWS, there were data on 88 patients. Seven of these patients were not on any medication at the time of resolution of CSWS, documenting its self-limited nature. Of the other 81 patients, 55 were taking valproate, 19 as monotherapy. Thirty-nine of the patients were on a benzodiazepine, mostly clobazam. A small number were on phenobarbital, vigabatrin, ethosuximide, and carbamazepine. These data indicate that valproate alone or in combination with a benzodiazepine has been the treatment of choice.

Corticosteroid therapy, either with adrenocorticotropic hormone (ACTH) or prednisone, appears to have favorable and long-lasting effects.[61,72] Although there were too few cases and insufficient follow-up time to permit a definitive conclusion on their effectiveness, some authors suggest that ACTH or corticosteroids should be the treatment of choice, especially in new-onset disease in a young patient.[18,29,38] Lerman et al.[38] reviewed the literature and reported on four cases with LKS that they treated with either ACTH or corticosteroids. They tended to use a high dose for a prolonged period of time (ACTH 80 IU/day with a 3-month taper; prednisone 60 mg/day with a 3-month taper). They noted, and this was confirmed in the Venice colloquium,[72] that there may be relapses with steroid reduction and some children may need to be on steroids for months to years. A commonly accepted dose is 3 to 5 mg/kg/day of prednisone for at least 3 months. It appears that the earlier treatment is initiated, the shorter the duration of steroids required, and the better is the ultimate outcome.[38] With steroid wean, most of these children were on additional AEDs, most commonly valproate or benzodiazepines. Lower-dose protocols with fewer adverse effects have been reported to be helpful.[61]

The long-term use of corticosteroids is fraught with side effects, including weight gain, cushingoid appearance, hypertension, glucose intolerance, electrolyte abnormalities, sleep disturbance, mood changes, and more serious conditions, including cataract formation, proximal myopathy, pathologic fracture, and immune dysfunction (see Chapter 144). The risks versus benefits must be clearly thought out and explained to all concerned parties, including patients, parents, and primary care physicians. Side effects of steroids may be acceptable in patients with an early onset of the active phase of spike-and-wave discharges and a severe and persistent epileptic disturbance because this group is at highest risk for significant residual neuropsychological sequelae.

Current practice is to treat initially with valproate with or without a benzodiazepine. If epileptiform EEG abnormalities and cognitive dysfunction persist despite high therapeutic AED levels, a course of prednisone 3 to 5 mg/kg/day[1] with careful laboratory and physical examination follow-up is usually offered. It is important to obtain serial EEGs that include slow-wave sleep in order to judge the efficacy of therapy. An attempt can be made to convert to every-other-day dosing in the second month of therapy, if there is therapeutic success. A slow wean during the third month is performed, although relapses are not uncommon.[18,38,46]

Morrell et al. originally reported on the surgical treatment by multiple subpial transection (MST) of 14 children suffering from LKS.[49] All children had been unable to use language meaningfully for more than 2 years and displayed continuous spike-and-wave discharges that were demonstrated to arise unilaterally in the superior temporal gyrus and surrounding perisylvian cortex. After MST resolved the paroxysmal EEG abnormality, there was dramatic improvement in language function over time, with 50% recovering age-appropriate language and returning to regular classroom school and 29% showing a marked improvement in language function but still undergoing speech therapy. They concluded that success in restitution of language function depended on proper selection of patients and resolution of the severe epileptiform EEG abnormality.[49] Presurgical evaluation requires delineation of an epileptogenic region involving one posterior temporal lobe, which is usually accomplished not only by standard imaging and electrophysiologic investigations, but also by the methohexital suppression test, and occasionally intracarotid amobarbital, electrical dipole mapping, and magnetic resonance imaging.[49]

Longer-term follow-up on the original 14 patients found that 11 of 14 demonstrated significant postoperative improvement in receptive-expressive language and that gains in language function are most likely to be seen years rather than months after surgery.[26] These results indicate that early accurate diagnosis and effective treatment optimizes outcome. This series has been recently extended to 24 children treated with MST to treat severe persistent language disturbance of more than 18 months' duration. MST resulted in recovery of functional language (speaking in complex sentences) in two thirds of children treated.[35]

Other investigators have confirmed these original findings that MST is an effective treatment in children with active CSWS and acquired aphasia despite treatment.[33,59]

The clinical response to MST in atypical LKS or autistic regression with epileptiform EEG, at times CSWS, had been reported, but long-term functional language improvement had not been demonstrated,[39,50] making accurate diagnosis critical in patient selection for MST.[62]

There is now a better understanding of treatment options in LKS and CSWS. It is necessary to eliminate the severe paroxysmal EEG disturbance to prevent serious neuropsychological sequelae in some patients.[41,46,66] Aggressive treatment is indicated in those with early onset of the active phase of spike-and-wave discharges who have a severe and persistent paroxysmal disturbance affecting neocortex that is critical to language and other higher cognitive function. In these children, high doses of traditional AEDs, corticosteroids, and occasionally surgery are justified because of the risk of serious and permanent cognitive dysfunction that will affect education, occupation, and activities of daily living.

Long-term Prognosis

Long-term prognosis for the seizure disorder in both conditions is good, with <20% suffering from persistent, usually rare, seizures.[10] However, the long-term prognosis for neuropsychological consequences is not nearly as good as was once thought.[17] In general, most patients who suffer from LKS or CSWS have some permanent sequelae that limit their activities. Those with the earliest onset of spike-and-wave discharges and longest persistence over time are most affected.

In 1980 Mantovani and Landau[40] reviewed the long-term prognosis of nine patients with LKS 10 to 28 years after onset. They found that the overall clinical status and language were normal in <50%. Many other studies agree that aphasia persists in the majority.[2,3,14,16,34,53] Only half of patients with a history of LKS are able to live a normal life.[2,34,41,49,53]

Long-term outcome with CSWS has also been reported as poor in most patients.[53] Again, outcome appears to be related to the age of onset and duration of the active phase of spike-and-wave discharges.[68] All four cases reported by Morikawa

P.2436

et al.[45] continue to have neuropsychological sequelae, with IQ ranging from 35 to 60, and require special schools or sheltered workshops.

The Venice colloquium confirmed that permanent neuropsychological sequelae are seen in the majority; in fact, only a few of the 59 children with adequate follow-up intelligence tests achieved a global IQ within the normal range.[44] Disturbances included short attention span, hyperactivity, affective symptoms, and language dysfunction, as well as intellectual impairment. Although there was a global improvement in all intellectual areas after resolution of CSWS, this did not lead to complete restoration of function, particularly in verbal ability, attention, and executive function.[44,53]

Summary and Conclusions

LKS and CSWS are two points on a spectrum of age-related functional disorders of childhood characterized by a severe paroxysmal EEG disturbance that can permanently alter critical synaptogenesis by strengthening synaptic contacts that should be pruned. They appear to be linked to other idiopathic localization-related epilepsies by a common pathophysiology. Although prognosis for seizure control is good, cognitive function deteriorates and serious permanent neuropsychological consequences are reported in the majority. At highest risk for permanent sequelae are those with the earliest and longest exposure to the active phase of continuous spike-and-wave discharges during sleep. In LKS the paroxysmal activity permanently affects the posterior temporal area and results in auditory agnosia and language deficits, whereas in CSWS the frontal lobes are more involved and other cognitive disturbances predominate. Aggressive treatment approaches to abolish the paroxysmal disturbance—such as high-dose AEDs, corticosteroids, or, in select LKS patients, surgery—should be seriously considered in the high-risk group.

Acknowledgment

This chapter is dedicated to the life and work of Frank Morrell (1926–1996), our teacher, mentor, colleague, and friend. The ideas and concepts contained in this work were greatly influenced by him.

Chapter 244

Juvenile Myoclonic Epilepsy

Eliane Kobayashi

Frederick Andermann

Eva Andermann

Introduction

Juvenile myoclonic epilepsy (JME) is a common type of idiopathic generalized epilepsy (IGE). The major landmark of JME is the occurrence of adolescent-onset myoclonic seizures. JME is both genetically and clinically heterogeneous, suggesting that different pathophysiologic mechanisms might be involved.[84]

Historical Perspectives

The first description of a patient with JME came from the French literature in 1867 by Herpin,[38] but the myoclonic jerks were only properly characterized in 1899 by Rabot.[63] The intermittent character of these jerks as compared to the myoclonus occurring in progressive myoclonic epilepsy, a neurodegenerative disease, was emphasized by Lundborg[47] in 1903.

The description of JME as a specific IGE syndrome was established almost at the same time by Janz and Christian in Germany[42] and by Castells and Mendilaharsu in Uruguay,[16] almost a century after the first patient was reported in the literature. However, because of varying terminologies employed by previous authors, the syndrome was only recognized as JME in the English-speaking literature in the mid-1980s.[5,22]

Definitions

JME is the most common form of IGE, and the myoclonic seizures are the hallmark of the syndrome. Isolated myoclonic jerks of the arms, especially shortly after awakening, are characteristic. Generalized tonic–clonic seizures (GTCSs) occur in most patients, and one third of individuals also have absences. Seizure occurrence is more likely with sleep deprivation, fatigue, and alcohol withdrawal. Onset is usually in adolescence but seizures may begin or be diagnosed only in the early 20s. Patients frequently come to medical attention only after a generalized convulsion, and the history of earlier myoclonic jerks is often obtained retrospectively. More recently, myoclonic epilepsy with adult onset (37 to 39 years) has been highlighted by different groups.[20,30,49]

Epidemiology

Prevalence

JME accounts for up to 26% of patients with IGE and up to 10% of all cases of epilepsy,[43] but misdiagnosis and delayed diagnosis remain common.[34]

Based on a 1% population risk for epilepsy by age 20,[36] the Risk of JME in the general population would be 1 per 1,000 to 2,000. It is less frequently seen in children and more frequently in adolescents and adults.[43] In adults with IGE, JME should be strongly considered, and detailed inquiries regarding a history of myoclonus beginning in the teens are essential.

Sex Ratio

Although an equal sex ratio is generally assumed in JME, there is a slight female predominance, with 515 males to 615 females, based on the summation of ten different studies.[43] Only one of the studies showed male preponderance (33 males to 20 females),[22] whereas another study showed marked female preponderance (77 males to 104 females).[24] A recent Irish study also showed significant female predominance for JME.[55] A large family study has also confirmed a very high female-to-male risk ratio.[59]

Age of Onset

The onset of JME is clearly age related. It varies between 8 and 26 years, with the majority between 12 and 18 years.[43] The average age of onset of myoclonic jerks is usually earlier than that of generalized tonic–clonic seizures.[24] The onset age of JME is generally earlier in photosensitive than in nonphotosensitive patients.[70,83]

Etiology and Basic Mechanisms

The pathophysiology of JME is unknown. Although clinically a well-defined syndrome, detailed investigations of JME suggest that this stereotyped clinical pattern may be the result of different genetic, pathologic, and pathophysiologic processes.[5a,84]

The electroencephalographic (EEG) pattern and other neurophysiologic studies, including those conducted in patients with reflex seizures induced by thinking, writing, or "action programming," suggest a variable focal or regional frontal hyperexcitability in many cases.[84] Even so, although subtle frontal morphologic changes can be found, they are not universal in JME, and neither is sensitivity to various cognitive triggers, which may be absent in a typical case or present in a patient with another IGE syndrome. The association with photosensitivity is also variable.

An association with clinical and EEG findings of a clearly focal epilepsy, namely, idiopathic photosensitive occipital epilepsy (IPOE, described below), also raises questions about the nosologic purity of JME as a generalized epilepsy syndrome.

The classic electrophysiological studies conducted by Gloor[31] led to the corticoreticular theory of generalized epilepsy: This theory postulates an underlying cortical hyperexcitability and abnormal response to thalamocortical input, which would operate in the absence of any lesional substrate. Genetic animal models of generalized epilepsy confirm the role played by thalamocortical circuits in cortical spike-wave

generation, and it has been proposed that genetically determined dysfunction of reticular thalamic neurons is responsible for the abnormal excitation. Since then, evidence has also been accumulating suggesting that subtle but probably significant neurochemical and morphologic alterations exist in both cortex and thalamus in IGE. Meencke and Janz[52] and Meencke and Veith[53] described subtle cortical neuropathologic changes in IGE ("microdysgenesis") believed to be migrational disturbances, but this has not been confirmed in other small series.[57]

Furthermore, there is much genetic heterogeneity in JME. A positive family history of epilepsy is common, and there is recent evidence that JME constitutes a single gene syndrome in some families,[19,23] although most families show complex inheritance. Some JME cases are apparently sporadic, others occur in families with other IGE syndromes, and occasional families have a pure autosomal dominant JME phenotype. However, the patients in these various groups are otherwise clinically indistinguishable by usual diagnostic criteria. Different genetic results may relate to different diagnostic criteria, including the importance given to detailed classification of EEG patterns, differing estimates of penetrance, and choice of models for linkage analysis.[9] Linkage to chromosomes 6p and 15q has been described,[25,33,46,79] and mutations in the CACNB4 gene (on chromosome 2q),[26] in the CLCN2 gene (on chromosome 3q),[21,35] in the GABRA1 gene (on chromosome 5q),[19] and in the EFHC1 gene (on chromosome 6p)[71] have been identified in JME patients.

The various mutations suggested for JME are all believed to influence neuronal excitability but involve different mechanisms. Both direct ion channel mechanisms and nonionic mechanisms have been proposed. How these interact with other possible susceptibility genes and with environmental factors is not yet clear. Vijai et al.[77] suggested that a potassium channel gene polymorphism may predispose to JME and that later gene expression of KCNQ3 may account for the striking age dependence that is typical of JME. Another potassium channel gene polymorphism in KCNJ10 has been associated with susceptibility to several common seizure types.[13] Chloride currents, which affect inhibition, are implicated in some studies. Families linked to chromosome 3q and with mutations in the ClCN2 gene, which encodes the ClC-2 voltage-dependent chloride channel, suggest a defect in γ-aminobutyric acid (GABA)-mediated inhibition. Altered GABA-mediated inhibition is also implicated in autosomal dominant JME. The GABRA1 mutation found in autosomal dominant JME encodes a mutant α_1 subunit of the $GABA_A$ receptor, but the functional effect, altered chloride current, and thus altered neuronal inhibition depend on the number of mutant subunits and their position within the pentameric structure of the ligand-gated chloride ion channel.[29]

Mutations in EFHC1 have more complex effects that may be associated with the pathogenesis of JME.[71] In animals, EFHC1 protein is not an ion channel protein but increases calcium currents in R-type voltage-dependent calcium channels and promotes calcium-related apoptosis; these effects are partly reversed by the mutations associated with JME.[71] Such mutations may thus interfere with apoptotic activity and prevent the normal elimination of neurons during postnatal development of the central nervous system in humans. This may result in increased density of neurons and formation of hyperexcitable circuits. Microdysgenesis, reported in JME, may be a visible manifestation of such a process, which may also be associated with age-dependent seizure onset. Mutations may also destabilize calcium homeostasis with resulting effects on sensitivity to sleep deprivation and other clinical triggers of seizures in JME. However, mutations in EFHC1 were found in only 6 of 44 families, and the authors suggested that unidentified mutations may exist in intronic or regulatory regions.[71] Similarly, the BRD2 gene, in which a mutation in JME was reported by Pal et al.,[60] is a putative nuclear transcription regulator and a member of a family of genes that are expressed during development and may thus be relevant to the reported abnormalities in imaging and age-related onset of JME.

Clinical Presentation

This is an age-dependent disorder with onset usually in the second decade, but occasionally earlier and not infrequently later. It is important to recognize this group of patients since they are generally fully controlled on valproate in about 80%,[14] but require lifelong treatment.

Myoclonic seizures, mainly involving the arms and occurring preferentially in the postawakening period, are the main feature of JME and are correlated with short bursts of generalized spike-wave or polyspike-wave complexes.[22] The myoclonus is quite variable in intensity, often unreported by patients until a GTCS occurs, and then identified only after specific questioning. It is often not considered to represent a major inconvenience to patients, who frequently prefer not to take medication in order to suppress it. Others, however, prefer not to be frequently reminded of their epilepsy by these minor symptoms. When minor manifestations such as myoclonus or absence coexist with major seizures, treatment with antiepileptic drugs (AEDs) such as valproate or clonazepam is mandatory.

The myoclonus usually responds quite readily to antimyoclonic agents such as valproate, clonazepam, piracetam, or levepiracetam, but it may be difficult to control during certain periods of the patient's life. The reasons for this are not entirely clear, but loss of seizure control may be correlated with emotional factors. The generalized attacks are often precipitated by the concurrence of sleep deprivation and being woken up from sleep, and this sequence should obviously be avoided, if at all possible. Further clinical features are discussed in recent detailed reviews of JME.[75,84]

In an effort to better define syndromes for genetic study, Taylor et al.,[74] working with Berkovic and Scheffer in Australia, showed overlap between the clusters of clinical features used to diagnose JME and IPOE, suggesting a relationship with this focal epilepsy syndrome, especially with respect to visual auras and conscious head version (which are typical of IPOE) in patients with JME. They identified coexistence of myoclonic seizures and occipital EEG spikes in the same individuals in both syndromes. The probands and their families were evaluated in detail by highly skilled observers, and one may suspect that such overlap exists more commonly than is currently realized but that patients are not usually questioned as carefully.

Diagnostic Evaluation

Although JME is considered a typical generalized epilepsy, earlier and more recent reports of clinical, EEG, and imaging studies have raised questions regarding the degree to which this classification can be strictly maintained. Clinical and EEG studies of JME and of reflex seizures in generalized epilepsies have suggested localized or regional hyperexcitability in generalized epilepsy syndromes, especially in JME.[5,15,40]

Electroencephalographic Findings

The typical abnormality on EEG is bilateral multiple spike- or polyspike-wave complexes at a rate of four to six per second, with anterior predominance. Photosensitivity occurs in about 30%, especially in women, but the two disorders appear to be inherited separately.

Scalp EEG showed focal interictal epileptiform discharges in 30.3% of JME patients studied in detail by Panayiotopoulos et al.,[61] and focal EEG abnormalities of all kinds in 36.7%.[2] In

our experience, frequent unilateral or bilateral temporal EEG abnormalities are seen as patients age.[66] Panayiotopoulos et al.[61] also commented on the precipitation of seizures by mental activation as part of the syndrome, which may represent seizures induced by thinking. Wolf emphasized the typical frontocentral predominance of the ictal EEG activity recorded with the myoclonic jerks of JME.[82] This regional predominance and cognitive activation have been discussed by several authors (for review, see Matsuoka et al.[51]).

Neuroimaging

Although JME is classified under the so-called idiopathic epilepsies, evidence from structural and functional imaging highlights the existence of underlying abnormalities. Studies in patients with JME have shown abnormalities in mesial frontal structures in many[81] and some have more widespread abnormalities of cortical gray matter. Using magnetic resonance spectroscopy (MRS), Savic et al.[68] showed reduction in frontal lobe *N*-acetyl aspartate (NAA) in JME, and later confirmed that frontal NAA was reduced in patients with JME but not in those with generalized epilepsy with tonic–clonic seizures.[69] These investigators also showed reduced thalamic choline and myoinositol concentrations in both IGE syndromes. Mory et al.[54] studied thalamic MRS in JME and reported reduced NAA/phosphocreatine ratios in nine out of ten patients. Similar findings were reported by Bernasconi et al.[11] in 12 out of 20 patients with IGE. Twelve patients had JME, but these cases were not analyzed separately.

Combined EEG and functional magnetic resonance imaging (fMRI) in patients with IGE, including JME, has demonstrated bilateral thalamic activation, with increased blood oxygenation level–dependent (BOLD) signal during bilateral spike-wave activity in most individuals and deactivation in bilateral frontal, parietal, and posterior cingulate regions.[1] Thus, although MRS and fMRI studies support a role for thalamic abnormalities in IGE, they also implicate more localized cortical neuroanatomic mechanisms in JME in particular. MRI and MRS studies thus support the suggestions made on clinical and EEG grounds that the frontal cortex is in some way preferentially involved in JME.

Biochemical Studies

Biochemical studies have also sought evidence of systemic metabolic abnormalities that would, when expressed in the brain, alter cortical function in generalized epilepsy. Platelets have been used as a model of GABAergic neurotransmission. Rainesalo et al.[65] reported reduced platelet GABA uptake in patients with JME and increased activity of the catabolic enzyme GABA-transaminase, which may indicate impaired cerebral GABAergic function. They also reported increased interictal plasma glutamate in JME patients, with no significant change in the postictal period.[64] This study confirms earlier findings in both generalized and focal epilepsies.[41]

Genetic Studies

Genetic studies have also contributed to our understanding of JME. Based on family and twin data, respectively, Andermann,[3] Berkovic et al.,[10] and other investigators concluded that most IGEs, as well as most idiopathic focal epilepsies, are inherited as multifactorial or complex traits, with the additive effects of several or many susceptibility genes and interaction with environmental factors to produce the final phenotype. Even in so-called monogenic epilepsies, the variation in phenotype among family members and between families is attributed to the effects of modifying genes and environmental or developmental factors. Multiple IGE subsyndromes may exist in the same family, even in those with a single gene defect.[4,12] Marini et al.[50] reported that, although childhood and juvenile-onset absence epilepsies share a close genetic relationship, JME appears to be genetically more distinct. A recent study also demonstrated different genetic influences between IGE families with absences and those with myoclonic seizures,[80] and other studies showed different linkage groups for childhood and adolescent absence epilepsy and for JME.[37]

The discovery that some well-defined epilepsy syndromes are channelopathies has also fueled efforts to describe the mechanisms underlying JME. Several genetic models have been proposed for generalized epilepsies and for JME in particular, and mechanisms of epileptogenesis have also been proposed based on these findings. Mulley et al.[56] pointed out that "all but one of the idiopathic epilepsies with a known molecular basis are channelopathies. Where the ion channel defects have been identified, however, they generally account for a minority of families and sporadic cases with the syndrome in question. The data suggest that ion channel mutations of large effect are a common cause of rare monogenic idiopathic epilepsies, but are rare causes of common epilepsies."

When a positive family history of epilepsy can be obtained, most JME occurs in families with a variety of IGE syndromes. Several loci have been mapped for IGE in such families, including 8q, 3p, and 1p (for review, see Gourfinkel-An et al.[32]). Sander et al.,[67] in a large genome-wide scan of families with IGE, reported linkage to chromosome 3q among other loci. The candidate interval on 3q includes the gene ClCN2 coding for the ClC-2 voltage-dependent Cl^- channel, largely expressed in cerebral neurones and inhibited by GABA. Haug et al.[35] reported three different heterozygous mutations in this gene in three unrelated families with IGE. These mutations segregate with the epilepsy phenotype in each family and all cause changes in function associated with neuronal excitability. These authors also detected a novel polymorphism in the ClCN2 gene based on 115 parent–child trios. ClCN2 is the first epilepsy gene with both rare major gene mutations and a common sequence variation (polymorphism) conferring a range of phenotypic effects. Mutations in this gene have also been reported in two other families: In one family the proband had JME and in the other the proband had focal epilepsy, thus confirming ClCN2 as a major gene for more than one type of epilepsy.[21]

Another gene located in the 3q26 region, KCNMB3, codes for regulatory subunits associated with calcium-activated potassium channels (B channels). Four polymorphisms in this gene were detected in a variety of patients with epilepsy including JME. These variants were found to be associated with functional deficits of the BK channel.[39]

A recent genetic study of a large French-Canadian family with autosomal dominant JME (ADJME)[19] showed that affected individuals are heterozygous for a missense mutation (A322D) in the gene coding for the α_1 subunit of the $GABA_A$ receptor (GABRA1) on chromosome 5q34. It is also of interest that this region overlaps the locus for GABRG2, one of the genes responsible for GEFS+ (generalized epilepsy with febrile seizures plus) syndrome as well as for absence epilepsy with febrile seizures.[8,78] As is often the case in genetic studies of epilepsy, autosomal dominant JME accounts for only a small proportion of JME, and studies of other families have yielded different results. Although the same mutation in GABRA1 was not found in a study of Indian JME families,[44] these investigators[77] suggested that polymorphisms in a potassium channel gene, KCNQ3 (EBN2, 8q24), may be important in predisposing to JME in South Indian families. They also suggested that the later expression of the KCNQ3 gene may help to explain the characteristic adolescent onset of JME, as compared with the neonatal onset of seizures in benign familial neonatal convulsions (BFNC) associated with major mutations in KCNQ2. However, major mutations in KCNQ3 have been identified in Mexican-American families with BFNC.[17] Susceptibility to seizures of many kinds has also been proposed in relation to a missense variation in the human potassium ion channel gene KCNJ10.[13]

Other investigators using linkage studies have proposed that susceptibility loci for JME exist at 6p11–12,[6,45,46,62] HLA-6p21.3 region,[33] 15q14,[25] and 5q34.[19] Recent studies conducted in Dutch families narrowed the region on 6p11–12,[62] known as EJM1. Suzuki et al.,[71] reviewing previous studies from Belize, Los Angeles, and Mexico[6,45,46] and extending them, described a novel gene, EFHC1, in this region. Five mutations in EFHC1 segregated with JME in 6 out of 44 families and were not found in healthy control individuals. EFHC1, unlike other epilepsy genes, does not encode ion channels but modulates and interacts with voltage-dependent calcium channels and has apoptotic activity. The authors proposed that EFHC1 is the gene on 6p12 that is associated with JME. Although mutations in both GABRA1 and EFHC1 are rare causes of JME,[48] disease-causing mutations in EFHC1 have been identified by other groups[48,69a] both in JME and in other forms of IGE.

Other families exhibit linkage to the 6p21.3 region associated with HLA rather than to 6p12. Pal et al.[60] suggested that JME at the 6p21 locus may be caused by a mutation in the BRD2 gene. The authors noted that the abnormal MRI in JME[81] would be consistent with involvement of BRD2.

Association studies suggest that the $a_{1\,A}$ subunit of the voltage-gated calcium channel gene (CACNA1A) may affect susceptibility to IGE.[18] This channel is responsible for seizures and ataxia in tottering and leaner mice[28] and has also been implicated in human episodic ataxia type 2, spinocerebellar ataxia type 6, and a form of familial hemiplegic migraine.[58] Escayg et al.[26] found coding and noncoding variations of the human calcium channel gene CACNB4 in patients with IGE and epithotic etaxia.

In summary, although several major genes have recently been identified for IGE, and for JME in particular, only mutations in the ClCN2 and EFHC1 genes have been replicated by different groups. Furthermore, no consistent genetic pattern has been revealed by association studies for any common idiopathic epilepsy syndrome.[73] A number of association studies of other ion channels in IGE, including JME, have yielded negative results.[7,27,72]

Differential Diagnosis

Two main differential diagnoses have to be considered here. In the cases where myoclonus is not well characterized, it may be confounded with a partial seizure with motor manifestations and, in this situation, a detailed clinical history is important. The main implication of the misdiagnosis of JME as a partial epilepsy is, of course, the choice of the wrong AED, and further classification of the epilepsy as a refractory one. The second differential diagnosis is for those patients who do not clearly report myoclonus, which may delay the diagnosis of JME. These patients may be diagnosed as having one of the various forms of idiopathic generalized epilepsies with generalized tonic-clonic seizures.[4] Again, a detailed clinical history is the essential tool. Other rare differential diagnoses include the progressive myoclonus epilepsies, especially Lafora disease and Unverricht-Lundborg disease, which also present in adolescence and may resemble JME in the early stages.

Treatment and Outcome

Valproate is the drug of choice. The newer AEDs, such as lamotrigine and topiramate, result in variable control of the myoclonus, but good efficacy for the GTCSs in JME. Levetiracetam appears to have significant antimyoclonic effect. Clonazepam is a good add-on drug for myoclonis, and can be used in monotherapy only in patients who have never had GTCs. The lack of responsiveness of JME to AEDs such as carbamazepine or phenytoin with, in some patients, even an increase in myoclonus due to these agents should be emphasized. In the European literature, the activation of minor epileptic manifestations of IGE such as absence or myoclonus by carbamazepine or oxcarbazepine as well as phenytoin, vigabatrin, and gabapentin has been stressed,[76] but this has only recently been accepted in North America.

Long-term Prognosis

The prognosis of myoclonus in this form of epilepsy is not entirely clear. Although AEDs can be withdrawn in only a minority (10% to 20%) of patients,[14,61] it is generally accepted that there may be improvement over time, particularly with respect to myoclonus, and that the process may be less active, but without complete remission in adult life. The great majority of patients responds to treatment with appropriate antimyoclonic and antiepileptic medication, and has an otherwise benign outcome with no other neurologic disturbances. Since most patients continue to be on medication, it is difficult to know how often the myoclonus remits spontaneously over time.

Summary and Conclusions

JME is a frequent type of IGE characterized by myoclonic seizures, most often implicating a lifetime use of valproate. Recent work suggests that JME may represent several different disorders with different genetic and pathophysiologic signatures found in patients who are clinically or practically indistinguishable.

Chapter 245

Overview: Non–Age-Related and Special Syndromes

Warren T. Blume

Peter Wolf

Introduction

Each of the chapters in this section uses a different approach to address one of two challenges in epileptology: (a) the relationship connecting seizure semiology, the structures involved in epileptogenesis, and related lesions and (b) the interplay between predisposing and precipitating factors in igniting seizures. In addition, chapters on familial epilepsies involving the temporal lobe (Chapter 248), frontal lobe (Chapter 249), and variable foci (Chapter 255) reflect the increasingly recognized role of genetics in the etiology of seizure disorders, including those without an apparent familial seizure history.

Semiology, Epileptogenesis, and Related Lesions

The precise definition of the structures or systems responsible for ictal phenomena has long posed a challenge to the best efforts of distinguished investigators. For Hughlings Jackson, "the study of partial seizures became the starting point for the study of localization of function within the central nervous system."[31] As described by Jasper,[31] Sherrington electrically stimulated the cortex of anthropoid apes to examine functional–structural relationships. The early stimulation studies in humans performed by Foerster[17] preceded the exhaustive studies carried out by Penfield and Jasper in the course of evaluating patients for epilepsy surgery; these culminated in their classic work, *Epilepsy and the Functional Anatomy of the Human Brain*.[31] Interictal electroencephalography (EEG) has provided helpful correlative data to clarify the localizing significance of ictal symptomatology,[11,31] as has intracranial recording.[3] However, Williamson and Engel (see Chapter 246) caution that sophisticated techniques for correlating ictal electrical activity with clinical phenomena have only revealed the complexities of anatomic–symptomatologic relationships.

A second method of identifying structures or systems responsible for ictal phenomena has been to correlate the latter with structural lesions. In Chapter 246, the authors indicate that Hughlings Jackson first recognized the correlation between ictal behavior and the location of structural abnormalities in the brain. Defining "specific lesions" as "discrete focal (or regional) structural pathologies that are associated with chronic partial epilepsy," Chapter 251 examines such relationships. These authors review changes in neurotransmitters in the vicinity of tumors, favoring excitation over inhibition. They cite the finding of Awad et al.[5] that lesionectomy alone more often renders patients seizure free than resection of epileptogenic cortex without regard to lesion, supporting a direct relationship between structure and ictogenesis. Fortunately, improved neuroimaging now more accurately identifies focal or regional epileptogenic lesions (Chapters 247 and 251).

However, several factors complicate such relationships. Penfield[31] demonstrated that the form of the attack is considered to be due to the functional characteristics of the local area of onset within the brain, the strength of initial discharge, and the path of its spread to other brain areas. Rasmussen[32] acknowledged this factor of propagation in elaborating a concept of secondary localizational aspects of epileptic phenomena. His review of seizure-free patients after frontal lobe resection found no correlation between surgery site and seizure characteristics. Variability of propagation patterns is a principal factor in confounding any anatomic classification of seizures.

Williamson[41] indicated that rapid spread of frontal seizures clouds the localizing value of many ictal phenomena. Varying and bilateral motor ictal phenomena may be consequent to multiply targeted intracortical and corticofugal projections within the motor system, including ipsilateral projections to proximal limbs.[8,14,41] Abundant projections from the occipital cortex to anterior temporal areas[24,35] effect the dyscognitive seizures from occipital epileptogenesis. More recently demonstrated temporal-to-occipital projections[4,16,25] are likely among factors producing visual auras from extraoccipital seizure origins.[7] In addition, a seizure disorder beginning while the brain is developing may lead to abnormal patterns of innervation.[19,38] For example, a seizure-related failure of "pruning" through apoptosis may produce a permanently abnormal connectivity.[22]

Moreover, epileptogenic regions may be remote from a lesion that is also epileptogenic (Chapter 251). Temporal epileptogenic regions may coexist with epileptogenic occipital lesions[10,29] or with parietal arteriovenous malformations.[43] For undetermined reasons, lesions may be unevenly epileptogenic around their peripheries. Thus, O'Brien et al. (Chapter 252) cite works indicating that resection of a lesion as well as epileptogenic cortex is necessary for optimal seizure reduction.[6,39,44] A further confounding factor impeding the establishment of structural–semiologic relationships is the possibility that lesions may extend beyond their manifestations on neuroimaging studies. This factor may underlie the relative ineffectiveness of surgery as treatment for epileptogenic neuronal migration disorders (Chapter 251).

Defining seizures or epilepsies according to lobes of the brain is inexact because none is fully functionally distinct from the others. This sharing of functions partially underlies the overlap of symptoms of seizures arising from different regions. Several examples of seizure types that transcend lobar boundaries are described in Chapter 246.

The aforementioned impediments suggest that epileptic seizures should be analyzed according to the systems involved rather than discrete cortical loci. For example, the intimate connections of thalamic nuclei with circumscribed cortical regions suggested to Penfield[31] that the cortex be divided according to thalamic projection areas. Rapid propagation of cortical discharge to related thalamic nuclei[36] and the decrease of cortical discharges by thalamic lesions[15,21,27,28] support this concept. The term "system" is applied here in the same way in which we otherwise speak in neurology about system disorders, actually referring to subsystems of the nervous system.

Probably the best example of an epilepsy involving a system is that of mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE-HS), described in Chapter 247. In contrast to anatomically based descriptions of seizure types, this is a localization-related syndrome with a semiology centered around the limbic system. The characteristic ictal semiology and mesial temporal pathology—hippocampal sclerosis—are the fundamental components of MTLE-HS. This is likely the most common correlate between semiology and structure encountered in practice. However, the persistence of auras after successful temporal lobectomy reflects the complex genesis of symptoms caused by epileptic discharge centered in the mesial temporal regions, which is a further example of a seizure type that transcends lobar boundaries. The system concept is further exemplified by the shared semiology of seizures propagating to the limbic system and those originating in that same system.[9,40] However, ever more precise stereoncephalography can disclose ictal semiologic distinctions within the temporal lobe. Thus, in some studies, laterally originating temporal seizures have been found to be shorter, more likely to have auditory symptoms, and secondarily generalize more than those originating mesially.[26]

The idiopathic localization-related epilepsies afford an additional opportunity to link systems involved in epileptogenesis with seizure symptomatology. Syndromes with focal seizures unrelated to any identifiable or presumed brain pathology but with associated characteristic EEG abnormalities, often in homotopic regions of both hemispheres, and with spontaneous remission have been described principally among children.[2]

Inherited channelopathies are associated with several epilepsy syndromes, usually with onset in childhood.[20] Some become lifelong disorders. "Febrile seizures plus," a genetic disorder involving mutant neuronal sodium channels, begins in childhood as febrile seizures and may continue into adulthood as one or more types of afebrile generalized motor seizures.[33] Similarly, autosomal-dominant nocturnal frontal lobe epilepsy, associated with mutations in genes encoding neuronal nicotinic acetylcholine receptors, begins in childhood but persists into adulthood despite its usually mild nature. Chapters 249 and 256 further describe these entities. The homogeneity of ictal semiology of these conditions and the lack of “contamination” of ictal genesis by associated lesions suggest that such benign conditions may clarify semiologic–structural relationships if newer methods of tracing an ictal pathway—such as functional magnetic resonance imaging—can be applied.

Predisposing and Precipitating Factors in Epilepsy

The second group of chapters deals with the complex interplay between predisposition for epileptic seizures and immediate provocative factors. As Dreifuss[13] stated, “The reason a person who is epileptic all the time does not manifest seizures all the time is that the necessary provocation sufficient to trigger the individual seizure is intermittent and is frequently the result of concatenations of circumstances.” The proportion of seizures that occur spontaneously is difficult to establish because triggering events may pass unrecognized or unappreciated. Nonetheless, the balance of each pathogenetic component—predisposition and provocation—varies with the epilepsy. These chapters describe various conditions, each with different proportions of predisposing and triggering components.

In posttraumatic seizures (Chapter 253), predisposing components predominate. The authors document forms of trauma that put a patient at a higher risk for the development of late seizures, the common factor being the presence of intracerebral blood. However, stress or lack of sleep may provoke the first late seizure.

Berkovic (see Chapter 252) presents a valuable update on the concepts and data pertinent to the progressive myoclonus epilepsies. These conditions provide convincing evidence of predisposing factors for the development of seizures. Features usually include myoclonic and tonic–clonic seizures, ataxia, and dementia. The distinctive features of each condition producing the syndrome, along with aspects relevant to differential diagnosis, are presented. The increasing importance of obtaining a family history and examining relatives of patients is emphasized. Even in conditions associated with a strong tendency for seizures, provocative factors are involved. Thus, the myoclonus of Unverricht-Lundborg disease may be precipitated by movement, stress, or sensory stimuli. Similar stimuli may evoke the myoclonic seizures of Lafora disease.[1]

Dreifuss' concept[13] of the relationship between predisposing factors and precipitants is again relevant to Chapter 254, in which solitary seizures are defined as events that may occur once in a lifetime or very rarely. Apart from seizures accompanying acute conditions, such as trauma or encephalitis, it may be assumed that a predisposition for an isolated seizure has existed for some time. Indeed, data from Wolf's series disclosed an identifiable predisposing factor in the majority of patients. Moreover, at least one seizure-provoking factor could be identified in 80 of his 104 patients. As in other studies,[18,23] lack of sleep was a common precipitant of isolated seizures.

Chapters 256 and 257 discuss forms of epilepsy in which an identifiable agent, such as fever, flashing lights, lack of sleep, or drug withdrawal, precipitates many or all of the seizures. Most such seizures are of the generalized tonic–clonic type. The relative importance of predisposition and precipitant factors varies among the broad categories described in each chapter, among entities, and among individual patients. In all cases, the sum of these factors intermittently exceeds the seizure threshold. For patients with these epilepsies, avoiding the precipitants helps to control the seizures.

The seizures of simple reflex epilepsies (Chapter 257) are associated with the most apparent and immediate specific provocators. As the authors emphasize, the seizure history must be scrutinized to discern and establish the relationship. Chapter 257 also describes precisely how visual stimulation should be applied during clinical EEG to confirm light- and pattern-sensitive epilepsy and presents clinical data concerning the photoparoxysmal response.

Photosensitive epilepsy is a model for the interplay of factors leading to tonic–clonic seizures. Although a genetic defect specific for photosensitive seizures has not been discovered, data suggest an autosomal-dominant inheritance.[12,30,37] Withdrawal of alcohol and benzodiazepines may be causes of temporary photosensitivity.

Startle epilepsy is a particularly crippling condition; its mechanism and effective management have proved elusive to investigators.

This section concludes with an interesting review of complex reflex epilepsy, in which precipitants also play essential roles in causing seizures. The attacks are triggered by relatively elaborate stimuli whose specific pattern is the determining

factor in seizure evocation. Reading, musicogenic, praxis-induction, and thinking epilepsies fall into this group. Because the precipitating stimuli involve higher cortical function, the relationship may be less immediate or obvious and may include anticipation of the stimulus complex. Discovering such epilepsies may be the reward for an ingenious historian or a perceptive patient. As in other precipitant-related epilepsies, these compound stimuli may evoke generalized tonic–clonic seizures. However, they may also elicit more restricted forms, such as myoclonus of the jaw in reading epilepsy and dyscognitive seizures in musicogenic epilepsy. Perhaps even more than the simple reflex epilepsies, the complex variety likely requires participation of several cortical and subcortical regions, further supporting the system concept of epileptogenesis.

It is of special interest, complex precipitating mechanisms like praxis induction of reading and talking seem to be particularly related to the syndrome of juvenile myoclonic epilepsy (JME). Perioral reflex myoclonias provoked by talking and reading are probably related genetic traits that JME shares with primary reading epilepsy, that is, an idiopathic localization-related epilepsy.[34,42] This observation is thought provoking because it seems to open a new view onto ictogenesis in the so-called generalized epilepsies, which are likely also to become redefined according to the concept of system epilepsies.

Summary and Conclusions

These chapters examine two relationships in epilepsy of importance to clinicians and basic scientists: (a) epileptogenesis and epileptic lesions on one hand and (b) predisposition and provocation of epileptic seizures on the other.

The intricate interaction between epileptogenic lesion and host, the surrounding brain, exhibits properties common to many patients but often harbors components unique to a particular patient. How this interaction produces the epileptic seizures may be understood by scrutiny of not only the histology and situation of the lesion, but also of the systems so engaged in the epileptogenesis. Several chapters in this section examine these aspects.

Why seizures occur only intermittently in a patient chronically harboring a seizure tendency, that is, predisposition versus provocation of epileptic seizures, is of interest in a second series of chapters. Greater realization of this interaction will improve clinical management and also shed light on several significant pathophysiologic mechanisms.

Chapter 246

Anatomic Classification of Focal Epilepsies

Peter D. Williamson

Jerome Engel Jr.

Introduction

The International Classification of Epilepsies, Epileptic Syndromes, and Related Seizure Disorders[2] recognizes five symptomatic localization-related epilepsies, four of which are anatomically defined: Temporal lobe epilepsies, frontal lobe epilepsies, parietal lobe epilepsies, and occipital lobe epilepsies. Only the fifth, chronic progressive epilepsia partialis continua of childhood, is not classified by location. If we accept the definition of an epileptic syndrome as a complex of signs and symptoms, with only one feature being the occurrence of electroclinically characteristic epileptic seizures.[1] then we can make a cogent argument for the existence of a syndrome of mesial temporal lobe epilepsy (MTLE)[47,55,208,218,222] (see Chapter 247). Otherwise, the classification of epilepsies by anatomic lobe appears to refer predominantly to conditions with characteristic seizure types as the only unifying feature. Recent reports of the International League Against Epilepsy (ILAE) argue against the view that these conditions are syndromes rather than seizures.[51] However, as there is as yet no new classification of syndromes, anatomically defined epilepsies with variably specific seizure types will be retained in this chapter. Other than MTLE, there may be a few examples with constellations of findings that do constitute true syndromes. These possible exceptions will be discussed later.

Much effort has gone into creating an anatomic classification of epileptic seizures, based largely on data obtained from epilepsy surgery centers. The anatomic classification has been greatly assisted by the introduction of high-resolution magnetic resonance imaging (MRI) more than 20 years ago, enabling the detection of small, circumscribed, potentially epileptogenic lesions in many patients with symptomatic localization-related epilepsy. Nevertheless, the validity, or for that matter, clinical value of devising an anatomic classification of epileptic disorders remains the topic of considerable debate. This chapter will review the subject, but emphasis, of necessity, will be placed on seizures rather than syndromes.

Historical Perspectives

John Hughlings Jackson is credited with being the first neurologist to recognize the correlation between ictal behavior and the location of structural abnormalities in the brain.[190] His work derived largely from observations of ictal signs and symptoms, followed by identification of lesions at postmortem examination, in an era of pioneering investigations of localization of function within the brain.[48] This work led directly to the application of surgical treatment for refractory partial epilepsy,[82] which, in turn, provided opportunities for invasive investigations of the human brain, such as direct stimulation to delineate anatomic substrates of specific ictal manifestations.[151] With the advent of the electroencephalogram (EEG), the location of focal interictal spikes was used as evidence for the site of origin of habitual seizures, and surgical treatment for "temporal lobe epilepsy" was introduced on the basis of EEG evidence alone.[11] Shortly thereafter, the pioneering efforts of Bancaud et al. related intracranial seizure recording to clinical seizure characteristics.[12]

The development of sophisticated electrophysiologic techniques for recording spontaneous seizures with intracranial electrodes and correlating this information precisely with videotaped ictal behavior has made anatomic classification of seizures more, rather than less, controversial. Because of variability of propagation patterns of ictal discharge, the area of brain giving rise to clinical signs and symptoms can be at considerable distance from the actual site of seizure onset. Consequently, virtually no signs or symptoms can be considered pathognomonic of the anatomic localization of the primary epileptogenic region.[4,121,124] Although the timing or sequencing of seizure manifestations may be as important as their presence or absence, this feature fails to localize precisely because of the potential for seizure origin in clinically "silent" brain regions.

Improvements in structural imaging also have not definitively clarified anatomic classification. High-resolution MRI can identify many structural cerebral lesions in patients with localization-related epilepsy,[107] and they are usually indicative of the epileptogenic region.[25] Many patients with partial seizures, however, have normal MRI evaluations; others have lesions that are unrelated to their epilepsy. Furthermore, it has become increasingly apparent from intracranial recordings of patients under evaluation for surgical treatment that a discrete, well-circumscribed epileptogenic region often does not exist in the human brain; instead there are diffuse or multiple areas of functional abnormality capable of generating interictal, and even ictal, discharges, even in patients for whom a specific localized structural lesion has been identified.[46,214,220] For these reasons, anatomically classifying a seizure disorder merely on the basis of the location of an observed structural abnormality is not always justifiable. Nevertheless, a continued effort to categorize epileptic seizures, and even epileptic disorders, according to a presumed anatomic substrate can be considered a reasonable exercise of some value, particularly for devising presurgical diagnostic strategies, as long as the limitations of such a classification are recognized and surgical interventions are not undertaken on the basis of ictal manifestations or MRI lesions alone. Combining clinical seizure characteristics, structural neuroimaging findings, and EEG results, however, has improved our understanding of partial seizures and helped to better define an anatomic classification.

Functional imaging using positron emission tomography (PET) has been employed at a few medical centers for many years and is currently becoming available at many more institutions. While early results in patients with temporal lobe seizures were and still are promising,[28,117] PET utility in patients with seizure origin outside of the temporal lobe

has been less consistent.[128] Newer radioligands and improved technologies will almost certainly improve results in extratemporal epilepsy with normal MRI[77,117] (see Chapter 80).

Ictal single positron emission computed tomography (SPECT) is being used widely to help identify regions of seizures origin.[75,92,101,117,130,143,182,201] Early injection is essential, particularly with brief seizures that propagate rapidly.[113,201] The subtraction product of interictal SPECT from ictal SPECT coregistered with MRI improves the resolution of this relatively difficult-to-obtain procedure.[141,142,143] Ictal SPECT has become an integral part of the presurgical evaluation in some centers. This is particularly relevant when the MRI is normal.

Magnetoencephalography (MEG)[45] superimposed on MRI and EEG-triggered functional MRI[104] have great promise for localizing sources of ictal, as well as interictal, epileptiform activity. In the former, dipole localization is easier than with EEG because differences in conductivity between brain, cerebrospinal fluid (CSF), bone, and skin do not need to be taken into account. In the latter, simultaneous EEG and MRI recording permit MRI acquisition during epileptiform discharges to be subtracted from MRI acquisitions in the absence of epileptiform discharges, so that the difference in blood oxygenation can be used to localize tissue activated during the EEG events of interest. Magnetic resonance spectrometry (MRS) is also being used to identify metabolic changes associated with interictal disturbances, and this has been particularly useful for confirming hippocampal epileptogenic lesions.[109,186]

Definitions

With the exception of MTLE, the designation of an epileptic condition by anatomic location denotes the occurrence of a specific type of seizure or seizures, rather than a complex of signs and symptoms that would ordinarily constitute a syndrome. In the purest sense, a temporal lobe epilepsy, for example, would be an epileptic condition in which seizures originate somewhere in the temporal lobe, as indicated directly by invasive electrophysiologic monitoring, or inferred indirectly from clinical seizure characteristics, scalp EEG monitoring, perhaps the presence of a discrete lesion on structural neuroimaging, functional disturbances revealed by neurologic examination, neuropsychological testing and functional neuroimaging, and disappearance of habitual events following a temporal lobe resection of some type. There remains some controversy, however, with this terminology. In much of the published literature on temporal lobe epilepsy, some patients are given this diagnosis when extratemporal ictal onsets preferentially project to mesial temporal structures that, in turn, are responsible for mediating the characteristic ictal manifestations. In many cases, such patients are diagnosed as having temporal lobe epilepsy because the extratemporal origin of their seizures is unrecognized, but in others the actual site of the primary epileptogenic region is ignored and classification is based on ictal characteristics.[208] If a temporal lobe seizure is one that is caused by seizures involving temporal lobe structures, then this could result from ictal initiation within the temporal lobe or an extratemporal “silent area” that preferentially projects to the temporal lobe. Thus, if temporal lobe epilepsy is characterized by the existence of temporal lobe seizures, then the broader definition is acceptable. Rather than dwell on the semantic difficulties associated with anatomic classification, this example can be used to argue the folly of attempting to construct an anatomic classification of epileptic disorders at all. On the other hand, if a specific temporal lobe epilepsy syndrome can be defined, then seizures originating elsewhere can, in part, be identified by virtue of not fulfilling all the characteristics of this syndrome.

Attempts to define seizures or epilepsies according to anatomic lobes of the brain are also confounded by the fact that none of the classical four lobes represents functionally homogenous or unique regions. For instance, parts of the frontal lobe, such as the precentral gyrus, are capable of generating specific ictal signs and symptoms, whereas others, such as the orbital frontal cortex, belong, in part, to the limbic system and can give rise to ictal signs and symptoms by virtue of propagation to other frontal regions or mesial temporal structures, or both (see section on frontal lobe seizures). The International Classification of the Epilepsies divides frontal lobe epilepsy into seven anatomic subtypes and temporal lobe epilepsy into two anatomic subtypes, based on the belief that these areas give rise to different characteristic ictal manifestations.[2] However, there are also functional areas of the brain that give rise to relatively stereotyped clinical seizure characteristics, despite the fact that they encompass more than one anatomic lobe. Thus, seizures arising from the perirolandic area can generate indistinguishable signs and symptoms from motor or sensory cortex, and there may be characteristic features associated with ictal discharges in the temporal-parietal-occipital junction, as well as regions of frontal parietal operculum and insula.

Nevertheless, as our understanding of the various specific and anatomically originating seizures improves, there may emerge clearer evidence on how these clinical characteristics can help localize regions of seizure origin, both by virtue of their uniqueness and their masquerading qualities. This may be particularly true of some, but not all, seizures of frontal lobe origin.

Epidemiology

Among the localization-related epilepsies, the relative incidence and prevalence of temporal lobe, frontal lobe, parietal lobe, and occipital lobe epilepsy have not been adequately determined, due largely to the recognized inaccuracies of identifying anatomic substrates without sophisticated diagnostic evaluation. Data from epilepsy surgery centers indicate that temporal lobe epilepsy is by far the most common of the four when only medically refractory patients are considered. In a review of surgical procedures performed worldwide for medically refractory epilepsy, approximately 70% have involved resections of temporal lobe abnormalities, whereas <20% involved resection of extratemporal cortex.[49,162,163,212] Of the latter group, frontal lobe resections are more common than occipital resections, and parietal lobe resections are least commonly performed. It is important to note, however, that these figures reflect the ease of identification of temporal lobe, frontal lobe, occipital lobe, and parietal lobe epileptogenic regions; the degree of intractability and disability of seizures associated with these areas; and the desirability of their surgical resection, as much as they reflect the incidence of epileptogenic abnormalities in these cerebral areas.

Mesial temporal lobe epilepsy may well be the most common epileptic syndrome, partly because of the peculiar epileptogenicity of hippocampal sclerosis (see Chapter 247). Studies of regional differences in epileptogenicity have shown that temporal lobe EEG spike foci are the most likely, and central EEG spike foci the least likely, to be associated with clinical seizures in children,[98] although these data are biased by the inclusion of patients with the benign centrotemporal spike EEG trait.[26] A different pattern of epileptogenicity is revealed by studies of posttraumatic epilepsy, which indicate that injury to the perirolandic region is most likely to give rise to seizures[87] and that frontal and temporal lesions are more epileptogenic than those in parietal and occipital areas.[31,91]

P.2467

Etiology and Basic Mechanisms

There are no specific causes or pathophysiologic substrates of the various anatomically defined epileptic disorders, with the exception of hippocampal sclerosis, which underlies most cases of MTLE (discussed in Chapters 13, 41, and 247). Any insult, lesion, or primary genetic abnormality capable of producing a localized epileptogenic region can account for the localization-related epileptic disorders classified by cerebral lobe. There are, for example, variants of the idiopathic benign childhood epilepsy with centrotemporal spikes that appear to originate in other cortical areas.[122]

Clinical Presentation

The symptomatic localization-related epilepsies discussed in detail below include only those for which there is reasonable documentation. Much of the information is derived from recently reported series using currently available technologies with localization often confirmed by surgery.

Clinical Characteristics of Seizures Related to Anatomic Region of Origin

Temporal Lobe Epilepsy

Wieser[206] extensively evaluated a limited number of carefully studied patients and concluded that there were five different types of "psychomotor" seizures. Four of these were of temporal lobe origin. While this concept failed to achieve wide acceptance, much of what he concluded remains valid, and it did direct attention toward the possibility of different temporal lobe epilepsy syndromes.

Mesial Temporal Lobe Seizures

Currently, temporal lobe epilepsy is divided into two types: Those with seizures originating in the medial temporal structures (MTLE), and those with seizures beginning elsewhere in the temporal lobe (e.g., neocortical temporal lobe epilepsy or lateral temporal lobe epilepsy). MTLE refers to a specific subset of patients with seizures originating in the medial temporal lobe structures (mesial temporal lobe seizures [MTLSs]); MTLE with hippocampal sclerosis (MTLE-HS) comprises the great majority of patients with MTLE. Although MTLE-HS is characterized by many features that are not shared by conditions with MTLS caused by other lesions, the seizures themselves are indistinguishable. For purposes of this chapter on anatomic classification, therefore, MTLE, with and without HS, need not be further discussed here, as the phenomenology is described extensively in Chapter 247. MTLE, however, serves as a prototypical benchmark for localization-related epilepsies. As noted previously, one of the first steps used to identify other anatomic symptomatic focal epilepsies is to examine them in comparison to MTLE to determine how far they stray from the typical syndrome.

Neocortical Temporal Lobe Epilepsy

Since the lateral temporal cortex only comprises a portion of the temporal neocortex, the preferred terms here are neocortical temporal lobe epilepsy (NTLE) and neocortical temporal lobe seizures (NTLSs).

Several reviews of temporal lobe epilepsy do not even attempt to differentiate medial from neocortical temporal lobe seizures.[102,133,208] A review specifically addressing the issue of neocortical temporal lobe epilepsy concludes that currently there is very little information about this type of epilepsy and that distinguishing seizure characteristics do not exist.[203] Patients with neocortical temporal lobe seizure origin are rare, particularly if examples with obvious epileptogenic lesions are excluded. Although exact statistics are not available, a reasonable estimate would be that <10% of patients with temporal lobe epilepsy, who do not have obvious circumscribed lesions, have seizure origin in the temporal neocortex. Patients with seizures due to temporal neocortical lesions are also uncommon. In one study spanning 14 years from a large epilepsy center, only ten examples of neocortical temporal lesional epilepsy were identified.[173]

One study comparing mesial versus neocortical temporal lobe seizures found very little difference in terms of risk factors, demographics, and scalp EEG patterns.[27] The only significant difference was increased lateralized memory impairment during intracarotid Amytal testing in patients with MTLSs. There was a trend toward early risk factors (below age 2 years) in the patients with MTLSs. Clinical seizure characteristics were not examined. An important contribution of this study is that patients with lateral temporal lobe seizure origin (none of whom had detectable lesions) had surgical outcomes as good as those associated with mesial temporal lobe seizure origin. This is in contrast to other studies reporting less favorable postsurgical results in patients with nonlesional lateral temporal lobe epilepsy.[76,184]

Extensive reciprocal connections between lateral temporal neocortex and medial limbic structures might explain why clinical features of seizures could be similar and possibly indistinguishable from both regions.[22,69,207] Even the auras may require participation of both areas.[22,69]

Nevertheless, despite some generally negative results obtained in attempting to define lateral temporal lobe seizures, there are some features that may help identify them. Auditory, vertiginous, and complex visual hallucinations have been equated with lateral temporal origin.[12,212] No one in a large "pure culture" of patients with MTLSs had this type of aura.[55] One study comparing patients with hippocampal sclerosis and temporal lobe tumors, however, did report auditory, visual, and vertiginous auras in both patient groups.[173] Three studies have noted that the motor manifestations observed in MTLSs are less common in lateral temporal seizures.[52,67,173] There are some scalp EEG and neuroimaging findings that might help distinguish the two types of temporal lobe seizures.[43,44,76,202]

During the past 10 years, additional converging evidence has been provided that there are some characteristics that can help differentiate seizures associated with MTLE from those originating in the temporal neocortex.[29,53,68,119,126,148] Patients with NTLSs have no history of febrile convulsions and have experiential auras (auditory and other sensory/experiential illusions and hallucinations, but not fear), early contralateral dystonic posturing in the absence of oral alimentary automatisms, early loss of contact and shorter seizure duration, and greater propensity to generalize compared to patients with MTLSs. Patients with MTLSs often have a history of febrile seizures (usually complicated), younger onset, evidence of hippocampal sclerosis on MRI, auras of visceral sensations, fear or olfactory hallucinations (rare), dreamy state, early oral alimentary automatisms, delayed contralateral dystonic posturing, and less tendency to generalize compared to patients with NTLS. All authors stress the importance of early findings in differentiating the two conditions. Many of the clinical seizure characteristics described in autosomal dominant lateral temporal epilepsy are the same as described here in neocortical temporal lobe seizures.[132]

P.2468

Frontal Lobe Epilepsy

Patients with seizures originating in the frontal lobes are the second most common to have localized surgical resections.[93,99,161,162,163,223] Frontal lobe seizures are not rare but, because of lack of familiarity with some of the clinical manifestations, they are often misdiagnosed.[96,205,211,214,217,219,220] Before 1985, scattered reports described different types of frontal lobe seizures,[4,63,65,125,151,193] but during the past 20 years, there has been heightened interest in frontal lobe seizures as reflected in the publications from two symposia specifically concerning this topic.[34,90] A current PubMed search of frontal lobe seizures from 2000 to 2006 yields 907 citations.

Whereas MTLSs are all similar with differences representing variations on a theme, the same is not true for frontal lobe seizures. A number of entirely different seizure types are associated with frontal lobe origin. Initially, because of protean clinical seizure manifestations, frontal lobe seizures seemed to defy classification into subtypes,[213] but recently some order has begun to shape this formerly chaotic situation. Frontal lobe seizures can now be grouped into six broad categories: Focal clonic motor seizures, asymmetric tonic seizures, frontal lobe hyperkinetic (psychomotor, hypermotor, complex partial) seizures, frontal lobe absence seizures, frontal opercular seizures, and frontal lobe seizures that closely resemble typical MTLSs, recognizing that there can be some admixture among the different types.[32,33,92,99,205,211,212]

Focal Clonic Motor Seizures

When focal clonic motor seizures occur in isolation, they are not associated with impaired consciousness and reflect ictal activity in the primary motor area. Focal clonic motor seizures are often part of other frontal and extrafrontal secondary activations of the primary motor cortex. They are discussed in detail in Chapter 44.

Asymmetric Tonic Seizures

Supplementary motor area (SMA) seizures are the classic type of asymmetric tonic seizures. SMA seizures were first described over 50 years ago.[5,150,151] Renewed interest in this relatively uncommon seizure type is reflected in recent publications describing both clinical seizure manifestations and cortical stimulation studies.[13,14,38,56,58,72,92,113,135,159,164,212,214,220] Despite the often dramatic and identifiable clinical seizure manifestations, the frequent absence of EEG abnormalities can still lead to the erroneous diagnosis of nonepileptic psychogenic attacks in patients with SMA seizures.[58,96]

SMA seizures can have subjective symptoms that include bilateral, contralateral, and ipsilateral somatosensory sensations of tightness, pressure, numbness, or tingling. This is fairly common, causing some investigators to prefer the term “supplementary sensorimotor area.”[38] A nonspecific general feeling of constriction or tightness can immediately precede visible motor activity. Because the majority of patients do not report specific somatosensory symptoms, the preferred term remains *SMA seizures*.[92] The objective manifestations of SMA seizures usually begin with the sudden, often explosive, assumption of a fixed posture, classically with the arm contralateral to the side of seizure origin abducted at the shoulder, externally rotated, and flexed at the elbow with the head and eyes deviated as if looking at the up-raised hand.[4] The leg on the side contralateral to seizure origin can be held in rigid extension or can be flexed at the hip. Forced vocalization can occur, usually repeated vowel sounds rather than formed words. More often, there is speech arrest. Seizures are brief, lasting seconds, and only rarely last longer than 1 minute. Toward the end of the seizure, there can be clonic motor twitches of the hand or face. These seizures can secondarily generalize into tonic–clonic seizures. Even when generalized convulsive seizures occur, the postictal clinical and EEG suppression is often surprisingly short when compared to other convulsive generalized seizures.[220] If they do not secondarily generalize, they stop as suddenly as they start. They can occur in clusters of many seizures per day. Nocturnal preponderance is common, but there are many exceptions. Patients with SMA seizures are often conscious during seizures. There seems to be no fundamental difference in terms of lateralization or clinical seizure characteristics that determines whether or not consciousness is impaired during SMA seizures. Responsiveness, however, often is not tested during these typically brief seizures. When given test phrases or words during these seizures with intense bilateral motor activity, one is often surprised to discover that patients clearly recall the test phrase during the immediate postictal period.

The classic motor manifestations of SMA seizures are probably the exception rather than the rule. Although to some extent representing variations on a theme, the motor manifestations of SMA seizures among different patients can differ widely, though they are usually stereotyped for a given patient.[14,38,58,92,99,135,145,164,220] Motor manifestations in relatively well-documented examples of SMA seizures can include symmetric tonic or dystonic posturing of both upper and lower extremities; unilateral rigid straight tonic upper extremity posturing; adducted, flexed posturing of the upper extremity with the fist clenched; flailing, thrashing movements of the ipsilateral arm; kicking and stepping activity of the lower extremities; tonic/dystonic posturing involving the contralateral lower extremity; and athetoid dystonic movements of the contralateral hand, arm, leg, or both.[214,217,220] SMA seizures can rarely present with automatisms without tonic motor activity.[92,211]

Startle epilepsy with asymmetric tonic seizures of presumed SMA origin has been the topic of several reports.[36,92,144,177] SMA origin was documented in some, but not all, of the reported patients. Similarly, reflex seizures due to more casual somatosensory stimuli (i.e., movement or rubbing) have been attributed to SMA seizure origin,[95,154] but SMA origin was not documented in any of these patients. In some of these patients seizures probably began in the parietal cortex.[95]

Both positive (tonic) and negative (atonic) motor activity have been attributed to SMA seizure activity.[95,131] Gelastic seizures in the absence of mirth have been described as a part of SMA seizures.[19,33] Finally, many of the features of SMA seizures seen in adults are also seen in children.[13]

Despite a wealth of reports on SMA seizures, some confusion persists, largely because asymmetric tonic seizures can be evoked practically anywhere in the neocortex.[3,83,215,216] In many of the reports of SMA seizures, origin of seizures is not well documented. In a careful study of four patients with asymmetric tonic seizures, various MRI lesions, and good surgical results, seizure origin was documented in the SMA in only one patient.[86] Two of these patients had seizure origin in the lateral frontal regions and the other patient had seizures beginning in the medial parietal cortex. All propagated to the SMA. These authors emphasized that asymmetric "SMA-type" seizures do not equate with SMA origin. These same authors, in a later report, examined clinical progression patterns in ten patients with presumed SMA seizures. SMA origin was based on clinical seizure characteristics and scalp EEG findings. Only three patients had intracranial studies, while two patients had parietal lesions on MRI. In an earlier report, they described two patients with parietal lesions and asymmetric tonic seizures.[83] Another study of SMA seizures with tonic limb posturing found the posturing to have poor localizing and lateralizing results in 14 patients studied with intracranial electrodes. Eleven patients had surgery and only three became free of seizures.[3] The lack of specificity of asymmetric tonic seizures has been well documented in earlier reports.[64,214,215,216,220] Although it is

often assumed that these tonic motor manifestations represent spread to the SMA,[3,83,84] this has seldom been proven[215] and sometimes has been specifically denied.[64]

Considering the sometimes confusing and conflicting data associated with seizures of SMA origin, can they be diagnosed with any degree of accuracy? The scalp EEG in patients with SMA seizures is notoriously inaccurate and may be misleading or completely uninformative.[15,33,54,179,184,200] A recent paper describing ictal and interictal magnetoencephalography in patients with medial/frontal lobe epilepsy reported good results but provided no evidence to verify the findings.[179] Ictal SPECT was used to study eight patients with presumed seizure origin in the SMA.[113] The importance of early (5 seconds or less) isotope injection was emphasized. Excellent results were realized in all eight patients. The ictal SPECT results in part explained the clinical seizure characteristics. Outcome was excellent in the five patients who had surgery. In a recent paper examining frontal lobe seizures in general, seven had seizure origins located in the SMA.[92] While not specifically stated, ictal SPECT was used to direct intracranial electrode placements in many of the patients included in this study. Of the seven patients with SMA seizure onset who had surgery, five are seizure free and one has had brief nocturnal seizures. The one patient with a poor result had a major postoperative complication that resulted in death 2 years later. No seizures occurred after surgery, but the patient was in a persistent vegetative state. Although normal MRI is said to predict less favorable outcomes,[50] the six patients from the Dartmouth series with good outcomes all had normal MRIs.[92] A small series of patients with presumed SMA seizure origin studied with invasive recording all experienced good results following surgery.[14]

SMA seizures, because of associated findings, may be a diagnostic entity. SMA seizures can often be recognized by the company they keep. Patients with brief, asymmetric tonic seizures with a sudden explosive onset and maintenance of consciousness, usually with speech arrest, nocturnal clustering, and normal or nonspecific EEG findings, have what might be considered to be an SMA epilepsy syndrome. This will not define all patients with SMA seizures. One of the seven patients with well-documented SMA seizure origin in the report by Jobst et al.[92] had the bizarre frontal lobe hyperkinetic seizures described in the next section.

A syndrome of autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) has been well defined recently[37,156] (Chapter 249). This phenotypic expression of ADNFLE is the result of at least three different genetic mutations with the majority of patients having, as yet, no recognized genetic marker. Seizure types associated with ADNFLE include asymmetric tonic seizures and hyperkinetic behavioral seizures described in the next section. Most of these patients respond well to antiepileptic drugs, so documentation of SMA origin has not been possible. Until recently, many of these patients, as well as nonfamilial forms, were thought to be suffering with a sleep disorder labeled nocturnal paroxysmal dystonia.[10,157,175]

Frontal Lobe Hyperkinetic Seizures (Frontal Lobe Seizures with Bizarre Behaviors, Hypermotor Seizures, and Frontal Lobe Complex Partial Seizures)

Certain types of peculiar nonconvulsive frontal lobe seizures occur with prominent motor activity but without tonic posturing. These seizures have been variably labeled frontal lobe complex partial seizures, frontal lobe seizures with bizarre behaviors, hypermotor seizures, and hyperkinetic seizures. The current preferred term is *hyperkinetic seizures*.[23] Isolated reports of these seizures date back to 1972,[193] and hints of their recognition can be found as early as 1954.[151] Several subsequent reports described patients with very unusual seizures of presumed frontal lobe origin.[62,63,65,125] The first detailed report of a series of these patients carefully studied with intracranial electrodes appeared in 1985.[211] Later reports confirmed the existence of this peculiar type of frontal lobe seizure disorder, which has now been extensively well defined.[40,92,103,188,205,213,214,217,220] The peculiar hyperkinetic automatisms are thought to be fairly specific for this type of frontal lobe seizure.[103] A recent report, however, did describe nocturnal hyperkinetic seizures of temporal lobe origin.[140] Although not specifically described, the frontal lobe system responsible for these ictal behaviors can presumably be accessed by other cortical areas as well.

Frontal lobe hyperkinetic seizures (FLHSs) usually occur frequently, often in clusters of many per 24 hours. As with SMA seizures, a nocturnal preponderance is common. The seizures are brief, lasting <1 minute with little or no postictal confusion. Motor automatisms are prominent and complex, beginning suddenly with a frenetic or agitated appearance. In some patients, aggressive sexual activity is a prominent part of the automatic motor activity.[63,185] Vocalization commonly occurs, varying from simple humming to growling and barking to shouted obscenities. Warnings are frequent but usually nonspecific. In approximately half of the patients with FLHSs, there is a history of nonconvulsive status epilepticus, which is often documented during evaluation[92,210] (see also Chapter 59). These attacks have a very bizarre, hysterical appearance, but they are stereotyped for each patient. As with other types of frontal lobe seizures, there can be transition forms between this seizure type and those of SMA origin, with some patients exhibiting components of both. Another important transition form occurs when there is delayed spread to medial temporal structures. In this situation, seizures will begin as FLHSs but then transition into the less dramatic MTLSs.[92] Focal clonic motor activity can also occur, but it is usually not a part of FLHSs. There is no specific region within the frontal lobe in which these seizures originate. They have been described with seizures of orbital frontal origin,[32,92,125,193,211] with seizures of mesial frontal origin (including the SMA),[92,205,211] and with seizures of frontal polar and dorsal convexity origin.[92,160]

Similar to SMA seizures, interictal and even ictal EEGs are often unrevealing in patients with FLHSs. This, coupled with the usually bizarre atypical appearance of these seizures, frequently leads to the erroneous diagnosis of psychogenic, nonepileptic seizures.[211,217] These seizures, however, are recognizable by virtue of their clinical characteristics alone; therefore, awareness of these characteristics is essential. Some specific features may help differentiate frontal lobe seizures in general from psychogenic seizures.[172] Features such as pelvic thrusting, side-to-side head movements, and kicking and a history of psychiatric diseases that have been used to define psychogenic seizures are also seen in FLHSs, whereas nocturnal preponderance, short seizure duration, young age at seizure onset, and prone position during seizures are more characteristic of FLHSs.

Analogous to SMA seizures, FLHSs are associated with a constellation of findings. These include often bizarre but stereotyped seizures, frequent brief seizures that occur in clusters with a nocturnal preponderance, normal or nonspecific interictal and ictal EEG patterns, and often normal MRI. All of these characteristics taken together could also constitute a syndrome. As noted previously, these seizures are also a part of the ADNFLE syndrome (see Chapter 249).

Frontal Lobe Absence Seizures

Rarely, frontal lobe seizures can present with absence seizures.[93,105,112,167] A variety of absence status of the elderly may be of frontal lobe origin.[194,195]

P.2470

Frontal Opercular Seizures

Seizures beginning in the frontal operculum have been described infrequently.[92,171,180,189] Opercular seizures consist of profuse salivation, oral facial apraxia, and possibly some focal facial clonic activity. To some extent, they resemble the opercular syndrome due to fixed lesions.[35]

Frontal Lobe Seizures Resembling Temporal Lobe Seizures

Seizures confined to the frontal lobes will have features resembling those previously described (i.e., frontal lobe absence, asymmetric tonic seizures, frontal lobe hyperkinetic seizures, and frontal opercular seizures).[93] Some FLHSs, particularly those originating in the orbital frontal region, will spread to the medial temporal structures. As previously discussed clinically, a bizarre FLHS will evolve into a more bland, temporal lobe–type seizure.[214,220] Other examples of orbital frontal seizure origin present with pure temporal lobe seizure manifestations, including scalp EEG findings.[92,178,183] This may be a particular feature of seizure origin in the medial posterior orbital frontal cortex. When this happens in patients without MRI-detected lesions, the potential for diagnostic error is very high.

Occipital Lobe Epilepsy

The prevalence and incidence of occipital lobe epilepsy documented with modern diagnostic technology is not known, but it is generally considered rare. In an older series reported by Gibbs and Gibbs,[66] occipital lobe seizures were thought to occur in 8% of 3,271 cases with focal partial epilepsy. In the large Montreal surgical series between 1928 and 1973, 25 of 1,702 patients without tumors, who underwent surgery for epilepsy, had occipital lobe seizures.[162] Six contemporary series of patients with well-documented occipital lobe seizure origin have been reported: Two examining seizures from the posterior hemispheres[21,39] and four specifically looking at occipital lobe seizures.[24,118,168,216] There have also been several reviews of occipital lobe seizures and epilepsies.[20,169,187,191,219] All contemporary reports on occipital lobe epilepsy are remarkable in the consistency of their findings, recognizing that many of the symptoms have been observed for more than 100 years,[70,71,88] and some of the “newly discovered” observations were reported 50 years ago.[5]

Occipital lobe seizures, as defined by subjective symptoms and objective signs, can be recognized by clinical seizure characteristics in most cases. Some clinical symptoms and signs reflect occipital lobe seizure origin, whereas others are indicative of spread anteriorly from the occipital lobe medially and laterally, above and below the sylvian fissure and contralaterally via the splenium of the corpus callosum with the potential for multiple additional spread patterns.[20,39,168,169,191,216] The manifestations of these multiple and highly variable seizure spread patterns are often the most prominent feature of these seizures, tending to overshadow more subtle findings of occipital lobe origin, leading to diagnostic error.

Elementary visual hallucinations, usually consisting of flashing or steady spots or simple geometric forms, either colored or achromatic, are the most common occipital lobe seizure symptoms. When lateralized, they occur contralateral to the side of seizure origin. They may be stationary or move across the visual field. Ictal amaurosis is the second most common symptom of occipital seizure origin.[24,168,187,216] This symptom, though not universally appreciated, has been consistently described.[7,9,20,149,166,168,198,216] Blindness can be limited to one visual field, but more often is bilateral, consisting of visual blackouts of vision or, rarely, whiteouts.[216] Bilateral (complete) ictal amaurosis implies early spread to the contralateral occipital lobe as previously discussed. An aura of eye movement sensation without detectable eye movement has been reported.[81,216]

Forced blinking or eyelid flutter at the very beginning of seizures can be objective evidence of occipital lobe origin.[24,136,146,216] Both tonic and clonic eye deviation have been noted, with the former much more common than the latter.[18,136,168,216] Concurrent head deviation may or may not be present. Oculoclonic status epilepticus has been reported.[94] Although eye deviation is usually contralateral to the side of seizure origin, ipsilateral eye deviation can occur.[168,216] Other features of occipital lobe epilepsy include ictal vomiting and other autonomic manifestations.[24,73,191] A series of carefully studied surgical patients were examined to determine whether there were differences between medial and lateral occipital seizure origins.[24] The only clear difference was absence of a field cut with lateral onset. There were no clinical seizure features that distinguished the two.

The important fact that seizures originating in the occipital lobe can have the potential for multiple different spread patterns was recognized almost 50 years ago,[5] and has been a consistent finding in recent reports.[20,24,73,118,168,191,216] Symptoms of spread outside of the occipital lobe include somatosensory auras and complex visual and auditory hallucinations. Signs of anterior spread from the occipital lobe include focal clonic activity (lateral, superior), asymmetric tonic seizures (medial superior), and various types of automatisms (inferior). These latter seizures are said to be indistinguishable from those seen in temporal lobe epilepsy.[149,168,169,216] Since most of the clinical seizure characteristics that occur after seizure origin reflect specific spread patterns, occipital lobe seizures can present with a wide variety of clinical patterns that do not reflect occipital lobe seizure origin but that do suggest seizure activity elsewhere. To further confound the issue, some patients exhibit different spread patterns during different seizures, thereby suggesting multifocal disease.[118,216] Static visual field defects, which help identify occipital lobe seizures, are reported in over half the patients in most recent studies.[168,216]

Neuroimaging detects occipital lobe structural abnormalities in up to three quarters of patients with occipital lobe seizures.[118,168,169,216] Focal cortical dysplasia, as a cause of occipital lobe epilepsy, may be undetectable, although newer high-resolution MRI makes this less common. Older literature included birth injury with anoxia in a high proportion of patients with occipital lobe epilepsy.[162] Other causes of occipital lobe seizures include Sturge-Weber variant or celiac disease with occipital lobe calcifications.[9,137,152,197] Occipital lobe seizures can occur in patients with hyperglycemia[78,204] and in women with eclampsia.[155]

Three benign idiopathic childhood epilepsy syndromes with occipital lobe seizures have been described.[59,60,61,106,110,196] These consist of an early type (Panayiotopoulos syndrome), a late type (Gastaut type), and a juvenile type with photic sensitivity (for a review see Taylor et al.[191]; also see Chapters 236, 237, and 257). The early-onset childhood epilepsy may not always have occipital features.[110] The early type is also noteworthy for the propensity to develop nonconvulsive status with pronounced autonomic features.

The prognosis of occipital lobe epilepsy usually relates to the cause. Permanent cortical blindness can occur following repeated occipital lobe seizures.[7] The prognosis of the benign childhood forms, as the name implies, is usually benign with complete resolution, in most but not all, by 19 years.[61] The clinical characteristics of the late childhood type (Gastaut type) of benign occipital epilepsy are identical to those with chronic symptomatic occipital lobe epilepsy, and the two must be differentiated if surgical intervention is being considered.

P.2471

Occipital lobe resection can be very effective in controlling medically intractable occipital lobe seizures, particularly when lesions are present.[20,168,169,216] This includes patients with celiac disease and occipital calcifications.[137] Partially or completely intact visual fields contralateral to the side of seizure origin can be converted to complete homonymous hemianopsias. Because most patients adjust to this visual neurologic deficit, homonymous hemianopsia is usually acceptable if medically intractable disabling seizures can be eliminated.[216] However, because postoperative field cuts are often not as severe as would be predicted, there may be reorganization of the visual cortex in some patients.[108] Patients with lateral occipital epileptogenic lesions can often be spared visual field deficits.[24,169] Patients with occipital lobe seizures consistently spreading into the ipsilateral temporal lobe usually do not do well following temporal lobectomy,[149,216] but there are exceptions.[146] Finally, cortical resections in the posterior regions are not associated with cognitive impairments, provided language areas are spared.[123]

Parietal Lobe Epilepsy

Certain clinical characteristics of seizures arising in the parietal lobes have been recognized since antiquity,[192] but patients with these kinds of seizures are uncommon. Parietal lobe seizures constitute no >5% of all partial seizures from surgical series.[162]

There have been several recent reports and reviews examining the clinical seizure characteristics, electroencephalographic findings, and neuroimaging results in patients with well-documented parietal lobe seizure origin.[6,21,30,39,80,100,187,215] Although there were some minor differences among these recent reports on parietal lobe seizures, most findings were consistent.

As with most focal seizures, there are subjective and objective manifestations of parietal lobe seizures. The most common symptoms are paresthesias consisting of numbness and tingling, sometimes described as a “pins and needles” sensation and, less commonly, as a feeling of crawling or itching. Ictal paresthesias, however, occurred in less than half of the patients reported in some series, and were not always correctly lateralizing.[30,80,215] One study, however, found somatosensory auras reliably lateralizing.[89]

Although pain has been recognized as an ictal phenomenon at least since Jackson's time,[88] it is considered rare.[114,199,209,224] Young and Blume[225] examined ictal pain in a series of patients and three types of pain were recognized. The most common was a burning dysesthetic sensation involving part or all of the hemibody opposite to the side of parietal lobe seizure origin. The second type was abdominal pain, sometimes severe, associated with temporal lobe seizure origin. The third type was ictal headache or head pain that had no localizing value. Other reports examining parietal lobe seizures described lateralized abdominal pain.[30,187] Other reports on epileptic pain described lateralized dysesthesias, abdominal pain, and head pain, all in patients with parietal lobe seizure origin.[181,221] Ictal abdominal pain has also been related to an intracranial parietal hemorrhage.[153]

Because pain is not thought to be a cortical sensation, this ictal manifestation might involve activation of corticothalamic circuits. Painful epileptic symptoms, however, have also been equated with seizure activity in the second sensory area,[225] as has widespread numbness.[224] Ictal pain can also be a manifestation of primary sensory cortex involvement.[153]

In a review of parietal lobe seizures, Sveinbjornsdottir and Duncan,[187] in addition to paresthetic, dysesthetic, and painful symptoms, described parietal lobe ictal sensations that included sexual sensations, apraxias, and disturbance of body image. Ictal vertiginous sensations have been attributed to seizure activity in the temporal parietal junction.[97] Gustatory hallucinations have been equated with seizures in the parietal operculum.[79] Some ictal parietal lobe dysfunction would never be detected except in extraordinary circumstances. For example, a patient in the Montreal program[151] had a seizure restricted to the parietal lobe while undergoing electrocorticography under local anesthesia. Two-point discrimination was impaired during the seizure but returned to normal when the seizure terminated. Some parietal lobe seizure symptoms can resemble panic attacks.[8] Parietal lobe seizures can occasionally be induced by complex somatosensory stimulation.[215] There is a case report of hot water–induced seizures related to a focal area of parietal cortical malformation.[116] Other unusual reported findings associated with parietal lobe seizure origin include expressive aprosody and amusica,[16] autoscopy,[127] kinetopsia,[111] and atonic seizures.[170]

Objective manifestations of seizures in the more anterior inferior aspects of the language-dominant parietal lobe would include the expected disorders of speech. If a seizure discharge remained confined to the parietal lobe and produced various apraxias and agnosias, the patient might present in a confused, disoriented state, but this could be true for seizures from almost anywhere. Most objective ictal manifestations of parietal lobe seizures reflect spread of seizure activity anteriorly into the frontal lobe, inferiorly into the temporal lobe, or posteriorly into the occipital lobe.[6] Tonic motor activity, automatisms, or both can occur in patients with documented parietal lobe seizure origin.[64,80,215] In a patient studied with intracranial electrodes, asymmetric tonic posturing occurred with spread to the ipsilateral supplementary motor area,[215] but another study using invasive monitoring did not find that relationship.[64] Subsequently, asymmetric tonic posturing in parietal lobe seizures resembling frontal lobe seizures has been reported repeatedly.[6,100,138] Secondary involvement of the medial temporal structures with associated automatisms has been documented during intracranial recording in patients with parietal lobe seizure origin.[57,64,215] Based on intracranial recording, two patients with unsuspected parietal lobe seizure origin underwent unsuccessful temporal lobectomy in the series reported by Ho et al.,[80] as did two patients from the Yale series.[215] Parietal lobe seizure origin was determined by detecting lesions using previously unavailable MRI and verified by successful surgery in the latter two patients. Ho et al.[80] determined parietal lobe seizure origin in their patients with ictal SPECT, including the two with previous unsuccessful temporal lobectomies.

There is a possible relationship between the location of parietal lobe seizure origin and the clinical seizure manifestations. Anterior parietal lobe lesions or seizure origin can be associated with initial ictal sensorimotor phenomena, whereas posterior seizure origin can be associated with more complex symptomatology.[30,80] Posterior parietal lobe complex partial seizures were described as "psychoparetic,"[80] which implied a psychic aura, such as fear or déjà vu followed by motionlessness and loss of consciousness. Parietal lobe onset seizures are associated with short postictal periods, even if they progress to complex partial seizures or secondarily generalized seizures[80] similar to that reported for frontal lobe seizures.[211,220] Some patients had elementary visual symptoms, presumably due to posterior spread, suggesting occipital lobe onset.[30,215]

Patients from several studies aimed at defining parietal lobe epilepsy all had epileptogenic parietal lobe lesions.[6,30,215] Because most of these patients had no clear lateralizing parietal sensory aura and the clinical seizure manifestations reflected spread outside of the parietal lobe, it can be concluded that a parietal lobe syndrome cannot be well defined. Although it can be argued that patients who present with consistently lateralized paresthesias and dysesthesias and possibly abdominal pain as part of their seizures may be identified as having a high likelihood of having parietal lobe seizure origin, focal tonic

seizure activity and seizures with automatisms cannot be considered criteria for or against parietal lobe seizure origin. The salient point regarding parietal lobe seizures is that they can present with all these variable manifestations, and sometimes with more than one seizure type occurring during different seizures in the same patient analogous to that seen in occipital lobe seizures.[100,215,216] Parietal lobe origin should therefore be considered in those patients who do not have clear evidence for seizure origin elsewhere. Ictal SPECT may provide localizing data not otherwise obtainable in these difficult cases[80] (see Chapter 81).

When parietal lobe seizures are refractory to medications, surgery is an option. Because, with the exception of the postrolandic gyrus, much of the parietal lobe is silent with respect to seizure symptoms, initial clinical manifestations will often reflect seizure spread outside of the parietal lobe.[6,139,215] Furthermore, scalp EEG findings may not be helpful and may even be misleading. Therefore, in the absence of a detectable parietal lesion, the presurgical evaluation can proceed in the wrong direction.[80,215] Although ictal SPECT can be helpful, lack of early seizure manifestations could preclude early injections. Nevertheless, when parietal lobe seizure origin could be documented, surgical results were good.[6,21,30,39,100,120,215] There is a report of a remarkable case of atypical Lennox-Gastaut syndrome that was dramatically improved by removing a parietal convexity dysembryoplastic tumor.[158] A patient with painful seizures who developed medically refractory nonconvulsive status epilepticus was cured following a medial parietal resection.[138] New cognitive deficits after parietal surgery have been evaluated and found to be relatively minor.[123]

Insular Lobe Seizures

Insular lobe involvement in temporal lobe seizures is a recognized common spread pattern.[85] In the past, the clinical features of seizures starting in the insula were thought to be indistinguishable from medial temporal lobe seizures, thus accounting for some of the surgical failures following temporal lobectomy.[74,147] Furthermore, surgery was often considered too risky because the insula is located just lateral to the lenticulo-striate arteries.[174] Recent reports dispute these assumptions by providing evidence that insular surgery can be done safely, albeit not without risk.[42,86]

Isnard et al.[85,86] described a series of patients with presumed temporal lobe epilepsy who were carefully studied with intracranial electrodes. They found that 10% of these patients had consistent seizure origin in the insula and not the hippocampus. A fairly stereotyped sequence of clinical events was observed, including a sequence of unpleasant, sometimes painful laryngeal constriction followed by dysesthesias, perioral or involving extensive cutaneous areas, then dysarthria, and culminating in focal clonic activity of the face and arm, all with full consciousness. Another case report of insular seizures documented these sensory phenomena and associated them with an unpleasant taste.[165]

Two reports by Duffau et al.[41,42] address the issue of resective surgery in the insular lobe in a series of patients with low-grade gliomas. Postoperative morbidity was high but cleared completely in 3 months in most patients. Three patients, however, were left with a permanent hemiparesis due to compromise of lenticulostriate arteries.

Diagnostic Evaluation

Accurate localization of the anatomic substrate of an epileptic disorder, as opposed to identification of a specific pathologic substrate, is only of clinical value when resective surgical treatment is being considered. In this situation, classification merely by lobe is inadequate to plan a resective procedure, and localization by clinical seizure characteristics and interictal scalp EEG is too often misleading to be used alone as an indication for surgical intervention.[120] When a discrete structural lesion is identified on MRI, the ictal clinical characteristics and location of interictal EEG spikes may be sufficient to confirm an anatomic diagnosis, although ictal EEGs are also usually performed prior to surgery to be sure that the intractable habitual seizures are the same as those arising from the presumed epileptogenic lesion. Focal functional deficits, as demonstrated by neurologic examination, neuropsychological testing, and functional neuroimaging such as PET, can offer additional confirmatory evidence when localization is equivocal. Ictal SPECT is becoming increasingly important in presurgical evaluations, particularly when the MRI is normal.[16,75,92,101,182,201]

The importance of very early injection in rapidly propagating neocortical seizures cannot be overemphasized.[115,201] It is important to recognize that structural lesions in patients with localization-related epilepsy occasionally may be fortuitous findings and unrelated to the epileptogenic process, and that interictal EEG spikes can propagate widely to predominate at a distance from the primary epileptogenic region. When localization is uncertain, particularly in patients with focal epilepsy who have normal MRI scans but stereotyped clinical seizure characteristics indicating the likelihood of a single discrete epileptogenic region, chronic recording with intracranial electrodes is generally performed. Depth electrodes are usually preferred when the epileptogenic region is presumed to be in deep limbic structures of the brain, whereas subdural grids or strips are commonly used to delineate neocortical epileptogenic regions. Because all these diagnostic approaches are those used in presurgical evaluation, the reader is referred to the chapters on diagnosis (Chapters 167,167,168,169,170,171,172,173,174,175) in the section in this book on surgical treatment for epilepsy. The objective of the presurgical evaluation is to precisely locate and delineate the epileptogenic region, and not merely to make an anatomic diagnosis.[124]

Differential Diagnosis

No specific issues of differential diagnosis are peculiar to the anatomic classification of focal epilepsies. The distinction between these disorders and those associated with paroxysmal nonepileptic phenomena that can be mistaken for epilepsy is the same as for epilepsy in general. Certain types of focal epilepsies, such as those discussed under frontal lobe epilepsy, are particularly prone to misdiagnosis, and only familiarity with them will prevent mistakes. It is worthwhile to note, however, that seizures can arise from a single anatomic location when MRI reveals a diffuse cerebral structural abnormality that would not permit a discrete anatomic classification. Conversely, patients can have seizures arising from a discrete epileptogenic region that propagate so rapidly that they appear to be generalized from the start, making a correct anatomic classification difficult. An example of the former would be a patient with a large developmental lesion, such as schizencephaly, where only a small part is responsible for generating the habitual ictal events; such patients can often benefit from localized resective surgery,[115] but invasive electrophysiologic recording is usually necessary to characterize the anatomic localization of the epileptogenic region. An example of the latter would be a patient with a localized frontal lobe lesion that gives rise only to generalized seizures that appear to have no electroclinical localizing features. In this situation, evidence of a localized disturbance, either from structural neuroimaging or tests of focal

functional deficit, is necessary before invasive electrophysiologic studies can be recommended.

Treatment and Outcome

Pharmacotherapy for focal epilepsy is not dependent on anatomic diagnosis, and there is no evidence of differential responses to medication based on anatomic localization of a neocortical epileptogenic region, although mesial temporal lobe epilepsy may be uniquely refractory.[176] In patients with medically refractory seizures, surgical treatment depends largely on precise localization and delineation of the epileptogenic region rather than anatomic diagnosis, and outcome reflects the accuracy of this process and the ability to resect the abnormal tissue completely. Total resection may be limited by involvement of adjacent essential primary neocortex, which cannot be damaged, or by failure to correctly map the epileptogenic substrate, as can often be the case with MRI-negative localization-related epilepsy. When the epileptogenic region involves essential cortex, seizures may be relieved by removal of a structural lesion without cortical margins,[29] or by multiple subpial transection, which is designed to disconnect propagation of epileptic activity along the surface of the brain without disrupting functional columnar cortical organization.[134] Results of the surgical intervention are excellent in a condition where a discrete epileptogenic lesion is identified and a circumscribed adjacent area of epileptogenicity can be delineated; this is considered to be one of the surgically remediable syndromes, with 70% to 80% of patients becoming seizure free,[25] and surgical intervention is recommended as soon as first-line medications fail[50] (Chapters 127 and 168).

Long-Term Prognosis

The long-term prognosis of localization-related epilepsy is determined by the pathophysiologic nature of the underlying substrate, and not by its anatomic location. Patients with discrete structural lesions as the cause of medically refractory epilepsy have the greatest chance of becoming seizure free, and remaining seizure free, following surgical resection, as opposed to patients with mesial temporal lobe epilepsy, who have a higher incidence of postoperative simple partial seizures, and patients with cryptogenic localization-related epilepsy, who are much more likely to have postoperative disabling seizures as well.[17,129] However, surgical results in MRI-negative localization-related epilepsy are also improving dramatically in some centers as we gain better understanding of clinical seizure patterns and develop new diagnostic techniques.[92,182]

Summary and Conclusions

The International Classification of Epilepsies and Epileptic Syndromes recognizes temporal lobe, frontal lobe, parietal lobe, and occipital lobe epilepsies as subtypes of the focal symptomatic epilepsies. With the exception of mesial temporal lobe epilepsy, these disorders describe seizure types rather than complexes of signs and symptoms that might be considered discrete syndromes. Some conditions with frontal lobe seizures and associated constellations of findings could, however, eventually be recognized as syndromes. A number of different characteristic seizures can be identified as indicative of epileptogenic regions in functionally distinct regions of these broad lobar designations. Furthermore, some seizure types are characteristic of epileptogenic regions that transcend lobar boundaries, particularly those arising in the perirolandic region, the perisylvian operculum and insula, and the temporal-parietal-occipital junction. Anatomic classification is of clinical value when surgical treatment is considered, but much more precise localization of the epileptogenic region is necessary before resection can be performed. In this situation, clinical seizure characteristics, routine EEG, and structural neuroimaging provide important localizing information, but more accurate delineation of a primary epileptogenic region for surgical resection usually requires ictal video-EEG monitoring, functional imaging, other tests of focal functional deficit, and, occasionally, intracranial EEG recording. Treatment and outcome are dependent more upon pathophysiologic substrate than anatomic localization, except in situations where surgical resection is limited by involvement of essential primary cortical areas or an inability to accurately define the boundaries of the epileptogenic region. Patients with medically refractory seizures due to discrete resectable structural lesions have an excellent long-term prognosis; this constitutes a surgically remediable form of epilepsy and is an indication for early surgical intervention. An understanding of the variety of focal seizure manifestations originating in different anatomic locations also helps prevent erroneous diagnoses of nonepileptic seizures by identifying specific unusual epileptic seizure types such as those originating in parts of the frontal lobes.

Chapter 247

Mesial Temporal Lobe Epilepsy with Hippocampal Sclerosis

Jerome Engel Jr.

Peter D. Williamson

Heinz Gregor Wieser

Introduction

The term *temporal lobe epilepsy* (TLE) has been used for many years to denote a variety of conditions associated with complex partial seizures of presumed temporal lobe origin. The 1985 International Classification of Epilepsies and Epileptic Syndromes[21] divided symptomatic localization-related epilepsies according to the cerebral lobe of origin and recognized a syndrome of temporal lobe epilepsy defined purely on an anatomic basis. However, anatomic localization was usually determined purely from electroencephalographic (EEG) evidence, which could be misleading.[39]

It has also been known for many years that the most common pathologic substrate of mesial TLE (MTLE), as loosely defined in the 1985 International Classification, is hippocampal sclerosis (HS).[5] Data have accumulated in recent years strongly suggesting that MTLE with HS (MTLE-HS) represents a discrete syndrome that can usually be recognized in life.[33,47,127,133,138] The International League Against Epilepsy (ILAE) recently convened a workshop of experts to discuss the natural history, pathologic features, pathogenesis, electroclinical, neurophysiologic, neuropsychological, structural, and functional imaging findings of MTLE-HS and to determine whether it should be considered a disease, a single syndrome, or a group of clearly distinct syndromes.[134] Their conclusion was that MTLE-HS should be considered a subtype of a greater syndrome of MTLE due to many causes, and that much more work is needed before MTLE-HS could be specifically characterized. Diagnosis of MTLE, and specifically MTLE-HS, early in the course of the disorder, however, is now considered important because disabling seizures and their consequences can be eliminated by anteromesial temporal lobectomy in 60% to 80% of patients, and early surgical intervention provides the greatest opportunity for complete psychosocial rehabilitation.[34,127,130,133]

Historical Perspectives

Bouchet and Cazauvieilh[11] first described the association between epilepsy and a sclerotic hippocampus in 1825, based on gross pathologic examination of brains from patients with “mental alienation seizures.” These lesions were believed to be an effect, rather than a cause, of epilepsy, which at that time referred only to generalized convulsions believed to originate in the medulla oblongata. In the latter part of the 19th century, however, Hughlings Jackson[63,64] recognized that partial seizures also represented epileptic phenomena and made an association between limbic-type seizures, which he called “intellectual auras” or “dreamy states,” and lesions in mesial temporal structures. During the same period of time, the neuropathologists Sommer[117] and Bratz[12] suggested that HS might be an epileptogenic lesion.

With the advent of EEG, Gibbs et al.[52] reported an ictal discharge pattern that they considered characteristic of psychomotor seizures; however, because they referenced all their electrodes to linked ears, they believed this phenomenon to be generalized. It was Jasper et al.[65,66] who pointed out that interictal and ictal epileptiform EEG abnormalities in psychomotor dreamy states and other phenomena now known to be limbic seizures originated in mesial temporal structures. Bailey and Gibbs[6] were the first to perform anterior temporal lobectomy on the basis of EEG evidence alone, but it was the en bloc resection of Falconer,[43] which included mesial temporal lobe structures, that made it possible to perform systematic pathologic analysis of resected tissue. Not only was HS identified as being present in a high percentage of patients with medically refractory temporal lobe epilepsy, but also surgical outcome in patients in whom this pathologic abnormality was demonstrated was exceptionally good, supporting the argument that this structural lesion was the cause, and not the effect, of recurrent epileptic seizures. Falconer[44,45] also recognized the association between HS and both febrile convulsions and a family history of epilepsy, which suggested the existence of a specific syndrome.

In large part as a result of the success of EEG monitoring in identifying mesial temporal epileptogenic tissue, anterior temporal lobectomy became, and has remained, the most common surgical treatment for medically refractory epilepsy. Crandall et al.[24] subsequently took advantage of the en bloc resection and long-term depth-electrode recording to initiate basic research on temporal lobe epilepsy.[37] HS is now the most studied epileptogenic lesion, and thus the fundamental neuronal mechanisms responsible for MTLE-HS are the best understood of any form of human epilepsy. The elucidation of a unique pathophysiology coupled with characteristic clinical features and an increasing ability to identify hippocampal disturbances noninvasively with functional and structural imaging have all helped to establish MTLE-HS as a discrete epileptic syndrome.[22,134]

Definitions

Definitions of temporal lobe epilepsy and temporal lobe seizures have varied through the years, and confusion persists concerning their usage.[35] The terms *temporal lobe seizure*, *psychomotor seizure*, and *limbic seizure* are often used interchangeably to denote seizures with signs and symptoms that derive from ictal activation of mesial temporal limbic structures. According to some workers, these terms are reserved only for seizures that originate in mesial temporal structures; other investigators, however, interpret the terms more loosely and use them also to define seizures that might originate in temporal or extratemporal neocortex but rapidly and preferentially propagate to mesial temporal structures.[31]

Whereas the 1970 International Classification of Epileptic Seizures introduced the term *complex partial seizure* in

P.2480

place of *temporal lobe seizure*,[49] the 1981 revision of this classification[20] redefined *simple* and *complex partial seizures* phenomenologically such that the latter term would be used to describe any partial seizure associated with impairment of consciousness. Because partial seizures can be associated with altered consciousness without involvement of mesial temporal limbic structures, not all complex partial seizures are temporal lobe seizures. Furthermore, because ictal discharges limited to one mesial temporal limbic area can produce characteristic symptoms such as epigastric rising, emotional and psychic experiences, and olfactory hallucinations during clear consciousness, temporal lobe seizures can also be simple partial seizures.[54] Consequently, whereas the 1981 International Classification of Epileptic Seizures has had definite clinical utility, the ILAE is now recommending that the concept of simple and complex partial seizures be abandoned. Seizures associated with MTLE are more correctly referred to as limbic seizures, whether or not consciousness is impaired.[36]

The 1985 International Classification of Epilepsies and Epileptic Syndromes divided partial epilepsies according to the cerebral lobe of onset and recognized a number of subcategories of temporal lobe epilepsy based on characteristic patterns of ictal onset and propagation as recorded with depth electrodes.[21,131] Because of controversy regarding the precision of such electrophysiologic localization, the 1989 classification[22] abolished anatomic categorizations but retained a syndrome of temporal lobe epilepsy based on associated clinical features, such as increased incidence of febrile convulsions and family history of epilepsy, as well as characteristic anterior temporal interictal EEG spikes and temporal lobe hypometabolism on positron emission tomography (PET). The term *temporal lobe epilepsy*, however, did not account for various etiologic factors and was used to denote the condition of patients both with and without apparent structural lesions. In some cases, patients with a diagnosis of temporal lobe epilepsy could conceivably have extratemporal epileptogenic regions that preferentially propagated to mesial temporal structures, producing characteristic temporal lobe seizures.

Before the advent of high-resolution magnetic resonance imaging (MRI), the term *cryptogenic temporal lobe epilepsy* had been frequently used to describe the condition of patients with the characteristic features of MTLE but no obvious lesions on structural imaging. Pathologic studies of mesial temporal tissue resected from patients with cryptogenic temporal lobe epilepsy revealed HS in most, so that the adjective *cryptogenic*, as opposed to *lesional*, was used tacitly to denote a subtype of MTLE that has now been more clearly defined as the syndrome of MTLE-HS.

Ammon's horn sclerosis and *mesial temporal sclerosis* are the two most common pathologic terms that have been used more or less synonymously with HS, although strictly speaking they imply different degrees of anatomic involvement.[4] The term *hippocampal sclerosis* refers to a specific type of hippocampal cell loss involving CA1 and hilar neurons most and CA2 neurons least, which distinguishes this entity from nonspecific cell loss with other causes.[5] Other characteristic features, such as mossy fiber sprouting[123] and selective loss of somatostatin and neuropeptide Y–containing hilar neurons,[25] also help to identify this distinct pathologic entity.

Epidemiology

Because the syndrome of MTLE-HS has only recently been clearly defined, and because only the medically refractory forms of this disorder referred to epilepsy surgery centers are usually identified, no epidemiologic information is available. It has been reported that 40% of patients with epilepsy experience complex partial seizures[50]; however, not all these patients necessarily have temporal lobe epilepsy, let alone MTLE-HS. In surgical series, careful pathologic analysis of hippocampal specimens, including cell counts and special staining procedures, reveals that as many as 70% of patients with medically refractory temporal lobe epilepsy may have HS,[5] indicating that the vast majority of patients with medically refractory temporal lobe epilepsy have MTLE-HS. Because of the probable increased incidence of a family history of epilepsy among patients who have MTLE-HS,[133] there may be some relationship between this syndrome and the recently described benign familial form of MTLE, which can also be associated with HS.[10,16] Although it is currently impossible to estimate the number of patients with MTLE-HS whose seizures are adequately controlled by antiepileptic drugs, two studies provide some evidence from nonsurgical series evaluated with high-resolution MRI. Semah et al.[114] reported on patients seen in a Paris epilepsy clinic over a 7-year period, approximately one half of whom had a diagnosis of temporal lobe epilepsy. Of these, half had evidence of hippocampal atrophy on MRI. At least one quarter of their population, therefore, could be given a diagnosis of MTLE-HS, and the percentage was probably higher because not all patients with this condition have sufficient atrophy to be visible on MRI. More importantly, of all the diagnostic categories, the most refractory to antiepileptic drugs was MTLE-HS. Only 11% of patients with this diagnosis, and only 3% with dual pathology (that is, HS and some other MRI lesion), had been seizure free in the previous year. This report suggests that MTLE-HS may be the most common, and most medically refractory, form of epilepsy. Another report from Glasgow by Stephen et al.,[121] however, found a similar proportion of patients with MRI evidence of HS, but only 46% of these were medically refractory (although this group was still the most intractable). The difference may be due to the fact that the Paris clinic included tertiary referral patients. The time at which patients with MTLE were referred may also influence the prevalence of intractability, because this condition typically has a stuttering course with long periods of remission. Berg et al.[8] reported on a large cohort of patients undergoing surgical treatment for medically refractory focal epilepsy, most of whom had MTLE, and found that it took an average of 9 years for the establishment of medical intractability.

Etiology and Basic Mechanisms

The epileptogenicity of this disorder results from loss of specific neurons in the hippocampus and synaptic reorganization of surviving cellular elements to cause hypersynchronization and hyperexcitability. The characteristic features of cell loss and reorganization, as well as the electrophysiologic aberrations that ultimately give rise to spontaneous seizures, are described in detail in Chapters 13 and 41. Although the pathophysiology of HS in fully developed MTLE-HS has been relatively well defined by studies of patients in epilepsy surgery centers and some very good experimental animal models exist, the events that initiate this process in humans are as yet unknown.

An association between mesial temporal sclerosis and febrile seizures was reported more than 30 years ago,[44] suggesting a causal relationship. Subsequent studies in both animals and humans have challenged this concept; some patients with MTLE-HS do not have a history of febrile convulsions,[47] and prolonged seizures in immature animals do not produce HS.[94] There are methodologic concerns with these studies, however, and more recent series of patients having MTLE-HS report a strong association with early risk factors, with as many as 66% of patients having prolonged febrile convulsions[14,15,47,60,61,115,116,138] and a variety of other early insults, such as trauma and infection.[83] Furthermore, there is

evidence that the process, once begun, does not stop after seizures appear but rather continues to progress over time.[47,82]

Also of etiologic importance is the observation that HS is sometimes associated with microdysgenesis[85] and occurs in patients with dysplastic lesions, such as hamartomas and heterotopias, but only rarely in patients with neoplasms.[79] This association, coupled with the increased incidence of a family history of epilepsy and febrile convulsions, suggests a genetic or congenital predisposition to epilepsy. Consequently, familial or congenital disturbances could be a necessary precursor that permits early noxious insult to give rise to the characteristic cell loss and neuronal reorganization necessary for the development of MTLE.

Clinical Presentation

The current characteristic clinical features of MTLE-HS are derived almost exclusively from patients with medically intractable seizures who are being evaluated for surgical intervention. Onset of habitual seizures typically begins toward the end of the first decade of life, and seizures often initially respond well to antiepileptic drug treatment. Characteristically, patients do well for several years, but seizures then return in adolescence or even early adulthood and become refractory to medical treatment. Of these patients with medically intractable seizures, the great majority have a history of complicated febrile convulsions or other initial precipitating injury.[47,83]

Evidence for Progression

Debate exists concerning the possibly progressive nature of MTLE-HS despite the fact that some animal models, such as kindling, clearly progress.[124] Based on the known pathophysiology, there is evidence that cell death and neuronal reorganization continue with recurrent seizures.[82] The latent period between occurrence of a precipitating event and onset of habitual seizures, and the period of control between initiation of medical therapy and development of medical intractability, also suggest an ongoing process.[47] The fact that some patients with MTLE-HS have persistent auras following extensive mesial temporal lobe resection that is successful in eliminating disabling complex partial seizures indicates that more than the sclerotic hippocampus is epileptogenic. Evidence that the degree of hippocampal atrophy on MRI[15] and persistence of auras and occasional seizures[38] correlate with duration of MTLE-HS further supports the existence of a progressive process. Progressive worsening of cognitive dysfunction in MTLE-HS, particularly involving memory and learning, has been disputed.[113] However, some degree of cognitive disability can be reversed by successful surgical intervention, indicating that it is related to recurrent seizures.[19,91,98,101,112,120] Although the subject is controversial, much has also been written about the possibility that patients with temporal lobe epilepsy are at greater risk for personality disturbances, depression, and psychosis, and numerous possible neurobiologic mechanisms have been put forth to justify a concept of epilepsy-induced enduring dysfunctions. It is conceivable that progressive changes peculiar to HS could make the appearance and exacerbation of nonepileptic psychologic and psychiatric disturbances reportedly seen in temporal lobe epilepsy a more specific feature of MTLE-HS in particular.

Clinical Seizure Characteristics

Mesial temporal lobe seizures (MTLS) occurring with MTLE-HS are generally thought to be indistinguishable from MTLS resulting from other forms of MTLE and therefore do not characterize the syndrome per se but are an important part of the symptom complex. Recent evidence refutes this concept in part, as there may be some differences between the seizures of MTLE-HS and other varieties of MTLE.[111] For example, ipsilateral limb automatisms, contralateral dystonic posturing, and oral-alimentary automatisms may be characteristic of MTLE-HS but not of MTLE resulting from neoplasms. More work is clearly needed to define this issue better.

The following descriptions of MTLS are based heavily on several reports from a relatively “pure culture” of patients with MTLE-HS,[47,135,138] as well as on recent studies describing various lateralizing or localizing features of these seizures.[1,41,72,73,74,88,93,99,140,142]

Ictal clinical characteristics can be divided into subjective and objective components. The subjective component in MTLS is the warning or aura. Auras in MTLS are very common, occurring in more than 90% of patients.[47,69] They can occur as the first manifestation of a complex partial seizure, and they often occur in isolation as simple partial seizures.[118,119] Auras in isolation may be a defining feature of MTLE, but not necessarily of MTLE-HS. By far the most common type of aura is a visceral sensation, usually in the epigastrium and often with a rising component.[27,47,81,95,129,132] Fear as an aura is a distant second. Other frequently described auras, such as déjà vu, jamais vu, micropsia, macropsia, olfactory hallucinations, and feelings of depersonalization, do occur, but they are uncommon.[47] Some aura symptoms may not have a counterpart in human experience and cannot be described. Patients who cannot describe their seizures verbally can sometimes do so in writing. Formed visual hallucinations and auditory hallucinations of any kind are not part of these seizures. Some patients have experienced auras in the past but no longer have them. This could be a consequence of seizure-related retrograde amnesia.[30] For example, during intensive monitoring, an occasional patient will consistently press the alarm button at the beginning of a seizure, yet deny any warning afterward.

The objective manifestations of MTLS, described by observers or recorded on videotape, usually occur when consciousness is impaired, so the patient is seldom aware of them. The objective manifestations of MTLS often begin with motor arrest, staring, and pupillary dilation. The seizure may not progress beyond this point (temporal lobe absence), but more often semipurposeful coordinated motor activities (automatisms) are a prominent part of MTLS. Oral-alimentary automatisms, although not seen exclusively in MTLS, are highly characteristic. They consist of lip smacking, chewing, licking, and tooth-grinding movements. Lip smacking can be so pronounced as to be audible on videotaped seizures, as can tooth grinding. Stereotyped automatisms that consist of fumbling, picking, and gesticulating movements are another common feature of MTLS. Automatisms suggesting reactions to environmental objects or situations are also common. Other, less common, automatic activity includes vocalization,[142] spitting,[56,68] and bicycling movements[122]; these, however, are also seen in seizures originating elsewhere. Ictal piloerection has also been reported in patients with MTLS.[26,107]

Emphasis has recently been placed on objective seizure characteristics that may have lateralizing or localizing value. These include lateralized motor manifestations, language signs, and postictal findings.

Head and eye deviation have long been recognized as clinical seizure manifestations,[2,55,97,125] but their lateralizing significance, particularly in MTLS, has been disputed.[92,100,106,140] Many reports suggest that head deviation, eye deviation, or both, occurring in temporal lobe seizures have lateralizing value, but this depends on when during the seizure such deviation takes place.[41,67,73,140] Early, relatively casual head deviation can be ipsilateral to seizure origin, whereas forced head

P.2482

and eye deviation occurring later in the seizure, often as a prelude to a secondarily generalized convulsive seizure, is almost always contralateral.

Unilateral tonic or dystonic posturing occurs in 15% to 70% of patients with MTLS and is reliably contralateral to the side of onset.[41,73,88] Studies using ictal single-photon emission computed tomography (SPECT) have equated this dystonic posturing with increased activity in the basal ganglia ipsilateral to seizure onset.[88] Although unilateral dystonic posturing has been considered a relatively new lateralizing sign, it was actually described 50 years ago.[2,81] Ajmone-Marsan and Ralston[2] provided illustrations of dystonic posturing (and ipsilateral/contralateral head turning) on pages 86 and 95 of their classic monograph, *The Epileptic Seizure*. This posture, termed *larval M2e*, was seen primarily during temporal lobe seizures. Contralateral dystonic posturing can include the leg and even the face and is often associated with ipsilateral automatisms.[73] Ipsilateral automatisms occurring alone are not as consistently lateralizing as dystonic posturing.[73] Conversely, contralateral ictal paresis has recently been reported as a reliable lateralizing sign.[92]

Ictal vomiting in MLTS has been related to right temporal lobe onset.[72,74,87] Unilateral eye blinking reportedly occurs on the same side as seizure origin.[7]

Language disturbance during seizures has been critically examined infrequently. Both ictal aphasia and ictal speech arrest have been equated with seizure onset in the language-dominant temporal lobe.[1,42] Ictal vocalization has been reported to have no lateralizing value,[142] whereas verbalization of coherent speech is associated with seizure onset in the temporal lobe that is not speech dominant.[142] Although uncommon, ictal automatisms with preserved consciousness occur with seizure origin in the nondominant hemisphere.[3,96]

Postictal aphasia as a lateralizing sign in MTLS has been controversial. Two early studies examining clinical features of temporal lobe seizures provided contradictory results: One reported that postictal language disturbances had no localizing value,[128] whereas the other noted highly accurate lateralization of seizure origin to the language-dominant side.[69] The controversy in part must be related to methodology. Postictal language disturbance is often difficult to separate from confusion, and it will be missed completely unless specifically tested for by trained examiners. More recent reports that specifically evaluated postictal language function following temporal lobe seizures confirm that postictal aphasia reliably lateralized seizure origin to the language-dominant side.[42,99] Although seldom evaluated, lateralized postictal motor deficits can occur in patients with MTLS. When detected, they are contralateral to seizure origin and usually follow seizures associated with prominent unilateral dystonic posturing. Patients occasionally wipe their nose at the end of an MTLS, and when they do, they almost always use the hand ipsilateral to ictal onset.[51,78]

Since MTLS with HS usually present with typical seizures, series with this condition in young children do not exist. Two recent reports examined temporal lobe seizures in children, some with documented HS.[103,126] In general, children under the age of 3 have tonic motor and clonic motor activity, while children over 10 years have the same clinical characteristics as adults. In between these years, seizures tend to be relatively simple (hypokinetic seizures) with progressive elaboration of automatisms as they grow older. This pattern was seen in children with HS.[103]

Mesial temporal lobe seizures are typically followed by postictal dysfunction of variable duration, as opposed to some extratemporal seizures with a minimal postictal phase or none.[59,136,137,139] The postictal state is usually obvious at the end of the seizure, often accompanied by visible relaxation; automated semipurposeful motor movements can persist. The postictal state is further characterized by confusion, disorientation, and, as noted above, disturbances of language. Reports have suggested that the duration of the postictal period that follows MTLS beginning in the language-dominant side is much longer than that following seizures originating in the nondominant side.[42,99] This is unquestionably related to gradual clearing of postictal language disturbance.

All these potentially lateralizing signs are helpful during the presurgical evaluation of patients with medically intractable MTLSs. Whether or not these signs also occur in other types of temporal lobe seizures, or in seizures originating outside the temporal lobes, and with what frequency, is not clear, but recent evidence suggests that they occur less often.[46,53,111] Further verification is needed.

Diagnostic Evaluation

Results of the neurologic examination are usually normal, with the exception of mild to moderate memory deficit that is generally material specific for the involved hemisphere. Formal neuropsychological testing is useful for demonstrating typical memory and learning disturbances.[139] When surgical treatment is being considered, the neuropsychological evaluation often includes an intracarotid amobarbital procedure to demonstrate that the temporal lobe contralateral to the planned resection is capable of supporting memory.[102] Dysfunction of the ipsilateral mesial temporal structures can be confirmed when injection of amobarbital into the contralateral carotid artery results in a global memory deficit.

Results of routine EEGs in patients with MTLE-HS can be normal or nonspecific, but only rarely will no epileptiform abnormalities be revealed during prolonged monitoring.[138] The characteristic interictal EEG abnormality is anterior temporal sharp waves, spikes, and slow waves. These can be bilaterally independent in up to one third of patients.[33,133,138] The discharges demonstrate a characteristic field with a maximum in basal derivations, such as sphenoidal, true temporal, or earlobe electrodes. Although bilateral synchronous interictal spikes and sharp waves are usually not a part of the MTLE-HS syndrome, occasionally bilateral frontal polar spikes are seen, but they are not considered clinically significant.[108] Ictal EEG onset usually consists of a characteristic unilateral 5- to 7-Hz rhythmic discharge, seen best in one basal electrode derivation and appearing within 30 seconds of the first ictal EEG abnormality.[105] Occasionally the scalp ictal pattern can be seen over the temporal lobe contralateral to obvious HS.[86] In this case, intracranial studies reveal seizure origin in the abnormal hippocampus ("burned-out hippocampus") without spread to the ipsilateral temporal neocortex but with contralateral spread. Specific ictal patterns can help differentiate mesial from lateral temporal lobe epilepsies.[29] Auras are usually not associated with any EEG changes, although frequent interictal spikes may be seen to disappear during the simple partial seizure. Stereotactic depth-electrode studies demonstrate that simple partial seizures usually are associated with hypersynchronous hippocampal discharges, with a transition to a low-voltage fast recruiting rhythm just before contralateral propagation and onset of the clinical complex partial ictal event.[32] Depth-electrode recordings reveal that hypersynchronous hippocampal ictal discharges can also occur without noticeable signs or symptoms.[119]

High-resolution MRI can demonstrate hippocampal atrophy in a high percentage of patients with medically refractory MTLE.[9,75,138] Volumetry is used by some investigators to demonstrate asymmetry,[13] although controversy exists as to the need for this quantitative technique. As technology for structural imaging improves, it may also be possible to diagnose hippocampal sclerosis by loss of the normal architectural pattern. T2-weighted images often show increased signal in the

area of hippocampal sclerosis, and this is also a useful finding for confirmation of a diagnosis of MTLE-HS.[9,75]

Positron emission tomography with ^{18}F-fluorodeoxyglucose (FDG-PET) remains the most sensitive interictal imaging technique for identifying the focal functional deficit associated with hippocampal sclerosis.[39,70] The area of hypometabolism can be quite large, involving more than the epileptogenic temporal lobe and including the ipsilateral thalamus, basal ganglia, and other cortical structures.[57] It is not clear at this time, however, whether such patterns might help to distinguish MTLE-HS from MTLE due to other lesions. Other PET tracers demonstrate zones of decreased cerebral perfusion approximating the area of hypometabolism,[141] increased binding of μ-opioid receptors[48] in lateral cortex of the involved temporal lobe, and decreased benzodiazepine receptor binding[117] of the sclerotic hippocampus. Bilateral reduced benzodiazepine binding suggests subtle damage in up to one third of contralateral hippocampi in patients with unilateral HS on MRI.[71] Bilateral limbic system dysfunction was also suggested in patients with unilateral HS by investigating MRI diffusion properties.[23] Interictal SPECT is also capable of showing unilateral temporal hypoperfusion in MTLE-HS, but with a much lower yield than PET. Ictal SPECT, however, demonstrates a characteristic pattern of hyperperfusion of the involved temporal lobe when the tracer is injected during a seizure, and of lateral hypoperfusion with persistent mesial hyperperfusion when it is injected shortly after a seizure, during the early postictal phase.[89,90] Again, it remains to be demonstrated whether this pattern has any specificity for MTLE-HS.

Magnetic resonance spectroscopy has demonstrated that HS is associated with a decrease in *N*-acetylaspartate.[77] Magnetic source imaging (MSI) with magnetoencephalography (MEG) can localize interictal and ictal epileptiform discharges to mesial temporal structures in patients with MTLE.[28]

Differential Diagnosis

Both MTLE and benign childhood epilepsy with centrotemporal spikes (BCECTS) can first appear in childhood as a single generalized convulsion and interictal temporal EEG epileptiform discharges. The broad centrotemporal spikes of BCECTS with a characteristic transverse dipole are located more posteriorly and superiorly, and morphologically they are easily distinguished from the characteristic, sharper anterior spike and spike-and-wave discharges of MTLE. The partial seizures of the benign childhood syndrome typically begin with sensory or motor phenomena around the mouth or upper extremity, and they are not likely to be confused with the complex partial seizures of mesial temporal origin.

The features of MTLE-HS most likely to distinguish this syndrome from MTLE caused by other lesions in mesial temporal structures include the earlier age of onset, history of complicated febrile convulsions and other early insults, increased incidence of seizures among family members, material-specific memory deficit, characteristic sphenoidal ictal onset pattern, and hippocampal atrophy on MRI. The same features help to distinguish patients with MTLE-HS from patients with complex partial seizures caused by lateral temporal or extratemporal lesions. In addition, the latter may have auras that indicate a site of origin closer to primary sensory or motor cortical areas.

Treatment and Outcome

The medical treatment of choice for MTLE-HS includes carbamazepine, oxcarbazepine, lamotrigine, topiramate, and levetiracetam. Seizures usually respond well for several years.[8] However, because a diagnosis of MTLE-HS is rarely made until the condition becomes medically refractory and the patient is referred for surgical treatment, there is no definitive information concerning the percentage of patients who remain adequately controlled with pharmacotherapy.

Once seizures return (usually in adolescence or early adulthood), high-dose monotherapy or combinations of drugs often result in intolerable side effects and fail to control disabling seizures.

Surgical treatment, on the other hand, is now reported to abolish all disabling complex partial seizures in 60% to 80% of patients with MTLE.[40,130] A report that patients with MTLE-HS are more likely to experience late postoperative seizure recurrence than patients with other forms of MTLE has now been refuted.[84] The presurgical evaluation can usually be achieved noninvasively with video-EEG monitoring, MRI, neuropsychological evaluation, and often functional imaging with either PET or SPECT.[34] At most epilepsy centers, surgical resection is now limited to the involved mesial temporal structures, the temporal pole, and only a small amount of lateral neocortex, resulting in no significant additional neurologic deficit. When material-specific memory is already impaired, this does not change postoperatively, but contralateral material-specific memory may improve and IQ may increase.[101] If material-specific memory is intact, however, anteromesial temporal resection will result in a postoperative deficit, particularly when performed on the language-dominant side. This can cause additional disability for highly functional patients who depend on verbal memory.[18,58,76,80,109]

The reason for the 20% to 30% surgical failure rate in MTLE-HS has not been extensively studied. Insular lobe seizure origin has been documented in a few cases,[62] whereas the importance of the temporal polar cortex has been emphasized by others.[17]

Long-term Prognosis

Patients in whom medically refractory MTLE-HS develops have a relatively poor prognosis with medical treatment. Seizures often become worse and interictal behavioral disturbances can ensue. MTLE-HS is, however, the prototype of a surgically remediable syndrome, as presurgical evaluation can now usually be accomplished noninvasively and a high percentage of patients become free of disabling seizures postoperatively.[34,127] Early surgical intervention, as soon as possible following demonstration of failure of two appropriate drugs at maximum tolerable doses, yields the best psychosocial outcome if patients are relieved of disabling seizures before these events interfere with critical social and vocational development during adolescence and early adulthood. If seizures continue through this period, irreversible psychosocial disturbances often result, so that seizures may be abolished by surgical treatment later in life but complete or even partial rehabilitation cannot be achieved, and the patient remains dependent.[104,120]

Summary and Conclusions

MTLE-HS is now generally recognized as a distinct syndrome, representing a subtype of MTLE caused by a variety of lesions. The incidence and prevalence of MTLE-HS are unknown, as patients with medically refractory seizures are preferentially identified; however, this is likely to be the most common single form of human epilepsy. Although HS is believed to be the epileptogenic lesion, its etiology is unknown. There is a strong association with an early precipitating insult, particularly complicated febrile convulsions, and a genetic predisposition. The

pathophysiology of MTLE-HS is now relatively well understood, and there is evidence that the disturbance can be progressive. The syndrome can be easily recognized in most patients by the characteristic presentation, seizure type, and diagnostic findings, which include increased incidence of febrile convulsions and family history of epilepsy, onset toward the end of the first decade of life, typical simple and complex partial limbic seizures, material-specific memory deficit, anterior temporal interictal EEG spikes and a characteristic ictal EEG onset pattern, temporal hypometabolism on FDG-PET, and hippocampal atrophy on high-resolution MRI. Once seizures become refractory to two appropriate antiepileptic drugs, further pharmacotherapy is not likely to be of benefit; disabling, irreversible psychosocial disturbances can result if aggressive treatment is not instituted. Surgical treatment, however, can abolish disabling seizures in 60% to 80% of patients with MTLE-HS, making this a surgically remediable syndrome. Early surgical intervention, therefore, offers the greatest potential for restoring a patient to a normal life.

Chapter 248
Familial Temporal Lobe Epilepsies

Fernando Cendes

Eliane Kobayashi

Iscia Lopes-Cendes

Frédérick Andermann

Eva Andermann

Introduction

A positive family history of seizures and/or epilepsy is frequently observed among patients with temporal lobe epilepsy (TLE).[67] These families cannot be included in only one group, however, and detailed characterization of affected family members is crucial for defining the familial epilepsy syndrome. Patients with TLE can be identified in the context of familial mesial temporal lobe epilepsy (MTLE),[9,16,19,37,43] familial TLE with auditory features,[34,49,50] familial partial epilepsy with variable foci (FPEVF),[56,69] and generalized epilepsy with febrile seizures plus syndrome (GEFS+),[23,45,55,58,66]

There are two groups of familial TLE, according to the evidence for involvement of mesial or neocortical structures. The majority of affected individuals with *familial MTLE* have a benign clinical course, and in some families all affected members have good seizure control, much like those originally described by Berkovic et al.[9,11] However, as in patients with nonfamilial MTLE, some affected family members may have poor seizure control and require surgical treatment.[19,40] Although hippocampal atrophy (HA) and other signs of hippocampal sclerosis (HS) were more frequent and more severe in those patients with refractory seizures, these changes were also observed in patients with good outcome[41,43] and even in asymptomatic family members (Fig. 1).[42] These are strong indicators that genetic factors play a role in the genesis of hippocampal pathology in patients with *familial MTLE*. The genetic background in familial MTLE, however, does not suggest a more widespread structural abnormality on magnetic resonance imaging (MRI).[25]

Familial TLE with auditory features, also described as *autosomal-dominant partial epilepsy with auditory features* (ADPEAF), and *familial lateral temporal lobe epilepsy* (FLTLE)[38] was first reported by Ottman et al.,[49] and additional families have been described by the same group and by other authors.[34,48,50,52,68] Seizure semiology pointed to an extrahippocampal epileptogenic area in the temporal lobes, and, characteristically, most patients had auditory auras. Patients have good seizure control, and epileptiform discharges may be observed over posterior temporal regions. No clear signs of HA have been described in different series, but abnormalities in the neocortical aspects of the temporal lobes may be present (Figs. 2 and 3).[44] Molecular studies identified linkage to chromosome 10q (ch10q),[49,52,68] and mutations in the *leucine-rich, glioma-inactivated 1* gene (*LGI-1*) have been identified.[34,48,50]

There is no evidence to suggest that partial epilepsy with auditory features, familial partial epilepsy with variable foci, or temporal lobe variants of benign childhood epilepsy with centrotemporal spikes ever evolve into MTLE with HS; this is further evidence for a clear distinction between familial MTLE and these other familial epilepsy syndromes.

Historical Perspective

Genetic factors in epilepsy have long been recognized. Until very recently, however, only generalized epilepsies were thought to be genetic in origin, whereas focal or partial epilepsies were largely attributed to environmental factors, such as birth injuries, infections, postnatal head trauma, and brain lesions such as tumors or vascular insults.

As in the generalized epilepsies, partial epilepsies were found to fit a model of multifactorial inheritance (now termed complex inheritance), in which there is an interaction of one or more genes and environmental factors.[2,3,6]

In the last decade, several autosomal-dominant forms of partial epilepsy were described (reviewed by Berkovic and Steinlein[13] and more recently by Andermann et al[6a]). These include autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE), familial MTLE, ADPEAF, FPEVF, and autosomal-dominant rolandic epilepsy with speech dyspraxia.

The first description of familial occurrence of TLE was in 1994 by Berkovic et al.; they described it as a benign syndrome with late seizure onset without a history of prolonged febrile seizures (FS) or MRI evidence for mesial temporal sclerosis (MTS). However, in subsequent FTLE series, patients had a less benign clinical course, and a high proportion of individuals with HA were described. Some of these patients required surgical treatment for their epilepsy.[19,40,43] These families showed phenotypic heterogeneity in different family members, as well as between families, with respect to a history of prolonged FS, severity of the epilepsy, and presence of HA. The original series of Berkovic et al.[9,11] was population based, arising from a twin study, whereas the later series were hospital based.

Recently, FTLE was included in the new proposal for classification of epileptic syndromes by the International League Against Epilepsy (ILAE), supporting it as a well-defined syndrome.[22]

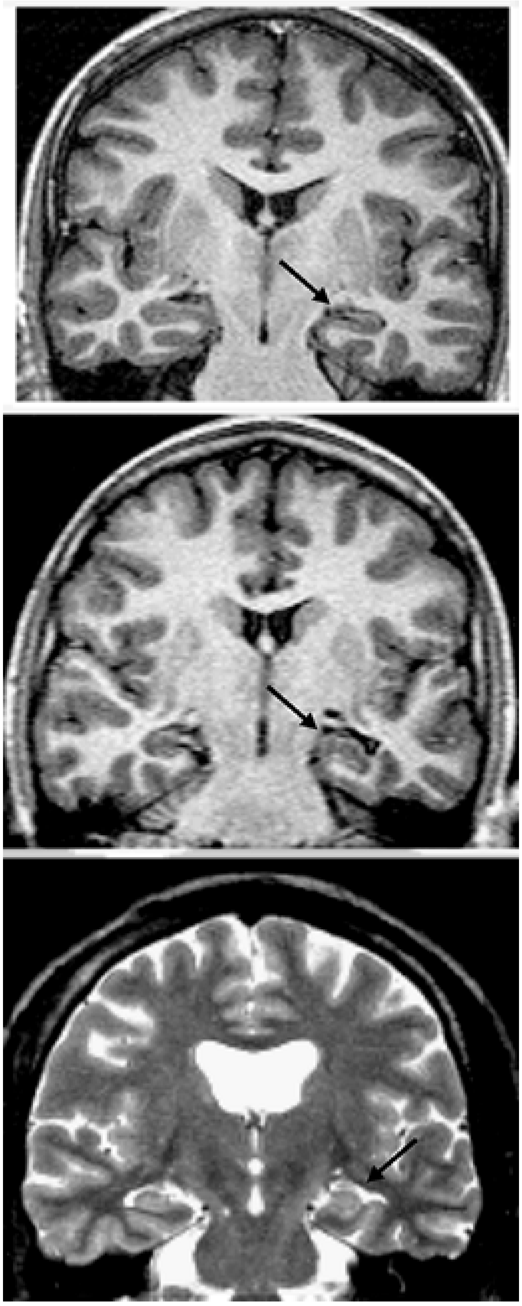

FIGURE 1. Hippocampal abnormalities in three asymptomatic individuals from families with mesial temporal lobe epilepsy. **Top**: Coronal T1-IR image of a 14-year-old boy, showing flattened and atrophic left hippocampus (*arrow*). **Middle**: Coronal T1-IR image from a 15-year-old boy. The left hippocampus is atrophic and bent clockwise and has an abnormal, "irregular" shape (*arrow*). **Bottom**: Coronal T2-FSE image from a 26-year-old man. The left atrophic hippocampus has an abnormal, "rounded" shape (*arrow*). In addition, the fusiform gyrus and collateral sulcus on the left have an abnormal shape. Note also the absence of septum pellucidum. (Reproduced, with permission, from Kobayashi E, Li LM, Lopes-Cendes I, et al. Magnetic resonance imaging evidence of hippocampal sclerosis in asymptomatic first-degree relatives of patients with familial mesial temporal lobe epilepsy. *Arch Neurol*. 2002;59(12):1891–1894.)

With the description of the neocortical form of familial TLE or ADPEAF[49] associated with mutations in the *LGI-1* gene on chromosome 10q,[34,48] the distinction between mesial and lateral forms became more obvious.[7,10,37,38,43,63]

It is important to emphasize that it is impossible to distinguish familial from nonfamilial TLE patients based solely on the clinical presentation, in both mesial and lateral forms. Because the family history is not always accurately documented, many so-called “sporadic” or “isolated” patients may actually have a familial epilepsy syndrome.

Definitions

Familial Mesial Temporal Lobe Epilepsy

The best definition of familial MTLE is based on the familial recurrence of MTLE, according to the ILAE clinical-electroencephalogram (EEG) criteria,[53] in the absence of any suggestion of other partial (including lateral TLE symptoms) or generalized epilepsy syndromes in other affected family members. Thus, the finding of at least two MTLE patients in one family is suggestive of familial MTLE. The observation of an autosomal-dominant inheritance pattern with incomplete penetrance implies the presence of asymptomatic carriers of the genetic abnormalities who can transmit the disease to their offspring. Therefore, we should consider inclusion not only of families with affected first-degree relatives, but also those with affected second- and third-degree relatives. This criterion has not been employed in some reported series, leading to exclusion of many possible familial MTLE kindreds.[51]

Familial Temporal Lobe Epilepsy with Auditory Features

Familial TLE with auditory features is a benign epilepsy syndrome, characterized by auditory auras (buzzing, roaring, radio- or motor-like sounds, distortions in sounds and words). Although other manifestations such as psychic, cephalic, and other sensory and motor phenomena can occur, the auditory auras are a landmark for this syndrome. Sometimes ictal aphasia and visual misperceptions can occur and, in some families, secondarily generalized tonic–clonic seizures (GTCS) are frequent.[16,29,47,52,68] The pattern of inheritance observed is autosomal dominant with incomplete penetrance.

Age of onset is variable, usually in the second or third decade of life, and seizures are easily controlled by antiepileptic drugs (AEDs). EEGs may show posterior temporal epileptiform discharges but are frequently normal. No signs of HA are found on MRI studies, but a lateral temporal malformation pattern has been observed in 45% of affected individuals, including one asymptomatic carrier of the mutation.[44] The left temporal lobes of these individuals seemed enlarged, and sometimes there was protrusion of the brain parenchyma laterally, with an “encephalocele-like” appearance. Anterior temporal lobe volumetry showed a significant global increase in volumes in only two individuals. The epileptogenic significance of these structural abnormalities is unknown.

Epidemiology

The prevalence and incidence of these two forms of familial TLE are unknown. However, familial MTLE is apparently more common than familial TLE with auditory features. There is no predominance in any particular ethnic group. Families with MTLE have been described in Australia, Canada, Brazil, Italy, Belgium, and France. FLTLE has been studied in the United States, Brazil, Japan, Germany, France, Italy, Spain, and Australia. This is probably an underestimate of the real prevalence of both forms of familial TLE worldwide, especially in families with predominantly good outcomes.

Ascertainment of these families requires detailed questioning of patients and family members. This has only been emphasized recently because, in the past, MTLE as well as other partial epilepsies were considered to be symptomatic and due largely to environmental factors. A preliminary hospital-based study found that familial MTLE represented 7% of all MTLE patients.[43]

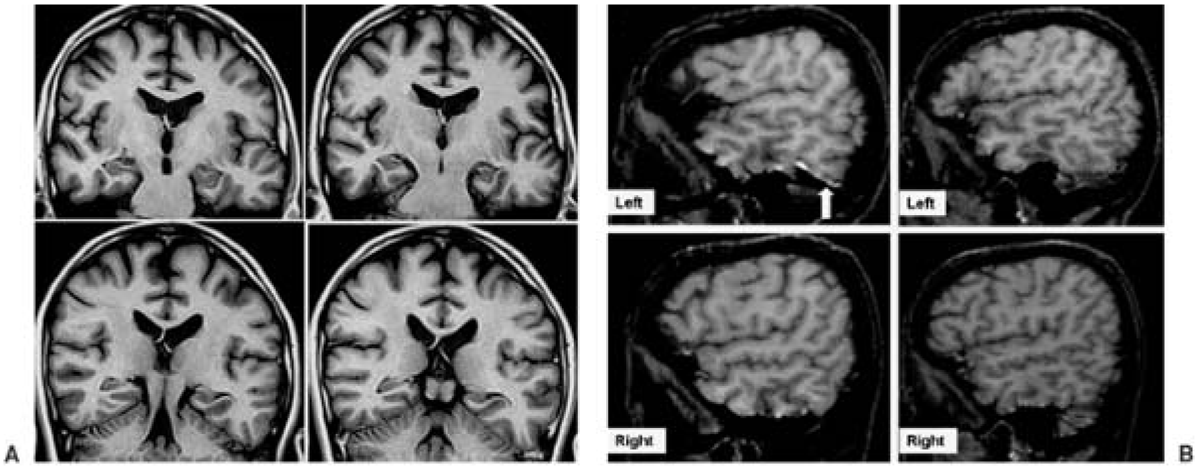

FIGURE 2. A: T1-IR coronal images from a patient with *LGI-1* mutation showing left temporal lobe dysgenesis, characterized by enlargement of the lateral temporal lobe, with small gyri (although not characterizing polymicrogyria). **B:** T1 sagittal images from the same patient showing absence of first and second temporal sulcus on the anterior and middle portions of the left temporal lobe. The posterior basolateral aspect of the left temporal lobe is also abnormal, with a protrusion of parenchyma downward, with an "encephalocele-like" appearance (*arrow*). Etiology and Basic Mechanisms

The etiology of familial epilepsies is first determined by the genetic pattern that indicates an inherited disease and second

by the structural/functional abnormalities that are associated with this genetic background.

Pathogenetic mechanisms underlying familial MTLE remain unknown. Seizures and HS in familial MTLE may result from interactions between genetic and environmental factors. No locus for familial MTLE with HS has been identified.

No single-gene molecular defect has been confirmed, although several loci for familial TLE have been mapped. Digenic inheritance with loci on chromosomes 1q25–q31 and 18qter was described in a large family with febrile seizures and familial TLE without HS,[8] as well as a locus on chromosome 12q22–q23.3 in another large family with autosomal-dominant familial TLE with febrile seizures without HS.[21] Whether these loci represent susceptibility for febrile seizures or for TLE remains to be determined. A more recent locus was described on chromosome 4q in a four-generation kindred with familial MTLE.[31] MRI data, however, did not show signs of HS in this family.[31] Investigation of these loci in other families has not been reported.

No families with familial MTLE were found to have an *LGI-1* mutation, even in those families in which one or more family members had auditory features alone or in association with mesial symptoms.[7,10,54] This further supports the determination that familial MTLE and familial TLE with auditory features constitute distinct genetic syndromes.

Some polymorphisms have been found in association with MTLE,[62] but these could not be replicated in a recent large cohort of patients.[18] Kanemoto et al.[35] found an increased frequency of the T allele at the 511 position of the interleukin 1ß gene among TLE patients with HS as compared with TLE patients without HS and with controls. The frequency of this polymorphism was further increased in patients with a history of prolonged FS. Stogmann et al.[59] found an overrepresentation of a functional polymorphism in the prodynorphin gene promoter (possibly related to seizure suppression) in patients with TLE and a positive family history of epilepsy as compared to controls. Gambardella et al.[27] recently demonstrated an overrepresentation of a $GABA_B$ receptor 1 polymorphism (G1465A) in patients with MTLE as compared to the normal population, especially in those with refractory seizures. However, more recent studies failed to replicate these findings.[46,61] The presence of all these polymorphisms would suggest a polygenic or multifactorial mode of inheritance, as first suggested by Andermann.[2,3,4]

The presence of clear-cut HA in both affected and asymptomatic family members in familial MTLE suggests that the

hippocampal abnormalities themselves could be inherited, and not necessarily lead to epilepsy.[42] The phenotype would then depend on interaction with other modifying factors. Two papers addressed the possibility of inherited hippocampal abnormality. Fernandez et al.[24] studied families of patients with a previous history of FS, including asymptomatic individuals. They observed subtle abnormalities in hippocampal configuration, internal structure, and volume in individuals with and without FS. This suggested the presence of preexisting hippocampal malformations as an associated factor leading to FS and subsequent HS. A study of children with prolonged FS and their monozygotic asymptomatic twins did not confirm these findings.[33] Volumetric studies of the temporal lobes showed similar patterns of atrophy in familial and nonfamilial MTLE patients.[25]

Qualitative pathology from surgical specimens obtained from operated familial MTLE patients showed the typical pattern of MTS: Selective neuronal loss in CA1, CA3, and CA4 with relative preservation of CA2, and variable involvement of the amygdala and parahippocampal region.[40] The observation of MTS in operated familial MTLE patients who became seizure free suggests that MTS represents the epileptogenic substrate, at least in some of these families; analogous to what is observed in nonfamilial or “sporadic” cases.

Most likely, Familial MTLE will be found to have a major gene leading to hippocampal abnormalities, and the phenotype could be influenced by additional genetic and environmental modifying factors.

The mechanism by which LGI-1 causes familial TLE with auditory auras is unknown. LGI-1 is not homologous to any known ion channel, and it is likely to be involved in brain development.[34,50] The *LGI-1* gene was cloned from a glioblastoma cell line and, although previous studies have suggested that *LGI-1* represents a tumor suppressor gene,[20] a more recent study was unable to establish a correlation between the gene and malignant glioma suppression.[28] *LGI-1* codes for a putative membrane-anchored protein of unknown function. The LGI-1 protein is characterized by a central leucine-rich repeat region,[32] which is involved in regulation of cell growth, adhesion, and migration. More recent studies have shown that *LGI-1* mutations in patients with familial TLE with auditory features are associated with loss of function, with the LGI-1 protein either not secreted or unstable.[57] The association of lateral temporal malformation patterns in some families may indicate a probable role of LGI-1 in the development of the temporal lobes.[44]

The *LGI-1* gene is mutated in approximately 50% of families with familial TLE with auditory features.[10,50] Although *LGI-1* mutations appear to be specific for familial TLE with auditory features, the identification of *LGI-1* mutations in only one half of families presenting the typical phenotype[10,50] suggests genetic heterogeneity. No mutations in *LGI-2*, *LGI-3*, and *LGI-4* have been identified in 71 families with various types of TLE, including 4 who had familial TLE with auditory features.[10]

Clinical Presentation

Familial Mesial Temporal Lobe Epilepsy

Familial MTLE is a well-characterized syndrome, with different degrees of seizure severity, although the majority of patients have good seizure control.[9,11,19,43] The mode of inheritance is autosomal dominant with incomplete penetrance. Patients with familial MTLE present with simple partial or complex partial seizures (CPS) or both, with characteristics of mesial temporal lobe origin (such as rising epigastric sensation, fear, *déjà vu*, *jamais vu*) that are indistinguishable from the sporadic form of MTLE.[1] Auras of *déjà-vu* and *jamais-vu* are particularly frequent, especially in families with benign outcome, and may be the only feature in some family members.[5] Memory impairment is often associated, even in asymptomatic family members with HA.[1] Secondary GTCSs are uncommon in patients with familial MTLE taking AEDs. Age at onset and the presence of a silent period follow initial febrile seizures are also similar to sporadic MTLE. However, an antecedent of febrile seizures in childhood is less frequent in patients with familial MTLE as compared to sporadic MTLE.[40,41,43]

Familial Temporal Lobe Epilepsy With Auditory Features

Seizure semiology in familial TLE with auditory features is characterized by auditory auras preceding complex partial and secondarily generalized seizures in many, but not all, patients.[50] Visual auras may occur,[52] and ictal aphasia has also been described.[16,29]

The most common initial ictal manifestations are described as buzzing, roaring, radio- or motor-like sounds, and distortions in sounds and words. Sometimes ictal aphasia and visual misperceptions can occur, and, in some families, secondarily generalized seizures are frequent.

The pattern of inheritance is autosomal dominant with incomplete penetrance. Age of onset is variable, usually in the second or third decades of life, and seizures are easily controlled with AEDs.

Diagnostic Evaluation

Electroencephalographic Findings

EEGs in patients with familial MTLE show interictal epileptiform discharges over mid- and inferomesial temporal regions with similar characteristics to those of sporadic MTLE. Ictal EEG recordings in familial MTLE patients undergoing presurgical evaluation also show the same pattern observed in sporadic MTLE. A normal EEG, however, does not exclude the diagnosis of familial MTLE.

EEGs in familial TLE with auditory features may show posterior temporal epileptiform discharges but are frequently normal.

Neuroimaging and Other Laboratory Examinations

Familial Mesial Temporal Lobe Epilepsy

MRI evaluation in familial MTLE has shown a high frequency of HA and other signs of HS,[19,41,43] even in individuals with seizure remission and asymptomatic family members (Fig. 1).[42,43] The identification of MRI signs of HS in familial MTLE patients with a benign clinical course confirms that the presence of HA is not always associated with refractory epilepsy.

Data indicate that MRI abnormalities are similar in familial and sporadic MTLE with HS.[25]

Familial Temporal Lobe Epilepsy With Auditory Features

There have been no signs of HS in MRIs of patients from the reported families with *LGI-1* mutation.[10,44,50] Enlargement and abnormal gyration suggesting developmental abnormalities in

P.2491

the lateral cortex of the temporal lobes was described in 53% of affected individuals in one family with *LGI-1* mutation[44] (Figs. 2 and 3), a finding that requires confirmation. However, the MRI findings in that family are clearly distinct from the MRI findings in familial MTLE and are consistent with the distinct seizure semiology in these two forms of familial TLE.[44]

Differential Diagnosis

A family history of seizures is common among TLE patients. Many of them have one or more relatives who have experienced a single episode compatible with either CPS or GTCS, and a history of FS is also frequently found. Unless there are two individuals in the family with well-defined MTLE, however, a diagnosis of familial MTLE cannot be made.

In addition, there are other familial epilepsy syndromes in which patients with MTLE are found. In FPEVF,[12,17,56,69] most reported families mapped to chromosome 22q, but the gene has not yet been identified. Affected family members may present with various forms of partial epilepsy, including frontal lobe epilepsy and MTLE.[39]

In GEFS+, related to mutations in genes *SCN1A*, *SCN2A*, *SCN1B*, and *GABRG2*,[23,30,45,60,64,65,66] patients may present heterogeneous epilepsy phenotypes. FS are the most common phenotype, followed by FS plus (FS+), in which individuals have seizures with fever that may persist beyond the age of 6 years and/or may be associated with afebrile GTCS.[55,58] Less frequent phenotypes seen in GEFS+ involve other generalized and partial seizure types, including MTLE.[55,58,65]

A new partial epilepsy syndrome with some individuals presenting seizure semiology consistent with MTLE has been described in one large Brazilian kindred and named partial epilepsy with pericentral spikes.[36] The majority of affected individuals, however, presented hemitonic or hemiclonic seizures, and molecular analysis showed linkage to chromosome 4p15.

It is essential to evaluate the phenotype of all possibly affected individuals before classifying the family as having a specific familial syndrome. In addition, because the severity of the phenotypes in family members may vary, we can never be absolutely sure that an “isolated” or “sporadic” MTLE patient does not have familial MTLE. Molecular studies can be helpful in excluding other familial epilepsies with already identified gene mutations.

The two main differential diagnoses for familial TLE with auditory features are sporadic neocortical TLE and familial MTLE, which can be clarified most of the time with a detailed history and seizure description.

Recently, the presence of patients with neocortical TLE but without a positive family history was highlighted by Bisulli et al.[14] The authors termed this syndrome idiopathic partial epilepsy with auditory features (IPEAF) and performed a clinical and genetic study in 53 sporadic cases. Mutations in *LGI-1* were excluded in all these IPEAF patients, although, except for the absence of family history, these patients had identical clinical manifestations to those seen in familial TLE with auditory features, including the always-good prognosis.[14] After the first description of their large series, the same authors reported a de novo mutation in the *LGI-1* gene in one patient with sporadic neocortical TLE,[15] but another, more recent series of similar patients found no *LGI-1* mutations.[26]

Since the severity of the phenotype in family members with familial TLE with auditory features may vary, and mild cases may not be known to other family members, we can never be absolutely sure that an "isolated" or "sporadic" neocortical TLE patient does not have familial TLE with auditory features. Molecular studies with testing for mutations of the *LGI-1* gene and of other genes associated with related familial epilepsies can be helpful.

In summary, in the differential diagnoses, a familial MTLE and familial LTLE, one may consider familial partial epilepsies with variable foci, temporal lobe variants of benign childhood epilepsy with centrotemporal spikes, and GEFS+.[58]

No family with familial MTLE has been found to have an *LGI-1* mutation, even in those families in which one or more family members had auditory features alone or in association with mesial symptoms.[7,10,54] This further supports the observation that familial TLE with auditory features and familial MTLE constitute separate genetic syndromes.

Patients with TLE are found in other familial epilepsy syndromes. In FPEVF, different family members may present with various forms of partial epilepsy, including TLE,[39] but the focus remains the same in each affected individual. Most reported families mapped to chromosome 22q, but the gene has not been identified.[12,17,56,69]

Treatment and Outcome

Treatment should be based on the patient's response to AEDs, and the rationale is similar to that in nonfamilial patients. Familial MTLE patients may have refractory seizures, and surgical treatment should be considered, based on clinical-EEG-MRI data, despite the context of a familial epilepsy syndrome.[19,40]

The majority of patients with familial MTLE have good seizure control, with low doses of AEDs indicated for partial epilepsies.[11,19,43] A large number of patients undergo seizure remission and maintain seizure freedom off medication. However, approximately 24% of our patients with familial MTLE were considered refractory to medical treatment.[19,37,43] Patients with refractory familial MTLE have excellent surgical outcome when unilateral or clearly asymmetric HA is identified on MRI.[40] The investigation of patients with familial MTLE should not differ from that of patients with sporadic MTLE, and the surgical decision should be based on the same clinical-EEG-imaging evidence for seizure lateralization and localization.

Seizures in patients with familial TLE with auditory features are easily controlled with small doses of AEDs indicated for partial epilepsies. Some of the affected family members with *LGI-1* mutation may present only a few seizures during their life time, with clear-cut precipitating factors, such as sleep deprivation or alcohol intake, and a decision to treat these patients with AED should be taken on an individual basis.

Long-Term Prognosis

Although the first description of familial MTLE defined it as a benign condition,[9,11] it is now well known that some patients may be refractory to medical treatment. In our series, 81% of familial MTLE patients achieved good seizure control on medication or remitted spontaneously. Refractory seizures were observed in 19%, and surgical treatment was considered in these cases.[40] When unilateral or clearly asymmetric bilateral EEG-MRI abnormalities were observed, familial MTLE patients had an overall likelihood of 85% of becoming seizure free following surgery.[40]

Whether the long-term prognosis for familial MTLE differs from that for sporadic MTLE is still to be determined. For those patients ascertained in epilepsy surgery programs, it appears that the long-term prognosis is similar in the familial and sporadic forms of MTLE. For the majority of patients with familial MTLE who have good seizure control on AEDs or seizure remission, it appears that the long-term prognosis is better than in the sporadic form of MTLE; however, this may represent an ascertainment bias.

Patients with familial MTLE with refractory seizures present a similar degree of memory impairment to patients with sporadic MTLE. In addition, we have shown that individuals with familial MTLE and hippocampal atrophy who have never had seizures also show significant memory-specific impairment on neuropsychological evaluation.[1] It remains to be determined whether this memory impairment in familial MTLE progresses independent of the seizures.

Familial TLE with auditory features has a benign clinical course, with no refractory patients reported.[16,47,49,52,68] Many patients may present only a few episodes and then have spontaneous remission. No neurologic disabilities are known in this syndrome. Long-term prognosis in familial TLE with auditory features is excellent, with most individuals being free of seizures with low doses of AEDs or off medication. There have been no patients with familial TLE with auditory features and *LGI-1* mutation described with refractory seizures requiring surgical treatment.

Summary and Conclusions

Two genetically distinct autosomal dominant familial TLE syndromes have been reported: (a) Familial MTLE and (b) Familial TLE with auditory features, ADPEAF, or familial LTLE.

Familial MTLE is a well-characterized syndrome, with different degrees of seizure severity, although the majority of patients have good seizure control. There is a high frequency of MRI signs of HS in affected individuals, including those with seizure remission or who have never developed seizures. The data suggest that the development of hippocampal abnormalities in these families may be related to genetic factors, although there is no gene mutation described so far. Whether familial MTLE without HS is part of the spectrum of the same condition or a distinct syndrome remains to be determined.

Familial TLE with auditory features, ADPEAF, or familial LTLE is characterized by auditory auras preceding complex partial and secondarily generalized seizures. The most common initial ictal manifestations are described as buzzing, roaring, radio- or motor-like sounds and distortions in sounds and words. The clinical course is usually favorable, with most patients being well controlled with AEDs. MRI investigations in this syndrome have not shown signs of HS. Half of the described families have mutations in the *LGI-1* gene, which is probably related to an abnormality in brain development.

It is essential to evaluate the phenotype of all possibly affected individuals before classifying the family as having a specific familial syndrome. To make a diagnosis of familial MTLE or familial TLE with auditory features, at least one family member should have the same clinical syndrome as the probant.

Chapter 249

Familial Frontal Lobe Epilepsies

Fabienne Picard

Eylert Brodtkorb

Introduction

Frontal lobe epilepsies, as with other focal epilepsies, were formerly invariably considered to be the consequence of an overt or obscure brain lesion. However, this view has changed during the last 10 years, as large families comprising several individuals with non–age-related partial seizures without manifest organic cause have been identified. Today, the genetic origin of nonlesional focal epilepsies is well accepted. Several familial focal epilepsy syndromes with an autosomal dominant mode of inheritance have successively been recognized, such as autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE), familial temporal lobe epilepsies, and familial focal epilepsy with variable foci.[46] They are considered idiopathic, like the classical benign localization-related epilepsies of childhood, since affected individuals do not exhibit any other etiology than a presumed genetic cause.

ADNFLE constitutes a reasonably homogeneous clinical syndrome. Mutations have been identified in genes coding for subunits of the cerebral nicotinic acetylcholine receptor (nAChR) in some families, establishing a clear link between ADNFLE and this ion channel. The many cases of sporadic nonlesional nocturnal frontal lobe epilepsy (NFLE) present similar clinical and electroencephalographic features.[66] It is likely that some of them represent unrecognized familial cases or are related to de novo mutations. Yet, others possibly share similar pathophysiologic mechanisms, even if their etiology is not predominantly genetic.

Historical Perspectives

In the last 30 years, several reports have described patients with sudden, brief nocturnal episodes of complex motor activity and a family history of similar attacks.[18,27,68] This clinical picture was originally thought to represent a movement disorder, so-called *paroxysmal nocturnal dystonia*,[32,33] but was later recognized as epilepsy.[23,37] In 1993, Vigevano and Fusco used the term *partial idiopathic epilepsy of frontal lobe origin* to describe otherwise healthy children presenting with nocturnal tonic postural seizures with a strong family history of epilepsy.[72] When families with a clear mendelian inheritance later were identified by Scheffer et al. in 1994, this disorder was designated ADNFLE.[59] The first reported families originated in Australia, Canada, and the United Kingdom. In the Australian family, linkage studies revealed mapping to the long arm of chromosome 20.[44] Subsequent sequencing demonstrated a missense mutation in the gene coding for a subunit of the neuronal nAChR.[63] This finding was a surprise, as it was not previously known that this receptor was involved in epileptogenesis. ADNFLE was the first epileptic syndrome with a proven monogenetic origin, a finding that may be considered a milestone in epileptology. Various mutations in genes coding for subunits of nAChRs have later been demonstrated in different families with this condition (Table 1).[4,8,14,21,24,30,34,35,36,39,42,43,44,55,56,58,59,62,63,64]

Definitions

ADNFLE was first described on the basis of its familial character, but does not differ clinically from the more frequently occurring sporadic cases of nonlesional NFLE. An attempt to define the general characteristics of frontal lobe epilepsy was part of the 1989 Classification of Epilepsies and Epileptic Syndromes by the International League Against Epilepsy (ILAE)[11]:

> "Frontal lobe epilepsies are characterized by simple partial, complex partial, secondarily generalized seizures or combinations of these. Seizures often occur several times a day and frequently occur during sleep. Frontal lobe partial seizures are sometimes mistaken for psychogenic seizures. Status epilepticus is a frequent complication."

A list of features strongly suggestive of the diagnosis was given:

> "(1) generally short seizures, (2) complex partial seizures arising from the frontal lobe, often with minimal or no postictal confusion, (3) rapid secondary generalization (more common in seizures of frontal than of temporal lobe epilepsy), (4) prominent motor manifestations which are tonic or postural, (5) complex gestural automatisms frequent at onset, (6) frequent falling when the discharges are bilateral."

ADNFLE contains several elements from this general outline. However, the unique seizure semiology in this disorder was found to fit poorly with the 1981 ILAE seizure classification.[12,31] Hence, the concept of hypermotor seizures was introduced in the more recent proposal of a semiologic seizure classification[31]:

> "Hypermotor seizures are seizures in which the main manifestations consist of complex movements involving the proximal segments of the limbs and trunk. This results in large movements that appear 'violent' when they occur at high speeds. The 'complex motor manifestations' imitate normal movements, but the movements are inappropriate for the situation and usually serve no purpose. Frequently, the movements are stereotypically repeated in more or less complex sequences (e.g. pedalling). Consciousness may be preserved during these seizures."

Finally, the term hyperkinetic seizure was included in the new glossary of descriptive terminology for ictal semiology by the ILAE Task Force on Classification and Terminology[6]:

> "(1) Involves predominantly proximal limb or axial muscles producing irregular sequential ballistic movements, such as pedalling, pelvic thrusting, thrashing, rocking movements. (2) Increase in rate of ongoing movements or inappropriately rapid performance of a movement"

ADNFLE follows an autosomal dominant inheritance with incomplete penetrance. The first identified families allowed the

P.2496

P.2497

delineation of the main clinical features,[58] which later have been refined (Table 2). Subsequently, other focal idiopathic epilepsies with an autosomal dominant transmission pattern were described: The familial temporal lobe epilepsies[2] and the autosomal dominant partial epilepsy with variable foci.[60] ADNFLE has together with these syndromes been included within the subgroup of "familial focal epilepsies" in the list of epilepsy syndromes recently proposed by the ILAE Task Force on Classification and Terminology.[15]

[a]In the 24 patients in whom age of onset was known.
[b]Data not provided separately for this family.

Table 2 Main Clinical Features of Autosomal Dominant Nocturnal Frontal Lobe Epilepsy

- Onset age is variable, although generally in childhood.
- There are brief hyperkinetic seizures, almost exclusively during sleep.
- Attacks may be numerous every night for long periods.
- Awareness during seizures is often retained.
- The course is nonprogressive and seizures may remit.
- Good response to antiepileptic drugs, especially to carbamazepine, is common.
- Pharmacoresistance occurs in almost one third of patients.
- Clinical neurologic examination and magnetic resonance imaging are normal.
- Cognitive deficits and psychiatric comorbidity may occur.

Epidemiology

To date, the number of reported ADNFLE families exceeds 100.[4,8,10,14,21,24,25,30,34,35,39,40,41,42,43,45,46,55,58,62] Undoubtedly, they only represent a small fraction of ADNFLE families worldwide and the prevalence of this disorder is obscure. Several known families have probably not been reported when genetic analyses have not been performed or have been inconclusive. In addition, it is likely that there still are families in which the epileptic nature of the paroxysmal nocturnal events has remained unrecognized or misdiagnosed. The reported ADNFLE families all comprise at least two affected first-degree relatives with an inheritance pattern suggestive of autosomal dominant transmission. Twenty-seven affected individuals have been reported in the largest and first described family in Australia.[44] Up until now, mutations have been found in genes encoding subunits of nAChR in 12 families and in one sporadic case (Table 1). Thus, identified mutations currently account for only a minority (10% to 12%) of published ADNFLE families. Sporadic NFLE cases are relatively common,[51] and some may harbor the same mutations that have been identified in ADNFLE.[43]

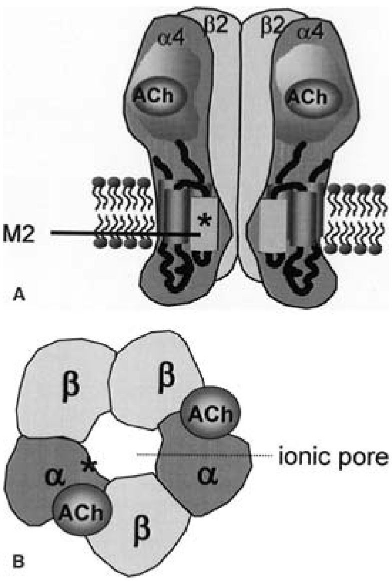

FIGURE 1. Schematic illustration of the neuronal α4 β2 nicotinic acetylcholine receptor (nAChR), a pentameric ion channel. **A:** Coronal section. **B:** Axial section. The α4 β2 nAChR results from the assembly of two *α* and three *β* subunits. The wall of the ionic pore is lined by the M2 segment of each subunit (second transmembrane domain). When acetylcholine binds to the nAChR, the ion channel opens and lets cations enter. The *asterisk* indicates the location of the mutations in the α4 subunit.

Etiology and Basic Mechanisms

ADNFLE was the first idiopathic epilepsy for which a responsible gene was recognized.

Mutations have been identified in the *CHRNA4* gene encoding the nAChR α4 subunit and in the *CHRNB2* gene encoding the nAChR β2 subunit (Table 1). Up until now, four different mutations have been described in *CHRNA4*: (a) S248F, a missense mutation replacing serine with phenylalanine in position 248 in the amino acid sequence, observed in an Australian, a Spanish, a Norwegian, and a Scottish family[36,56,63,64]; (b) 776ins3, an insertion of three nucleotides at nucleotide position 776, leading to the insertion of a leucine in the amino acid sequence, in another Norwegian family[62]; (c) S252L, a missense mutation replacing a serine by a leucine in position 252 in the amino acid sequence in a Japanese, a Polish, and a Korean family, and in a sporadic case of Lebanese origin who subsequently had an affected son[8,21,24,35,43,55]; and (d) T265I, another missense mutation, in a German family.[30] Some authors use an alternative codon numbering, which may cause nomenclature confusion.[10,55,56] Three different mutations (V287L, V287M, and I312M) are described in the *CHRNB2* gene in an Italian, a Scottish, and an English family, respectively.[4,14,42]

The nAChRs are pentameric ligand-gated ion channel receptors consisting of different functional subunit combinations (Fig. 1). When acetylcholine (ACh) binds to the nAChR, the ion channel opens and lets cations enter. The known ADNFLE mutations are located within the second transmembrane domain (M2) of the subunits, which constitutes the walls of the ionic pore, except for the mutation β2-I312M, which is in the third transmembrane domain. Thus, it appears that mutations with a principally direct effect on the ionic pore may cause ADNFLE. The fact that the major nAChRs in humans are made from an assembly of α4 and β2 subunits explains well that defects in both subunits are associated with the same disorder. The α4β2 nAChRs are the most abundant form and are found in the entire brain, with a predominance in the thalamus. They may have a presynaptic or a postsynaptic location. The first have a neuromodulatory role (facilitation of neurotransmitter release), whereas the latter induce a depolarization of the postsynaptic neuron. To assess the changes in the electrophysiologic properties of the mutant receptors, a system of

heterologous expression in frog (*Xenopus*) oocytes has been used. These cells were injected with an equivalent amount of the mutant and nonmutant allele, in addition to cDNA coding for the other normal subunit, in order to obtain mutant "heterozygous" receptors mimicking an autosomal dominant disorder. Six different mutations led to a significant increase in sensitivity to ACh of the mutant receptors.[4,5,30,38,42] The seventh mutation, the *CHRNB2* V287L mutation, caused retardation of channel desensitization.[14] Thus, contrary to the first conclusions obtained from the assessment of homozygous mutant receptors, the current studies suggest a gain of function of the mutant nicotinic receptor for the various mutations. In contrast, another study of five mutations proposed a reduction of the Ca^{2+} dependence of the ACh response, which could explain an increase of glutamate release during bouts of synchronous activity, as an alternative common mechanism.[52] However, the precise cellular mechanisms leading to epileptogenesis in ADNFLE remain elusive. In particular, it is not clear how an alteration of an nAChR subtype that is present in the thalamus and in the entire cortex may cause a partial epilepsy.

Currently, it is assumed that the mutant nAChRs alter the activity level of frontal thalamocortical loops, which play a major role during sleep. A positron emission tomography (PET) study using 2-[^{18}F]-F-A-85380, a high-affinity agonist of the heteromeric (α4β2) nAChRs, has recently offered an opportunity to investigate some in vivo consequences of the molecular defect.[48] Eight ADNFLE patients with an identified mutation in nAChRs were studied. Their pattern of nAChR brain distribution was clearly different compared to healthy volunteers. A significant decrease in nAChR density in the right dorsolateral prefrontal region and a significant increase in the epithalamus, ventral mesencephalon, and cerebellum were demonstrated. The regional decrease in the nAChR density in the prefrontal cortex appears congruent with a frontal lobe epilepsy. We propose two explanations for the regional increase in the nAChR number in the mesencephalon: (a) a regional malformation of central nervous system (CNS) circuits, with an increase of synaptic density, since nAChRs may have a role in the migration of neocortical neurons and in synaptogenesis[53]; and (b) a regional nAChR up-regulation, related to the hypersensitivity of the mutant nAChRs to ACh and the richness of local ACh release sites. A consequence of the increased nAChR density in mesencephalon could be an overactivated cholinergic pathway ascending from the brainstem. This pathway acts on postsynaptic nAChRs on thalamocortical cells and participates in "desynchronization" and interruption of the sleep physiologic oscillations at the time of the arousals.[13,28,65] Thus, the findings of the recent PET study[48] support the theory that ADNFLE seizures are due to a defective interruption and a pathologic transformation of synchronized sleep oscillations.

Other in vivo functional studies using transgenic animal models have also enhanced the understanding of ADNFLE pathogenesis. A *CHRNA4* knockout mouse showed increased anxiety compared with the behavioral phenotype of the wild type, but did not exhibit spontaneous seizures.[54] *CHRNB2* knockout mice showed abnormal functional organization in the dorsal lateral geniculate nucleus,[19] reduced sensitivity to nicotine-induced locomotor depression,[70] and reduced fragmentation of non–rapid eye movement (REM) sleep by micro-arousals.[29] This last phenotypical trait is an interesting finding, as sleep microstructure analysis of NFLE and ADNFLE patients has revealed sleep fragmentation with an increase in arousals and sleep instability in all non-REM sleep stages.[67,74] Knockin mice containing a point mutation in the pore-forming M2 domain of the α4 subunit (Leu9'Ser) showed increased anxiety, increased sensitivity to induced seizures by agonists (such as nicotine, the nicotinic agonist epibatidine, but not the γ-aminobutyric acid $(GABA)_A$ receptor blocker and proconvulsant bicuculline), but no spontaneous epileptic seizures,[16] and also dopaminergic deficits.[26] When tested in oocytes, the α4β2 nAChRs with this specific mutation displayed an increased ACh sensitivity, as observed with the human ADNFLE mutations.[5,26] In addition to these mice models, a new transgenic rat model harboring a true ADNFLE mutation is currently under investigation.[22] This model appears more interesting as it expresses spontaneous seizures resembling those of ADNFLE.

For a long period of time, no other genes than those coding for nAChR subunits were reported to be responsible for this condition. Just recently, mutations have been identified in the promoter of the corticotropin-releasing hormone (CRH) gene.[9] The first mutation, a polymorphism present in 3% of the general population, was detected in three families and in two sporadic cases. The second, not present in 115 healthy subjects, was detected in one ADNFLE proband. However, in vitro the first mutation caused an increase in the protein level, whereas the second resulted in a decrease.[9] Although the nAChRs are known to activate CRH release,[7,57] the pathophysiologic link between CRH and nAChRs in ADNFLE is still obscure.

Clinical Presentation

The main clinical features are listed in Table 1. Mean age of onset of ADNFLE varies between 8 and 11.5 years, according to clinical studies. It starts below 20 years in 85% of cases. Onset ages as low as 2 months and as high as 56 years have been reported.[46,58] The penetrance appears to be up to 80%. Males and females are equally affected.[10] Seizures arise from sleep. They are more or less stereotyped in each patient over the years. It is remarkable that sudden arousals are characteristic for ADNFLE[4,39,56,64] in contrast to the reduced consciousness that typically occurs in seizures with medial temporal lobe onset. Some patients describe an aura. They are nonspecific and include a broad variety of phenomena: Somatosensory (shivering/tingling, either diffusely or localized, mostly in the head, sometimes in the limbs; and also epigastric discomfort), special sensory (e.g., sensations of light, auditory hallucinations, vertigo), psychic (fear, malaise, déjà vu, dreaming activity), and autonomic (breathing difficulty).[58,64]

The motor manifestations are characterized by a wide range of clinical features, which in part can be regarded as a release of subcortical activity. Extrapyramidal features are often prominent. Behavior and autonomic elements may reflect limbic overactivity. The mildest form consists only of a sudden awakening with an elevation of head and trunk, often associated with the expression of fear. Abrupt and rapidly changing movements of the limbs and the trunk may occur, leading to a bizarre sequence of various brief dystonic postures, reminiscent of a mechanic puppet. Hyperkinetic activity (frantic movements with bipedal activity, pelvic thrashing) or tonic stiffening are common features. During the seizure, a breathless sensation is reported by many patients.[36,42,43,46,56,58] Seizures usually last less than 1 minute, with a mean duration of 30 seconds,[46,58] but some seizures are prolonged and may take the form of nocturnal wanderings. Postictal symptoms are absent or very brief. Rare secondarily generalized seizures are observed in about half of the patients, but the unusual semiologic pattern may cause classification difficulties. Some patients report that awareness is partly retained even during apparent generalized convulsions, a phenomenon that may wrongly raise the suspicion of psychogenic seizures.

Seizures frequently occur in clusters, predominantly during the first few hours after falling asleep or early in the morning. Some patients have attacks every night, while others report mild and rare symptoms. Periods with high seizure frequency may alternate with seizure-free intervals. In one study, the mean seizure frequency was around eight episodes per night.[58]

Diurnal seizures, apart from during naps, are very rare, but may be observed in the most severe cases, particularly during periods of poor seizure control.[40,46,64] Some patients may also experience status epilepticus. Stress, sleep deprivation, and menstruation may increase seizure frequency. Sensory stimulation during sleep (e.g., shaking the body of the patient or a sudden sound) may sometimes provoke seizures.[24,43,55] On the background of a video-polysomnographic study of a large number of patients, the attacks were classified into four categories according to duration, semiology, and complexity of motor behavior (minimal, minor, major, and prolonged episodes).[40,41] The mildest form is described as paroxysmal arousals, consisting of a sudden awakening with dystonic posturing of upper or lower limbs.[49,50,69] They can recur with a periodic repetition, every 30 seconds to 2 minutes during light sleep. Paroxysmal arousals are probably the most frequent type of seizures, but, due to their short duration, many patients remain unaware of them. The information from relatives about apparently unaffected individuals is thus hampered with a high degree of uncertainty. Structured interviews of all pedigree members and their proxies, particularly their bed partners, are thus necessary to recognize the true penetrance of this disorder. The clinical observation is the major diagnostic tool in NFLE, particularly since even ictal electroencephalograms (EEGs) may be inconclusive. Nocturnal video recordings, preferably with polysomnographic parameters, may be necessary for the clinical diagnosis.

Clinical neurologic examination is normal. A normal intelligence was one of the ADNFLE features originally described.[58] Nevertheless, subsequent descriptions reported neuropsychological deficits in some patients. In four families with typical ADNFLE, most patients also suffered from mild to moderate intellectual disability.[4,8,24,25] Two of these families had an α4-S252L mutation, one the β2-I312M mutation and one no identified mutation. The patient with the de novo α4-S252L mutation was reported to be of low average intellect.[43] Several of the cognitively affected patients had pronounced memory deficits. A neuropsychological study of two other patients from ADNFLE families without identified mutations showed specific frontal lobe neuropsychological disturbances.[46] Currently, it is unknown whether the observed neuropsychological deficits are a consequence of the seizure disorder or a behavioral phenotype primarily associated with the genetic defect. In addition, in some families psychiatric disturbances have been reported in up to half of the patients during the active phase of their epilepsy.[4,24,35,36,46] Behavioral disorders with hyperactivity, irritability, aggressiveness, and impulsive behavior are the most frequent findings, but psychosis have also been reported in some patients.[35] The psychiatric impact may contribute to the diagnostic confusion, which still may occur in this disorder.

No obvious clinical elements seem to differentiate mutation-positive from mutation-negative families.

Diagnostic Evaluation

Electroencephalographic Findings

Many patients have a normal interictal EEG. Most studies report waking EEG abnormalities in only 10% to 25% of patients.[8,40,56,58] Other authors who retrospectively looked at all previous EEGs of their patients reported waking EEG abnormalities in up to 60%, mostly recorded during periods of frequent seizures.[46,64] When present, the abnormalities consist of focal intermittent theta or delta slow waves and/or sparse focal sharp waves or spikes. They are usually located over the frontal regions and exceptionally over the temporal areas.[8,46] Interictal sleep EEG sometimes demonstrates abnormalities in patients with a normal waking EEG.[40,46] In a study of 40 patients, 10% had an abnormal waking EEG and 50% an abnormal interictal sleep EEG.[40] When unilateral interictal or ictal EEG abnormalities are identified, they appear to remain lateralized on the same side throughout the evolution of the disorder. Ictal EEG recordings may also fail to show specific discharges. Cortical activity is often concealed by movement artefacts. An ictal pattern appears in 40% to 80% of the patients, according to studies, but rarely consists of clear-cut epileptiform activity in the frontal regions. Most often a diffuse flattening or a rhythmic theta or delta activity with predominance over anterior quadrants is seen. Thus, at least a quarter of the patients have normal interictal as well as ictal scalp EEGs.[40] Video-EEG-polysomnographic recordings show that almost all seizures arise during stage 2 non-REM sleep. Intracerebral EEG recordings performed in a patient with a typical ADNFLE surprisingly demonstrated that seizures originated from the left insular cortex, whereas ictal surface EEG showed diffuse flattening or left frontoprecentral fast activity at the onset of seizures.[46]

Neuroimaging and Other Laboratory Examinations

Brain magnetic resonance imaging (MRI) is normal in all patients with ADNFLE. Functional imaging studies include single photon emission tomography (SPECT) and positron emission tomography (PET) studies. ^{18}F-fluorodeoxyglucose (FDG)-PET was described in eight patients with ADNFLE from three different families.[8,20] The study was considered normal in seven patients and showed a hypometabolism in the frontopolar region in one.[20] A statistical parametric mapping (SPM) analysis was performed in six patients with a normal PET and permitted the detection of glucose hypometabolism in the left superior and middle frontal gyrus in five of them, but also in the left central and parietal regions and the right anterior superior frontal gyrus.[8] Recently, a PET study using a tracer of the nicotinic receptors has been performed in eight ADNFLE patients with an identified mutation[48] (see Etiology and Basic Mechanisms). An interictal SPECT using 123I-IMP (*N*-isopropyl-p-iodoamphetamine) showed no abnormality in a patient from Japan, while an interictal SPECT using 99mTc-ECD (ethyl cysteinate dimer) showed low perfusion in both frontal lobes in another patient from the same family.[24] Another study using ^{99}Tc-HMPAO (technetium-99m hexamethyl-propylamineoxime) showed perfusion changes on interictal and ictal SPECT in the left frontopolar region, congruent with the focal hypometabolism observed in interictal PET in one patient, and right parasagittal, midfrontal hyperperfusion on ictal SPECT with a hypoperfusion in the same area on interictal SPECT in another patient with an identified mutation.[20]

Differential Diagnosis

Diagnostic difficulties have been recurrent problems in many families with ADNFLE. Nocturnal seizures often occur without eyewitnesses, and if present, the beginning of even dramatic episodes is often not seen. Darkness and covers frequently restrict the detailed observation by bedroom partners. Even ictal EEG recordings may be inconclusive. Previously, many patients with NFLE were considered to suffer from a primary movement disorder termed *paroxysmal nocturnal dystonia*[32,33] (see Historical Perspectives). Misdiagnoses as parasomnias, in the form of night terrors, nightmares, and somnambulism, have been common. Based on the history alone, the differential diagnosis

P.2500

from benign parasomnias may be difficult in children. Attack frequency differs and symptoms usually occur as single or isolated recurrent episodes in the parasomnias in contrast to the frequent clustering of nocturnal frontal lobe seizures. Due to pronounced autonomic and emotional symptoms with arousal and fear, psychiatric disorders such as panic attacks and hysteria may also be suspected. REM behavior disorder is characterized by agitated, sometimes violent movements occurring during REM sleep. The majority is males above age 60 and other neurologic disorders such as Parkinson disease or multisystem atrophy are common.[1,10,24,50,58,69] Other members within the same family can certainly be afflicted with these disorders, but hardly with a distinct autosomal dominant transmission pattern. Besides hypnagogic myoclonias, short nocturnal movements resembling mild seizures can be present in healthy subjects. However, in NFLE the episodes are more stereotypical and include sudden movements with dyskinetic or dystonic components. When characteristic hyperkinetic seizures during sleep are video-recorded, the diagnosis of NFLE is usually readily made.

A careful pedigree analysis confirms the familial occurrence of the disorder and differentiates ADNFLE from the more common sporadic forms of NFLE. Other autosomal dominant focal epilepsies (e.g., from the temporal lobe) may also manifest themselves with nocturnal seizures, but have otherwise different ictal semiologies. However, families with autosomal dominant partial epilepsy with variable foci may contain patients with a seizure pattern similar to NFLE. They can thus wrongly be considered as ADNFLE families before the phenotypic variability is appreciated. In this syndrome, seizures arise from different cortical regions in different family members and a predominance of seizures while awake may be observed in some individuals.[3]

Treatment and Outcome

Carbamazepine has been postulated to be the drug of choice in ADNFLE. It has been reported to be more effective than valproate and appears to suppress seizures completely in about two thirds of patients with this syndrome.[46,58] Low doses of carbamazepine (around 600 mg/day in adults) are often sufficient. The detection of an association between nAChR mutations and ADNFLE gave the opportunity to compare the effect of carbamazepine on mutated and wild-type receptors in vitro. Studies in *Xenopus* oocytes demonstrated that carbamazepine most probably acts as an open channel blocker and generally inhibits α4β2 nAChRs, but that most mutants display a higher sensitivity to this effect.[5,47] Carbamazepine may shut down the mutant receptors, whereas remaining wild-type receptors are less affected.[47,64] Pharmacoresistance to carbamazepine and other antiepileptic drugs has nevertheless been observed in one third of patients. Most reported families have at least had one pharmacoresistant individual, whereas other affected family members have had a good therapeutic response.[10] There is indeed considerable interfamilial and intrafamilial clinical variability concerning epilepsy severity and effect of antiepileptic therapy in this condition.

Acetazolamide was reported to reduce or control seizures in one family without evidence for nAChR mutations.[71] In one single patient with uncontrolled seizures from the original Australian family, transdermal nicotine appeared to be very effective when added to carbamazepine in both an open and a double-blind placebo-controlled fashion.[73] These preliminary data encourage attempts to treat patients who prove to be refractory to standard antiepileptic therapy with these agents.

The effect of surgical treatment has not been reported in ADNFLE in spite of its localization-related clinical manifestations. A priori, resective surgery does not appear to be an appropriate option in disorders caused by mutations affecting receptors with widespread distribution in the brain. Prudence should also be exercised in sporadic NFLE.

Long-term Prognosis

The phenotypic expression of this condition spans from a persistent, severe disability to only a mild intermittent sleep disruption, not recognized as an epileptic manifestation by either the affected individuals or their proxies. Even with frequent seizures, remissions can occur during adolescence and adulthood, without seizure recurrence after discontinuation of drug therapy.[17,34,36,39,42,46,64] However, relapses may occur after many years, and in some families, ADNFLE persists through adult life in many of the affected individuals.[58,62,64,66] Genetic or environmental factors that determine penetrance or remission are not yet identified. The reported efficacy of nicotine administration[73] is interesting in this respect, and to date it is not known to what extent chronic consumption of nicotine could influence the course and prognosis of this disorder. The fact that the attacks are exclusively sleep related in most patients and usually do not change their chronodependency is important when assessing these patients for motor vehicle driving.

Summary and Conclusions

ADNFLE was the first idiopathic epilepsy for which a distinct genetic basis was identified. Mutations in two genes (*CHRNA4* and *CHRNB2*) coding for neuronal nicotinic receptor subunits (α4 and β2) have been identified. ADNFLE is characterized by nocturnal attacks that tend to cluster and can recur several times during one night. Seizures have prominent motor features and mainly occur during non-REM sleep, particularly shortly after falling asleep, before waking up in the morning, and during daytime naps. Onset age varies, but is usually within the two first decades of life. Currently, it is hypothesized that the pathogenetic mechanism is linked to overactivity in ascending cholinergic circuits that control arousal, leading to an imbalance of function in the frontal lobes. The ictal symptoms are thought to represent a paroxysmal disinhibition of subcortical activity in the form of automatic motor and limbic activity. The hyperkinetic sleep-related seizure is the clinical hallmark of the disorder. Interictal cognitive and psychiatric symptoms have been described in some families, but it is uncertain whether these features are true phenotypic traits. Most patients respond to antiepileptic therapy, especially carbamazepine, but one third of patients are pharmacoresistant. Some patients report long seizure-free periods. Unknown factors influence penetrance, treatment response, severity, and remission. Further studies, clinical as well as on the molecular level, are needed for a more complete understanding of ADNFLE. Nevertheless, the recent discoveries in ADNFLE have suggested new neurobiologic mechanisms for familial epilepsy and throw new light on the pathogenesis of epilepsy in general.

Chapter 250

Hypothalamic Hamartoma with Gelastic Seizures

A. Simon Harvey

Orvar Eeg-Olofsson

Jeremy L. Freeman

Introduction

The syndrome of hypothalamic hamartoma (HH) with gelastic (laughing) seizures (GSs) is a rare but important epileptic syndrome (HHGS), being one of the most refractory, disabling, and poorly understood seizure disorders affecting children and adults. Over the last decade, much has been learned about the nature of HH and its often progressive neurologic and behavioral manifestations, and effective surgical treatments have also been developed.

Historical Perspectives

Le Marquand and Russell[44] first used the term hamartoma in 1934 to describe a tumor-like lesion of the hypothalamus found at postmortem in a boy with precocious puberty. Chronic epilepsy associated with a hypothalamic lesion, designated an astrocytoma but likely an HH, was first reported 2 years earlier[86] in a boy with precocious puberty and mental retardation who died from status epilepticus. The first report of GS in a patient with HH was in 1938,[18] the patient also having precocious puberty and pervasive developmental delay. Isolated reports of probable or proven HH with gelastic seizures followed.[27,45,50,59,60,66,78] In 1988, the association was better characterized by Berkovic et al. as a recognizable and possibly progressive epileptic syndrome, their series incorporating neuroimaging diagnosis.[4] The first report of a patient surviving surgical resection of an HH was in 1967,[59] but it was not until the mid-1990s that GSs were shown conclusively to arise in the HH[39,41,54] and surgical treatment for refractory seizures flourished. Over the last 10 years, there has been great interest in the nature of HH and its association with GSs, and great efforts in developing minimally invasive surgical techniques for treatment of the refractory seizure disorder. For further details concerning GSs, see Chapter 53.

Definitions

A hamartoma is a focal malformation that resembles a neoplasm, composed of an abnormal mixture or proportion of tissue elements normally present in that site, which develop and grow at virtually the same rate as normal tissue.[71] HHs are usually spherical in shape with a diameter between 0.5 and 4 cm, in most cases <1.5 cm. HHs arise from the tuber cinereum or from one or both mammillary bodies, and if large, may bulge into the third ventricle and compress (but not disrupt) the hypothalamic nuclei and fiber tracts.[45] Asymmetric location and attachment are seen in about two thirds of patients.[21]

Several anatomic classifications of HH based on magnetic resonance imaging (MRI) features have been proposed, distinguishing different sizes and patterns of hamartoma attachment to the hypothalamus.[1,8,15,85] The most important separation from clinical, pathophysiologic, and surgical perspectives seems to be the distinction between HHs sitting within the third ventricle that are attached to the mammillary bodies and/or the hypothalamic walls (sessile, intraventricular, intrahypothalamic) from those HHs beneath the third ventricle with attachment to the tuber cinereum (pedunculated, extraventricular, parahypothalamic). HHs associated with epilepsy are almost always intraventricular, at least in part, with a significant mammillary body attachment.

Histologically, HHs resemble normal gray matter,[57] though some neurons may show variation in size and shape[8,14,37,59,62,75] and may appear in discrete nests or nodules of cells.[8,29,59] Fibrillary gliosis is also found,[8] and cystic changes have been observed in large lesions.[70] Dysplastic neurons and balloon cells are not seen in HHs.

Epidemiology

HHGS is an uncommon epileptic syndrome, with a prevalence in childhood of about 0.5 in 100,000.[9] Most early reports of HHs were in patients with central precocious puberty,[91] but most recent reports concern HHs and GSs. The current literature is biased toward surgical patients with severe seizure and other neurologic manifestations, making it hard to determine the proportion of patients with different clinical features. Also, it is likely that there are patients with HHs who are asymptomatic or have only mild or undiagnosed seizure manifestations,[81] leading to underreporting of HH. A greater number of males with HHs and epilepsy is reported.[82]

Etiology and Basic Mechanisms

HHs are a nonfamilial, congenital malformation usually occurring in isolation. They are rarely associated with other intracranial malformations such as callosal dysgenesis, heterotopias, arachnoid cysts, and microgyria.[8,21,30] Rarely, HHs may occur as part of a multiple congenital malformation syndrome, most notably the autosomal dominant Pallister-Hall syndrome, which includes HH, polydactyly, hypopituitarism, imperforate anus, and dysplastic nails.[7] Seizures occur in about 15% of patients with Pallister-Hall syndrome and are often mild, despite HHs often being very large. Patients with Pallister-Hall syndrome have mutations of the zinc-finger transcription factor gene *GLI3* on chromosome 7p13,[35,40] but the role of *GLI3* mutation in patients with sporadic HHs[24] is unconfirmed and so the etiology of sporadic HHs remains uncertain.

The genesis of seizures associated with HH is also incompletely understood. Mechanical irritation or distortion of the adjacent hypothalamus or midbrain by the HH was initially believed to be the cause of seizures.[45] The severity and

P.2504

generalized nature of seizures and associated neurologic and behavioral problems in many patients with HHs, and the early poor results of HH surgery,[10,49,69,75] led to speculation that patients with HHs had widespread occult cerebral dysgenesis.[4,79] GSs were eventually shown to arise from the HH by stereotactic depth electroencephalographic (EEG) recording of seizures from the HH, by reproduction of symptoms with electrical stimulation of the HH, and by demonstration of HH hyperperfusion with ictal single photon emission computed tomography (SPECT).[34,36,37,38,39,41,54] This led to a change in view from the HH simply being an epiphenomenon to the HH being intrinsically epileptogenic.[6] Such intrinsic hyperexcitability has been documented with single cell studies of small neurons within cell clusters in resected HHs exhibiting pacemaker-like spontaneous repetitive firing,[90] similar to that seen in focal cortical dysplasia.[48,63]

The reasons for marked variability of the neurologic manifestations of HHs, and the relationship between the size and attachment of the HH, and the neurologic manifestations remain uncertain. Some reports suggest that seizures are more frequent or severe in patients with larger HHs.[47,81] A connection of the HH with the mammillary bodies seems to be integral to epileptogenesis.[1,21,85] Tonic seizures that develop in a proportion of children do not seem to arise from the HH,[37] but rather occur as a related but independent neocortical phenomenon. The whole electroclinical picture of symptomatic generalized epilepsy, with slow spike-wave on EEG and generalized tonic seizures, may develop in patients with HHGS as a consequence of secondary epileptogenesis in the neocortex.[22]

Clinical Presentation

GSs are the characteristic epileptic manifestation of HH, occurring in nearly all patients (see Chapter 53). Early onset of GSs is characteristic[9,82] and onset from the day of life is well known.[4,16,17,41,62,78] The sound produced during GSs associated with HH is described variously as laughter, chuckling, or giggling, often qualified by words such as unnatural, mechanical, mirthless, and inappropriate. Dacrystic (crying) seizures are noted in many patients,[10,28,37,45,65,78,80,87,89] invariably accompanied by GSs. Very frequent, brief GSs occurring during wakefulness and sleep are common in infancy. A mild form of GSs is described in adults with small HHs, the patients sometimes describing only a "pressure to laugh"[81] or an "urge to giggle."[52] Consciousness is said to be preserved during brief gelastic seizures.[4,12,78] Often accompanying laughter in gelastic seizures are autonomic features such as facial flushing and pupillary dilation, hypermotor automatisms, oro-alimentary automatisms, head and eye deviation, and tonic or clonic facial contraction.[4,78]

West syndrome is reported in association with HH,[3,9,22,53] such that HH should be included in the differential diagnosis of infants presenting with epileptic spasms.

An epileptic progression with development of focal seizures, tonic/atonic seizures, and tonic–clonic seizures occurs in more than half of patients.[82] Many patients develop Lennox-Gastaut syndrome with disabling drop attacks. There is a paucity of detailed clinical and EEG descriptions of these associated seizures occurring in patients with HHs, in contrast to GSs. The interrelationship of these different seizure types is uncertain, but focal seizures associated with HHs often have frontal and temporal lobe features, tonic seizures and spasms associated with HHs often have focal motor features, and laughter may precede or follow all of these.

Cognitive and behavioral impairments are common in patients with HHGS who have seizures beginning in childhood, especially refractory seizures that begin in infancy and evolve to focal and generalized seizures with marked EEG disturbances. These vary in severity from mild impairments of memory, attention, and learning[4,20,52,81] to severe intellectual disability.[15,33,62] Aggressive behavior, rage attacks, and other psychiatric comorbidities are widely reported in patients with HHGS.[4,88] The relationship of behavior disturbance to GSs and intrinsic hypothalamic dysfunction is uncertain.

Central precocious puberty is common in patients with HHGS (see below), occurring in 30% to 40% of patients with epilepsy,[21,82] usually following the onset of seizures and associated with larger HH size and involvement of the tuber cinereum.[21] Treatment of central precocious puberty with gonadotropin-releasing hormone (GnRH) agonists is usually effective, and patients rarely undergo surgery for this indication alone.

Diagnostic Evaluation

The diagnosis of HHGS is usually based on the recognition of pathologic laughter attacks and the finding of an HH on MRI; EEG is rarely informative early in the course of the epilepsy. The diagnostic evaluation for patients undergoing epilepsy surgery is similar to that for patients with refractory epilepsy of cortical origin except for the need for perioperative endocrine assessment, the need for precise anatomic imaging of midline brain structures, and less attention paid to scalp EEG localization of seizures and interictal discharges.[32]

EEG Findings

Scalp EEG in patients with HHs is variable, reflecting the age of the patient and the evolution of the seizure disorder. In young children with only GSs, and in adults with mild symptoms, the interictal EEG is usually normal,[60] potentially leading to missed diagnosis. Interictal EEG abnormalities may not appear until later childhood,[46] coinciding with the appearance of additional seizure types.[82] Initially, the interictal record may only be abnormal during sleep.[12] Spike-wave activity is prominent over the frontal and temporal regions initially and may be bilaterally synchronous or predominantly unilateral.[11,82] Unilateral abnormalities tend to occur on the side of predominant HH attachment. In patients with tonic and other generalized seizures, background slowing is common and multifocal or generalized spike-wave activity, paroxysmal fast activity, and electrodecremental patterns are recorded, often with electrical status in sleep.[22] The interictal EEG abnormalities in patients with HH must be secondary neocortical phenomena, as a small mass of nonlayered gray matter deep in the middle of the cranium cannot generate electrical potentials of significant amplitude to be recorded on the scalp surface. In fact, intracranial EEG recordings show that interictal discharges arise independently in the HH and the neocortex.[22,37] Furthermore, interictal discharges persist over the neocortex immediately following resection of the HH,[22] though they may subside in the weeks and months that follow successful surgery.

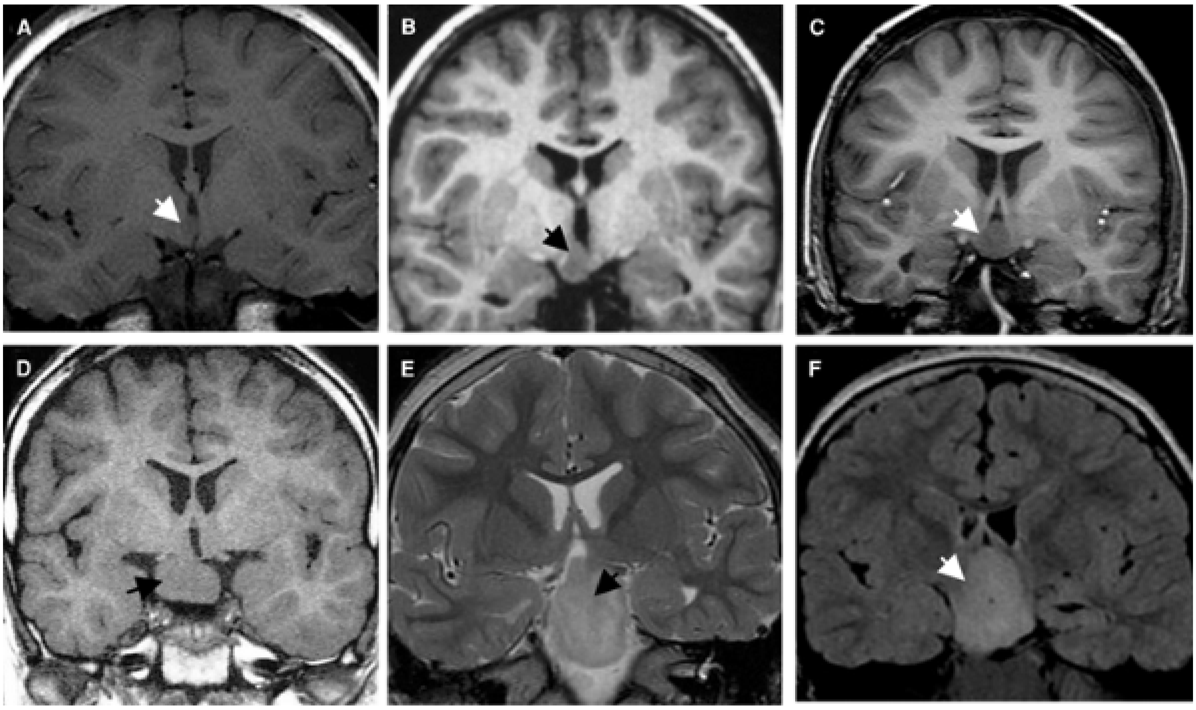

FIGURE 1. Coronal magnetic resonance images of six patients with gelastic seizures and hypothalamic hamartoma (HH) of different sizes and attachments. **A, B:** Small, unilateral, intraventricular HHs. **C:** A moderate size, bilateral, intraventricular HH. **D, E:** Large, unilateral HHs attached broadly to the ventricular wall and tuber cinereum. **F:** A large, bilateral, intraventricular HH, which distorts the hypothalamus and extends into the interpeduncular cistern.

Ictal scalp EEG may show no change during brief GSs,[60] or just a desynchronization of the background activity.[9] Later, as tonic seizures and interictal slow spike-waves develop, GSs are marked by suppression of the interictal discharges and attenuation of background rhythms, with or without widespread low-voltage fast activity.[4] In patients with partial seizures, ictal EEG recordings may show focal rhythms or spike-wave activity, either unilaterally or bilaterally. Misleading focal ictal onsets in the frontal or anterior temporal lobes of patients studied with intracranial EEG recordings, but without electrodes in the HH, once led to unsuccessful focal cortical resections.[11] Depth EEG recordings from the HH[37,38,39,41,54] show that GSs are associated with an ictal discharge within the HH that, in most

P.2505

cases, remains confined to the HH. Electrical stimulation of the HH via the depth electrodes in these cases may provoke the characteristic ictal laughter. In contrast, depth EEG recording of tonic seizures reveals discharges remote from the HH involving various cortical areas.[37]

MRI

MRI (Fig. 1) is far superior to computed tomography (CT) of the brain in revealing and characterizing HHs.[4] Small HHs may be difficult to detect unless the hypothalamic region is specifically examined. HHs usually have increased signal compared to gray matter on T2-weighted and fluid-attenuated inversion recovery (FLAIR) sequences, and low signal on T1, but do not enhance with contrast and remain in proportion with the rest of the brain over time.[21] T2-weighted sequences in the three orthogonal planes are well suited to displaying the high-signal HHs in relation to the low-signal, heavily myelinated hypothalamic nuclei and tracts. Proton magnetic resonance spectroscopy suggests neuronal attenuation and relative gliosis compared with normal gray matter.[21]

PET and SPECT Imaging

Positron emission tomography (PET) studies are few and show either scattered areas of focal cortical or regional hypometabolism, with lateralization usually being concordant with the side of HH attachment.[62,74] Ictal SPECT studies during GSs demonstrate focal hyperperfusion in the region of the HH[17,34,41,43]; HH hypermetabolism is reported in a patient studied with ^{18}F-fluorodeoxyglucose (FDG)-PET during status epilepticus.[64] Asymmetric cerebral perfusion during seizures is common in HHGS,[9] with hyperperfusion ipsilateral to the side of predominant HH attachment, suggesting preferential cortical spread of seizure activity from the HH.[23]

Differential Diagnosis

Pathologic laughter is reported as an epileptic and nonepileptic manifestation of various lesions and processes affecting the temporal lobe, frontal lobe, and brainstem (see Chapter 53). Craniopharyngiomas and tumors of the hypothalamus and third ventricle are imaging differentials of HHs but are generally distinguishable on MRI and rarely present with chronic epilepsy. A search for associated cerebral malformations on MRI and a clinical examination for midline malformations and polydactyly should be undertaken in a patient with seemingly isolated HHs to look for syndromic features.

Surgery and Outcome

Antiepileptic medications are generally ineffective in the management of epilepsy associated with HHs.[4,9] While they may have some impact on the severity or frequency of partial and generalized seizures, antiepileptic drugs generally have little impact on GSs. Vagal nerve stimulation may provide partial benefit in some patients.[9,55]

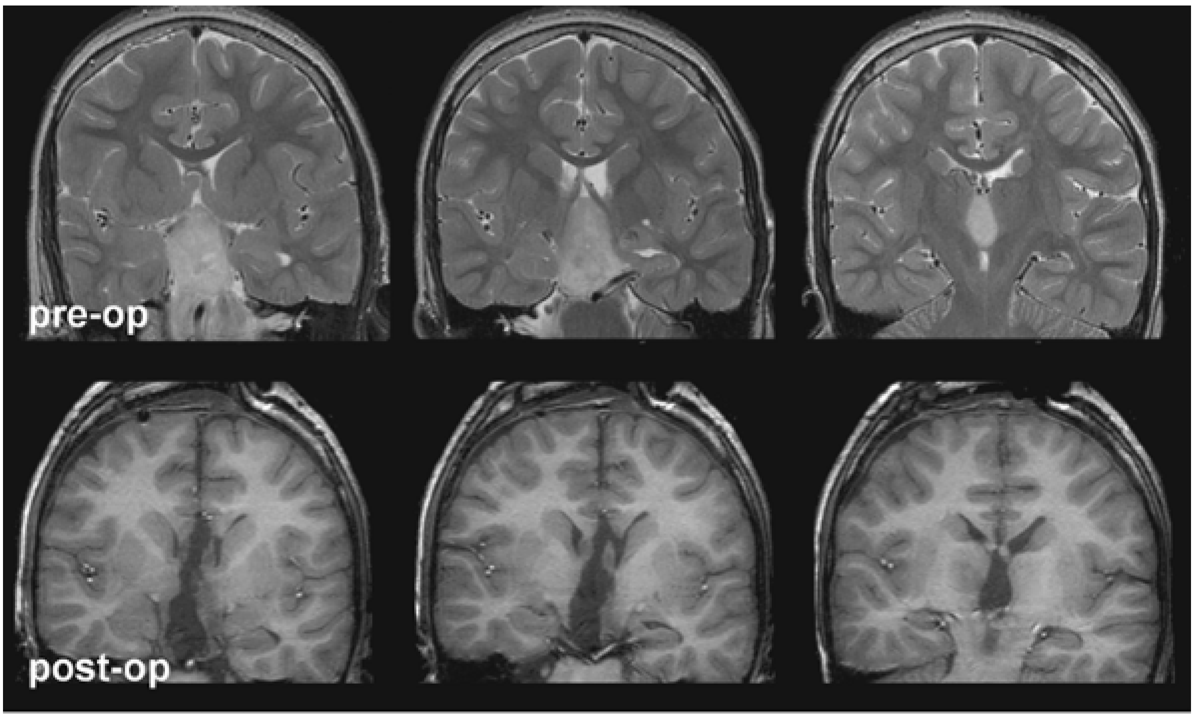

FIGURE 2. Coronal magnetic resonance images of a child with a large bilateral hypothalamic hamartoma and intractable gelastic seizures, before **(top row)** and after **(bottom row)** transcallosal resection.

Early attempts at HH removal were not particularly successful,[10,69,75,78] but with refinements in technique and advances in technology, epilepsy surgery has since become the

accepted treatment of choice for refractory epilepsy associated with HHs.[5,6,31,68] Several operative approaches are currently reported, including open craniotomy (pterional, frontotemporal, paramedian) for either microsurgical or endoscopic resection or disconnection of the HH, and minimally invasive stereotactic approaches with endoscopic, radiofrequency, or radiosurgical ablation.

Open Craniotomy

Pterional and large frontotemporal craniotomies provide access to the inferior part of the HH via a transsylvian, transfrontal, subtemporal, or subfrontal approach.[15,46,51,58,62,85] In some cases the temporal pole or orbital cortex is resected. Such surgical approaches to HHs have proven ineffective in many cases, as only the subventricular component of the HH can be removed, leaving the intraventricular component attached to the mammillary bodies.[5,6,62] Furthermore, there is significant risk of endocrine complications, stroke, and oculomotor paresis with these approaches.[15,62] Delalande proposed disconnection as a safer alternative to resection during frontotemporal approaches.[15]

An interhemispheric, transcallosal approach to intraventricular resection of HHs was developed by Rosenfeld et al.,[73] with superior results and fewer neurovascular complications reported. This approach passes between the columns of the fornices to access the HH within the third ventricle, allowing direct vision of the intraventricular component of the HH under the operating microscope, and complete or near-complete resection or disconnection of the intraventricular HH with the ultrasonic aspirator (Fig. 2). In a series of 29 consecutive young patients undergoing transcallosal surgery for HHs, complete or near-complete resection was achieved in 22. Seizure freedom was achieved in 15 patients and >90% seizure reduction in seven.[33] Most striking in this series was the improvement in patients with symptomatic generalized epilepsy, in whom tonic seizures were frequently abolished and generalized, multifocal spike-wave on scalp EEG was improved, and improved language and behavior were observed.[22,33] "Running down" of generalized seizures was observed in several patients.[22,33] These results dispel the notion that these HHGS have diffuse and irreversible cerebral dysfunction or dysplasia. Morbidity consisted of short-term memory impairment, weight gain, hypothyroidism, and transient hypernatremia.[25,33] Similar results are reported from another center.[56]

Stereotactic Radiofrequency Ablation

Stereotactic radiofrequency thermocoagulation was employed early in the development of surgical treatments for HHs with intractable epilepsy.[26,41,65] Multiple lesions are produced in the HH, often after seizures are recorded from the implanted electrode and symptoms are reproduced with electrical stimulation. The need for repeat procedures is not uncommon and low seizure-free rates are reported, most likely reflecting the limited impact of the small lesions induced. Stereotactic radiofrequency thermocoagulation may only be suitable for small HHs.[42]

Neuroendoscopy

Neuroendoscopy is being increasingly utilized to resect or disconnect HHs,[13,15,42,62] with access to the third ventricle being obtained via a transcortical approach through the frontal horn of the lateral ventricle and the foramen of Monro.

Radiofrequency thermocoagulation can be combined with endoscopic access to disconnect or lesion HHs. Postoperative hospital stay is reduced with such minimally invasive procedures, but whether efficacy and safety are comparable with open craniotomy and resection is yet to be demonstrated in large series.

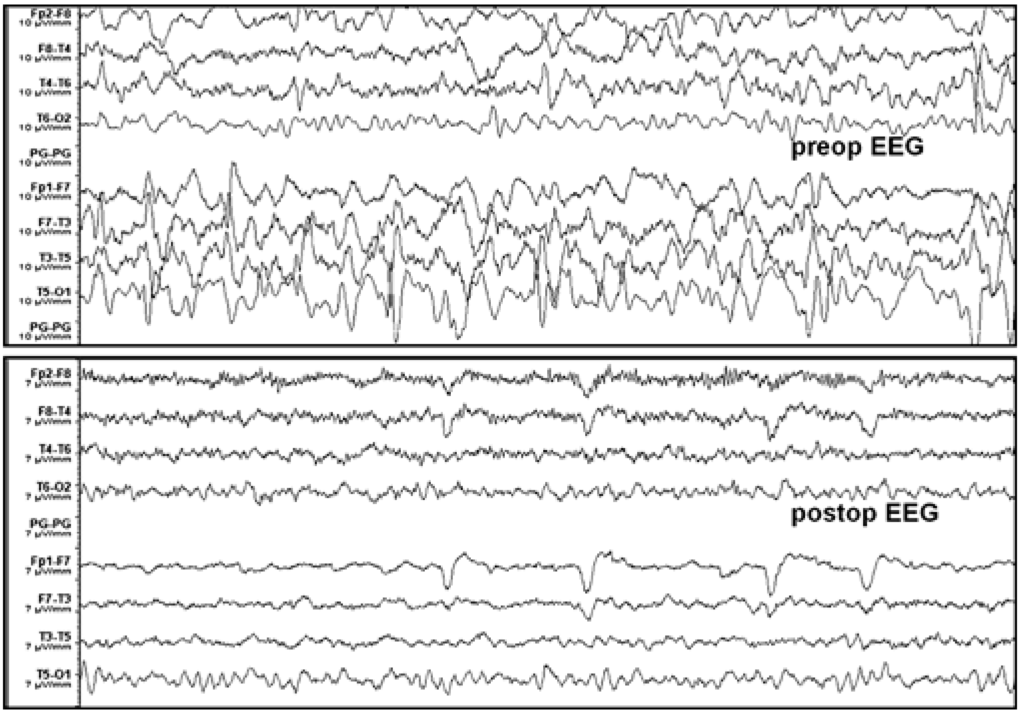

FIGURE 3. Interictal scalp electroencephalographic (EEG) recordings in a child with gelastic seizures and hypothalamic hamartoma who underwent transcallosal resection of the hamartoma. The preoperative awake EEG 8 days before surgery **(top)** showed multifocal epileptiform discharges predominantly on the left, which were abolished on the postoperative awake EEG 21 days following surgery **(bottom)**.

Stereotactic Radiosurgery

Stereotactic radiosurgery, such as with the Gamma Knife, delivers high-dose, ionizing radiation to a stereotactically defined intracranial target, with a steep radiation fall-off outside of the treated volume. Gamma Knife radiosurgery has been extensively applied to the treatment of HHs.[2,19,72,83,84] Like stereotactic radiofrequency ablation, Gamma Knife surgery is probably best suited for small HHs or for the hypothalamic attachment of larger HHs. Minimal morbidity and short hospital stays are clear advantages, whereas delayed seizure reduction is a disadvantage. Seizure-free rates are difficult to determine as large series are lacking. Stereotactic implantation of ^{125}I seeds into the HH is an alternative radiosurgical approach.[76,77]

Surgery Outcomes

If seizure outcomes are compared in patients undergoing only one surgical technique, and analysis is confined to series with adequate reporting and minimum 1-year follow-up, Engel class I or II outcome (seizure freedom, auras only, rare seizures only) is reported in 66% of patients undergoing transcallosal resection, 60% of patients undergoing endoscopic procedures, 38% of patients undergoing Gamma Knife surgery, 36% of patients undergoing pterional or frontotemporal approaches to resection or disconnection, and 27% of patients undergoing stereotactic radiofrequency ablation.[31] Neurovascular complications are significantly greater for operative compared with stereotactic approaches, especially for pterional and frontotemporal approaches. Endocrine and memory disturbances appear to be more common with the transcallosal approach. Seizure outcome does not seem to be related to patient age, the presence of generalized seizures, or HH size[33] such that all patients with HHs and refractory epilepsy should be considered for surgery. More data with longer patient follow-up are required to properly evaluate radiosurgery. Callosotomy and neocortical resection are failed operative approaches that are no longer advocated in patients with HHs.[11,61]

Improvements in behavior, school performance, and aspects of development are reported in many patients undergoing HH surgery, regardless of approach and seizure outcome. Amelioration of autistic features has also been noted in one case with postoperative seizure freedom.[67] Reduction of interictal spike-wave following HH surgery is reported[22] (Fig. 3) and is associated with improvements in alertness, language, and behavior. However, reversal of intellectual impairment is not reported.

Long-term Prognosis

In patients with HHs in whom seizures begin early in childhood, the prognosis for seizure control and neurologic development and behavior seem poor, especially if seizures begin in infancy and there is early evidence of seizure evolution. Favorable treatment outcomes seem only to occur in patients who undergo successful surgery early in childhood, before the development of severe neurologic sequelae.

Summary and Conclusions

A rare, severe, and once untreatable epileptic syndrome, HHGS is now better understood and being effectively treated with surgery. Early diagnosis is important and requires recognition of pathologic laughter and adequate MRI imaging and interpretation. While controlled trials of surgical treatments are unlikely, greater experience with transcallosal, endoscopic, and radiosurgical approaches should lead to a better understanding of the most effective and safe treatment for this condition.

Chapter 251

Localization-related Epilepsies Due to Specific Lesions

Noojan J. Kazemi

Terence J. O'Brien

Gregory D. Cascino

Introduction

The localization-related epilepsies are epileptic syndromes in which seizures arise in a geographically restricted area within a part of one or alternate hemisphere(s) (partial or focal seizures).[30] Lesional localization-related epilepsies are the most common group of medically intractable epilepsies seen in adults and are also an important cause of intractable seizures in children.[58,162] Magnetic resonance imaging (MRI) is the most sensitive and specific modality for imaging lesions in patients with focal epilepsies and has greatly improved our understanding of the nature and frequency of these lesions.[19,31,72,85]

Approximately 30% of patients who undergo surgical treatment for intractable epilepsy have a foreign tissue lesion detected on pathologic examination.[6] There is a strong correlation between the site of the lesion and the site of the epileptogenic zone.[5,14,25,119] The identification of an epileptogenic lesion on MRI has been cited as being as predictive of a poor response to antiepileptic drugs.[43] Furthermore, such patients are more likely to become seizure free postoperatively than those in whom no structural abnormality is found.[94,127,144] In a randomized, controlled trial for surgery versus medical treatment for medically refractory mesiotemporal lobe epilepsy, 58% of those treated surgically in addition to drugs were seizure free at 12 months compared with 8% in the only conservatively treated group.[159]

Historical Perspectives

Focal structural lesions, particularly brain tumors, have been recognized as a cause of seizures since ancient times.[148] Hughlings Jackson[73] wrote extensively of the relationship between partial seizures and underlying focal brain pathology. He stressed that seizures could be the first and only manifestation of the tumor, that ictal behavior may predict the cerebral localization of the lesion, and that the severity and type of seizures were not predictive of the nature of the underlying pathology. Horsley in 1886[66] reported three patients who had been cured of seizures by surgical excision of an underlying focal structural lesion. In the earlier part of this century, it was particularly the work of Penfield and colleagues[87,121] at the Montreal Neurological Institute (MNI) and of Falconer and Serafetinides[48] in London that advanced our understanding of localized cerebral lesions and epilepsy and of the surgical treatment of these conditions. It has been only since the advent of modern neuroimaging, however, that the true importance of local structural lesions as a common, surgically treatable cause of both temporal and extratemporal focal epilepsy has been appreciated.[6]

Definitions

For the purposes of this chapter, "specific lesions" are defined as discrete local (or regional) structural pathologies that are associated with chronic focal epilepsy. These local lesions most commonly occur in an otherwise structurally normal brain. More diffuse cerebral pathologies that may be associated with partial seizures but do not typically present as discrete mass lesions (e.g., diffuse neuronal migration disorders, Rasmussen encephalitis) are discussed elsewhere (Chapters 259 and 243). Mesial temporal sclerosis is discussed fully in Chapter 247.

Epidemiology

A large surgical series of patients with focal structural lesions comes from the MNI; Table 1 summarizes the results of this series and other selected epilepsy surgery series along with reported pathology. Surgical series, however, are subject to significant biases because patients with a known mass lesion are more likely to be referred to an epilepsy center and then proceed to surgery.[101] There is also a bias regarding the sites of the lesions reported in these series, with patients having temporal lobe seizures more likely to undergo epilepsy surgery. Furthermore, most of the patients in these series were collected before the advent of modern neuroimaging, when only large masses could be detected preoperatively. It is important to note that a number of pathologies associated with focal epilepsy, notably focal cortical dysplasias (FCDs) and dysembryoplastic neuroepithelial tumors (DNETs), were not recognized until the advent of high-quality magnetic resonance imaging.

Studies using high-resolution MRI have the potential to reduce some of the biases of these surgical series, and they may give a more accurate representation of the incidence and sites of occurrence of neocortical lesions in focal epilepsy. Because these series also come from large epilepsy referral centers, however, they are subject to some of the same referral biases. Ta-ble 2 summarizes four large, high-resolution MRI series. In comparison with the pathologic series, it is noteworthy that the proportion of extratemporal lesions is higher, as is the incidence of certain types of lesions, particularly FCDs and DNETs.

[c]Figures available for "brain tumors" only.
[d]Includes porencephaly and neurocysticercosis cases.
[e]Defined as gliosis.

Epidemiologic population-based studies of epilepsy have the potential to reduce the biases seen in both the surgical and MRI series.[57,71] Hauser and Kurland,[58] in one of the largest such studies (Rochester, Minnesota, from 1935 through 1967), found a focal mass lesion in only 27 (5.2%) of 516 cases given a diagnosis of epilepsy during this period. Of these patients, 21 had brain tumors (18 primary and 3 metastatic), 4 had vascular malformations, and 1 patient had tuberous sclerosis. This study was also performed before the advent of modern neuroimaging, however, and therefore it is likely to have underestimated the true incidence of lesions because most are indolent and produce

P.2512

no focal clinical impairment or electroencephalographic (EEG) slowing.[150]

The incidence of cerebral tumors in children undergoing epilepsy surgery may be higher than in adults, with estimates as high as 46%.[13,101] Studies using MRI also suggest that before the age of 12 years, lesional epilepsy, particularly gangliomas and disorders of cortical development (DCDs), may be more common and mesial temporal sclerosis (MTS) less common.[85,119,122]

Etiology and Basic Mechanisms

The pathophysiologic mechanisms by which intracranial mass lesions cause chronic seizure activity is poorly understood, but a number of theories have been advocated. One proposed mechanism is "denervation hypersensitivity," which results from the partial isolation of a part of the neocortex through tumor growth or brain scarring, thus creating enhanced excitatory status and epileptogenic potential.[41] The degree of mass effect of the lesion, however, is unrelated to the incidence of epilepsy.[8,95] There is some evidence that there may be a familial predisposition to epilepsy developing with mass lesions, but much of the data on this are conflicting.[14,109]

Low-grade tumors, which predominate in series of chronic lesional epilepsy, are rarely associated with pathologic evidence of hemorrhage, necrosis, inflammation, or ischemia, nor are they usually associated with significant mass effect.[101] Cerebral tumors may induce changes in the surrounding neocortex that affect the balance of neurotransmitter levels, synaptic receptors (especially for *N*-methyl-D-aspartate [NMDA] or γ-aminobutyric acid [GABA]), or ion channels (e.g., increased leakage of axonal calcium or chloride channels).[21] In support of this theory, Bateman et al.[8] demonstrated an increased concentration of glutamine (the precursor to the excitatory neurotransmitter glutamate) in the gliomas of patients with epilepsy compared with gliomas from patients without seizures. Glutamine has been shown to be released and taken up by glioma cells.[106,156] Decreases in concentrations of the inhibitory

P.2513

neurotransmitter GABA have also been demonstrated in gliomas of patients with seizures[8] and in the surrounding non–tumor-infiltrated neocortex.[10] Expanding tumors may also interfere with vascularization of the surrounding cerebral cortex, creating a region of relative cerebral ischemia having an increased epileptogenic potential.[126]

In vascular malformations, pathologic studies have shown the presence of neuronal loss, gliosis, demyelination, and hemosiderin deposition in the surrounding cerebral cortex, which may act as a focus for epileptogenesis.[97,145] It has been suggested that the increased epileptogenic potential associated with these lesions is caused at least in part by the effects of repeated subclinical hemorrhage and resultant hemosiderin deposition.[21,145,169] Dodick et al.,[38] however, showed that hemosiderin deposition could not be the sole mechanism of epileptogenesis in patients with vascular malformations. Alternatively, ischemia in the brain surrounding an arteriovenous malformation (AVM) caused by arteriovenous shunting of blood may result in an area of epileptogenic encephalomalacia.[167]

Clinical Presentation

It has been appreciated for more than a century that the clinical history and ictal behavior may give a clue to the site of the underlying epileptogenic lesion.[73] Since the advent of MRI, however, it has become clear that a large overlap exists in the ictal symptomatology produced by lesions at different cortical locations. Lesions at any site may result in simple partial, complex partial, or secondarily generalized seizures. Complex partial seizures are often thought to indicate temporal lobe seizures, but in a study of high-resolution MRI in 129 consecutive patients with video-EEG-proven complex partial seizures, discrete neocortical lesions were detected in 58 (45%), of which 22 (37.9%) were extratemporal (15 frontal, 4 frontoparietal, 1 parietal, and 2 occipital).[108] Boon et al.,[14] in 51 patients with lesions, found that although all patients with temporal lesions had complex partial seizures, 74% of patients with extratemporal lesions also had complex partial seizures. This study also found that although visual auras may give a clue to the presence of an occipital lesion, the nature of the aura was not otherwise useful in predicting the location of the lesion.

The clinical features, including seizure type, age of patient at onset, and duration of epilepsy, response to antiepileptic drugs, and findings of neurologic examination, are not useful in predicting the nature of the underlying lesion.[126] Patients tend to have a long history of seizures before surgery, and even patients with tumors do not commonly have an increasing frequency of seizures.[87,101,140] Careful neurologic examination in patients with low-grade tumors may occasionally detect focal signs, such as visual field loss, unilateral facial weakness, or progressive sensory loss or hemiparesis, but findings are normal in the vast majority of patients.[21,101]

Diagnostic Evaluation

The identification of a lesion in a patient with intractable epilepsy is not sufficient grounds to proceed directly to surgical excision, because the zone of seizure onset may occasionally be at a site remote from the lesion.[5,14,20,85]

P.2514

Furthermore, patients with potentially epileptogenic lesions have been found after evaluation to have idiopathic generalized epilepsy or nonepileptic seizures. It is therefore important that all patients with intractable epilepsy have a comprehensive presurgical evaluation to ensure that the identified lesion is the source of the seizures. A great deal of caution, however, should be exercised before determining that the MRI lesion is *not* the source of the seizures; both extracranial and intracranial EEG can be misleading in lesional epilepsy,[5,23] and if the apparent epileptogenic zone is excised without the lesion, the results are likely to be poor in these patients.[50] Of course the reverse also holds true. The second important aspect of the presurgical evaluation is precise definition of the location and extent of the lesion, so that an operative strategy can be planned allowing maximal potential for a seizure-free outcome while minimizing the chance of a disabling postsurgical neurologic deficit.

Clinical Evaluation

As with all epilepsy patients, it is very important that a thorough history be taken. Questions should specifically be asked about factors that may suggest another source of seizures than the identified lesion—for example, a history of febrile convulsions, significant head trauma, intracranial infections, other neurologic disorders, or a family history of epilepsy. A careful neurologic examination should be performed in which focal deficits that may help to localize or lateralize the lesion are sought with particular care. It is now generally accepted practice that all patients also undergo visual perimetry, neuropsychological, and psychiatric evaluation before undergoing epilepsy surgery.

Neuroimaging

High-resolution MRI seizure protocols have virtually a 100% detection rate for tumors and vascular malformations, and improvements in technique have allowed the vast majority of focal DCDs also to be detected.[31,71] It may be difficult from the MRI appearance to predict the precise histologic tumor type, and FCD can sometimes be difficult to distinguish from low-grade cortical tumors.[71] The presence of a lesion on MRI concordant with the site of seizure onset has proved to be the best prognostic factor for a good postsurgical outcome if the lesion is included within the planned resection.[5,12,14,23,60,139]

The MRI data should be acquired using a seizure protocol that includes thin (1.5 or 1.6 mm), T_1-weighted volumetric slices of the *whole brain*.[71] This maximizes structural resolution and allows for reformatting, which is essential for the accurate detection of small cortical dysplasias, in which the only abnormality may be a subtle thickening of the cortex that is difficult to distinguish from volume averaging of normal cortical gyration.[31,71] T_2-weighted spin-echo and spin-density sequences may reveal areas of high signal in small cortical tumors, cortical dysplasias, and cortical sclerosis in some patients that are not obvious on the T_1 images.[71] Certain pulse sequences, especially fast fluid inversion recovery imaging (FLAIR), may increase the sensitivity for small cortical abnormalities.[132]

Even after the detection of one lesion, the whole-brain MRI needs to be carefully examined for the presence of coexistent hippocampal atrophy or a second neocortical lesion because a number of patients with lesional epilepsy may have dual pathology.[6,21,26,51] Cendes et al.[26] found that 15% of 167 patients with lesional epilepsy also had hippocampal atrophy. The incidence was particularly high in patients having DCDs (25%), porencephalic cysts (31%), and reactive gliosis (23.5%) compared with those having tumors (2%) or vascular malformations (9%), which suggests a common etiology during embryogenesis or early development. The identification of coexistent hippocampal atrophy in a patient with lesional epilepsy can alter the surgical strategy because these patients may have a worse outcome following lesionectomy alone.[24,51]

A carefully analyzed high-resolution MRI is essential for presurgical planning and accurate definition of the site and extent of the lesion.[31] This is especially important if a stereotactic lesionectomy is planned rather than epilepsy surgery with excision of the surrounding epileptogenic cortex.[25] Functional MRI can be used to localize eloquent cortex when the planned excision may impinge on these areas.[86]

Functional Neuroimaging

^{18}F-Fluorodeoxyglucose Positron Emission Tomography

There is evidence from studies of patients with MTS that the focal region of hypometabolism seen on ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) in many patients with focal epilepsy represents a functional rather than a structural change.[60,110] Therefore, FDG-PET may potentially have a role in defining the extent of the surrounding epileptogenic zone in lesional epilepsy. Traditionally, studies had found a poor correlation between the extent of the hypometabolic area and the extent of electrically abnormal cortex.[42] Due to major technical improvements in PET imaging, however, recent studies have demonstrated correct localization of the seizure focus, as correlated with MRI or EEG, in 62% to 100% of patients.[76,103,146,164] O'Brien et al.[107] demonstrated that FDG-PET had a significant effect on changing management in 45% of patients with intractable epilepsy, with a further 13% benefiting through increased confidence in localization and ultimately epilepsy surgery, despite the availability of other localizing information. The evidence is suggestive that localization of epileptogenic lesions by PET is greater for temporal lobe lesions than for extratemporal lobe lesions, especially when PET is assessed visually.[100,107]

Single Photon Emission Computed Tomography

Weis et al.[158] found that in temporal lobe epilepsy (TLE), the sensitivity of ictal single photon emission computed tomography (SPECT), in which the radiotracer (^{99m}Tc-D, L-hexamethylpropylene amine oxime [HMPAO]) is injected during a seizure, was lower in patients with structural lesions of the temporal lobe (56%) than in those with MTS (92%) or a normal MRI (88%). Coregistration of the ictal SPECT and MRI (SISCOM) constructs a difference image between the ictal and interictal SPECT and then coregisters it to the patient's MRI for anatomic localization. SISCOM aids in accurately identifying the regions of activation with ictal SPECT and also provides an objective way to quantitatively compare images from different patients or groups of patients.[111,112,113,114,115] SISCOM can play a role in lesional epilepsy when other data about the relationship of the structural lesion to the epileptogenic zone are conflicting and might aid in identifying the epileptogenic lesion in the case of dual pathology, but this requires further study.

Interictal Electroencephalography

Focal polymorphic delta activity, which is said to be the EEG hallmark of cerebral mass lesions, is relatively uncommon in patients with chronic lesional epilepsy.[14,67,140] Boon et al.[14] found that interictal focal sharp waves were more common than focal slow waves, but that 34% of patients had neither. O'Brien et al.,[109] comparing TLE patients having temporal neocortical lesions with those having MTS, found that the lesional patients have a higher incidence of interictal epileptiform activity (60% vs. 37%) and focal slowing (66% vs. 41%). However, no interictal EEG abnormality was found in 27% of lesional patients.

Boon et al.[14] found that unilateral temporal spikes predicted the side of the lesion correctly in 29 of 30 patients; however, the correlation of location of the spikes with site of the lesion was poor, being correct in only 30% of patients. A similar proportion of patients with temporal and extratemporal lesions had ipsilateral temporal spikes (44% vs. 39%), with bilateral independent spikes occurring in 22%. Other studies have also demonstrated that bilateral independent temporal spikes are not uncommon with unilateral lesions but that this does not correlate with a poor surgical outcome.[21,125,127]

Video-electroencephalography

Closed-circuit video-EEG is an important part of the routine presurgical evaluation of a patient with lesional epilepsy. At least one typical seizure should be recorded. In most cases, careful analysis of the seizure semiology and the ictal EEG will allow a confident determination that the site of seizure onset is concordant with the site of the lesion.[21,162] It is important to note, however, that extratemporal neocortical lesions can spread rapidly to the mesial temporal structures, producing semiology and ictal EEG findings that are indistinguishable from those of temporal seizures.[50,160,161]

The scalp ictal EEG is often poorly localizing in patients with lesional epilepsy.[21] O'Brien et al.,[109] analyzing 46 seizures in 15 patients with temporal neocortical lesions, found a clearly localized ictal EEG onset in only 14 (30.4%), with another 15 (32.6%) having an onset that began diffusely in the temporal lobes. The ictal EEG was more accurate in lateralization, with the onset being correctly lateralized in 31 (78%), nonlateralized in 8 (20%), and incorrectly lateralized in only 1 (3%). However, Boon et al.[14]

found an unequivocally lateralized scalp ictal EEG in only 58% of their patients, and one of these cases was falsely lateralized. Morris and Estes[101] reported that in their series of patients with brain tumor, the combination of ictal and interictal EEG agreed with the lobe of the lesion in 72% of cases and was correctly lateralized in another 17%.

Intracranial Electroencephalography

Intracranial EEG monitoring is not routinely required for all patients with lesional epilepsy.[21] If the results of the noninvasive evaluation are concordant with the site of the lesion, then surgery can be recommended without invasive studies being required. Intracranial studies are principally reserved for two situations: (a) Results of the noninvasive evaluation give conflicting information or suggest that the lesion is remote from the source of the seizures, and (b) preoperative mapping of the eloquent cortex using subdural strips is required when the planned resection may involve these areas.

Unfortunately, even intracranial EEG is often nonlocalizing or misleading in patients with lesional epilepsy.[41] Williamson et al.[160] studied 9 patients having parietal mass lesions with depth electrodes, parietal grids, or both, and consistently found a localized seizure onset in the parietal lobe in only 3. In 4 patients, the onset was diffuse and poorly localized, and in 2 the seizures were apparently of mesial temporal onset (1 bilateral independent).

Intraoperative Neurophysiologic Techniques

Intraoperative electrical cortical stimulation can accurately define the speech area and the motor strip and allows the cortical resection to be performed to within 1 cm of these areas.[101] Intraoperative mapping requires a very cooperative patient, however, because it is performed under local anesthetic, and the complexity of the language tasks that can be tested is limited. Intraoperative somatosensory-evoked potentials can also be helpful in defining the motor strip.[102] Functional mapping can also be performed using an implanted subdural electrode array.[14,94] This technique has the dual advantage of enabling the recording of interictal and ictal intracranial EEG and allowing the patient to be evaluated in a more comfortable setting with more complex and extensive tests.[21]

Differential Diagnosis

Tumors

Epilepsy caused by brain tumors represents 3.5% to 5% of all cases of epilepsy and 16% of cases seen in adults, and tumors are the most common cause for new-onset epilepsy in persons between the ages of 35 and 55 years.[46] Low-grade or slow-growing or indolent tumors are the most highly epileptogenic.[157] In their review of the MNI series, Le Blanc and Rasmussen[87] determined that the incidence of epilepsy in patients with supratentorial tumors was approximately 50%. The site of tumors in the hemispheres is related to their epileptogenicity; individuals with tumors of the centrotemporoparietal region have the highest incidence of epilepsy (approximately 75%). Lund[95] found in 615 cases that the depth of the tumor also was related to the incidence of epilepsy, with epilepsy occurring in association with 63% of “superficial and cortical” tumors and only 29% of “deep and noncortical” tumors.

Gliomas

Gliomas account for 72% to 88% of tumors in patients with chronic epilepsy, of which 50% to 70% are low-grade astrocytomas; oligodendrogliomas, gangliomas, and mixed gliomas account for the remainder.[80,127] Le Blanc and Rasmussen[87] found that oligodendrogliomas had the highest epileptogenic potential (92%), followed by astrocytomas (70%) and glioblastomas (35%). High-grade glial neoplasms and metastatic tumors are rare in series of patients with chronic epilepsy.

Astrocytomas most often appear in the third and fourth decades, and seizures are the most common clinical manifestation.[101] Oligodendrogliomas tend to appear in the fourth to fifth decades, although they can occur in children.[28,93] Some calcification is present in up to 90% of patients, and therefore many are seen on CT. Gangliomas represent only 0.7% to 6% of brain tumors overall, but they are overrepresented in series of patients with chronic focal epilepsy, with estimates of their incidence ranging from 10% to 50%.[4,81,101,163] These tumors seem to occur preferentially in the temporal and frontal lobes.[70]

Meningiomas

Meningiomas are the most common benign intracranial tumor, especially in middle age, representing about 15% of all primary

P.2516

brain tumors.[46] Seizures are estimated to occur in 60% to 75% of all patients with these tumors.[79,87]

Dysembryoplastic Neuroepithelial Tumors

Dysembryoplastic neuroepithelial tumors are an important cause of focal epilepsy that has only relatively recently been recognized.[35] A number of the patients that were classified as having low-grade gliomas or hamartomas in older series probably had DNETs. A recent series of 216 temporal lobectomies found that DNETs comprised 8% of lesional cases.[163] They have a predilection for the temporal lobes, but they also often occur extratemporally, especially in the frontal lobes.[35] These lesions usually develop within dysplastic cortex, and it is thought by some authors that they would be better classified as a neuronal migration disorder rather than as a tumor.[71]

Disorders of Cortical Development

Taylor et al.[147] first recognized cortical dysplasia in their pathologic study of postsurgical specimens of patients with intractable epilepsy. The importance of DCDs as a cause of focal epilepsy, however, has been widely appreciated only since the development of high-resolution MRI. The derangement of cortical structure associated with these lesions can be relatively subtle and is not well detected by CT or earlier MRI methods.[31,71,85,119] Even with high-resolution MRI, these lesions are easily overlooked because they are often difficult to detect on standard planar images acquired with thick slices (see Chapter 79 for further discussion).

The DCDs have been classified according to MRI findings as generalized, unilateral hemispheric, and focal.[20] In this chapter, the focal DCDs are emphasized; these include FCDs, focal subependymal heterotopias, polymicrogyria, and schizencephaly (see Chapter 259 for a more complete discussion).[20,85,119] In a series of 49 patients with DCD and chronic focal epilepsy reported by Andermann and Palmini,[3] 30 had unilateral localized areas of abnormalities (either FCD or tuberous sclerosis in forme fruste), 10 had bilateral abnormalities, and 9 had a generalized DCD.

Focal cortical dysplasias, schizencephaly, and microdysgenesis usually have no apparent inheritance pattern and are likely caused by cerebral insults occurring during perinatal development.[71] The initial seizures in patients with focal DCD usually occur in the first decade of life.[119,147]

Focal cortical dysplasia is the most common type of focal DCD. Definitions of the term *cortical dysplasia* have varied from a subtle degree of disorganized cortical architecture with or without neuronal cytomegaly to profound abnormalities, such as lissencephaly and polymicrogyria.[154] Tuberous sclerosis in forme fruste is usually classified as a DCD because clinical and imaging studies cannot reliably differentiate it from FCD, and pathologically it is also often very difficult to make the distinction.[80]

Neuronal heterotopias may include several patterns, but nodular and laminar heterotopias are most frequently associated with epilepsy.[80] Nodular heterotopias consist of discrete, isolated regions of gray matter that occur in the periventricular region. They may also be associated with other abnormalities, such as polymicrogyria or pachygyria. Laminar heterotopias are elongated islands of neurons that occur as bands in the white matter separated from the cortex or ventricular wall. Heterotopias are believed to result form an arrest during neuronal migration.

Focal schizencephaly is characterized by a communication between the ventricle and the surface of the brain, which is often lined by polymicrogyrous cortex.[3] Focal unilateral schizencephaly is commonly associated with epilepsy, and surgical excision of the most epileptogenic areas can lead to a reduction in seizure frequency.[89]

Cerebral Vascular Malformations

The estimated seizure risk in patients with vascular malformations is 1.5%/person-yr.[34] The types of vascular malformations are, in decreasing order of frequency, arteriovenous malformations (AVMs), cavernous hemangiomas, venous angiomas, and capillary telangiectasias.[142] Venous angiomas and capillary telangiectasias are only rarely associated with seizures.[6]

Arteriovenous Malformations

Arteriovenous malformations are congenital vascular abnormalities consisting of communicating arteries and veins without intervening capillary beds. Seizures represent the second-most-common presenting feature of AVMs after cerebral hemorrhage (17%–40% of cases).[63,88,168] In an international multicenter trial, Hofmeister et al.[63] demonstrated that 30% of all patients with AVMs experienced generalized seizures, with 10% experiencing focal seizures. Hoh et al.[64] reported that male gender, age <65 years, AVM size <3 cm, and temporal lobe AVM location were significantly associated with an increased incidence of seizures. Posterior fossa and deep locations were not statistically associated with seizures.

Others have also confirmed that patients with larger AVMs (>3 cm) are more likely to have seizures.[88,123] Seizures are more frequent with AVMs situated in the posterofrontal and temporal lobes.[123]

Cavernous Angiomas

This benign vascular anomaly consists of a tangled mass of tightly arranged abnormal vessels made of common hypocellular walls,[80] and it represents about 5% to 20% of all vascular malformations of the central nervous system.[49] Seizures, estimated to occur in 40% to 70% of patients, are often the most common and only clinical manifestation of cavernous angiomas,[29,151] typically commencing in the 30- to 40-year age group.[49] On MRI, these lesions have a characteristically high T_2 signal core surrounded by a low signal halo (caused by hemosiderin deposition in macrophages), which results in a "targetlike" appearance.[141] It is theorized that the excess iron deposition may act as an electron donor providing free radicals and lipid peroxides, which can lead to neuronal excitability and hence seizures.[82,155] In some patients the coexistence of hippocampal sclerosis may be present (dual pathology), complicating potential surgical management.[24]

Cysts

Several studies have found a higher-than-expected frequency of seizures in patients with porencephalic cysts.[1,149] Porencephalic cysts have also been found in surgical specimens from patients undergoing resective surgery for intractable partial seizures.[1] One study of 10 patients with arachnoid cysts and intractable seizures found no other explanation for the seizures in 8.[129] Accurate localization of the epileptogenic foci has been difficult traditionally, and hence either surgical resection has been discouraged or functional hemispherectomy has been performed, especially on patients with significant deficits.[62,68]

Infectious Lesions

Neurocysticercosis

In countries where it is endemic, neurocysticercosis may affect from 2% to 4% of the population.[36] It is estimated that 50% to 70% of patients with neurocysticercosis have epilepsy, and it is the most common cause of adult-onset epilepsy in developing countries.[37,99] It is now being increasingly recognized as a cause of epilepsy in Western countries as a result of increased migration from endemic areas and of improved neuroimaging, which can detect the typical multiple cystic lesions.[126] In most patients with neurocysticercosis, epilepsy is the only clinical manifestation, with only a minority of patients having focal neurologic symptoms or signs.[37]

Cerebral Tuberculoma

Cerebral tuberculomas are now very rare in Western countries, but they still represent up to 20% to 40% of intracranial tumors in developing countries.[126] They can appear even after the apparently successful treatment of systemic or central nervous system tuberculosis, and seizures are not uncommonly the first manifestation.[56]

Treatment and Outcome

Antiepileptic Drugs

The medical treatment of lesional epilepsy does not essentially differ from that of other localization-related epilepsies. Monotherapy with carbamazepine or phenytoin is generally accepted as the first line of treatment in many countries, and the drugs are probably of equal efficacy.[96] Valproic acid, alone or in combination with one of the aforementioned drugs, is also effective in some patients. Phenobarbital and primidone may control seizures, but they frequently result in unacceptable behavior and cognitive disturbances and therefore are no longer recommended as first-line therapy. Many patients with lesional epilepsy continue to have poorly controlled seizures despite treatment with antiepileptic drugs (AEDs),[43] and these patients need not be subjected to prolonged, unsuccessful trials of multiple different drugs, or polypharmacy, before surgical therapy is considered.

Surgical Treatment

It is well documented that surgery is a successful treatment for medically intractable localization-related seizures associated with structural lesions.[21,39,55,159] As mentioned previously, in a randomized, controlled trial comparing surgical resection with medical treatment for intractable temporal lobe epilepsy, 58% of those undergoing surgery in addition to continued AED treatment were seizure free compared with 8% in the purely medical group at 12 months.[159] The greatest controversy in the surgical treatment of lesional epilepsy is the relative importance of excision of the structural lesion as opposed to the epileptogenic zone. The nature of the relationship between the two is relatively poorly understood, and hence the surgical strategy lacks an irrefutable physiologic basis.[51]

Resection of the Epileptogenic Region

A number of series have found that up to 90% of patients with intractable seizures secondary to tumors become seizure free when both the structural lesion and the epileptogenic cortex are resected ("seizure surgery").[10,13,14,15,18,165] There is some evidence that epileptogenic cortex may develop independently secondary to a noncontiguous structural lesion and that the epileptogenic zone may not be restricted to the lesion site.[5,39,54] Some authors have also found that complete excision of both structural lesion and epileptogenic cortex is necessary for worthwhile seizure reduction.[11,135,167]

However, resection of the epileptogenic zone in addition to the structural lesion involves a larger area of brain excision. The rate of operative morbidity increases dramatically when eloquent cortex is removed in an attempt to resect the epileptogenic zone,[117] and this approach does not necessarily improve postoperative seizure control.[128,138] Resection of the epileptogenic cortex alone, without the structural lesion, is likely to result in an unfavorable outcome. Siegel et al.[135] found that seizure freedom occurred in their patients only when a second operation was performed to resect an epileptogenic zone surrounding a previously resected cavernous angioma. Fish et al.[50] found that of 19 patients with small posterior structural lesions who had had resections limited to the epileptogenic zone in the anterior temporal lobe, only 2 became seizure free. The epileptogenic zone is likely to be a direct consequence of the structural lesion,[157] and therefore epilepsy surgery should include excision of the structural lesion whenever possible.

Lesionectomy

Patients often become seizure free, or have a decrease in seizure frequency, after simple lesionectomy.[22,61] Furthermore, the structural impact of the lesion appears to be reversible in some patients following lesionectomy, so that the previously epileptogenic cortex is free of electrical activity.[157] In addition, Falconer et al.[47] showed that even when the EEG abnormalities remain after the structural lesion is removed, clinical seizures often do not persist.

The studies of both Casazza et al.[17] and Zevgaridis et al.[171] did not find that the additional excision of hemosiderin-stained tissue around a cavernous angioma improved seizure freedom compared with resection of the lesion alone. Goldring et al.,[55] in a study evaluating the surgical outcome of 20 patients undergoing temporal lobe lesionectomy mainly for low-grade tumors, found that only one patient continued to have long-term postoperative seizures. Awad et al.[5] found that 79% of patients became seizure free when the epileptogenic cortex was completely resected without regard to the structural lesion, compared with 90% following lesionectomy alone regardless of complete excision of epileptogenic brain tissue. An alternative to standard neurosurgical lesionectomy is stereotactic lesionectomy. This is particularly useful in reducing morbidity in patients with deep-seated intra-axial lesions and lesions encroaching on functional cortex.[2,25,78] Cascino et al.[25] found that 74% of 23 patients who underwent stereotactic lesionectomy had a marked reduction in seizure activity, with 5 patients able to discontinue antiepileptic drugs.

Table 3 Results of surgical series of patients undergoing lesionectomy only

Study (ref.)	Structural lesion	Number of cases	Follow-up	Seizure free (%)

Unfortunately, few studies have directly compared lesionectomy with more extensive epilepsy surgery. Awad et al.[5] found no significant difference in seizure-free outcome between patients who underwent simple lesion removal and those who underwent surgery directed at removal of the epileptogenic zone (Tables 3 and 4). Weber et al.[157] used meta-analysis to compare studies reporting outcomes of simple lesionectomy with those reporting more extensive epilepsy surgery, and found that more patients were seizure free 2 years after “seizure surgery” than after lesionectomy. Tables 3 and 4 compare selected studies reporting postsurgical outcome in patients undergoing lesionectomy alone and those undergoing surgery involving resection of the epileptogenic cortex.

P.2518

Treatment and Outcome for Different Lesions

Tumors

Older AEDs, including phenytoin, carbamazepine, and phenobarbital, have been reported to produce more idiosyncratic effects in patients with brain tumors than in the general epilepsy population.[130] These anticonvulsants induce cytochrome P450 enzymes, and it has therefore been proposed that they interfere with other commonly used drugs and increase chemotherapeutic agent clearance.[152] Most cerebral tumors are considered for surgical resection. In 51 patients who were operated on at the Mayo Clinic for intractable epilepsy caused by low-grade neoplasms, 66% were rendered seizure free and 88% experienced a significant reduction in seizure frequency.[15] Le Blanc and Rasmussen[87] reported that of 171 patients with astrocytomas and other low-grade cerebral neoplasms treated with tumor resection and excision of the epileptogenic cortex, 41% were rendered seizure free and 70% had at least a marked reduction in seizure frequency. Most patients in this study also had postoperative radiotherapy; this is of unproven benefit, however, in patients with low-grade gliomas in whom a complete tumor resection has been achieved and is generally reserved for cases of tumor recurrence.[101] In patients with unresectable gliomas, radiotherapy alone, after biopsy conformation of the pathologic diagnosis, may result in a significant reduction in seizure frequency, with some patients being rendered seizure free.[55,131]

Complete resection of meningiomas is usually curative.[46] Surgical excision of meningiomas can achieve seizure freedom in up to 63% of patients.[92] Patients with gangliomas generally have a good postsurgical prognosis with regard to seizures, and Otsubo et al.[118] found that 22 of 25 surgically treated children were either seizure free or had >50% reduction in seizures. In a series of 29 adult and pediatric patients experiencing intractable seizures associated with gangliogliomas, Im et al.[69] reported that 76% were rendered seizure free and 59% had completely ceased anticonvulsant medications after surgical resection.

Radiotherapy is usually reserved for patients with postsurgical tumor recurrence, or the rare patient with an anaplastic ganglioma.[74] Complete surgical excision is usually curative for DNETs, and an excellent outcome with respect to seizures can be expected in about 90% of patients.[35] Chan et al.[27] demonstrated that temporal lobectomy for DNETs was significantly better associated with seizure freedom than was lesionectomy (83% Engel class 1). In contrast, however, only 10% of patients with glioblastomas and other aggressive malignant lesions become seizure free postoperatively.[128]

P.2519

Disorders of Cortical Development

There is some evidence that focal DCD have a worse outcome following epilepsy surgery than other lesional types, with only 2 of 26 patients reported by Andermann and Palmini[3,119] becoming seizure free and 9 having >90% reduction in seizure frequency. They found a good correlation between outcome and amount of the lesion removed. Sisodiya et al.[137] demonstrated that in 15 of 18 patients with FCD, the abnormalities in distribution of gray and subcortical white matter volumes extended beyond the margins of the lesions as visualized on MRI. Therefore, the apparently worse outcome in patients with focal DCD may be a result of the lesion often being more extensive than the region of surgical excision. More recently, other authors report better postsurgical results, with Kral et al.[83] finding that 38 of 53 patients with focal cortical dysplasia who had cortical resections became seizure free postoperatively; a similarly good outcome was found by Hong et al.[65]

Vascular Malformations

Arteriovenous malformations are associated with a significant lifelong risk of hemorrhage and a significant risk of morbidity and mortality; prevention of this complication is the most common indication for surgical excision in these patients.[16] The efficacy of surgery in treating seizures associated with AVMs is more controversial. A number of earlier authors report disappointing results, with some even finding an increase in seizure frequency postoperatively.[33,104,120] Most recent surgical series, however, have found that many patients with AVMs have a good postoperative outcome with respect to seizures.[38,64,123,150,167,169] Dodick et al.[38] found that three fourths of patients with epilepsy secondary to a vascular malformation were seizure free after lesion resection, and most of the remaining patients had a significant reduction in seizure frequency. Yeh et al.[169] found that several factors correlated with outcome, including age at seizure onset, duration of seizures, location of lesions, and cortical excision of the epileptogenic zone. Radiosurgery is an accepted treatment measure for AVMs not suitable for surgical resection and is largely reserved for lesions <3 cm in size.

In cases of intractable seizures caused by cavernous hemangiomas, Cohen et al.[29] advocated lesionectomy alone for patients having fewer preoperative seizures and shorter seizure histories (<1 year) but an increased margin of resection for patients with longer seizure histories or more frequent seizures. In cases of dual pathology, however, lesionectomy has not resulted in seizure control, and subsequent resection of the mesial temporal structures is necessary to achieve a satisfactory outcome.[17,24,90]

Neurocysticercosis

Patients with inactive calcified neurocysticercosis can usually be adequately controlled on standard monotherapy for most localization-related epilepsy, for example, with carbamazepine or phenytoin. However, Del Brutto et al.[37] found that seizure control was significantly improved in patients with active neurocysticercosis by simultaneous treatment with anticysticercal drugs (praziquantel or albendazole), with 83% of such treated patients remaining seizure free compared with only 26% of those treated with antiepileptic drugs alone. In patients with multiple cysts, increased seizures and neurologic signs may develop soon after commencement of anticysticercal drugs as a result of an intense inflammatory reaction to the dying cysticerci in the surrounding brain. Coadministration of cortico-steroids may minimize this complication.[36] Occasionally, large cysts causing significant mass effect may require surgical removal (see also Chapter 265).

Long-Term Prognosis

When seizures are adequately controlled with antiepileptic drugs, patients must usually continue to take them indefinitely. Recurrence of seizures will occur in most patients on withdrawal of antiepileptic drugs because they merely suppress seizures, whereas the underlying epileptogenic lesion remains unchanged.

Following epilepsy surgery, patients who have discrete structural lesions (including mesial temporal sclerosis) have a better long-term outcome with respect to seizures than those who do not.[44] An earlier study by Berkovic et al.[12] using actuarial analysis to assess the outcome at 60 months in 135 surgically treated patients with TLE found that 69% of patients with a foreign tissue lesion on the preoperative MRI had no postoperative seizures, compared with 50% of those with hippocampal sclerosis and 21% of those with normal findings on MRI. In a more recent publication by the same group assessing long-term outcome, 328 patients underwent anterior temporal lobectomy over a 20-year period.[98] This study reported that 59.6% of lesional patients achieved seizure freedom at 10 years, with 47% of patients with hippocampal sclerosis achieving the same in this time period. The group with no discernible lesions on preoperative studies did most poorly, with 18.2% achieving seizure freedom at 10-year follow-up. These results are confirmed by other studies.[40,170]

Tumors

As previously discussed, tumors resulting in chronic epilepsy are usually of low grade and slowly growing. In patients with gliomas in whom seizures are the sole clinical manifestation, the clinical course tends to be more protracted and indolent than in other patients with gliomas, and survival for 10 to 20 years is not uncommon.[124,134] Depending on the grade, patients with oligodendrogliomas have been reported as demonstrating 5-year survival of 73% and 10-year survival of 49%,[59] with median survival time of 11.6 years.[116] Overall, patients with gangliogliomas have a better prognosis for long-term survival than those with histologically similar astrocytomas or mixed glial tumors, but gangliogliomas arising in the midline may be more aggressive and are associated with a poorer prognosis.[74]

Serial MRI is mandatory to follow patients with low-grade tumors in whom surgery has not been performed, and the appearance of such lesions can remain remarkably constant on repeated examinations over time.[55,140] An increase in size, mass effect, or degree of contrast enhancement of the lesion or the development of surrounding cerebral edema, however, suggests transformation to a higher-grade tumor. Serial MRI is also mandatory in following patients who have had surgery because recurrence of the tumor may be an indication for further treatment such as radiotherapy. Tumor recurrence may also be suggested by return of seizures in a patient who was initially rendered seizure free following surgery.[101]

Disorders of Cortical Development

Most patients with DCD reported in the literature have had medically intractable seizures, but this is likely to reflect at least in part a selection bias because almost all these series are from large epilepsy referral centers.[3] More recent studies report that among patients with focal cortical dysplasia, up to 72% may be

P.2520

rendered seizure free with epilepsy surgery.[84] Routinely, studies examining outcome from medical treatment alone report lower rates of seizure freedom, ranging from 24% to 54%.[7,133,143]

Vascular Malformations

Crawford et al.,[32] in a long-term follow-up study of 217 patients with unoperated AVMs, found that those without a history of hemorrhage in whom epilepsy was the primary clinical manifestation have a somewhat lower long-term risk for hemorrhage than other patients with AVMs (30% vs. 42% at 20 years). If there was a history of hemorrhage, however, the risk for a further hemorrhage increased to 51% at 20 years. Of the patients in this study who had a hemorrhage during the follow-up period, 25% died as result of that hemorrhage. The risk for cerebral hemorrhage with cavernous hemangiomas is lower than that for AVMs but is reported to occur in 10% to 30% of patients.[49]

Hoh et al.[64] demonstrated that in AVMs treated via a multidisciplinary approach, short seizure history, seizures linked to intracranial hemorrhage, generalized tonic–clonic seizures, deep and posterior fossa AVMs, and surgical resection and complete AVM obliteration were associated with Engel class 1 seizure frequency outcome. Thorpe et al.[150] found that multiple seizures and poor neurologic outcome postoperatively were independent factors predictive of the incidence of postoperative seizures.

Neurocysticercosis

Despite the fact that excellent control of seizures is usually obtained with antiepileptic and anticysticercal drugs, achievement of a long-term seizure-free state without drug therapy is difficult. Del Brutto et al.[37] found that 16 of 21 patients with epilepsy and neurocysticercosis who had been seizure free for 2 years while taking antiepileptic drugs relapsed when the drugs were withdrawn.

Summary and Conclusions

Of all patients who undergo surgery for chronic intractable epilepsy, 30% have a discrete structural lesion. There is a strong correlation between the site of epileptogenesis and the epileptogenic zone. Common structural lesions include low-grade neoplasms, vascular malformations, and disorders of cortical development. Cysticercosis and tuberculomas are increasingly being seen in developed countries and they are still a prevalent cause of epilepsy in endemic regions.

The pathophysiology of lesional epilepsy is uncertain, but a number of explanations have been proposed, and the mechanisms may vary for different lesional types.

Magnetic resonance imaging is the most sensitive and specific investigation in the detection of structural lesions. Evaluation for surgery involves careful clinical assessment, structural neuroimaging, and video-EEG in all patients. Intracranial monitoring, functional neuroimaging, and intraoperative neurophysiologic techniques may be useful in some cases.

Epilepsy surgery is the treatment of choice for intractable partial seizures caused by focal structural lesions. In most reported series, more than 50% of patients are rendered seizure free. It is controversial whether resection of the epileptogenic cortex in addition to the structural lesion is required for optimal seizure control. Stereotactic lesionectomy is a useful technique for minimizing morbidity with deep-seated lesions and those involving eloquent cortex.

Title: *Epilepsy: A Comprehensive Textbook, 2nd Edition*

Chapter 252

Progressive Myoclonus Epilepsies

Samuel F. Berkovic

Introduction

Progressive myoclonus epilepsy (PME) is an uncommon epilepsy syndrome caused by a large number of rare specific disorders. In its fully developed form with florid, unremitting myoclonic seizures and progressive neurologic deterioration, the syndrome can hardly be missed. Diagnosis of the PME syndrome can be more difficult in the early stages, and confusion with more benign epilepsies is common. Diagnosis of the specific type of PME is challenging, as most individual clinicians' experience with these rare disorders is limited. Molecular genetics has had an enormous impact on the clinical approach to these disorders, and PME is the clinical syndrome par excellence showing the value of careful clinicomolecular correlations leading to advances in practical clinical diagnosis and fundamental biologic understanding. This chapter will focus on diagnosis of the PME syndrome and of the more common specific causes.

Historical Perspectives

The rarity and complexity of the disorders causing PME have resulted in a confusing literature since the first description by Unverricht in 1891 (Fig. 1).[130] Eponymous names were used in conflicting ways, and there were often erroneous putative clinicopathologic correlations. In particular, the term *Ramsay Hunt syndrome* generated enormous confusion (for review see references 11, 18, 84, and 95).

Pathologic studies since the 1930s established that there were at least three separate pathologic substrates of the PME syndrome: Lafora bodies, lipid storage, and "degenerative" changes.[36,54,56] However, in clinical practice, PME was often the final clinical diagnosis, as there was no way to diagnose specific forms during life.

Over the last three decades a number of clinical, pathologic, genetic, biochemical, and molecular advances have led to considerable clarification of this subject, allowing a sophisticated and rational approach to diagnosis in life of the patient with PME.[7,14,46,84,116] First, in many of the specific causes of PME, characteristic clinical patterns have been recognized. Second, ethnic and geographic clusters of certain disorders have been identified, accounting for the different perspective of PME by authors in various countries. Third, the broad pathologic group of "lipidoses" causing PME has been classified by clinical, biochemical, and pathologic studies into neuronal ceroid lipofuscinoses, sialidoses, and Gaucher disease. Fourth, the mitochondrial disorder MERRF (myoclonus epilepsy and ragged red fiber syndrome) was discovered and found to be a major cause of PME. Fifth, the "degenerative" type of PME was found to be heterogeneous, comprising at least three distinct conditions: Unverricht-Lundborg disease, MERRF, and dentatorubral-pallidoluysian atrophy. Sixth, minimally invasive methods for diagnosis during life were developed. Finally, important molecular genetic findings have further refined understanding of these disorders and are playing an increasing role in routine diagnosis.

Definitions

The syndrome of PME consists of myoclonic seizures, tonic–clonic seizures, and progressive neurologic dysfunction, particularly ataxia and dementia. Onset can be at any age, but is usually in late childhood or adolescence. There are a large number of causes of the PME syndrome; most are due to specific genetic disorders, which can now be accurately diagnosed in life.[7,46]

Myoclonus in PME is typically fragmentary and multifocal, and often precipitated by posture, action, or external stimuli such as light, sound, or touch. It is particularly apparent in facial and distal limb musculature. Bilateral massive myoclonic jerks, which tend to involve proximal limb muscles, may also occur.

The origin of and generators for myoclonus in PME is a confusing and controversial area. Neurophysiologic studies show that some but not all myoclonic jerks are accompanied by obvious electroencephalographic (EEG) spikes, polyspikes, or spike-and-wave complexes. Where EEG accompaniments of jerks are not obvious, back-averaging techniques may reveal preceding EEG changes. These data, coupled with the frequent finding of giant somatosensory-evoked potentials (SSEPs) and of evidence suggesting abnormal cortical hyperexcitability using transcranial magnetic stimulation, suggest that the myoclonic jerks are often of cortical origin—*cortical reflex myoclonus*. Electrophysiologic studies of bilateral jerks suggest that some are generated in the cortex unilaterally and spread rapidly contralaterally via the corpus callosum, whereas others may be generated in the brainstem—*reticular reflex myoclonus*.[50,109,118,119] The lack of demonstrable EEG change with some jerks might lead to the conclusion that these are examples of "nonepileptic" myoclonus, akin to that seen in certain movement disorders. Unfortunately, no absolute clinical or indeed experimental technique exists to determine the epileptic nature or otherwise of particular jerks. Moreover, the coexistence of "epileptic" and "nonepileptic" myoclonus in one patient is counterintuitive. From a pragmatic clinical viewpoint, therefore, "epileptic" myoclonus can be diagnosed in cases where tonic–clonic or other seizures coexist or where obvious epileptiform discharges accompany some, but not necessarily all, myoclonic jerks.

The progressive myoclonus epilepsies. In: Pedley TA, Meldrum BS, eds. Recent advances in Epilepsy. Edinburgh: Churchill Livingstone; 1986:157–187.)

Epidemiology

PMEs account for <1% of people with epilepsy seen at specialist centers.[46] Series from different countries reveal considerable

geographic and ethnic variability in the occurrence of specific types of PMEs.[1,36,40,46] Details of known geographic clusters of specific PMEs are given below. Knowledge of the patient's ethnic background can provide an essential clue to the likely differential diagnosis of the type of PME.

The incidence and prevalence of specific PMEs are largely unknown. In Finland, Unverricht-Lundborg disease has an incidence of at least 1 per 20,000,[95] but outside the Baltic region the incidence is probably at least an order of magnitude less, although a recent study in The Netherlands using molecular methods suggested that Unverricht-Lundborg disease is underdiagnosed.[35]

Specific Disorders

Unverricht-Lundborg Disease

Etiology and Basic Mechanisms

Unverricht-Lundborg disease is the prototypic cause of PME.[65,77,130] No storage material is present but there is neuronal loss and gliosis particularly affecting the cerebellum, medial thalamus, and spinal cord.[51]

It is an autosomal recessive condition[95] initially recognized as a geographic cluster in Finland and eastern Sweden (*Baltic myoclonus*). An erroneous, but frequently held, view is that this disorder is confined to the Baltic region. Clusters of a phenotypically identical disorder occur in Southern Europe and North Africa, so-called "Mediterranean myoclonus."[47] It is also found sporadically worldwide in Caucasians, Blacks, and Japanese.[40,84] Indeed, it appears that Unverricht's original family was of Baltic German extraction, and not Estonian as widely believed.

The disorder was linked to the long arm of chromosome 21 in Finnish cases in 1991[71] and cystatin B was identified as the responsible gene in 1996.[104] The clinical prediction that similar cases seen outside the Baltic region have the same condition was confirmed by showing the identification of mutations in cystatin B (*CSTB*) in families from around the world. The most common mutation, responsible for about 90% of abnormal alleles, is an unstable expansion of a dodecamer repeat in the 5′ untranslated promoter region. The remaining mutations are missense mutations.[69,70,72] CSTB is a cysteine protease inhibitor. The *CSTB* mutations lead to marked reduced expression of *CSTB* mRNA. Development of a mouse model with targeted disruption of the mouse *Cstb* gene has shown increased apoptosis affecting particularly cerebellar granule cells. It has been suggested that deficiency of CSTB protein results in increased activity of cathepsins with increased apoptosis in specific neuronal cell types.[72,103,117]

A variant has been described where *CTSB* has been excluded as the causative gene. This form maps to chromosome 12 but the gene is presently unknown.[15]

Clinical Presentation

Clinical onset is with myoclonus or tonic–clonic seizures between the ages of 8 and 13 (mean 10, range 6 to 16 years). The myoclonus is usually quite severe and may be precipitated by movement, stress, and sensory stimuli. Repetitive morning myoclonus is also typical, frequently building up and culminating in a major tonic–clonic seizure.[63,64] Seizures may be difficult to control, but progression in terms of ataxia and dementia is mild and late. The clinical course is variable and there may be considerable intrafamily variation in the

severity of the seizures. Some patients are relatively mildly affected and survive to old age.[78] A more fulminant course with death within a few years of onset has been observed; this outcome is rarely if ever seen now and may have been due to unrecognized deleterious effects of phenytoin.[40,58]

The EEG background may show some diffuse theta that increases over years, as well as some frontal beta activity. Epileptic activity comprises 3- to 5-Hz spike-wave or multiple spike-wave activity with the maximum field being anterior. Sporadic focal spikes, particularly in the occipital region, may be seen but are usually not prominent (Fig. 2). Photosensitivity is typically marked. During non–rapid eye movement (REM) sleep the spike-wave activity is diminished.[18,64]

Diagnostic Evaluation

Unverricht-Lundborg disease is recognized clinically by its characteristic age of onset and clinical pattern, with an absence of other clinical or pathologic features. Diagnosis is confirmed by molecular analysis of the cystatin B gene.

Myoclonus Epilepsy and Ragged Red Fibers

Etiology and Basic Mechanisms

The MERRF syndrome has emerged as one of the most common causes of PME. It may be familial or sporadic. Most familial cases of MERRF are transmitted through the maternal line and are examples of mitochondrial inheritance.[111] The peculiarities of mitochondrial inheritance provide an explanation for the wide phenotypic variability in patients with MERRF and for the extraordinary intrafamily variation.

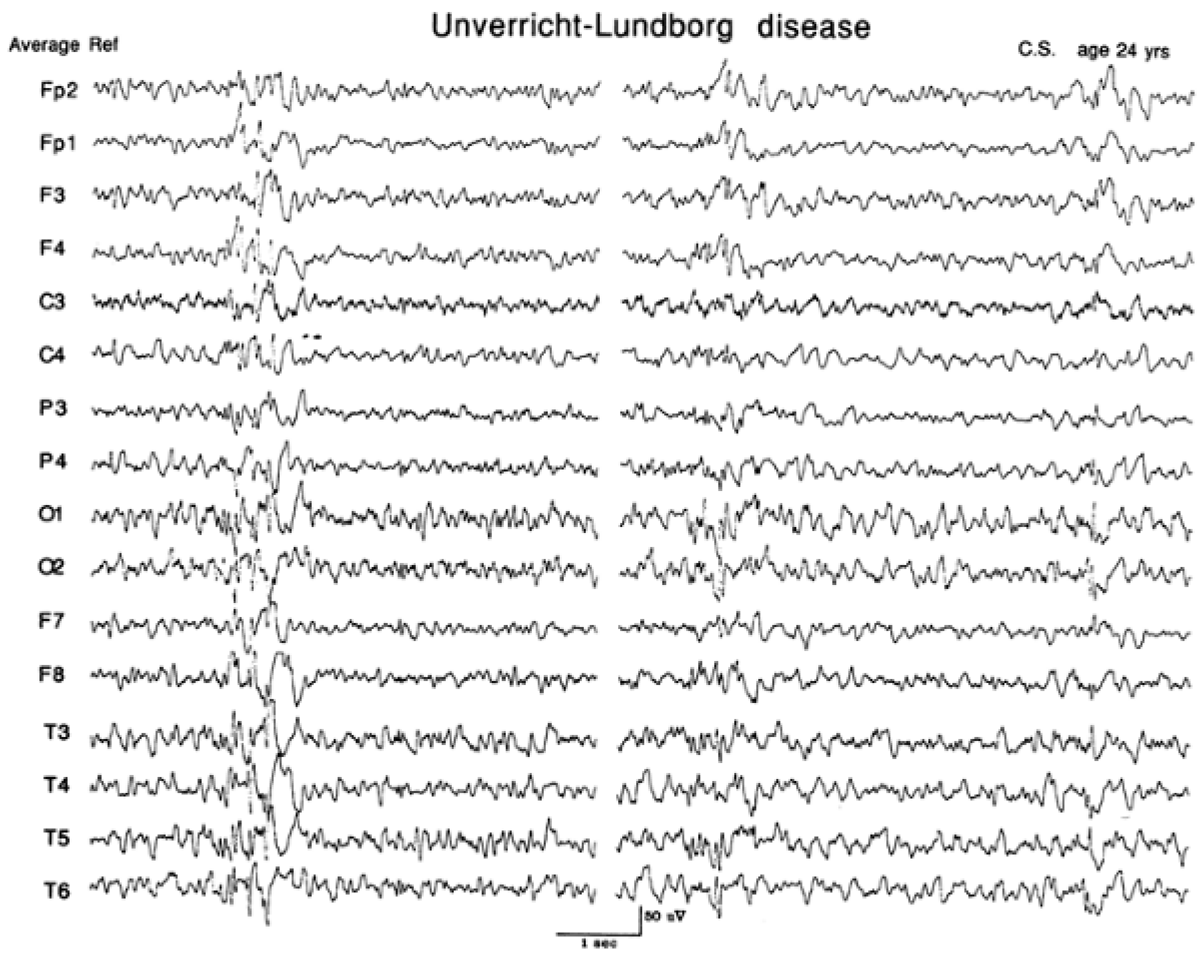

FIGURE 2. Unverricht-Lundborg disease. Waking electroencephalogram in a 24-year-old woman showing generalized polyspike-and-wave discharges on a slow background (**left panel**) with occasional focal occipital discharges (**right panel**).

A single base substitution at nucleotide pair 8344 of mitochondrial DNA, causing an A-to-G substitution in the $tRNA^{Lys}$ gene, occurs in many familial cases of MERRF.[120] The fact that this mutation affects tRNA, rather than a gene for a respiratory enzyme, probably explains the heterogeneous results for respiratory enzyme assays reported in MERRF. This $tRNA^{Lys}$ mutation appears to underlie most, but not all, familial cases and some sporadic examples of MERRF.[17,52,53,138] Other rare identified molecular causes of MERRF also affect the $tRNA^{Lys}$ gene.[121] Recently, autosomal recessive mutations in the nuclear encoded mitochondrial gene polymerase-*γ* (POLG) have been identified in some MERRF cases.[129]

Pathologically the brain shows "degenerative" changes, particularly affecting the dentate nucleus and inferior olive. In more severely affected cases, lesions typical of Leigh disease are also found. Positron emission tomography shows decreased metabolism for glucose and oxygen with relatively preserved cerebral blood flow, findings compatible with a respiratory chain defect.[13] Phosphorus magnetic resonance spectroscopy of the brain is normal but studies of resting muscle show an increase of inorganic phosphate and a decrease of the phosphocreatine-to-inorganic phosphate concentration ratio.[86]

Clinical Presentation

MERRF was first described in cases with a florid clinical myopathy and myoclonus epilepsy.[43,128] It is now clear that the clinical spectrum of MERRF is extremely broad. It should be suspected in a wide variety of situations, even when clinical and pathologic evidence of myopathy is absent.[8,13] Symptoms can begin at any age and there may be marked intrafamily variation in the age of onset and clinical severity.[13,111] The clinical features include myoclonus, tonic–clonic seizures, dementia, ataxia, and less common findings of myopathy, neuropathy, deafness, and optic atrophy. Some cases show striking axial lipomas. Occasional patients or families have focal neurologic events and there is an overlap with the syndrome of mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS), where strokelike episodes frequently preceded by migrainous headaches with vomiting are characteristic.[8,102]

It has been previously suggested that a wide variety of cases of PME known by eponyms, clinical signs, or particular patterns of system degeneration were examples of mitochondrial disease.[4,7,13] This has now been confirmed for PME with lipomas,[13,39] and for at least some cases of PME and deafness[87,131] and of so-called Ramsay Hunt syndrome.[4,10,84] PME with Friedreich ataxia[122] and PME with deafness, focal cerebral deficits, alopecia, and a transient response to biotin[21] may also be due to mitochondrial disease.

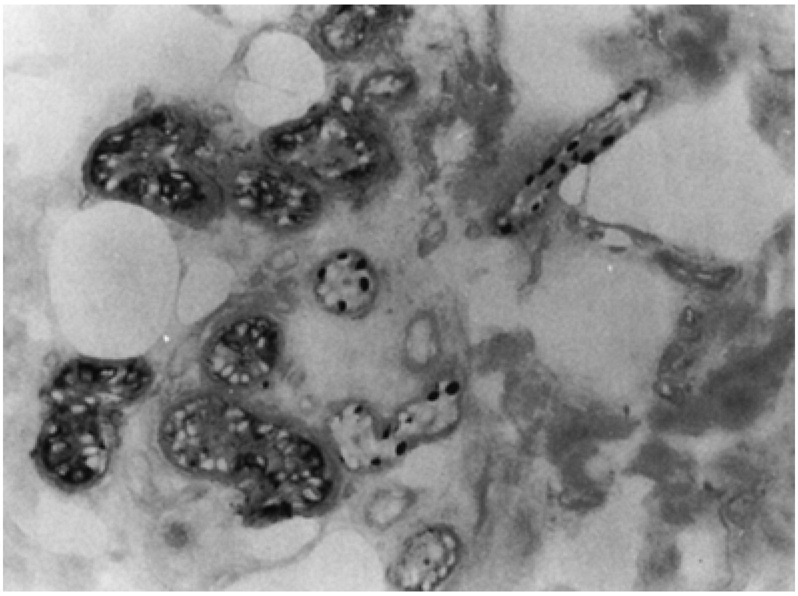

FIGURE 3. Lafora disease, skin biopsy. Cryostat section of skin stained with periodic acid-Schiff showing oval densely staining inclusions in eccrine duct cells. The secretory ascini (on the **left**) show normal glycogen staining (×225). (Reproduced from Berkovic SF, Andermann F. The progressive myoclonus epilepsies. In: Pedley TA, Meldrum BS, eds. Recent advances in Epilepsy. Edinburgh: Churchill Livingstone; 1986:157–187.)

The EEG shows slowly progressive background slowing paralleling degree of clinical deterioration. There are generalized spike-and-wave discharges at 2 to 5 Hz or multiple spike-and-wave discharges. Sporadic occipital spikes and sharp

P.2528

waves may be seen. Prominent photosensitivity may occur. Non-REM sleep is disorganized and spike-and-wave discharges are diminished.[18,123]

Diagnostic Evaluation

The unifying feature of these cases is dysfunction in the mitochondrial respiratory chain. This is most simply demonstrated by ragged red fibers in skeletal muscle, although these can be absent. Biochemical assays of the mitochondrial respiratory enzymes may show abnormalities, but these too may be normal.[13,134]

Diagnosis can usually be suspected clinically and may be difficult to confirm with laboratory markers. The clinical clues to the diagnosis include deafness, optic atrophy, myopathy, lipomas, intrafamily variation in age of onset and severity, and a pattern of inheritance compatible with maternal transmission.[13] Serum lactate, ragged red fibers, and respiratory enzyme activities in muscle can all be normal in patients known to be affected (e.g., family members of proven cases). Magnetic resonance spectroscopy of muscle may show elevated levels of inorganic phosphate and a decrease of the phosphocreatine-to-inorganic phosphate concentration ratio.[86] Molecular defects in mitochondrial DNA or POLG can be detected, when present, in peripheral blood or muscle.[53,138] Screening for the mitochondrial DNA 8344 mutation should be done first; if negative, then more extensive DNA testing of mitochondrial DNA or POLG may be indicated.

Lafora Disease

Etiology and Basic Mechanisms

Lafora disease is characterized by the presence of Lafora bodies, which are polyglucosan inclusions found in neurons and in a variety of other sites including heart, skeletal muscle, liver, and sweat gland duct cells[25,68] (Fig. 3).

It is an autosomal recessive condition. The largest series have been reported from Southern Europe,[125] but it is found worldwide, apparently without a marked racial or ethnic predilection. Approximately 90% of cases have mutations in the gene *EPM2A,* which encodes a dual phosphatase known as laforin,[89,114] or in *EPM2B* (also called *NHLRC1*), which codes for an E3 ubiquitin ligase known as malin.[28,48] There is evidence for a third as yet unknown locus.[27]

Clinical Presentation

Onset is between the ages of 10 and 18 years with a mean age of onset of 14. Clinical features are myoclonus, tonic–clonic seizures, and relentless cognitive decline. Focal seizures, particularly arising from the occipital regions, occur in about half the patients. Recognition of Lafora disease in its fully developed form is not difficult. At the onset, however, the disorder can resemble a typical benign adolescent generalized epilepsy with no evidence of cognitive decline. It may also present as a dementing illness with relatively infrequent seizures, or it may mimic a nonspecific secondary generalized epilepsy because myoclonus is not obvious.[11,107,110] The prognosis of Lafora disease is dismal, with death occurring 2 to 10 years after onset and the mean age of death being 20 years.

The clinical picture, including the relatively narrow age range of onset and relentlessly progressive course to death within 2 to 10 years of onset, is constant in all reports with the exception of a few cases. These cases, sometimes erroneously labelled as "type Lundborg," had symptoms beginning in late adolescence or early adult life with a milder protracted course.[36,60,66] Certain mutations in *EPM2B* may cause a milder course.[6] Conversely, an early-onset form with marked cognitive decline has been reported with mutations in exon 1 of *EPM2A*.[44]

At onset the EEG background is well organized and there are multiple spike-and-wave discharges that are increased by intermittent photic stimulation. Erratic myoclonus is seen without EEG correlation. Spike-and-wave discharges are not accentuated during sleep. Over the next few months to years, the background deteriorates, the physiologic elements of sleep become disrupted, and only REM sleep can be identified. Multifocal, particularly posterior, epileptiform abnormalities appear in addition to the generalized bursts, and in the terminal phase of the illness the EEG is quite disorganized.[125]

Diagnostic Evaluation

The age of onset, eventual inexorable dementia, and frequent occurrence of focal occipital seizures are clinical clues to the diagnosis.[110,127] Lafora bodies can be demonstrated in many tissues, but diagnosis is most simply made by examination of eccrine sweat gland ducts by a simple skin biopsy[25] and can

P.2529

now be confirmed in most cases by molecular study of *EPM2A* and *EPM2B*.[57]

Neuronal Ceroid Lipofuscinoses

Etiology and Basic Mechanisms

The neuronal ceroid lipofuscinoses (NCLs) are characterized by the accumulation of abnormal amounts of lipopigment in lysosomes. There are four classical clinical forms: Infantile, late-infantile (Jansky-Bielschowsky), juvenile (Spielmeyer-Vogt-Sjögren), and adult NCL (Kufs), of which all but the infantile form may present as a PME syndrome. The infantile form presents differently with regression, hypotonia, and impaired vision and is not considered here. The childhood forms are sometimes collectively referred to as Batten disease.

The various forms are genetically distinct and occur worldwide, but with peculiar patterns of geographic clustering. In Finland there are large numbers of infantile and juvenile cases, whereas in Newfoundland late-infantile and juvenile cases are seen with increased frequency.[3,108] All forms have autosomal recessive inheritance. Kufs disease, however, also occurs in families with dominant inheritance.[20]

The storage material proved extremely difficult to characterize, and for many years was thought to be lipid. Subunit c of mitochondrial adenosine triphosphate (ATP) synthase, a very hydrophobic protein, was subsequently identified as the major storage protein in an ovine model[99] and in human late-infantile, juvenile, and adult cases.[49,98] Clinicomolecular studies have now designated eight variants (*CLN1 to 8*) for which the gene has been isolated in six.[90]

Clinical Presentation

The classic late-infantile form (*CLN2*) has an onset between 2½ and 4 years. Seizures are usually the first manifestation with myoclonic seizures, tonic–clonic seizures, atonic seizures, and atypical absences. Within a few months of onset, ataxia and psychomotor regression are seen with visual failure generally developing late. Examination of the optic fundi reveals attenuated retinal vessels and macular degeneration. The seizures are usually intractable, dementia is relentless, and there is progressive spasticity with death about 5 years after onset.[11,107] The EEG shows background slowing and disorganization with generalized epileptiform discharges. Photosensitivity is marked and single flashes may provoke giant posterior-evoked responses. Visual-evoked potentials (VEPs) are abnormally broad and of high amplitude, and SSEPs are enlarged. The electroretinogram

(ERG) becomes progressively attenuated.[101,107,136] *CLN2* encodes a lysosomal enzyme tripetidyl peptidase (TPP1).[90]

The late-infantile variant form, described in Finland (*CLN5*), differs in the following ways. Onset is later, between 5 and 7 years; psychomotor regression and visual failure occur earlier, with myoclonic and tonic–clonic seizures generally appearing at around age 8 years; and progression is somewhat slower.[113] Electrophysiologic findings are similar to those of the late-infantile form except that the marked response to photic stimulation develops around age 7 to 8 years and disappears by ages 10 to 11 years, and the visual-evoked response (VER), which is initially large, progressively attenuates.[113] *CLN5* encodes a glycosylated lysosomal protein.[90]

CLN6 encodes a membrane protein found in the endoplasmic reticulum and is associated with a late-infantile variant form, which presents between 5 and 7 years with seizures and motor impairment, while visual failure occurs later. This disorder has been described in many countries.[90] Late-infantile cases are frequent in Turkey; some have mutations in *CLN8,* which encodes a membrane protein found in the endoplasmic reticulum, and others have been designated as *CLN7*, but the gene has not been identified.[90]

Juvenile NCL (*CLN3*) begins between the ages of 4 and 10 years. The majority of patients present with visual failure, and have the gradual development of dementia and extrapyramidal features, with seizures being a relative minor manifestation. Funduscopy reveals optic atrophy, macular degeneration, and attenuated vessels. Inheritance is autosomal recessive. The course is variable, with death about 8 years after onset.[107] The EEG shows background slowing and generalized epileptiform discharges that are often of the slow spike-and-wave type. Sleep activates the epileptic abnormality but photic stimulation does not. VEPs are of low amplitude and sometimes cannot be elicited. The ERG is flat.[101,107,136] The gene encodes a glycosylated membrane protein probably localized to lysosomes.[90]

The adult form (*CLN4*) is considerably rarer. It can present as a PME syndrome around the age of 30, although other cases present with a picture of dementia and extrapyramidal or cerebellar disturbance. Visual auras may occur before some seizures. Blindness is notably absent and the optic fundi are normal. The clinical course from onset to death is approximately 12 years.[12] The EEG shows generalized fast spike-and-wave discharges with marked photosensitivity. Single flashes may evoke paroxysmal discharges. The background activity may be normal in the early stages, and ERGs are normal.[9,12] The genes have not been identified.

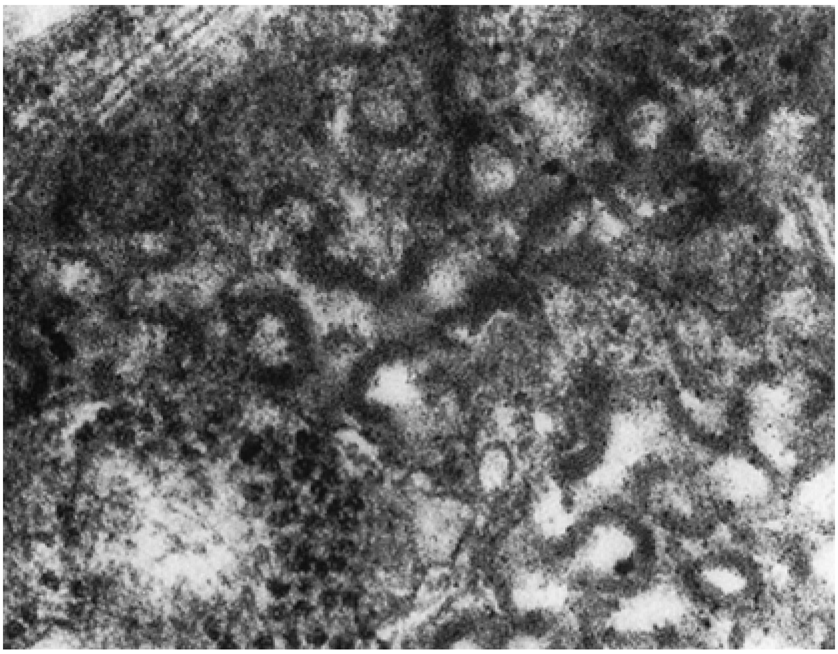

FIGURE 4. Late-infantile neuronal ceroid lipofuscinosis, skin biopsy. Electron micrograph of a skin biopsy showing curvilinear profiles from an eccrine secretory cell (×120,000). (Reproduced from Berkovic SF, Andermann F. The progressive myoclonus epilepsies. In: Pedley TA, meldrum BS, eds. Recent advances in Epilepsy. Edinburgh: Churchill Living Stone; 1986:157–187.)

Diagnostic Evaluation

Diagnosis can often be suspected clinically, particularly if there are visual changes. The electrophysiologic findings described above can be helpful. Vacuolated lymphocytes may be noted in the juvenile form. Neuroradiologic studies show cerebral and particularly cerebellar atrophy. Diagnosis can be made by the demonstration of characteristic inclusions by electron microscopy. These can be found in a variety of cell types including eccrine secretory cells. The inclusions take various forms, with curvilinear profiles being characteristic of a late-infantile NCL, fingerprint profiles being usual in the juvenile and adult forms, and granular osmiophilic deposits occurring in the infantile form (Fig. 4). A number of variations occur, however, such as rare cases of the adult and juvenile cases showing granular osmiophilic deposits. Considerable expertise may be required in the pathologic interpretation of the electron micrographs.[24,26] In the case of suspected *CLN2*, enzymatic assays for TPP1 are available and molecular testing can be performed for *CLN2, CLN3, CLN5, CLN6,* and *CLN8.*[90]

Sialidoses

Etiology and Basic Mechanisms

The sialidoses are the least common of the major forms of PME. They are autosomal recessive disorders associated with deficiencies of *a-N*-acetyl-neuraminidase. Sialidosis type I is due to a primary deficiency in a neuraminidase. Many of the published cases were of Italian origin.[75] Sialidosis type I is due to mutations in the *a-N*-acetyl-neuraminidase gene *(NEU1)* on chromosome 6.[115]

Sialidosis type II comprises a complex group of phenotypes. The juvenile form presents as a PME and occurs predominantly in Japan. In addition to the neuraminidase deficiency, a partial deficiency of ß-galactosidase is also found in most if not all cases.[75,85] The combination of neuraminidase and ß-galactosidase deficiency (galactosialidosis) is due to a lack of a 32-kilodalton protein that is required to protect

P.2530

galactosidase from degradation and is essential for the catalytic action of neuraminidase.[34,100] Missense mutations in the gene lysosomal protective protein/cathepsin A (PPCA) on chromosome 20 cause the juvenile form with PME.[91,139]

Clinical Presentation

In sialidosis type I (*cherry red spot-myoclonus syndrome*), there is onset in adolescence with myoclonus, gradual visual failure, tonic–clonic seizures, ataxia, and a characteristic cherry-red spot in the fundus. The myoclonus is usually very severe. Lens opacities and a mild peripheral neuropathy with burning feet may occur. Dementia is absent.[42,75,106,107,124]

Juvenile sialidosis type II presents as a PME with features like sialidosis type I except that onset is sometimes a little later. There may be additional features of coarse facies, corneal clouding, dysostosis multiplex, hearing loss, and low intellect, which can be present from early life.[75,85]

The EEG background comprises low-voltage fast activity, but some slowing can be seen in demented patients. Generalized spike-and-wave bursts are absent or infrequent; rather massive myoclonus is associated with trains of 10- to 20-Hz small vertex positive spikes preceding the EMG artefact. Non-REM sleep is disorganized, and although myoclonus diminishes, the vertex spikes persist and become very frequent in deep sleep.[41,107]

Diagnostic Evaluation

Sialidoses should be identified clinically because of the characteristic optic fundus. Periodic acid-Schiff–positive inclusions may be seen in lymphocytes, bone marrow cells, neurons, and Kupffer cells. Diagnosis is confirmed by grossly elevated urinary sialyloligosaccharides and by a deficiency of cryolabile α-N-acetylneuraminidase in leucocytes or cultured fibroblasts.[75]

Rare Causes of Progressive Myoclonus Epilepsy

Dentatorubral-pallidoluysian atrophy (DRPLA) is an autosomal dominant condition that has been extensively studied in Japan. It is caused by a triplet repeat expansion in a gene on chromosome 12p; the function of the gene is as yet unknown.[62,93] DRPLA has a distinct pathology with neuronal loss and gliosis in the dentatorubral and pallidoluysian systems. A variety of clinical phenotypes occur, which may all be seen in one family. PME is one mode of presentation and tends to occur in cases with onset in childhood or adolescence. Other patients, usually with onset in adulthood, present with ataxic-choreoathetoid or chorea-dementia (mimicking Huntington disease) phenotypes.[59,94] Diagnosis is by detection of the abnormal triplet repeat expansion. DRPLA was previously thought to be extraordinarily rare outside Japan. Molecular diagnosis has recently revealed a number of non-Japanese families, although the PME phenotype appears to be uncommon.[23,105,135]

Noninfantile neuronopathic Gaucher disease presents as a PME, with supranuclear gaze palsy and splenomegaly without dementia. Neurologic manifestations may appear in childhood or as late as 38 years.[61,137] Pancytopenia, elevated serum acid phosphatase, and low leukocyte β-glucocerebrosidase activity are found. Inheritance is autosomal recessive. The glucocerebrosidase gene is on chromosome 1. A large variety of mutations causing disease have been identified.[19]

Atypical inclusion body disease has inclusions that are limited to the brain and are histochemically and ultrastructurally different from Lafora bodies.[30,37] Clinical onset is between 7 and 31 years, and dementia is prominent. Diagnosis requires brain biopsy. The initially reported cases were sporadic, but it has been suggested that at least some of these cases may be related to familial encephalopathy with neuroserpin inclusion bodies.[32,33]

A remarkable autosomal recessive disorder has been described in French Canadians with tremor and a PME syndrome beginning at around the age of 19, followed shortly by renal failure with proteinuria. Dementia is absent. An unusual pattern of pigment deposition is seen in astrocytes. EEGs show typical features of a PME with marked photosensitivity.[2] This condition has recently been recognized outside French Canada in a number of countries.[5,132]

Neuroaxonal dystrophy rarely presents in late childhood or adolescence as a PME. Additional clinical features include dementia, ataxia, chorea, and lower motor neuron involvement.[38,126] Diagnosis is made by demonstrating the presence of axon spheroids, which may be seen in peripheral nerves, in brain and by electron microscopy around eccrine secretory coils.

Celiac disease can be associated with generalized myoclonus, seizures, and ataxia,[76] although palatal myoclonus, rather than a PME syndrome, is more common in the malabsorptive disorders of celiac and Whipple diseases. Other very rare causes of PME are atypical late-infantile or juvenile forms of GM_2 gangliosidosis,[22] an unusual form of β-galactosidase deficiency with normal neuraminidase activity,[92] familial encephalopathy with neuroserpin inclusion bodies,[33] and possibly pantothenate kinase-associated neurodegeneration.[112] Alzheimer disease beginning in the third or fourth decade can present as a typical PME.[16]

Differential Diagnosis

Distinguishing Progressive Myoclonus Epilepsy from Other Epilepsies and Myoclonic Syndromes

It is usually not difficult to diagnose the syndrome of PME some years after onset with the distinctive diagnostic triad of myoclonic seizures, tonic–clonic seizures, and progressive neurologic decline. At the beginning of the illness, however, the clinical and EEG features may be similar to that of benign idiopathic generalized epilepsies, particularly mimicking juvenile myoclonic epilepsy. Response to therapy may be relatively favorable initially. With the passage of time, however, seizures may become more frequent, and progressive neurologic decline occurs. Failure to respond to therapy and progressive neurologic signs should lead to consideration of the presence of a PME. Conversely, the clinical picture of patients with idiopathic generalized epilepsies may mimic those of PME if they are inappropriately treated and intoxicated with antiepileptic drugs leading to ataxia, impaired cognitive function, and poorly controlled seizures.

Myoclonus in PMEs is usually quite severe, but in some patients, it may be relatively inobvious with convulsive seizures and intellectual decline dominating the clinical picture, leading to a misdiagnosis of a nonspecific symptomatic (secondary) generalized epilepsy or Lennox-Gastaut syndrome. In such cases, a careful search for myoclonus should lead to consideration of the PME syndrome.

Neurophysiologic assessment may also provide clues to the presence of a PME. The EEG background rhythm may be relatively well preserved in the early phases, but as the condition progresses generalized slow activity appears. This is particularly so in those forms of PME associated with relentless dementia, such as Lafora disease and NCL. Generalized epileptiform abnormalities are seen during the resting record, usually in the form of fast spike-and-wave, multiple spike-and-wave, or multiple spike discharges. Photosensitivity is common and may be marked. Focal, particularly posterior, epileptiform abnormalities are common in Lafora disease but also may occur in other forms.[18] SSEPs frequently show giant responses.[118,119]

PMEs should be distinguished from degenerative disorders where seizures and/or myoclonus can occur but do not form part of the clinical core or usual initial presentation of the disorder. The causes of such progressive encephalopathies with seizures are numerous and include GM_2 gangliosidosis, nonketotic hyperglycinemia, Niemann-Pick type C, juvenile Huntington disease, and Alzheimer disease. The distinction between this diverse group of disorders and the PMEs, while not absolute, is clinically useful and provides a practical framework on which to begin specific differential diagnosis.[11] For example, typical Alzheimer disease may have myoclonus as a relatively late feature, and would not be confused with a PME. Rare early-onset cases may, however, present as a PME in early adult life. Myoclonus is also prominent in certain static encephalopathies, of which postanoxic myoclonus (Lance-Adam syndrome) is the best known. The absence of progression and the usual clear history of the causative encephalopathy enable clear distinction from PME.

The PME syndrome should also be distinguished from the progressive myoclonic ataxias. This term was introduced to denote a group of patients, usually adults, with progressive ataxia and myoclonus but with few if any tonic–clonic seizures and little or no evidence of dementia.[84] Previously, some authors used the term *Ramsay Hunt syndrome* for these patients, although others used this term for quite different clinical groups, leading to considerable confusion in the literature.[4,83] The causes of progressive myoclonic ataxia partially overlap with the causes of PME but also include spinocerebellar degenerations, celiac disease, and Whipple disease. While it is now possible to specifically diagnose most patients with the PME syndrome in life (see below), a larger proportion of carefully studied cases with progressive myoclonic ataxia remain without a specific cause being established.[82,84]

Japanese authors have highlighted a condition of benign myoclonic epilepsy of adulthood. In this autosomal dominant disorder, onset is usually between 20 and 40 years, with myoclonus and rare tonic–clonic seizures.[88] Generalized epileptiform EEG abnormalities and giant SSEPs are present, but there is little or no evidence of progression. A number of other families have been described, under various names, that share adult onset, distal action tremor and myoclonus, epileptic seizures, autosomal dominant inheritance, benign course, effectiveness of antiepileptic drugs, and possibly cognitive decline, and the term *familial cortical myoclonic tremor with epilepsy* has been suggested.[133] This condition may be the same or similar to that previously described in the German literature as myoclonus epilepsy of Hartung type.[36]

Finally, the condition of benign familial myoclonus needs to be distinguished. In this autosomal dominant disorder, nonepileptic myoclonus begins in the first three decades of life, but is not associated with major seizures, epileptiform EEG abnormalities, or neurologic deterioration.[31,80]

Diagnosing the Specific Type of Progressive Myoclonus Epilepsy

Once the clinician is convinced that a patient has the PME syndrome, the critical question is to determine which specific disorder is present. This is essential for proper clinical and genetic counseling of the family (see below).

It is now possible to provide a specific diagnosis in life for the vast majority of patients with PME using clinical methods and minimally invasive investigations. An approach to this problem has been described previously.[7,14] The clinician should first consider the five major disorders causing PME, with the addition of DRPLA in patients of Japanese origin. Once these conditions are excluded, the rarer disorders should be considered.

Clinical Features

Although patients with the PME syndrome may appear superficially to have similar clinical features, knowledge of the specific clinical patterns of the common causes of PME often allows the differential diagnosis to be narrowed. Age at onset of symptoms provides some guidance in making the diagnosis, although MERRF may begin at any age. Certain seizure patterns are helpful; very prominent myoclonus suggests Unverricht-Lundborg disease, MERRF, or sialidosis. Partial seizures, particularly of occipital origin, can occur in a variety of the disorders but are often noted in Lafora disease. Characteristic fundal changes are almost invariable in sialidosis and are

frequent in the neuronal ceroid lipofuscinosis. Dementia is a constant feature of Lafora disease, the neuronal ceroid lipofuscinoses, and neuroaxonal dystrophy, whereas it is characteristically absent or mild in Unverricht-Lundborg disease, sialidosis type I, noninfantile Gaucher disease, and the action myoclonus-renal failure syndrome. The presence of deafness, lipomas, optic atrophy, myopathy, or neuropathy is a clinical pointer to MERRF. Neuropathy may also occur in sialidosis and neuroaxonal dystrophy. Dysmorphic features are usual in sialidosis type II and may occur in MERRF. Chorea can occur in dentatorubral-pallidoluysian atrophy, neuroaxonal dystrophy, and MERRF. Splenomegaly and supranuclear gaze palsy suggest Gaucher disease. Transient alopecia was seen in biotin-responsive encephalopathy.

Family History

A detailed family history, including examination of relatives, is essential. Recessive inheritance is usual, and the finding of parental consanguinity or early clinical signs in asymptomatic siblings would support this pattern. Maternal transmission is characteristic of MERRF. In MERRF and in the autosomal dominant disorders, older relatives may be found to have mild, incomplete forms of the condition.[14]

Neurophysiology

Findings that may be useful in specific diagnosis include the finding of vertex spikes as the main epileptiform abnormality in sialidosis, activation of epileptiform abnormalities in non-REM sleep in the sialidoses and the late-infantile and juvenile forms of NCL, photosensitivity to single flashes in late-infantile and adult NCL, and absent ERG in late-infantile and juvenile NCL.[18]

Laboratory Findings

Hematologic examination may reveal lymphocyte vacuolation in sialidosis and in certain cases of neuronal ceroid lipofuscinosis. Pancytopenia is common in Gaucher disease.

Routine biochemical tests are not helpful, with the exception of findings of elevated lactate levels in blood and cerebrospinal fluid in some cases of MERRF, elevated serum tartrate-resistant isozymes of acid phosphatase in Gaucher disease, and proteinuria with impaired renal function in the action myoclonus-renal failure syndrome. More sophisticated testing includes assays for TPP1 in leukocytes or fibroblast culture to diagnose late-infantile NCL, urinary thin-layer chromatographic oligosaccharide screen to detect sialidosis, urinary organic acid estimation for biotin-responsive encephalopathy, and β-hexosaminidase A and B screens of serum and leukocytes for GM_2 gangliosidosis. Specific enzyme assays for the sialidoses (α-*N*-acetylneuraminidase and β-galactosidase) and Gaucher disease β-glucocerebrosidase) and definitive assays for the various forms of β-hexosaminidase deficiency in GM_2 gangliosidosis using fibroblast cultures and special substrates are performed only when the relevant diagnosis is strongly suspected.

Pathologic Studies

A tissue diagnosis is essential for a number of these disorders. Skin biopsy with or without skeletal-muscle biopsy is the initial procedure. Lafora disease can be reliably diagnosed by examining eccrine sweat gland duct cells with stains for polysaccharides.[25] The diagnosis of neuronal ceroid lipofuscinosis may be suggested by an acid phosphatase stain, but electron microscopy of the skin biopsy specimen is essential for the definitive identification of inclusions. These inclusions are detectable in many cell types in the late-infantile form of the disease, but in the juvenile and adult varieties, diagnostic inclusions may be limited to eccrine secretory cells.[24] False-negative skin biopsies in Lafora disease and in late-infantile and juvenile NCL are, in our experience, due to failure to examine the appropriate cell type properly. In suspected Lafora disease it is essential to ensure that sweat gland ducts are included in the biopsy and properly examined. Where doubt remains, skin biopsy should be repeated because of the serious prognostic implications of the diagnosis of Lafora disease. The reliability of diagnosis of Kufs disease from skin biopsy is not yet clear.

Axon spheroids may be seen in autonomic terminals around eccrine secretory coils in cases of neuroaxonal dystrophy, but the sensitivity of this finding has not been established. Study of muscle biopsy specimens with modified Gomori trichome and oxidative enzyme reactions may demonstrate ragged red fibers in MERRF. Abnormal mitochondria may be identified in muscle or skin using electron microscopy. Normal light and electron microscopic studies of muscle do not rule out the diagnosis of MERRF and, in clinically suspicious cases, a second biopsy may be indicated.

Molecular Genetic Studies

Molecular genetic studies are playing an increasing role in the diagnosis of the PMEs. Simple DNA tests for the dodecamer repeat in Unverricht-Lundborg disease and mitochondrial DNA mutations in MERRF and for the triplet repeat expansion in DRPLA are readily available. Testing for mutations associated with Lafora disease, neuronal ceroid lipofuscinoses, and sialidoses is available from more specialized or research-orientated laboratories (see http://www.genetests.org).

Treatment and Outcome

Treatment of these disorders may be distressingly difficult. Accurate diagnosis is the first step as informed genetic counseling must be given. It is very important to distinguish MERRF, which may show maternal inheritance, from autosomal recessive disorders such as Unverricht-Lundborg disease, Lafora disease, sialidoses, and the neuronal ceroid lipofuscinoses, and from dominant disorders such as DRPLA, familial encephalopathy with neuroserpin inclusion bodies, and rare dominant families with Kufs disease. Genetic counseling may now be extended to prenatal diagnosis in some cases. Specific diagnosis also allows an accurate prognosis to be given, including a realistic appraisal of the educational and vocational goals of the patient.

For symptomatic control of myoclonus, valproate and/or clonazepam should be used. Phenytoin has a clear deleterious effect in Unverricht-Lundborg disease.[40,58] Phenytoin should not be used in the other PMEs either. Small doses of barbiturates may be helpful, but sedation should be avoided. Piracetam may be useful in certain cases.[96] Care must be taken not to render the patient intoxicated with drugs, although there is some evidence that carefully monitored polytherapy may be more effective in some patients as opposed to the usual practice of aiming for monotherapy.[97] Combinations of L-tryptophan or 5-hydroxytryptophan with carbidopa have been used[73,74] but are not generally of long-term benefit. Zonisamide[55,67] and levetiracetam[29,79,81] may be quite effective. Drugs that may exacerbate myoclonus, including carbamazepine, vigabatrin, and gabapentin, should be avoided.

Programs of physical therapy may be of benefit, and attempts should be made to search for strategies allowing movement without precipitating myoclonus in individual patients. Alcohol may provide symptomatic benefit in some patients, but must be used judiciously.[45]

Strategies for replacing enzymes in the storage disorders and for augmenting mitochondrial function in the mitochondrial

disorders are being developed, but presently they remain in the experimental phase and results to date have been disappointing.

Long-term Prognosis

The prognosis of all the PMEs is poor, and is discussed under the specific diseases. In general, the worst prognosis is seen in the storage disorders (NCL and Lafora), where there is an associated relentless dementia. The prognosis is somewhat better in Unverricht-Lundborg disease, where some patients can remain ambulant and active for many years or even decades after diagnosis. The prognosis of MERRF is highly variable; cases with an earlier onset generally have a more rapid course.

Summary and Conclusions

The PMEs are a group of rare genetic disorders previously shrouded in nosologic confusion. Recent advances have clarified the features of these disorders and provided a rational approach to diagnosis. The major causes of PME are now known to be Unverricht-Lundborg disease, MERRF, Lafora disease, neuronal ceroid lipofuscinoses, and sialidoses. In the last 15 years a series of molecular genetic findings have further refined the understanding of the PMEs. The genes responsible for most forms of PME have been identified. Precise diagnosis in life is now possible in virtually all cases using clinical methods, biochemical tests, skin and muscle biopsies, and molecular genetic techniques. Accurate diagnosis allows determination of prognosis, rational genetic counseling, possible prenatal diagnosis, and consideration of emerging therapeutic strategies. Although the PMEs are among the rarest of the inherited epilepsies, because of molecular genetic discoveries, they are best understood at a molecular level. It is hoped that the great strides that have recently been made in the biochemical and molecular genetics of these disorders will soon transfer into rational and effective therapeutics.

Chapter 253

Posttraumatic Seizures

Frederick G. Langendorf

Timothy A. Pedley

Nancy R. Temkin

Introduction

The risk for epilepsy is increased at least threefold in patients with head injury compared with the general population.[4] Head injury is a major risk factor, comparable with bacterial meningitis, heroin abuse, or a family history of seizures.[32,33] Each year in the United States, about 1.5 million people sustain a traumatic brain injury.[64] Although trauma accounts for only about 5% of all epilepsy cases, this is still a problem of considerable magnitude. More importantly, it is a potentially preventable cause of epilepsy.

The link between head trauma and epilepsy raises a number of important issues. A rational approach to treatment and prevention requires knowledge of the incidence of posttraumatic seizures and the specific aspects of injury that are associated with the development of epilepsy. How should posttraumatic seizures be treated, and is there a role for prophylactic antiepileptic drug therapy? Finally, because seizures develop after a known injury to the brain, posttraumatic seizures offer the opportunity to investigate mechanisms of epileptogenesis.

Historical Perspectives

That head injuries could be associated with acute seizures was known to Hippocrates. Duretus (1527–1586) attributed epilepsy in an 18-year-old man to a skull fracture that had occurred 6 years earlier. Head injury appears in 19th-century tabulations of causes of epilepsy, although it ranked well behind fright and masturbation in importance.[61] Modern concepts of head injury and epilepsy derive from studies of British and American veterans of four major 20th-century wars.[11,55]

Definitions

Implicit in the designation *posttraumatic seizures* is the notion that the injury not only preceded, but also caused the seizures. Posttraumatic seizures are classified as *early* (occurring within 1 week of injury) or *late* (occurring more than 1 week after injury); in some studies "early" encompasses a longer interval, or means the phase of recovery from the acute effects of injury. Early seizures include a subgroup of immediate or impact seizures, which occur at the time of, or immediately after, the injury. Early seizures are acute symptomatic seizures. Late seizures are remote symptomatic seizures; they may be single or multiple. Conventionally, only recurrent late seizures represent *posttraumatic epilepsy*. In practice, posttraumatic seizures and posttraumatic epilepsy are sometimes used interchangeably.

Head injuries have traditionally been divided into two categories: *Penetrating* injuries from "missile" damage (mostly gunshot wounds) and *closed* injuries from "blunt" trauma (mostly caused by falls, motor vehicle accidents, and assaults not involving firearms). There has not been uniform agreement about what constitutes mild, moderate, and severe head injury. *Mild* injury generally excludes evidence of intracranial structural pathology and neurologic abnormalities other than brief loss of consciousness or amnesia. *Severe* injury implies significant structural damage to the brain (either focal or diffuse), or coma, encephalopathy, or amnesia lasting more than 24 hours. Victims of head injury can be stratified more objectively based on the neurologic examination using the Glasgow Coma Scale.[36]

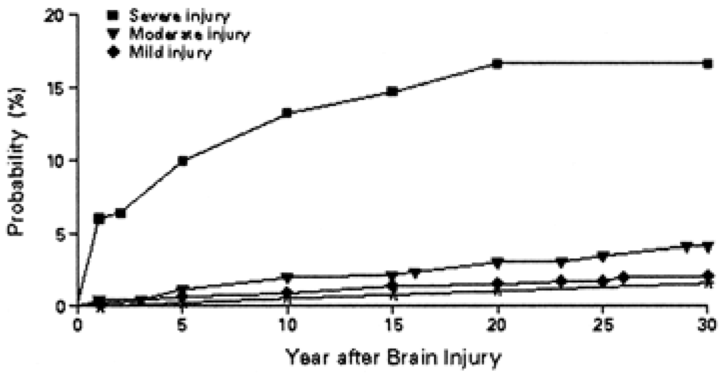
Epidemiology

Head Injury

In the United States, the annual incidence of hospitalization or death from traumatic brain injury is about 100 per 100,000 population.[64,65] Men are more often affected than women. The age-related incidence peaks are in young adults 15 to 24 years of age and in the elderly. Next most affected are young children. The incidence of fatal head injury is about 20 per 100,000. Among survivors of moderate to severe head injury, only about half recover to baseline in such functional domains as home management, financial independence, and social integration.[18] It is estimated that 5.3 million Americans (2% of the population) are living with disability as a result of a traumatic brain injury.[64]

Seizure Studies

It is difficult to establish the incidence of posttraumatic seizures accurately because of a number of methodologic pitfalls. Case ascertainment varies from study to study. For example, head injuries may be noticed only because of a seizure. In some patients, other risk factors for seizures may be present, including pre-existing epilepsy, previous head injury, or alcoholism. Ascribing acute seizures to the effects of brain injury may be confounded by alcohol withdrawal, medication toxicity, or metabolic encephalopathy. In determining the incidence of late posttraumatic seizures, acute symptomatic seizures should be excluded, and the expected incidence of unprovoked seizures occurring in the general population must be taken into account. Many patients are lost to follow-up, and these may not be representative of the study population. As a result of all of these pitfalls, estimates of posttraumatic epilepsy tend to be inflated.



No. of Patients				
Mild injury	2,758	1,751	1,191	609
Moderate injury	1,455	934	660	351
Severe injury	328	181	136	74
Total	4,541	2,866	1,987	1,034

FIGURE 1. Cumulative probability of unprovoked seizures in 4,541 patients with traumatic brain injuries, according to the severity of the injury and the incidence of seizures in the general population. The cumulative incidence in the population was derived from incidence rates with the use of the density method to convert the rates to risk estimates. The *asterisks* indicate the incidence in the general population at specified points in time. (From Annegers JF, Hauser WA, Coan SP, et al. A population-based study of seizures after traumatic brain injuries. *N Engl J Med.* 1998;338:20–24, with permission.)

Early Seizures

Early seizures occur in 2% to 5% of all patients with head injuries,[3,15,37] and they are more common in children than

adults. After severe head injury, the frequency of early seizures is 10% to 15% for adults and 30% to 35% for children.[3,28,58] Most early seizures occur within 24 hours of injury.

Late Seizures

In the Vietnam Head Injury Study,[55] 53% of veterans who suffered a missile injury eventually experienced at least one seizure, with multiple seizures occurring in the great majority. The relative risk in the first year was 580. In about half the patients, the first seizure occurred within 12 months of injury, but in more than 15% of patients, seizures did not develop until 5 or more years later and the relative risk remained elevated at 10 years. In earlier studies of veterans with military head injuries, late seizures occurred in 35% to 45%.[11]

In Jennett's large series of patients in Oxford and Glasgow who were hospitalized because of nonpenetrating head injury, late seizures occurred in 5%.[34] However, of those patients with severe trauma, late seizures occurred in up to 35%.

In a seminal work, Annegers et al. studied civilian head injury (mostly, but not exclusively, nonpenetrating injury) in Olmsted County, Minnesota, and determined the incidence of late seizures, taking into account the incidence of unprovoked seizures in the general population.[3,4] Children under 15 constituted 38% of the study population. The 5-year cumulative probability of seizures for mild, moderate, and severe injury was 0.7%, 1.2%, and 10%, respectively (Fig. 1). Late seizures occurred in 7.4% of children and 13.3% of adults with severe trauma, with the elderly at still greater risk. The relative risk of late seizures (single or multiple) for mild, moderate, and severe injury was 1.5, 2.9, and 17.0, respectively. After severe injury, about half of the first seizures occurred in the first year, but the risk of a first late seizure remained elevated even 10 years later. After mild injury, this risk had largely subsided at 4 years.

The demonstration (for the first time) of a link between mild head injury and seizures is tempered by the very low relative risk. It follows from a relative risk of 1.5 that an unprovoked seizure following a mild head injury is twice as likely to be unrelated to the injury as it is to be related.

Seizure Recurrence

Early seizures are followed by late seizures in 25% to 35% of adults; early seizures are less predictive of late seizures in children.[3,16,37] The relative risk is in the range of 3 to 5,[4,5,19] but risk factors for early and late seizures are similar, and early seizures did not appear to confer a large independent risk of late seizures in a multivariate analysis.[4]

A first late seizure will have a high risk of recurrence.[3,12,55] In one study of moderately to severely injured patients (penetrating and nonpenetrating) with a first late seizure, recurrence occurred in 47% at 1 month and 86% at 2 years, with at least four additional late seizures in half of these patients.[30]

Immediate seizures have been studied phenomenologically and epidemiologically in Australian rugby players. When not associated with other evidence of significant injury, they appear not to significantly increase the risk for later seizures. They may be no more than a transient symptom of concussion.[45,46]

Risk Factors

For penetrating injury, retained metal fragments, intracranial hematoma, persistent neurologic deficits, and degree of brain volume loss as estimated from computed tomography (CT) images were all associated with increased seizure risk.[55] For nonpenetrating injury, depressed skull fracture and intracranial hematoma (both subdural and intracerebral) are risk factors for both early and late seizures.[4,15,34] Multiple cerebral contusions may place a patient at particularly high risk.[20] The presence of parenchymal blood, whether caused by trauma or stroke,[39] appears to be an important element in the development of seizures. Coma duration and Glasgow Coma Scale score correlate with occurrence of both early and late seizures.[20] There is some controversy as to whether intracerebral hemorrhage[14,16] or severity of diffuse encephalopathy[42] best predicts seizures. Seizures are seen in a higher proportion of abusive injuries than accidental injuries in children; the abusive injuries were more serious by other measures as well.[8]

Genetic influences have long been suspected as a factor in the development of posttraumatic seizures. Although some investigators have reported that a family history of epilepsy is more common in subjects in whom epilepsy does develop following head injury than in those in whom it does not,[12,21] the most careful studies to date were unable to demonstrate any increase in the frequency of seizures among relatives of probands with head injury.[50,56] Similarly, the Vietnam Head Injury Study failed to show any increase in family history of seizures among those in whom posttraumatic epilepsy developed.[55] Despite a lack of evidence, it is possible that genetic susceptibility increases the risk for epilepsy in people with milder injuries, individuals who constitute a small proportion of the posttraumatic seizure population.

The use of seat belts and helmets substantially decreases the severity of brain injuries resulting from bicycle, motorcycle,

and automobile accidents.[1,49,63] Although it has not yet been shown directly that these measures also reduce the occurrence of late posttraumatic seizures, a mitigating effect can be assumed. The current proliferation of firearms ominously forecasts an increase in the most severe category of head injury, with a consequent increase in posttraumatic epilepsy. Firearm deaths related to head injury are clearly increasing in the United States.[64]

Etiology and Basic Mechanisms

Trauma produces many structural, physiologic, and biochemical changes in the brain. Acceleration and rotational forces shear nerve fiber tracts, rupture blood vessels, and produce diffuse axonal injury characterized histologically by gliosis, microglial scar formation, axonal retraction balls, and wallerian degeneration.[25] Both contusions (focal injuries characterized by a mixture of blood, edema, and necrosis) and frank hemorrhage may occur. Damage to the hippocampus, especially the CA1 region, occurs in a high proportion of fatal head injuries[40] and may be important in the development of epilepsy in survivors. Interestingly, Lowenstein et al.[43] demonstrated that even a brief, relatively minor percussive blow to the dura of rats could result in selective hilar cell loss and hyperexcitability of granule cells that may be a necessary substrate for some kinds of partial seizures. In another rat model of head injury, selective hippocampal cell loss (hilus and area CA3), granule cell hyperexcitability, and mossy fiber sprouting could be seen, and these rats demonstrated enhanced susceptibility to seizures.[23] The findings in the hippocampus are similar to those of mesial temporal lobe epilepsy.

Parenchymal blood with subsequent hemosiderin deposition is a major risk factor for epilepsy, and experimental studies have demonstrated that neocortical injection of ferrous or ferric chloride produces focal electroencephalographic (EEG) epileptiform discharges and seizures.[70] The epileptogenic effect of iron is related to the formation of free radicals, and development of seizures can be blocked by antiperoxidant compounds.[27,71,72] The exact mechanisms of this process are unknown. Low levels of hemoglobin-binding protein have been described in families with epilepsy (although not posttraumatic epilepsy).[52] Because individuals with low levels of hemoglobin-binding protein may clear intracerebral blood less efficiently, this could prolong iron exposure and increase the risk for posttraumatic seizures.

In rats, seizures occurring immediately or shortly after traumatic injury are accompanied by increased glutamate and aspartate levels,[48] a finding documented with seizure onset in humans as well.[54] Excitatory amino acids are highly epileptogenic as well as cytotoxic to neurons; these effects can be blocked by *N*-methyl-D-aspartate (NMDA) antagonists.[13] Release of excitatory amino acids may also be responsible for the large, calcium-dependent increase in extracellular potassium seen after experimental brain injury.[38] Increased extracellular potassium further increases neuronal excitability and may contribute to interictal–ictal transitions. It is unlikely, however, that a unitary mechanism for posttraumatic seizures will be found.

That there is generally a latent or "silent" period between the actual brain injury and first seizure has been known since Gowers. It is most likely that trauma initiates a dynamic epileptogenic process that progressively alters neuronal excitability, establishes or obliterates critical interconnections, and perhaps results in critical structural remodeling so that an epileptogenic network of sufficient size is established, resulting in clinical seizures. It is also possible, however, that head injury resets the seizure threshold downward relatively rapidly. In this case, the delay between injury and the first posttraumatic seizure would not necessarily reflect a progressive, evolving process but rather the outer fringe of a probabilistic spread of first seizure latencies.

With head injury (unlike brain tumor), the moment of onset of a potentially epileptogenic process is known with precision. This would allow for the early initiation of neuroprotective agents. There appears to be a critical period for intervention in rats.[24] However, the successful use of antioxidants and NMDA receptor blockers as neuroprotective agents in rats, as mentioned above, has not so far translated into human head injury trials.

Clinical Presentation

Seizures caused by head injury have similar semiologies to those occurring in other contexts. Thus, the full spectrum of simple and complex partial seizures as well as generalized tonic–clonic seizures can be seen following head injury. Both cortical ("epileptic") myoclonus[29] and epilepsia partialis continua[62] have been described. Generalized absence seizures probably do not occur as a consequence of head injury.

Because individual patients may have both partial and generalized seizures, it is difficult to estimate the relative frequency of different seizure types with accuracy. Recognized early seizures are predominantly generalized tonic–clonic in type,[15,41,44] particularly seizures on the very first day.[6] A study of continuous EEG monitoring for an average of 1 week after moderate to severe injury revealed electrical seizures without clinical accompaniment in 11 of 94 patients.[66] These subclinical, typically unrecognized seizures could not, however, be temporally correlated with increased intracranial pressure or decreased cerebral perfusion pressure, nor did they predict poorer outcome. The majority of patients with late posttraumatic seizures have at least one generalized tonic–clonic convulsion.[34,55] Perhaps a quarter will have complex partial seizures,[6] though this particular seizure type is probably underrecognized in the head-injured population.

Diagnostic Evaluation

Electroencephalographic Findings

Electroencephalography plays only a limited role in the evaluation of early posttraumatic seizures. It is usually most useful in clarifying the basis of intermittent behavioral changes in obtunded or semicomatose patients. It is not of value in predicting the development of posttraumatic epilepsy.[35] The EEG is also less helpful in predicting recurrence after a first late posttraumatic seizure than it is in predicting recurrence after a first idiopathic seizure.[9]

Neuroimaging and Other Laboratory Examinations

The initial diagnostic approach to head trauma is based on the characteristics of the injury and the assessment of the patient's neurologic and general medical status. Patients with moderate or severe head injury require urgent CT imaging. Because intracerebral hemorrhage, subdural hematoma, and hydrocephalus may be delayed, repeated imaging is mandatory in patients who do not improve as expected or deteriorate in the face of appropriate treatment. Development of seizures after the initial CT scan is also an indication for repeated imaging. The role of brain imaging after mild head injury is more

controversial, but it is certainly indicated if a seizure occurs or if there is any other unexpected turn in a patient's course. In a large study of adults with mild head injuries,[41] 47% of those with early seizures had intracranial abnormalities; 7% of these required surgical intervention. In a meta-analysis, seizures predicted intracranial pathology in relatively mild injuries.[19] The need for magnetic resonance imaging (MRI) in the acute phase depends on factors other than the presence of seizures.

The first late seizure should be evaluated as any new, unprovoked seizure, including consideration of other etiologies.

Differential Diagnosis

Fluctuations in level of consciousness and intermittent changes in behavior may pose diagnostic problems, especially in the first 1 to 2 weeks after injury, when patients with severe head injuries are likely to be encephalopathic or otherwise neurologically abnormal. Momentary lapses without other symptoms or signs, emotional outbursts without alteration of consciousness, and attacks of directed violence should not be attributed to seizures. Persistent emotional, cognitive, or behavioral changes are likewise unlikely to be caused by seizure activity. On the other hand, the behavior of an individual with frontal lobe partial seizures may be bizarre, and such seizures are frequently misdiagnosed as nonepileptic events. Even the more typical complex partial seizures may be hard to recognize if they occur in a setting clouded by underlying encephalopathy. Determining which changes may be caused by seizure activity is important for management. Video-EEG monitoring may be necessary for definitive diagnosis in some cases.

Nonepileptic seizures (NESs; also psychogenic seizures, pseudoseizures) can occur in head-injured adults[7,69] and children.[51] Indeed, head injury seems to be a risk factor for NES, though the precipitating head injury is usually minor. Most head-injured NES patients have pre-existing or concomitant psychiatric disorders. Some may be malingering or involved in litigation.

Treatment and Outcome

Patients with moderate and severe head injuries are often medically unstable and especially vulnerable to such physiologic consequences of seizures as metabolic acidosis, sudden increases in cerebral blood flow and intracranial pressure, and compromised respiratory function, including pulmonary edema. Convulsive movements may further injure a patient with multiple trauma. Postictal depression complicates neurologic assessment. For these reasons, antiepileptic medication is appealing, at least in the early phase.

Several prospective, randomized, controlled trials[47,53,58,59,73,74] examined the efficacy of antiepileptic drugs in preventing early or late seizures, with mixed results owing to methodologic problems, particularly underpowering. The topic of antiepileptic drug prophylaxis was, for some time, controversial. The most comprehensive studies are those of Temkin et al. In a study of phenytoin in head injury patients at high risk for seizures,[58] phenytoin levels were maintained in the high therapeutic range; side effects were modest.[31] Phenytoin was very effective in suppressing early seizures, with a relative risk of 0.25 at 1 week. However, phenytoin was ineffective in reducing the incidence of late seizures, with no difference between treated and untreated groups at 2 years (Fig. 2). In a second study, valproate was not statistically different from phenytoin in preventing early seizures (though with a trend to less efficacy), but was ineffective late, after 6 months of treatment.[59] For unclear reasons, the valproate group had a trend toward higher mortality. An earlier study found that carbamazepine was also ineffective in preventing development of late seizures.[22] These data imply that although phenytoin, valproate, and carbamazepine are useful *antiseizure* drugs, they do not affect mechanisms involved in the development of posttraumatic epilepsy—they are not *antiepileptogenic* drugs. The situation is similar in patients with other disease processes that promote epileptogenesis, such as brain tumors: long term antiepileptic drug prophylaxis does not prevent the development of a first seizure.

The use of glucocorticoids was examined in the data set of the phenytoin study described above. The early exposure to glucocorticoids did not appear to affect the rate at which late seizures developed.[68] A study of magnesium sulfate has recently been completed. It showed no positive effects on late seizures or neurobehavioral outcome. Almost all participants received phenytoin for the first week, so the early seizure rate was too low to evaluate any effect of magnesium on early seizures.[60]

Recommendations

Patients with severe head injuries should be treated with phe-nytoin for the first week after injury to minimize complications from seizures occurring during acute management. Phenytoin (or fosphenytoin) should be given intravenously in a dose equivalent to 20 mg/kg; subsequent doses should be adjusted to an unbound ("free") blood level of 2.0 to 2.5 μg/mL. It is not appropriate to continue phenytoin beyond 1 week or the acute phase of injury, if no seizures have occurred, given its neurobehavioral effects.[17] Phenytoin is the drug of choice for preventing and treating early seizures because of its demonstrated efficacy and the availability of an effective formulation for intravenous administration. The hepatic metabolism of phenytoin may be increased and its plasma protein binding decreased in patients with severe head injury.[10,26,75] It is therefore advisable to monitor unbound (“free”) phenytoin levels in these patients. While the cause of increased mortality in valproate-treated patients is unclear, it makes valproate a much less attractive alternative to phenytoin. The clearance of valproate in head-injured patients is increased.[2]

In patients who have a single posttraumatic seizure, treatment decisions should be based on the anticipated risk for further seizures. Late seizures follow early posttraumatic seizures no more often than they do a first unprovoked seizure in the general population.[3,9,16,22,37] Thus, long-term antiepileptic drug treatment after early seizures is usually not indicated. In contrast, a first late posttraumatic seizure is usually followed by recurrent seizures, and long-term treatment is usually indicated. There is no settled doctrine on duration of treatment. Antiepileptic drug treatment of early seizures can usually be stopped after a period of weeks or months. Treatment of late seizures, particularly recurrent late seizures, would generally continue for a minimum of 2 years.

Standard antiepileptic medications should all be effective for late seizures; a choice is made as in other contexts, with particular attention to the sedating and behavioral effects of the medications.

Status epilepticus related to head injury is treated in the same manner as in other contexts.

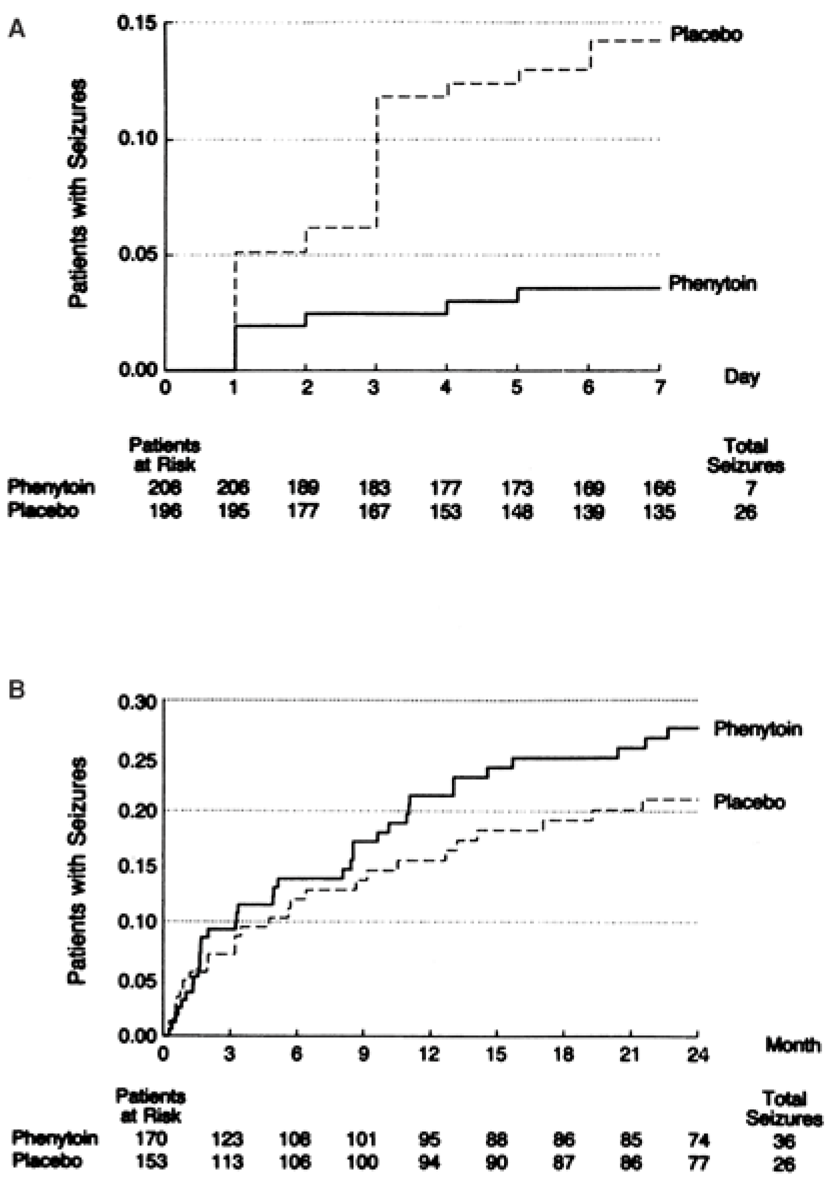


FIGURE 2. Treatment of patients with severe head injury with phenytoin or placebo. Cumulative fraction of patients with early **(A)** or late **(B)** seizures in the two groups. (From Temkin NR, Dikmen SS, Wilensky AJ, et al. A randomized, double-blind study of phenytoin for the prevention of post-traumatic seizures. *N Engl J Med.* 1990;323:497–502, with permission.)

Long-term Prognosis

The same problems that plague incidence studies of late seizures make it difficult to assess prognosis. About half of head-injured patients with late seizures have prolonged remissions,

P.2541

although it is not always clear if patients with early seizures or single seizures were excluded.[12,55,67] Remission rates for epilepsy are somewhat higher (70% or so) in the general population.[32] In the Vietnam Head Injury Study, the average duration of active seizures was 93 months.[55] Intracranial hematoma, partial seizures, and frequent seizures during the first year substantially decrease the chance for extended remission.

Summary and Conclusions

Seizures complicate about 50% of penetrating head injuries and about 5% of closed head injuries. Early seizures are related to the acute effects of trauma and are more common in children than adults. The risk for both early and late seizures is increased by depressed skull fracture, intracranial hematoma, and severe encephalopathy. Early seizures increase the likelihood of late seizures, and late seizures have a high recurrence rate. Iron deposition related to hemosiderin, cytotoxic effects of excitatory amino acids, and free radical formation may all play a role in the pathogenesis of posttraumatic seizures. Phenytoin is effective in reducing the chance of early seizures but does not prevent development of posttraumatic epilepsy.

Chapter 254

Isolated Seizures

Peter Wolf

Introduction

All epilepsies begin with a first seizure. However, a first seizure does not necessarily mean that epilepsy will develop (Chapters 7 and 122). It may turn out to be an isolated event, symptomatic of some other pathologic condition (Chapter 8), or indicative of an inherent increased risk for development of epilepsy and the need to prevent such development.

This chapter does not deal with the first of these possibilities—the epileptic seizure as an acute symptomatic event—but rather with the second, which is often discussed under the heading of "first unprovoked seizures." The discussion of these has mostly addressed two questions: How probable is it that a first "unprovoked" seizure signifies epilepsy, and should treatment begin after a first seizure? In this literature, treatment is always conceived of as pharmacotherapy, and a thorough definition of seizure provocation is rarely given. Important as these aspects may be, the theoretically more interesting question of nosology—the relation of isolated seizures to the established epileptic syndromes—is asked rarely, if at all, although apart from dealing with the occasional patient in such a situation, physicians hear about isolated seizures perhaps most frequently when taking the family histories of patients with epilepsy.

Historical Perspectives

The statement of Gowers[10] that "we have no means of ascertaining, on any considerable scale, the frequency with which a single epileptic fit occurs without successors" clearly shows that he and his contemporaries were quite aware of the possibility of isolated seizures. However, this was not a major concern with the classic epileptologic writers. Apart from the specific subgroup of febrile seizures in infants, isolated seizures mostly were mentioned in epidemiologic and genetic investigations. These were briefly reviewed by Janz[16] in a section on *Gelegenheits-Epilepsien*. His remarkable conclusion was that this is "at the same time the most frequent and mildest form of epilepsy, and the one with the highest rate of heredity."

It was mainly for epidemiologic, prognostic, and similar statistical purposes and quantitative studies of therapy that epilepsy was defined as a minimum of two unprovoked seizures. This definition left isolated seizure events as a separate group that logically—and provided that the diagnosis of an epileptic seizure was reliable—had to be included in the classification of epilepsies and epileptic syndromes.[4] The new International League Against Epilepsy (ILAE) and International Bureau for Epilepsy (IBE) definition of epilepsy as a disorder "characterized by an enduring predisposition to generate epileptic seizures" and requiring "the occurrence of at least one epileptic seizure"[9] gives the possibility in certain instances of coming to a diagnosis of epilepsy even after one seizure, but these cases will probably be the exception rather than the rule.

Definitions and Nosologic Place

Isolated seizures can be defined as solitary seizure events that may occur once in a lifetime or very rarely, at lengthy intervals. A seizure event according to this definition would be one single seizure or a short series of two or more seizures in the course of 24 hours, or an isolated episode of status epilepticus.[14]

The best-known type of isolated seizure, febrile convulsions of early childhood, is considered to be a separate entity and is not discussed here.

The relationship of isolated seizures to other epilepsy syndromes has rarely been given much attention, let alone systematically considered. However, it appears that the rare recurrences of seizures in later life among patients with idiopathic localization-related childhood epilepsies are usually isolated generalized tonic–clonic seizures.[19] The same seems to be true for another benign idiopathic epilepsy syndrome, benign familial neonatal convulsions,[22] and isolated seizures may be found in the pedigree of patients with this syndrome.[3]

Epidemiology

Stress convulsions, defined as epileptic attacks in adults exposed to various "stressing" exogenous influences who have not previously had unprovoked epileptic attacks, were diagnosed in 37 of 1,250 patients with convulsive disorders studied during a 13-year period by Laue Friis and Lund.[18] These patients can be considered a subset of the patients discussed here.

Hauser et al.[12] reported 244 patients with a first idiopathic or remote symptomatic seizure. These were drawn from a total of 1,047 patients with newly diagnosed seizures who had been enrolled during a 4 1/2-year period. They compared them with 334 patients who had acute symptomatic seizures and 435 who had had two or more seizures at first diagnosis; 34 patients were excluded from study. After 36 months of follow-up, seizures had recurred in 27% of the persons with only one seizure—that is, in 73%, the seizure had been an isolated event.

In the National General Practice Study of Epilepsy,[23] which was a prospective, population-based cohort study of 1,195 patients with newly diagnosed or suspected epileptic seizures, 220 patients had febrile seizures, and definite epileptic seizures were diagnosed in 564. Of these, 252 were registered at the time of their first seizure, 89 of whom were followed for 3 or more years. Of the latter group, 56% had had a seizure recurrence at 3 years of follow-up—that is, in 44%, the seizure had remained isolated.[11]

The focus of these and similar studies, however, differs slightly but significantly from the subject of this chapter. They

were aimed at establishing the risk for recurrence after a first seizure and did not ask whether a second seizure signifies epilepsy or is only the recurrence of an isolated event, or *Gelegenheitsanfall*.

When seizure types are considered, it turns out that in all studies of this matter, generalized tonic–clonic seizures are by far the most frequent type. Percentages ranged between 61% (27% with simple and 10% with complex partial seizures; the remainder were unclassified, although these figures apply only to the cryptogenic group, the semiology of remote symptomatic seizures not being recorded)[12] and 97.5%.[15] This important difference from the usual distribution of seizure types in clinical cohorts is probably attributable to the fact that with minor and less frightening seizures, a physician is frequently not seen after a first seizure, but is seen only later. These cases are frequently lost for studies of first seizures.

However, as Loiseau et al. pointed out, partial seizures also may occur as isolated events, and these have been reported in several studies.[20]

Etiology and Basic Mechanisms

Apart from the bias toward generalized tonic–clonic seizures, it would appear that these patients are not nosologically homogeneous. Rather, they comprise both a group with an innate risk for development of some type of idiopathic generalized epilepsy and a mixed bag of patients at risk for development of symptomatic localization-related epilepsies of various etiologies.

Of the 564 patients with first seizures in the series of Sander et al.,[23] the seizures of 346 were classified as idiopathic/cryptogenic, those of 119 as remote symptomatic, those of 83 as acute symptomatic, and those of 16 as associated with neurologic deficit.

In the extended follow-up study of Hauser et al.[13] of 208 patients with first seizures, the seizures of 149 were diagnosed as idiopathic and those of 59 as remote symptomatic. There were no acute symptomatic cases in this study.

The prospective cohort of adolescents and adults with first seizures of Wolf[26] comprised 104 patients as of January 31, 2002. Of these, 26 (25%) had a positive family history of epilepsy or febrile convulsions. Febrile convulsions were a previous manifestation of seizure susceptibility in 5 (4.8%), and 1 patient had had benign rolandic epilepsy in childhood. Twenty-five (24%) were photosensitive and thus revealed a trait most frequently seen in association with idiopathic generalized epilepsy syndromes.[24] In an additional 20 (19.2%), the electroencephalogram (EEG) showed some other type of generalized epileptiform discharge. On the other hand, indications of a remote symptomatic etiology were present in 15 (14.4%), and 41 (39.4%) displayed some focal trait (clinical, EEG, or both). In 16 patients (15.4%), no definite indicators of either a focal or a bihemispheric onset were found.

Clinical Presentation

There is good reason to assume that the manifestation of epilepsy of any type is often preceded by a stage of increased risk for development of seizures. This risk may be discovered on EEG if for some reason it happens to be performed. More often, risk becomes apparent through a first seizure. In a continuum stretching from no risk through low risk and high risk to active epilepsy, an isolated seizure would identify a person as belonging to a high-risk group for development of any type of epilepsy.

Risk for Relapse

The usual approach to this issue is to define the risk for relapse after a first seizure, which is the inverse expression of the chance of its remaining isolated. The discussion of this risk is highly controversial. The percentages in various recent studies vary from a low of 16% in the first year of follow-up and 27% in 3 years[12] to a maximum of 67% after 1 and 78% after 3 years.[11]

The reasons for these variances are not entirely clear. They could not be explained by differences in therapy. In the study of Annegers et al.,[1] 60.6% of 424 patients received drugs. In cryptogenic ("idiopathic" in the authors' terminology) cases, the relapse rates in patients taking drugs were considerably higher after 3 years (44% vs. 36%) and 5 years (60% vs. 41%), whereas in remote symptomatic cases there was no difference (70% for each group at 3 years and 80% vs. 76% at 5 years). In the Royal College of Physicians Study,[15] 41 of 306 patients (13.4%) had had drugs prescribed by their family doctor or neurologist, and this had no influence on the relapse rate.

It has been suggested that the figures for recurrence in the optimistic studies were unrealistically low because the patients who had already had a second seizure were excluded from them at the onset of a prospective follow-up—thus excluding the group with the highest risk for relapse.[8] This is certainly true, but when Hauser et al.[13] in a second study included such patients who had been excluded from their previous one, only a minor increase in the relapse rate resulted. According to Berg and Shinnar,[2] with retrospective ascertainment, the success of follow-up may depend on the outcome because the patients who have recurrence are easier to find and follow. In addition, they pointed out that in such studies, "the investigator may have little control over the quality of the initial assessment."

A serious methodologic weakness of the British studies showing a high relapse rate is indeed that most[15] or even all[11] patients were not given their diagnoses by the investigators; rather, the diagnoses of other physicians were relied on, and no special precautions were taken to exclude the possibility that a patient with a first major seizure leading to a diagnosis had previously been subject to minor seizures. Some of these, such as absences, myoclonic seizures in juvenile myoclonic epilepsy, or isolated auras, can easily escape the attention of an inexperienced observer. In the study of Sander et al.,[23] which relied on information collected by general practitioners, only 3% of 564 patients with "definite epileptic seizures" were given diagnoses of "true absences or myoclonic jerks with or without generalized tonic–clonic seizures." Obviously, these diagnoses were frequently missed, as can also be seen in another article from the same investigation.[21] In this study of 1,195 primarily registered patients, only 9% were excluded because it was determined that they had already had seizures. In contrast, in the investigation of Hauser et al.,[13] who are the only authors who discussed this problem and provided for it, 74% of patients "with newly identified unprovoked seizures had experienced multiple seizure episodes prior to their first medical contact"; these authors even excluded 13 patients referred by neurologists after a "first seizure" because a history of complex partial seizures had been overlooked—a diagnosis that would be thought hard to miss. It cannot be ruled out and seems even probable that the studies reporting high relapse rates comprise an unknown and potentially large number of patients with established but undiagnosed epilepsy.

Several studies have tried to identify subgroups with higher and lower risks for relapse. Hauser et al.[12] reported that risk was significantly higher in patients with remote symptomatic than with cryptogenic seizures. In the latter group, it was

increased if the patients had generalized slow-wave activity in the EEG (n = 13) but not focal EEG abnormalities (n = 61). (These results may very well be a question of numbers.) Risk was increased if patients had a sibling with seizures (n = 17) but not a parent with seizures (n = 6).

Annegers et al.[1] found that the risk increased for patients whose seizures had a presumed etiology, and among their "idiopathic" (cryptogenic) cases, EEG abnormalities, neurologic findings, and initial partial seizures were significant independent predictors of higher recurrence risks.

In the study of Hopkins et al.,[15] the only clinical variable associated with recurrence was seizure occurrence between midnight and 9:00 AM.

According to Hauser et al.,[13] the risk for recurrence was increased by the history of an identified insult to the central nervous system. Further factors in cryptogenic cases were generalized slow-wave activity in the EEG, a history of acute symptomatic seizures, and a sibling with epilepsy; in remote symptomatic cases, they were a history of acute symptomatic seizures, a history of status epilepticus or multiple seizures, and Todd's paresis.

In the National General Practice Study,[11] the risk was increased when the age at first seizure was <16 or >59 years, when a neurologic deficit was presumed present at birth, or when the first seizure was simple or complex partial. (Seizures of partial onset evolving to generalized tonic–clonic seizures seem in this study for unexplained reasons to have been lumped together with primarily generalized tonic–clonic seizures.) The risk was decreased in this study when the seizure was precipitated acutely by an insult to the brain (occurring within 3 months) or by alcohol. In this same study, relative risks are given for many subgroups (etiology, seizure type, age, index seizure first, or subsequent seizure).

Donselaar et al.[5] found that against an overall 2-year risk for relapse of 40% in 151 patients, 15 of 16 patients with epileptiform discharge in the standard EEG and 12 of 19 additional patients with discharge in the EEG after sleep deprivation had a relapse. They concluded that "the decision to initiate or delay treatment should be based on EEG findings." In this investigation, however, no particular efforts were made to exclude a history of minor seizures, and no steps were taken to ensure that the epileptiform EEG activity was only subclinical. Especially in the case of generalized spike-and-wave discharges, absences may be difficult to rule out. Sometimes this requires a video-EEG investigation with tests of reaction and awareness, which were not part of this study.

In the study of Wolf,[26] in which all measures, including those mentioned in the preceding paragraph, were taken to exclude preexisting epilepsy with difficult-to-diagnose seizures, the relapse rate was not influenced by EEG, antecedents, or focal versus generalized seizure onset.

Of course, the ultimate question behind these studies is not how often a second seizure occurs, and the concept of "isolated seizures" is not identical to the concept of one single seizure in a whole lifetime. The substantial question is how often epilepsy develops. However, most studies stop at the second seizure, probably because two unprovoked seizures, in studies of epidemiology and therapy, are often considered sufficient for a diagnosis of epilepsy, and "unprovoked" is frequently understood to mean no indication of an acute symptomatic background.

Elwes et al.,[7] however, looked at retrospective sequences of up to five initial generalized tonic–clonic seizures in 183 patients. They found that the intervals between seizures of 82 patients with more than two seizures decreased in 48 individuals, did not change in 16, and increased in 18. They concluded that "in many patients… an accelerating disease process may occur at least in the early stages.” However, they also believed that this was not an invariable phenomenon, and “as well as processes of acceleration of epilepsy the brain may generate processes of remission.”

Donselaar et al.[5] investigated the outcome of 58 of 151 patients with an idiopathic first seizure and no drug treatment who had had a relapse during the 2 following years. Of these, 6 had no further seizures although they remained untreated, 25 were started on drug treatment immediately after their second seizure, and 26 were started on drugs following additional seizures. One patient refused drugs despite several recurrences and was excluded. Forty patients (70%) became seizure free (including the aforementioned untreated 6), and 17 (30%) continued to have seizures—only sporadically in 8 cases.

An analysis of factors influencing the risk for relapse after a first seizure would thus suggest that a variety of candidate factors exist, some of which have reached statistical significance in some studies and some in others. None of them is surprising, and none would sort out isolated seizures in any specific way. Rather, they seem to corroborate the conclusion of the previous nosologic considerations that across epileptic syndromes, isolated seizures characterize a group of patients with an increased relative risk for the development of seizures and, eventually, some specific syndrome.

The question arises whether this risk can be enhanced by any specific or nonspecific precipitating factors. The more important the influence of nonspecific precipitating factors, the closer we come to the concept of isolated seizures, and the more important the influence of specific precipitating factors, the closer we come to the concept of reflex epilepsies.

Provocation of Isolated Seizures

Provocation of the first seizure is an aspect not uniformly dealt with in the literature. Some studies exclude all provoked seizures, others some, and still others none. More important, there is no uniform definition of seizure provocation. Seizures occurring “in the context of uncertain precipitants such as sleep deprivation or ‘stress’ were considered unprovoked” by Hauser et al.[13]

Sander et al.[23] stated that “the circumstances of the… first seizure [in 252 cases] were explored but did not suggest any striking precipitating factors”—a surprising statement from an investigation that did not include any expert interviews and had therefore no means to look into this question seriously.

Others[16,17,25] consider lack of sleep as a potent and common seizure precipitant. Even if many of the provoking factors have not yet been discovered, some epileptologists could imagine that provocation of seizures is the rule.[6]

In addition to such nonspecific provocative or facilitating factors of seizures, the role of specific sensory precipitants has received little attention in the literature, although early identification of such risk factors for the development of reflex epilepsy is, of course, important.

In the most recent update of the follow-up study of Wolf,[26] on January 31, 2002, at least one facilitating or precipitating factor could be identified in 80 of 104 patients (Table 1), and this knowledge was used therapeutically (see later discussion). In only 10 patients (9.6%) was the seizure unprovoked beyond suspicion.

Table 1 Facilitating or precipitating factors of first seizure in life in 104 adolescents and adults

Nonspecific (facilitating)

Disturbances of the sleep–wake cycle	69	(66.3%)
Extraordinary physical or emotional stress	23	(22.0%)
Acute excessive intake of alcohol	11	(10.6%)
Fever, infectious disease	3	(2.9%)
Hunger, hypoglycemia	3	(2.9%)
Miscellaneous (migraine, hyperhydration)	3	(2.9%)
Specific (precipitating or reflex epileptic)		
Intermittent lights (environmental) and television	14	(13.5%)
Video games, praxis induction	4	(4.8%)
Other specific movement, complex visual)	2	(2.0%)
Questionable	14	(13.5%)
No probable or suspected factors	10	(9.6%)

Epilepsy Evolving From a First Seizure

Berg and Shinnar[2] tried to distinguish methodologically between “first-seizure” studies and “new-onset epilepsy” studies, but this distinction is not always as clear as these authors would have us believe. All epilepsy starts with a first seizure, and it is a mere convention when physicians start to call a condition *epilepsy*. It is surprising to see what little attention the question

of how epilepsy evolves from a first seizure has received from modern writers.

Not much progress seems to have been made since Gowers,[10] who, in his chapter on the course of epilepsy, differentiated three modes of onset. The first is:

> by minor seizures which occur alone for months and years before there are severe attacks…. The second mode of commencement is by severe fits recurring at short intervals, without any preceding *petit mal*…. The third mode of onset is with a single severe fit, and no other fit or sign of epilepsy for months and even years, when another attack occurs, after which they usually become frequent. Between the last two forms there is every gradation of varying interval between the first and second fit.

The situation addressed in this chapter clearly is closest to the third mode of onset.

Elwes et al.[7] pointed out the possible interaction of factors of "acceleration" and remission in the development of epilepsy, and according to Janz,[17] the development of epilepsy with grand mal on awaking is characterized by a shift from initial seizures with clearly exogenous precipitating factors to a much more spontaneous mode of seizure recurrence. Would it, then, be possible to prevent the development of at least this particular type of epilepsy by "isolating" the first one or few seizures by preventing further recurrences? This question is discussed later.

Diagnostic Evaluation

The first and immediate question to be answered after a first epileptic seizure is whether it was the symptom of an acute or undiscovered progressive illness. Alcoholic and other toxic/metabolic causes have to be ruled out. The diagnostic program, beyond history and physical investigation, normally comprises the usual tests for exclusion of an acute inflammatory disorder; the EEG, mainly in view of possible signs of acute conditions such as encephalitis or metabolic-toxic disorders, or indicators of existing epilepsy or such specific traits as photosensitivity; and magnetic resonance imaging (MRI), now the most reliable method for detecting any morphologic changes. Only if MRI is unavailable or in case of emergency would computerized tomography (CT) be performed.

Differential Diagnosis

Frequently, when a first seizure takes everybody by surprise, there is little reliable information about what really has happened. Often there is no witness at all, or only a fraction of the seizure has been seen, perhaps by a poor observer. Patients may give the most important clues when they remember a typical—epileptic or vasomotor—aura. Indirect indicators of an epileptic seizure are a sudden fall without an aura, lateral tongue biting and enuresis (infrequent!), a slow recovery with Todd's paresis, feelings of physical exhaustion or muscular aches, and periocular petechiae. It is better to leave the diagnosis unresolved when the obtainable information is poor than to jump to rapid conclusions and take incorrect therapeutic measures. When a seizure is unmistakably a generalized tonic–clonic seizure, it is extremely important to remember that a first convulsive seizure may be just the tip of an iceberg and that minor seizures may long have been present. Intense, pointed, knowledgeable, and sometimes repeated questioning is often required. Isolated epileptic auras and absences are the types that most frequently go unnoticed by patients and relatives, and the jerks of juvenile myoclonic epilepsy are the type that physicians most often forget to ask about. They are practically never volunteered by patients, who usually are unaware that they are a pathologic phenomenon.

The EEG may be an important indicator of established epilepsy. Seemingly subclinical groups of bilateral spikes-and-waves require intensive monitoring, including video registrations and cognitive tests (tapping, counting, response to an acoustic stimulus), to be sure that they do not represent actual seizures. It is quite amazing how many patients with a presumed first seizure actually have epilepsy!

Treatment and Outcome

After a first seizure, "secondary prevention" rather than "therapy" seems the appropriate term for the recommended interventions because no disease has yet developed. The controversial question of whether antiepileptic pharmacotherapy should be recommended after a first seizure is discussed in Chapter 122.

In the longitudinal investigation of Wolf,[26] the only systematic interventions were the detailed and close instructions given to patients regarding avoidance of precipitating factors that had been identified individually. These were given verbally to patients and, if at all possible, to relatives or friends. In addition, patients received a printed memorandum (Table 2) explaining the significance of a single epileptic seizure, the risk for development of epilepsy, and the necessity and principles of preventing recurrences.[25] The question of drugs was not treated dogmatically. Possible benefits and risks of available antiepileptic drugs were explained, as well as the necessity, if drugs were to be given, of regular intake for a period of at least 2 years. The patients were invited to make their own choice regarding drug treatment. However, if no precipitating factor for the seizure could be defined, drug treatment was recommended. Of the 104 patients in this study, 29

(27.9%) were already taking some antiepileptic drug at enrollment, and these all chose to continue taking drugs for variable periods of time.

Table 2 Items to be discussed with patient and handed out in print

Single seizures (*Gelegenheitsanfälle*) do not yet mean the diagnosis is epilepsy.
They indicate a high risk that epilepsy will develop unless preventive measures are taken.
Every additional seizure is one step in the development of epilepsy.
A special danger with seizures is the risk for accidents; even a single seizure means temporary unfitness for driving.
Drug treatment is not always necessary but may be advisable, depending on the individual circumstances.
Several antiepileptic drugs are available; they are usually well tolerated, but no effective drug is without possible untoward effects.
Even in the best case, drug treatment has to be pursued for several years, and regular intake every day is necessary; missed doses mean a risk for withdrawal seizures.
In most instances, first seizures do not occur “out of the blue sky” but are precipitated by factors such as disturbances of the sleep–wake cycle; recurrences can often be prevented by control of precipitating factors.
Rules to be followed concerning the use of alcohol.
Rules to be followed concerning sleep–wake habits on workdays and holidays. Night shifts must be discontinued, if applicable.
Rules to be followed concerning specific precipitating mechanisms (e.g., photosensitivity).

Table 3 Calculated and observed recurrences in first year of follow-up in patients whose treatment consisted of avoiding precipitating factors

Fifty-Two patients with 1 seizure expected rate of 37%	19.2
Thirty-five patients with >1 seizure expected rate of 47%	16.5
Total recurrences expected	35.7 (41%)
Total recurrences observed	15 (17%)

Eighty-seven patients were followed for ≥1 year; the expected rates of recurrence are according to Hart et al.[11]

As of January 31, 2002, 87 patients of this cohort had been followed for a minimum of 12 months and a maximum of 10 years. Because 35 of these patients had already had more than one seizure when they were enrolled, the expected number of recurrences in the first year of follow-up was 35.7 (41%), calculated from the respective risk rates reported by Hart et al.[11] for patients with one and with more than one seizure (Table 3). A slightly higher rate would have been expected from Hauser et al.,[13] who estimated the recurrence rate after more than one seizure to be greater than 65%. In contrast, the observed rate was 15, or 17%. Sixty-three of these patients had been followed for at least 2 years, and 6 cases of recurrence were observed in the second year. Forty-six patients were followed for at least 3 years, and another 5 recurrences were observed in the third year. The majority of recurrences were provoked by factors similar to those associated with the previous seizure, and this was true for all of the few recurrences after >3 years. Spontaneously recurrent seizures requiring treatment, that is, epilepsy, developed in 13 patients (15% of those followed for at least 1 year), 2 with a diagnosis of idiopathic generalized epilepsy, 1 with an idiopathic focal epilepsy (a remanifestation at age 33 years after a history of probable childhood rolandic epilepsy), 2 with generalized tonic–clonic seizures without clear focal or generalized signs, 1 with both generalized and focal signs, and 7 with symptomatic or cryptogenic focal epilepsy. Considering that 42 of these patients at onset presented with generalized signs and symptoms, 27 with focal ones, and 18 could not be assigned to either category, a relapse in the presence of focal features is more likely to indicate the establishment of epilepsy, whereas in the presence of generalized features it is more likely to represent another isolated seizure or *Gelegenheitsanfall.*

It can therefore be concluded that appropriate preventive measures taken after first seizures, including the avoidance of specific and nonspecific precipitating factors and, probably, administration of antiepileptic drugs in selected cases, can be highly successful in keeping seizures isolated and preventing the transition to epilepsy, especially in the patients who are at risk of developing an idiopathic generalized type of epilepsy.

Long-Term Prognosis

In the majority of cases, the question of whether a first seizure will remain isolated or mark the onset of epilepsy is resolved within 1 to 2 years. If by then epilepsy has not developed, a good prognosis can be expected. The data from existing studies do not indicate that epilepsy is likely to develop once this period of time has elapsed after one or a few isolated seizures. On the other hand, there are sufficient observations of late recurrences of isolated seizures to indicate that the increased risk for seizures is lifelong (see also Chapter 7).

Summary and Conclusions

A first seizure may signify the onset of epilepsy, but it may also remain an isolated event. Isolated seizures can be defined as solitary seizure events that may occur once in a lifetime or very rarely, at lengthy intervals. In the literature, the most common approach is to define the risk for recurrence after a first seizure, which is the inverse expression of the chance of its remaining isolated. However, most studies of first seizures analyze recurrence risk but not the development of epilepsy with ongoing seizures. Therefore, the epidemiology of isolated seizures cannot be definitely determined at present. Their relation to other epileptic syndromes has never been systematically investigated. Isolated seizures, apart from the febrile seizures of early childhood, may not be a separate syndrome, but rather they may represent, across syndromes, the group of patients having the most benign course and the lowest risk for seizures.

In studies of first seizures, by far the most common seizure type is generalized tonic–clonic. The most important and often rather difficult diagnostic task, besides exclusion of an acute symptomatic or progressive etiology, is to make sure that the patient does not already have epilepsy, hitherto manifested only as unrecognized minor seizures. Once this possibility is safely ruled out, the therapeutic aim is the secondary prevention of epilepsy in those patients who, by having had a first seizure, can be identified as individuals with a clearly increased risk for epilepsy.

The indication for antiepileptic drug treatment after an isolated seizure is controversial. An often neglected aspect is the precipitation of isolated seizures by specific or nonspecific factors. Control of these seems to be the most important therapeutic intervention, and it drastically reduces the risk for recurrence, especially in patients with a risk of idiopathic generalized epilepsy.

Chapter 255

Familial Partial (Focal) Epilepsy With Variable Foci

Eliane Kobayashi

Frédérick Andermann

Eva Andermann

Introduction

Familial partial (focal) epilepsy with variable foci (FPEVF) is a distinct syndrome among the familial partial epilepsies, in that different clinical and electroencephalographic (EEG) features can be observed in different family members, suggesting that different epileptic foci may be determined by the same genetic mutation. On the other hand, the epileptic focus in any one individual remains the same.

Recently, FPEVF was included in the new diagnostic scheme for epileptic syndromes proposed by the International League Against Epilepsy (ILAE). Although it is displayed as a syndrome in development, this inclusion supports its uniqueness.[8]

Historical Perspectives

FPEVF is a unique syndrome first reported in 1998 in an Australian kindred by Scheffer et al,[28] and in the following year in two French–Canadian kindreds by Xiong et al.[36] Other more homogeneous familial partial epilepsy syndromes, including autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE),[27] familial temporal lobe epilepsy (FTLE),[1a,2] and autosomal-dominant partial epilepsy with auditory features (ADPEAF)[21] had been described (reviewed in Andermann et al.[1]). To date, only 10 pedigrees of FPEVF have been identified and reported in the literature.[3,4,25,28,35,36]

Definitions

Due to its uniqueness, FPEVF can only be defined on the basis of family rather than individual phenotypes. The occurrence of at least two different partial epilepsy syndromes in first- and second-degree relatives with no identifiable structural brain abnormality and segregating in a sufficient number of individuals in more than one generation is suggestive of FPEVF. Nevertheless, it has to be highlighted that, since the first report by Scheffer and colleagues,[28] many small families have been ascertained that could indeed have represented FPEVF, but both the diagnosis and the inheritance pattern could not be definitely confirmed.

Epidemiology

FPEVF kindreds have been identified in Australia, Canada, Spain, Holland and other European countries. Three of the 10 families are French-Canadian, originating from the region around Quebec City and sharing the same haplotype on chromosome (chr) 22q, suggesting a founder effect (Figs. 1 and 2).[3,35] FIGURE 2 demonstrates that a Spanish family has a completely different haplotyes than the French-Canadian families. Several small families have also been identified in the Eastern Townships region of Quebec, where linkage to the same region on chr22 is suggested, but these families have a different haplotype (P. Cossette, personal communication). Another Spanish family, which links to chr22, has also been described.[19] This family originates from a different region of Spain and has a different haplotype from the first Spanish family (J. Serratosa, personal communication).

Due to the variable seizure pattern among affected family members and the usually benign clinical outcome, FPEVF might often be underdiagnosed, as is the case for other familial partial epilepsy syndromes. It seems to be less frequent than other familial partial epilepsies, but, in the absence of genetic confirmation, it is impossible to estimate its frequency at present.

Etiology and Basic Mechanisms

In terms of etiology, it should again be emphasized that only 10 pedigrees have been reported in the literature.[3,4,25,28,35,36] All are compatible with an autosomal-dominant inheritance pattern with approximately 70% penetrance. Two different loci have been associated with FPEVF, the first with suggestive linkage on chr 2q,[28] and the second on chr 22q.[36] However, the gene(s) have not been cloned. Only one reported kindred had suggestive linkage to chr 2q,[28] but the family was not large enough to confirm linkage. Although linkage to chr 22q has now been confirmed in six families,[3,4,19,35,36] the gene has not been identified. Sequencing with mutation analysis has excluded the coding regions of >60 genes in the region on chr22q (A. Kerstin Lindblad-Toh, personal communication).

The mechanisms by which these molecular abnormalities can present as different types of idiopathic partial epilepsy within the same family are intriguing. Modifying genes and environmental factors should be further investigated.

Clinical Presentation

In FPEVF, affected family members may present with different types of partial epilepsy, which are, however, invariable within each subject. Frontal lobe seizures are the most frequent manifestation, but they have a different pattern in FPEVF as compared to that observed in ADNFLE (Table 1): The seizures are less frequent, clusters and auras are rare, and daytime seizures as well as secondarily generalized seizures are more frequent.[3] Age at seizure onset is variable; onset usually occurs in the first three decades, with two peaks at approximately 5 and 25 years of age.[35,36] Although temporal lobe seizures are also commonly found, centroparietal and occipital seizures are less frequent. There is also marked intrafamilial heterogeneity in seizure severity and outcome.

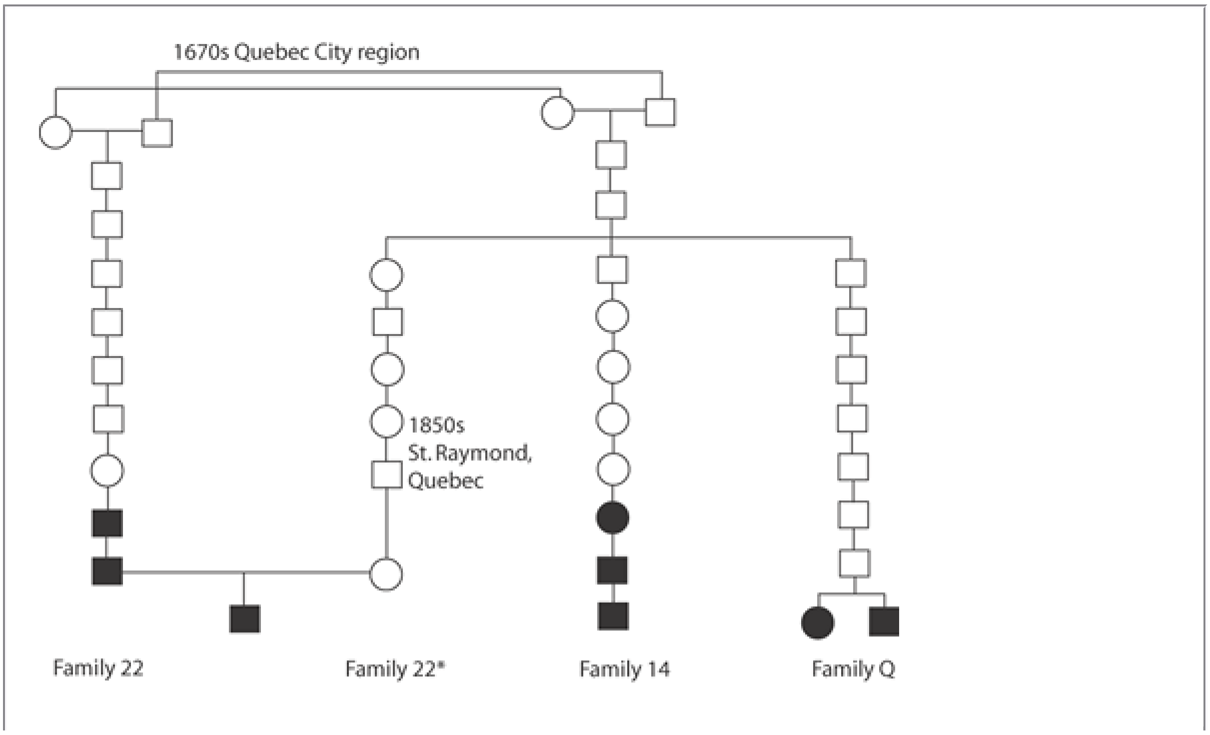

FIGURE 1. Genealogic representation of three French-Canadian families (F22, F22*, F14) demonstrating a founder effect.

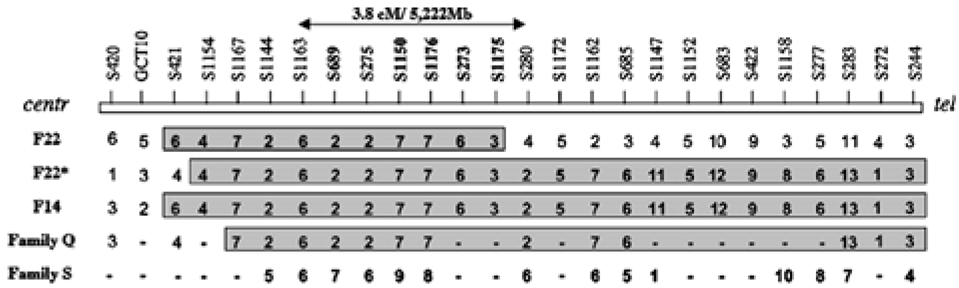

FIGURE 2. Disease haplotypes in familial partial epilepsy with variable foci (FPEVF) families. The order of markers is based on the DNA sequence of chromosome 22. F22, F22*, F14, and family Q all represent haplotypes of French-Canadian families from the Quebec City region (same families as shown in Fig. 1). Shared haplotype portions are shaded. Note that the Spanish family (S) has a totally different haplotype. Markers within the candidate interval defined by recombination analysis are in bold. The 3.8-cM candidate region is marked by an arrow. Dashes indicate that the marker was not typed. (From Berkovic SF, Serratosa JM, Phillips HA, et al. Familial partial epilepsy with variable foci: clinical features and linkage to chromosome 22q12. *Epilepsia*. 2004;45(9):1054–1060, with permission.)

Diagnostic Evaluation

A detailed clinical evaluation with clear description of the seizures by the patient and close relatives is the first important requirement for diagnosis of FPEVF.

Electroencephalographic Findings

Electroencephalograms (EEGs) in patients with FPEVF may disclose temporal, frontal, and, less frequently, occipital and centroparietal foci. Although the variable foci are a landmark of this familial syndrome, the focus remains stable throughout life in each affected patient.

Neuroimaging and Other Laboratory Examinations

No structural magnetic resonance imaging abnormalities have been described in kindreds with FPEVF. In large families, studies to search for linkage to the chr 2 or chr 22 loci can be performed. In French-Canadian families with two or more individuals having different forms of focal epilepsy, origin from the same geographic region and/or the finding of the same haplotype as described in the original three families[36] is strongly suggestive of the diagnosis.

Differential Diagnosis

Sporadic benign partial epilepsies constitute the main differential diagnosis, but it is impossible at present to know whether these individuals may have mutations in the same gene or genes as patients with FPEVF. It should be noted that some sporadic patients could in fact be part of an FPEVF kindred in which the other family members are only mildly affected and sometimes unrecognized. In the case of sporadic French-Canadian patients, however, origin from the same region of Quebec and/or identification of the same haplotype on chr 22q as in the previously reported French-Canadian families[3,35.36] constitutes a high probability for a positive diagnosis of FPEVF. Even in smaller families, linkage to the two loci for FPEVF can be excluded but not confirmed.

Table 1 Comparison of clinical and genetic features in two forms of familial partial epilepsy with variable foci (FPEVF) and autosomal-dominant noctural frontal lobe epilepsy (ADNFLE)

	ADNFLE	FPEVF	
Genetics			
Inheritance	AD	AD	AD
Penetrance	~70%	~70%	~60%
Linkage (gene if known)	20q (*CHRNA4*) 1q (*CHRNB2*)	22q	?2q
Age at onset			
Mean	12yr	12 yr	13 yr
Median	8 yr	10 yr	10 yr
Range	2 mo–35 yr	1 mo–52 yr	9 mo–43 yr
Seizure features			
Frontal origin	Always	Often	Often
Temporal origin	No	Often	Often
Centroparietal origin	No	Rare	Rare
Occipital origin	No	Occasional	Rare

Nocturnal clusters	Almost always	Occasional	No
Seizures when awake	Very rare	Present in some	Common
Secondarily generalized	Rare	Common	Common
Interictal discharges			
Frequency	Rare	Occasional	Common
Localization	Frontal	Variable foci or poorly localized	Variable foci
Structural imaging	Normal	Normal	Normal
Intrafamily variation			
Seizure localization	No	Yes	Yes
Epilepsy severity	Yes	Yes	Yes

AD, autosomal dominant.
(From Berkovic SF, Serratosa JM, Phillips HA, et al. Familial partial epilepsy with variable foci: clinical features and linkage to chromosome 22q12. *Epilepsia*. 2004;45(9):1054–1060, with permission.)

For differential diagnosis of the two commonest clinical presentations FPEVF patients might have, genetic testing to exclude mutations in the known genes for ADNFLE and FTLE could also be helpful.

P.2551

Among the genetically determined partial epilepsies, the most important differential diagnosis is ADNFLE because frontal lobe seizures are the most frequent type found in affected family members with FPEVF. However, frontal lobe seizures have a different pattern in FPEVF as compared to that observed in ADNFLE: The seizures are less frequent, clusters and auras are rare, and daytime seizures as well as secondarily generalized seizures are more frequent (Table 1).[3,36]

For ADNFLE, three loci and two genes have been identified: ENFL1 (chr 20q13.2), with four different mutations in the *CHRNA4* gene, coding for the alpha 4 subunit of the neuronal nicotinic acetylcholine receptor (nAchR)[12,17,23,30]; ENFL2 (chr 15q24, gene unknown)[24]; and the *CHRNB2* gene on the ENFL3 locus (chr 1q), coding for the beta 2 subunit of the AchR.[7,10,22] However, most families with ADNFLE do not map to any of these loci and do not have mutations in either the *CHRNA4* or the *CHRNB2* gene. Thus, in the absence of genetic confirmation, the differential diagnosis between FPEVF and ADNFLE should be based on the clinical and EEG characteristics of the frontal lobe seizures, as well as family members with seizure patterns that indicate foci outside the frontal regions in the former.

The familial temporal lobe epilepsies, both familial mesial temporal lobe epilepsy (FMTLE)[1a,2,5,6,14,16] and familial lateral temporal lobe epilepsy (FLTLE) or ADPEAF,[5,15,21] also should be considered in the differential diagnosis if one or more affec-ted individuals in the family presents clinical and EEG features of temporal lobe epilepsy.[5] A confirmed extratemporal focus in a family member would exclude the diagnosis of FMTLE or FLTLE and suggest FPEVF. Genetic testing is only possible for FLTLE, in which mutations in the *LGI1* gene on chr 10q[13,20] have been found in about half of the families investigated.

In generalized epilepsy with febrile seizure plus (GEFS+), related to mutations in genes *SCN1A*,[9,18,32] *SCN2A*,[31] *SCN1B*,[33,34] and *GABRG2*,[11] different family members also present heterogeneous epilepsy phenotypes, as in FPEVF. Febrile seizures (FS) are the most common phenotype, followed by FS+, in which individuals have seizures with fever that may persist beyond the age of 6 years and/or may be associated with afebrile generalized tonic–clonic seizures.[26,29] Less frequent phenotypes seen in GEFS+ involve other generalized and partial seizure types, including MTLE.[5,16,26,29,33]

Treatment and Outcome

Treatment should be based on the patient's response to antiepileptic drugs (AEDs), and the rationale is similar to that in nonfamilial patients with partial epilepsies. Usually, patients with FPEVF are well controlled with small doses of the same AEDs indicated in other partial epilepsies, and the seizures may remit spontaneously.

Long-Term Prognosis

FPEVF has an overall benign clinical course, although some patients with refractory seizures have been reported. One of our refractory French-Canadian patients was homozygous for

P.2552

the haplotype, having received it from both parents,[35,36] although only one of the parents had epilepsy (1 and 2). Only one individual from another French-Canadian family underwent a temporal lobectomy, but this was not effective in controlling his seizures.[3,35] No neurologic disabilities are known in this syndrome.

Summary and Conclusions

FPEVF is a characteristic epilepsy syndrome with different types and localization of focal epilepsy within families, in the absence of any structural lesion.[28,36] Seizures and epileptic EEG abnormalities are consistent over time in each affected family member and may be frontal, temporal, or occipital, but they vary among family members, which may lead to the misdiagnosis of other familial partial epilepsy syndromes. Two different loci have been associated with FPEVF, an unconfirmed locus on chr 2q,[28] and a confirmed locus on chr 22q.[36] The gene(s) have not yet been identified.

Chapter 256

Generalized (Genetic) Epilepsy with Febrile Seizures Plus

Ingrid E. Scheffer

Samuel F. Berkovic

Introduction

Generalized epilepsy with febrile seizures plus (GEFS$^+$) is a familial epilepsy syndrome characterized by heterogeneous epilepsy subsyndromes or phenotypes within families.[50] GEFS$^+$ has been key in advancing understanding of the genetic interrelationship between epilepsy and febrile seizures. The clinical concept of GEFS$^+$ led directly to the discovery of the role of sodium channels in epilepsy and has also highlighted the importance of γ-aminobutyric acid $(GABA)_A$ receptor subunits in causing seizure disorders.

The majority of families with GEFS$^+$ have generalized seizure types and generalized spike-wave activity on the electroencephalogram (EEG) in addition to febrile seizures.[7,9,37,45,50,54,55] Studies of families around the world have highlighted that focal seizures may also occur, leading some authors to question the nomenclature of "generalized" in generalized epilepsy with febrile seizures plus.[3,7,9,30,51,58] We suggest that the nomenclature be altered to "*genetic* epilepsy with febrile seizures plus" to reflect this observation. It must be emphasized that generalized epilepsies are considerably more frequent in GEFS$^+$ families.

Historical Perspectives

GEFS$^+$ was originally described in 1997 in a large Australian family comprising many affected individuals who showed a spectrum of phenotypic severity.[50] The phenotypes ranged from febrile seizures to mild generalized epilepsies to the severe end of the GEFS$^+$ spectrum, which included myoclonic-astatic epilepsy (MAE, or Doose syndrome; see Chapter 232). This work built on the extensive clinical genetic studies of Doose, where he concluded that MAE was a polygenic disorder.[17] Doose showed that family members of MAE probands most commonly had febrile and afebrile convulsions in early childhood. Evidence to support Doose's hypothesis that MAE has a genetic basis has been gained from the conclusive findings of mutations found in some GEFS$^+$ families, including family members with MAE.

Subsequently, the clinical spectrum of GEFS$^+$ was further elucidated in a study of nine families, the majority of whom were identified through probands with MAE.[54] The clinical genetics of GEFS$^+$ were extrapolated further with the study of probands of families with severe myoclonic epilepsy of infancy (SMEI, or Dravet syndrome; see Chapter 230) where family members with seizure disorders had GEFS$^+$ phenotypes.[53,60]

In 1998, the first gene for GEFS$^+$ was discovered in another large Australian family. This was a mutation of the sodium channel β1 subunit gene, *SCN1B*,[64] and was the first time that sodium channel genes were implicated in epilepsy. In 2000, Escayg et al. reported mutations in *SCN1A*, the gene encoding the α1 subunit of the sodium channel, in GEFS$^+$ families,[21] a finding later confirmed by other groups.[3,20,30,63] The recognition that patients with SMEI, also known as Dravet syndrome, began with febrile seizures led Claes et al. to find that all seven of their patients with Dravet syndrome had *SCN1A* mutations.[13] This work led many others to replicate the findings, highlighting the importance of *SCN1A* in the severe epileptic encephalopathies[47] as well as in milder GEFS$^+$ phenotypes.

The $GABA_A$ receptor γ2 subunit gene, *GABRG2*, has also been implicated in GEFS$^+$ in several kindreds.[7,27,62] More recently, mutations in possible "susceptibility genes" have been reported in the $GABA_A$ receptor *δ* subunit gene *GABRD* and the calcium channel subunit gene *CACNA1H*; these observations require confirmation.[16,29]

Definitions

GEFS$^+$ is defined as a "familial epilepsy syndrome." This syndrome is diagnosed on the basis of more than one individual within a family with a history of seizures that fits into a specific subsyndrome or phenotype of the GEFS$^+$ spectrum (Fig. 1). It remains to be seen whether the phenotype of febrile seizures plus (see below) can be diagnosed in isolation and whether the same genes will be implicated. GEFS$^+$ is best conceptualized as a spectrum of phenotypes seen within a family ranging in severity from mild to severe seizure disorders.

Febrile seizures (FSs) are defined as convulsive seizures with fever above 38°C that occur between 3 months and 6 years of age at their broadest limits.[2]

The phenotype of febrile seizures plus (FS$^+$) refers to a number of different presentations. The most straightforward example is where febrile seizures continue past the defined upper limit of FS of 6 years. Rarely, seizures with fever may start before 3 months of age and would also be called FS$^+$. Additionally, afebrile convulsions may occur in the setting of a child who has febrile seizures. These afebrile seizures may occur during the typical age range of FS (i.e., from 3 months to 6 years), or alternatively, they may follow on from the febrile seizures after 6 years. The afebrile convulsions may also occur after a break of several years after the last febrile seizure.

FS or FS$^+$ may occur with afebrile generalized or partial seizures. For example, individuals may have FS/FS$^+$ and absence, myoclonic, or atonic seizures or a constellation of generalized seizure types.[50]

Partial seizures emanating from the temporal or frontal lobes may also occur with FS or FS$^+$.[3,7,30,52] Although temporal lobe epilepsy (TLE) may occur in the context of hippocampal sclerosis (HS), presumably secondary to FS/FS$^+$, TLE may also occur with normal neuroimaging and pathology and in the absence of preceding FS.[51]

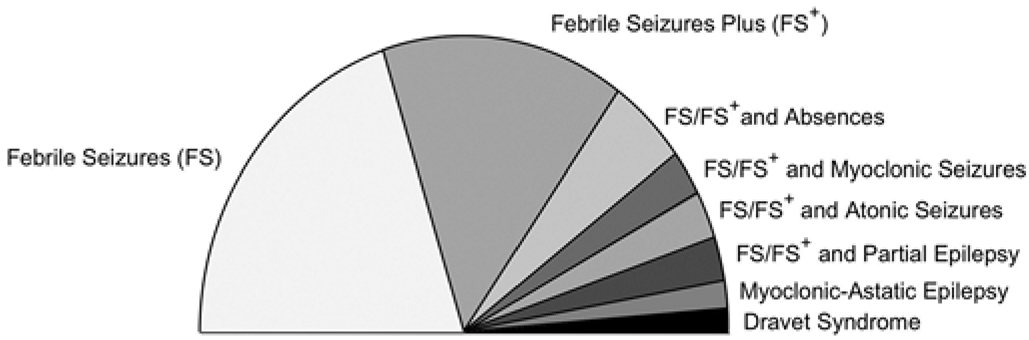

FIGURE 1. Generalized epilepsy with febrile seizures plus (GEFS$^+$) spectrum: The spectrum illustrates the phenotypic heterogeneity seen in GEFS$^+$ families ranging from benign phenotypes such as febrile seizures to severe epileptic encephalopathies such as Dravet syndrome.

At the severe end of the GEFS$^+$ spectrum are MAE and the epileptic encephalopathy Dravet syndrome.[18,26] It is unusual for a family to have multiple severely affected individuals with

P.2554

these syndromes, as most family members have more benign phenotypes.

Epidemiology

The idiopathic generalized epilepsies (IGEs) account for about 15% to 20% of all epilepsies.[28,32] The IGEs can be divided into two major subgroups: The classic IGE and GEFS$^+$. Families in which a number of individuals have IGE typically show phenotypic heterogeneity. However, GEFS$^+$ families show different phenotypic patterns compared with the classic IGE where childhood absence epilepsy, juvenile absence epilepsy, juvenile myoclonic epilepsy, and “generalized tonic–clonic seizures alone” segregate within families.[1,42] Although overlap between the classic IGE and GEFS$^+$ phenotypes does occur within families,[41,54] this is not frequent, suggesting that these major subgroups arise due to distinct, but at times overlapping, groups of genes. No formal epidemiologic studies of GEFS$^+$ have been performed.

Etiology and Basic Mechanisms

GEFS$^+$ is a genetic disorder that has been recognized through study of large multiplex families where there is clinical genetic evidence of a gene of major effect. It sometimes is erroneously stated that GEFS$^+$ is an autosomal dominant syndrome based on the initial genetic discoveries. Whilst autosomal dominant families do occur, the majority of GEFS$^+$ families have clinical genetic evidence of complex inheritance. The rare dominant families led to the appreciation of the phenotypic variation seen in GEFS$^+$ families and the genetic relationship between these phenotypes. However, even in these large kindreds, there is evidence for “complex monogenic” inheritance, which would explain why one family member has a benign phenotype such as FS while another has MAE or Dravet syndrome. In these latter cases, presumably other genes, with or without environmental factors, contribute to produce a severe phenotype.

Mutations of a number of ion channel genes have been identified in GEFS$^+$ kindreds. These include sodium channel subunit and $GABA_A$ receptor subunit genes. The most frequently reported is *SCN1A,* which encodes the pore-forming α subunit of the sodium channel and comprises four transmembrane domains. Missense mutations spread throughout the gene have been associated with the full spectrum of GEFS$^+$ phenotypes including MAE, Dravet syndrome, partial seizures, FS, and FS$^+$ with other generalized seizure types.[3,20,21,30,63]

In contrast, *SCN1A* mutations usually arise de novo in Dravet syndrome and are truncation mutations in at least 50% of cases. Only about 5% of *SCN1A* mutations occur in patients with Dravet syndrome who have familial missense mutations where other family members have milder GEFS$^+$ phenotypes.[22,47,48] Recent reports of low levels of parental somatic and germline mosaicism explain cases of apparently de novo mutations in affected siblings; the parent may be unaffected or have a mild phenotype such as FS.[15,23]

Studies of the functional effects of *SCN1A* mutations yield variable results, with some mutations leading to loss of channel function while others suggest gain of function.[38,39,57] Indeed, different functional effects have been demonstrated using the same mutation in different expression systems.[4,39] In general, missense mutations may lead to gain of channel function, whereas truncation mutations in Dravet syndrome cause loss of function; however, this is by no means universal.[44] Computer simulation of the effects of several GEFS$^+$ mutations suggests a unifying functional endpoint, with each showing an increased propensity to fire repetitive action potentials and thus hyperexcitability.[56]

The first gene implicated in GEFS$^+$ was *SCN1B,* which encodes the β1 subunit of the sodium channel, the auxiliary subunit with a role in channel-gating kinetics and localization of the ion channel.[43] There are now four different mutations of *SCN1B* reported, three missense and one deletion mutation.[6,51,61,64] An analysis of six families with *SCN1B* mutations highlighted that the most common of the known mutations, C121W, is associated with TLE, including patients with and without HS.[51] Functional studies suggest that these mutations cause loss of function.[6,64] The C121W mutant causes subtle effects on channel function and subcellular distribution; initial studies suggested that the major effect was due to slowing of the sodium current inactivation time course.[64] More recent studies showed increased sodium channel availability at hyperpolarized membrane potentials and reduced sodium channel rundown during high-frequency channel activity, as well as altered protein–protein interactions critical for sodium channel localization.[43]

One small family with a GEFS+-like phenotype has been reported with a missense mutation in the sodium channel gene *SCN2A*,[59] and there is one report of a more severe childhood encephalopathy in a child with a nonsense *SCN2A* mutation.[34] Missense mutations in *SCN2A* have been clearly associated with the benign familial neonatal-infantile seizure syndrome, which is unrelated to GEFS+, and in our experience, SCN2A mutations have not been found in GEFS+ families.[8]

The second group of genes associated with GEFS+ encodes subunits of the $GABA_A$ receptor, the ligand-gated chloride channel, which mediates fast synaptic inhibition. The γ2 subunit gene, *GABRG2,* has been confirmed to play a role in GEFS+ families, in some cases in association with classic childhood absence epilepsy.[7,27,41,62] The latter is an intriguing finding given the key role of $GABA_A$ receptors in corticothalamic pathways that mediate generalized spike-wave activity. Functional studies of *GABRG2* mutations suggest loss of function or abnormal trafficking, whereby the receptors do not reach the cell surface.[7,10,27,35,36,40]

Although GEFS+ has been recognized through large dominant families, in most cases GEFS+ follows complex

P.2555

inheritance where a number of genes are presumed to be involved with or without an environmental contribution. Initial insights into susceptibility genes that contribute to complex inheritance are just developing through discovery of alleles in small kindreds where there is evidence of a functional effect of gene variants. It is not known how many such susceptibility genes are needed to produce a GEFS+ phenotype, either for a mild picture such as FS or a severe one such as MAE.

Interestingly, different changes in the *GABRD* gene encoding the *δ* subunit of the $GABA_A$ receptor were found in small families with GEFS+ and IGE.[16] These changes showed reduction of GABA current, suggesting increased excitability given the central role of GABA in inhibition. The *δ* subunit confers different characteristics to the heteropentameric $GABA_A$ receptor compared with the γ2 subunit. The *δ*-containing receptor has a perisynaptic or extrasynaptic localization and has a role in tonic inhibition, whereas the γ2-containing receptor is subsynaptic and mediates phasic inhibition.[16] The finding of *GABRD* changes in GEFS+ and the classic IGE reinforces the concept that $GABA_A$ receptor subunits are involved in both major subgroups of IGE, whereas sodium channel subunits appear to be primarily involved with GEFS+ phenotypes.

The genes currently known for GEFS+ account for <20% of large families studied[44,63]; thus, there remain many genes of major effect to be discovered. Moreover, the number of genes contributing to complex inheritance is not known, nor is the effect size of each gene. Does a GEFS+ phenotype require five or ten genes? Do the molecular permutations and combinations explain phenotypic differences? How do we distill the environmental effects that may underlie aspects of phenotypic heterogeneity? Current molecular and mechanistic insights into GEFS+ highlight how much we are yet to understand regarding the neurobiology of this complex familial syndrome.

Clinical Presentation

Clinical evaluation in GEFS+ involves a detailed history and examination with careful attention to the presence of a documented fever, rather than the presumption of a fever, when attacks occur. This may require sourcing the ambulance and emergency department notes to determine if a fever was present as families often equate fever with the observation that a child feels hot, yet the child may be afebrile when his or her temperature is formally taken.

The nature of the attacks needs to be determined ideally through an eyewitness account. Many attacks may mimic febrile seizures such as febrile delirium, febrile syncope, rigors, and breath-holding attacks. It is important to accurately determine that a convulsion occurred. Clues to unwitnessed convulsions should also be sought such as a bitten tongue or rare enuresis in a child not prone to enuresis.

Specific questioning regarding other seizure types is necessary as myoclonic seizures, atonic seizures, or staring spells may not be mentioned spontaneously; indeed, a child may just be considered to be a day-dreamer, “nervous,” or jumpy. Absence seizures may be less frequent than in typical childhood absence epilepsy, with rare but definite attacks lasting <30 seconds and occurring several times per year, rather than several times per day. Symptoms of focal seizures should also be sought with emphasis on temporal lobe auras and complex partial seizures.

When considering phenotypes at the severe end of the GEFS$^+$ spectrum, the electroclinical presentation of syndromes such as myoclonic-astatic epilepsy of Doose and Dravet syndromes is quite specific (see Chapters 232 and 230).

Family History

The key to a diagnosis of GEFS$^+$ is the family history as this is a *familial* epilepsy syndrome and requires at least two affected individuals in a family to have GEFS$^+$ phenotypes.

The family history should explore the presence of seizures in family members and consanguinity. One should always ask specifically about febrile seizures or febrile convulsions in addition to epilepsy, as families often do not think the former is of relevance. Frequently the matriarchs of the family hold the key to this knowledge and the family should be encouraged to speak with older family members and report back to the clinician at subsequent visits. Where there is controversy about attacks, the clinician may need to directly contact family members, with the permission of the proband's family, to understand the nature of the attacks in other branches of the family. This aids in diagnosing whether a specific individual's phenotype is likely to be part of the GEFS$^+$ spectrum. As epilepsy is common, it is not unusual for an individual with epilepsy in a GEFS$^+$ family to have an unrelated seizure disorder such as symptomatic epilepsy; this must be carefully considered when performing and interpreting genetic studies.[64]

Diagnostic Evaluation

Electroencephalographic Findings

Although no systematic EEG studies in GEFS$^+$ have been performed, the EEG is often normal in the milder phenotypes in GEFS$^+$. Irregular generalized spike wave can occur in FS$^+$ individuals and is likely to be an age-dependent abnormality. Similar changes were reported in a cohort of children with seizures with fever; it is possible this cohort included cases that we would now regard as FS$^+$.[5] With the more severe phenotypes, the EEG findings are as anticipated by their seizure types. For example, epileptiform discharges emanating from the region in which the seizures originate may occur in focal seizures. Similarly, fast generalized spike wave would be seen in MAE, and generalized spike wave and focal discharges in Dravet syndrome.[19,25]

Neuroimaging and Other Laboratory Examinations

Magnetic resonance imaging (MRI) of the brain is almost always normal in GEFS$^+$ phenotypes. Where ongoing focal seizures occur, MRI is indicated as HS has been found in certain cases, including some with known sodium channel mutations, and has typically followed a history of FS or FS$^+$.[31,51] Some patients with TLE and *SCN1B* mutations have been rendered seizure free following anterior temporal lobectomy,[51] but they still require comprehensive presurgical characterization as with other patients undergoing epilepsy surgery.

Mutational analysis of *SCN1A* is indicated in Dravet and related syndromes such as the borderline variant of Dravet syndrome. Mutations are found in about 70% to 80% of children with classic Dravet syndrome, and around 95% arise de novo. Very recently, exonic deletion of *SCN1A* has been shown to be a novel mechanism underlying Dravet syndrome, responsible for some patients negative by conventional mutational analysis.[46] In these children, the discovery of a mutation obviates the need for other potentially invasive investigations such as lumbar puncture and muscle and liver biopsy. It also supports more aggressive strategies to achieve seizure control to potentially improve developmental outcome.

P.2556

Mutational analysis in GEFS$^+$ is more controversial. While mutations have been found in GEFS$^+$ in sodium channel and $GABA_A$ receptor subunits, these are uncommon and do not modify treatment approaches. Further research is needed, as with current knowledge the presence of a familial mutation does not inform the clinician regarding phenotype or outcome. Indeed, the finding of a mutation in a family does not explain the phenotypic heterogeneity that is the hallmark of GEFS$^+$. Deeper understanding of the complex genetics of GEFS$^+$ is necessary to explain why one family member has a benign versus a severe phenotype.

Differential Diagnosis

The differential diagnosis of GEFS$^+$ includes an understanding of the phenotypic variation that occurs in GEFS$^+$ families and those phenotypes that are not regarded as part of the spectrum. For example, malformations are not seen in GEFS$^+$ and are unlikely to be due to the same genetic mutations.

Diagnosis of FS requires an understanding of attacks that can be misdiagnosed as FS such as febrile delirium and febrile syncope. It cannot be emphasized sufficiently that a clear description of the event is necessary, ideally from an eyewitness. Moreover, distinction of different phenotypes within GEFS$^+$ may require additional effort, such as establishing whether a fever was actually present at the time of the attack.

There are many childhood epilepsy syndromes that are not characteristically seen in GEFS$^+$ families. These include benign childhood epilepsy with centrotemporal spikes and the benign occipital epilepsies of childhood. As they are relatively common disorders, they may occur in a GEFS$^+$ family just by chance; a mutation common to both disorders would need to be demonstrated to prove a molecular relationship.

Treatment and Outcome

Children with FS and FS$^+$ usually do not require medication. Recognition of FS$^+$ allows the clinician to defer antiepileptic therapy where infrequent brief convulsions with fever persist after 6 years in a developmentally normal child. If, on the other hand, frequent or afebrile seizures occur at any age, the clinician should consider antiepileptic therapy. There are no trials of the efficacy of treatment; however, our experience suggests that valproate is effective in FS$^+$ or where the child has FS/FS$^+$ with other generalized seizure types. If seizures are refractory to valproate monotherapy, lamotrigine should be considered. The usual principle of treating the child until he or she has been seizure free for 2 years should guide therapy. If convulsions are prolonged, benzodiazepines may be considered acutely. If convulsions occur frequently, interval use of benzodiazepines may be used when fever occurs prophylactically.[49]

For the phenotypes at the more severe end of the GEFS$^+$ spectrum, choice of antiepileptic drug should be based on the seizure types and syndromes. For example, seizures in Dravet syndrome may be exacerbated by lamotrigine,[24] whereas, seizure control is often better with clobazam and topiramate.[14] The experimental drug stiripentol was effective in one double-blinded study of Dravet syndrome suggestive of a syndrome-specific effect.[12]

Long-term Prognosis

The outcome is usually good, with most GEFS$^+$ phenotypes being benign. Seizures settle by adolescence in FS$^+$, although rare adult convulsions may occur under conditions of stress or sleep deprivation. Where other generalized or focal seizures occur in addition to febrile convulsions, the outcome is often, but not universally, good. For example, TLE may cease by midchildhood or, alternatively, prove refractory, warranting surgical consideration.[51]

MAE is known for its variable cognitive outcome from normal to severe intellectual disability, and this is clearly evident where MAE occurs in GEFS$^+$ families.[54] Seizure frequency improves with age although may not cease altogether. The majority of patients with Dravet syndrome have poor cognitive outcome, although rare individuals have normal intellect. Seizures typically continue into adult life and comprise nocturnal tonic–clonic seizures, although partial, absence, and myoclonic seizures may also occur.[33] These patients often have pyramidal signs and ataxia, and rarely manage to live independently as adults.

Genetic Counseling

Genetic counseling is an important aspect of management of patients and families with GEFS$^+$. The diagnosis of a GEFS$^+$ phenotype acknowledges the relationship with other familial seizure disorders but does not allow the clinician to predict prognosis. A finding of a mutation, if present, cannot be used alone to offer prognostic counseling because of the wide phenotypic and outcome variability; thus, prognostic counseling should be based on the clinical phenotype. Familial mutations are usually associated with a penetrance of 60% to 80%, so it is difficult to predict the outcome in carrier offspring.[37,54]

Genetic counseling is critical in Dravet syndrome, where *SCN1A* mutations are found in 70% to 80% of children with Dravet syndrome and 95% arise de novo. It is rare for families to have two children with severe phenotypes such as Dravet syndrome and the borderline variant of Dravet syndrome. This rare occurrence has recently been explained by the finding of parental germline and somatic mosaicism.[15,23]

A recent pertinent issue is the risk to offspring of adults with Dravet syndrome who have an essentially normal cognitive outcome. Such questions have only arisen since recognition that this may occur.[11,33] For example, in the case of a familial GEFS$^+$ mutation where the patient has Dravet syndrome, the outcome for offspring may be relatively good as the severe phenotype is likely to have a polygenic basis. On the other hand, where the adult has a de novo *SCN1A* mutation, it is more likely that offspring may have a similarly severe phenotype. Whether this is indeed the correct interpretation will depend on careful observation of such patient groups.

Summary and Conclusions

GEFS$^+$ is an important form of idiopathic epilepsy recognized throughout the world and forms one of the major subgroups of the IGEs. GEFS$^+$ is a clinical diagnosis that depends on recognition of the clinical syndrome in the familial context. The concept of a familial epilepsy syndrome aids in understanding the interrelationships of seizure disorders such as epilepsy and febrile seizures. Recognition of the phenotypes that fit into the GEFS$^+$ spectrum helps in diagnosis and may inform investigations, treatment selection, and prognostic and genetic counseling.

GEFS$^+$ led directly to the discovery of mutations of sodium channels and GABA receptors in epilepsy, further reinforcing the key role of ion channels in the pathophysiology of the epilepsies. The finding of *SCN1A* mutations in Dravet syndrome is of significant clinical importance and is the key investigation in these individuals. Nevertheless, the diagnosis of Dravet syndrome is based on electroclinical features and is not dependent on molecular testing. Equally, the finding of an *SCN1A* mutation does not necessarily mean that a child

P.2557

has Dravet syndrome; this diagnosis depends on the clinical setting. New genetic counseling issues are arising with recent discoveries. GEFS$^+$ has opened many doors to understanding the genetics of the epilepsies but has also highlighted the large task ahead in solving this complex area.

Acknowledgments

The authors are grateful to the many patients and families who have participated in their research studies. Funding has been received from the National Health and Medical Research Council of Australia and Bionomics Ltd.

Chapter 257

Reflex Seizures

Benjamin G. Zifkin

Renzo Guerrini

Perrine Plouin

Introduction

Reflex seizures are reliably triggered by some identifiable factor.[200] Reviews include Beaumanoir et al., Zifkin et al., and Wolf et al.[11,210,213] The identification of a patient with reflex epilepsy depends on the physician's awareness and on the observations of the patient and witnesses. The epileptogenic trigger must occur often enough in everyday life so that its relation to the resulting seizures can be suspected. If the trigger is ubiquitous, however, the seizures appear to occur by chance or with no obvious antecedent.

The study of reflex seizures has also furthered understanding of cortical organization in man and has implications for our understanding of how and why some apparently generalized seizures may begin.

Definition and History

Seizures induced by light stimulation were known from classical antiquity, and in the 20th century before the electroencephalographic (EEG) era.[166,189] The use of the term *reflex* has been controversial. Hall[85] first applied it to epilepsy in 1850. Arguing that no reflex arc is involved in reflex epilepsy, others proposed terms such as *sensory precipitation*[65,156] or *stimulus-sensitive epilepsies*.[42] Wieser noted that sensory precipitation epilepsy is a misnomer because some reflex seizures, for example, those triggered by cognition, are not precipitated by sensory stimuli.[197] In the 19th century, Brown-Séquard[27] noted that "certain parts of the central nervous system possess an elevated excitability so that any minimal stimulation may cause a crisis." Both Gowers[77] and Hughlings Jackson[95] described reflex seizures triggered by various causes including sudden noise, bright sunlight, movement, and tapping the head, which are still accepted reflex seizure types. In the 20th century, Adrian and Matthews[1] first documented the effect of light on the normal EEG. The stroboscope became available after World War II and rapidly led to further progress as flicker stimulation and its clinical and EEG effects could be easily studied. Important studies by Walter and Walter,[195] and later by groups led by Gastaut in France and by Bickford in America, yielded basic information about those EEG responses to stroboscopic flicker (intermittent photic stimulation [IPS]), which were reliably linked to seizures. Television screens and sunlight are the most common environmental triggers of visual-sensitive seizures; triggering by television broadcasts and video games has become notorious in recent years, leading to increased interest in reflex seizures.

Classification

Some earlier classifications and the publications on which they were based described "simple" and "complex" reflex epilepsies. Binnie[19] noted: "A distinction should be made between seizures evoked by simple, unstructured sensory stimuli and those precipitated by complex cognitive activities, often with an emotional component. The former are interpretable in terms of known physiological events (not strictly reflex processes) following a stimulus, whereas the latter may offer insights into the complex mechanisms underlying cognition." Wolf and Inoue[209] described reading epilepsy and praxis induction as complex reflex epilepsies.

Complex reflex epilepsies are characterized by seizures triggered by relatively elaborate stimuli whose specific pattern is the determining factor in seizure evocation. The attacks are precipitated by stimuli involving integration of higher cortical function, rather than by relatively simple sensory stimuli, and may be evoked by anticipation of the stimulus. Latency from stimulus onset to the clinical seizure or evoked abnormal paroxysmal EEG activity is typically longer than in simple reflex epilepsies, such as photosensitive epilepsy, in which the response to flicker is usually almost immediate. These properties, enunciated in the 1985 proposal for classification of epilepsies,[42] had been systematically described in the pioneering work of Forster.[61] To avoid confusion, it should also be emphasized that the term *complex*, as applied to reflex epilepsy, does not refer to a classification of the induced seizures. Although many varieties are not accepted as epileptic syndromes in the current international classification, partly because of the occurrence of spontaneous seizures in the same patients, they are described as "epilepsies characterized by specific modes of seizure precipitation."[43] Despite this, the induction of attacks in these patients is prominent and often quite stereotyped, and the Commission's 1989 definition of a syndrome—"a cluster of signs and symptoms customarily occurring together"—may be met. In others, for example, with "language-induced seizures," the clinical pattern may overlap other more clearly defined entities.

The current classification proposal[55] defines reflex epilepsy syndromes as those "…in which all epileptic seizures are precipitated by sensory stimuli. Reflex seizures that occur in focal and generalized epilepsy syndromes that are also associated with spontaneous seizures are listed as seizure types." Thus, this proposal also recognizes few reflex epilepsy syndromes:

- Idiopathic photosensitive occipital lobe epilepsy
- Other visual-sensitive epilepsies
- Startle epilepsy
- Primary reading epilepsy
- Musicogenic epilepsy

Reflex seizures are often classified according to the stimuli that trigger them rather than by the type of seizure that is triggered. The classification proposal also includes, under seizure types, a list of precipitating stimuli for reflex seizures. These stimuli are:

- Visual stimuli
- Flickering light—color to be specified when possible
- Patterns
- Other stimuli
- Thinking

P.2560

- Praxis
- Reading
- Somatosensory
- Proprioceptive
- Eating
- Music
- Hot water
- Startle

It is important to note that reflex seizures are not distinguishable from spontaneous seizures except for the fact that they are triggered in some identifiable way; that is, a reflex generalized tonic–clonic seizure is clinically the same as one that occurs spontaneously.

Basic Mechanisms of Reflex Epilepsy

Animal Models

There are two types of animal model of reflex epilepsy. In the first, diffuse or regional cortical hyperexcitability is induced chemically or by the creation of a lesion. The second model involves naturally occurring reflex epilepsies or seizures induced by specific sensory stimulation in genetically predisposed animals.

The first approach has been used since 1929, when Clementi[38] induced convulsions with intermittent photic stimulation after applying strychnine to the canine visual cortex. Strychninization of auditory,[39] gustatory,[40] and olfactory cortex[140] also produced focal irritative lesions that could produce seizures with the appropriate afferent stimulus. EEG studies showed that the clinical seizures (chewing movements), which were induced by photic stimulation in rabbits with strychnine lesions of the visual cortex, resulted from rapid transmission of the epileptic discharge from the visual cortex to masticatory areas.[190] Paroxysmal discharge from visual cortex may also spread to frontorolandic areas during seizures.[63,66] The ictal EEG spread was thought to represent corticocortical conduction,[38,63] although later work with pentylenetetrazol also implicated thalamic relays[66] and demonstrated spread of the visual-evoked potential to the brainstem reticular formation.[64] Hunter and Ingvar[96] identified a subcortical pathway involving the thalamus and reticular system and an independent corticocortical system for radiation of visual-evoked responses to the frontal lobe. In cats and monkeys, the frontorolandic region was also shown to receive spreading-evoked paroxysmal activity from auditory and other stimuli.[18,28]

The second approach, the study of naturally occurring or induced reflex seizures in genetically susceptible animals, has been pursued in chickens with photosensitivity,[45,105] rodents susceptible to sound-induced convulsions,[35] the E1 mouse sensitive to vestibular stimulation,[179] and the Mongolian gerbil sensitive to a variety of stimuli.[126,127] Most of these are of limited relevance to human epilepsy but are of interest to the drug industry as rodent models are useful as relatively cheap and standardized methods for testing possible antiepileptic drugs.

The only species in which naturally occurring reflex seizures and EEG findings are similar to those in humans is the baboon Papio papio,[113] but the light-induced epileptic discharges in baboons occur in the frontorolandic area, rather than in the occipital lobe as they do in human photosensitive epilepsy.[112] EEG, visual-evoked potentials, intracerebral recording, and lesion and pharmacologic studies show that visual afferents are necessary to trigger frontorolandic light-induced epileptic discharges in these animals. Unlike human photosensitivity in which the occipital cortex is hyperexcitable, in the baboon the occipital lobe does not generate this abnormal activity, but sends corticocortical visual afferents to hyperexcitable frontal cortex, which is responsible for the epileptiform activity.[137] The interhemispheric synchronization of the light-induced paroxysmal EEG activity and seizures depends mainly on the corpus callosum and not on the brainstem. Brainstem reticular activation depends initially on frontal cortical mechanisms until a seizure is about to begin, at which point the cortex can no longer control reticular activation. The genetically determined hyperexcitability may be related to cortical biochemical abnormalities, involving regulation of extracellular calcium concentration,[51,161] or an imbalance between excitatory and inhibitory neurotransmitter amino acids[124] similar to those described in feline generalized penicillin epilepsy and in human epilepsy.[74]

Visual-sensitive Epilepsies and Seizures

Reflex seizures and epilepsies sensitive to visual stimulation, especially flashing light, are the commonest and longest known, and will be described first. Visual sensitivity has been defined as "having seizures evoked by the physical characteristics of a visual stimulus in daily life or by IPS."[111] Recognition of seizures induced by flashing light predates the EEG. Before clinical EEG, seizures were reported with environmental flicker or with sudden changes in light intensity. Gastaut et al. reported an early series of patients investigated with stroboscopic IPS during EEG recording.[68] Historically, photosensitivity has meant an abnormal response to light and since the development of the stroboscope, an abnormal response to flicker stimulation during EEG recording is generally called photosensitivity. This flicker sensitivity is common to different types of seizures induced by visual stimuli, but subtypes in which patients are reproducibly sensitive to more complex visual stimuli can be distinguished among patients, who are almost always sensitive to intermittent photic stimulation at some time. Pure photosensitive epilepsy, in which seizures occur only with environmental light stimulation, is the most common reflex epilepsy. The induction of focal occipital lobe seizures by the same types of visual stimuli is more common than previously thought. Television and sunlight are the most common environmental triggers of visual-sensitive seizures; triggering by television broadcasts and video games has become notorious in recent years. Visual-sensitive epilepsy is included as a reflex epilepsy syndrome in the most recent proposed classification of epilepsy syndromes.[55]

Several types of EEG response to flicker have been described. An epileptiform EEG response to IPS is a photoparoxysmal response (PPR). These may be restricted to the occipital area or be apparently generalized. Different responses may occur in the same patient depending on the stimulator used, the stimulation protocol, age, and medication effects. In untreated subjects, only generalized paroxysmal epileptiform discharges in response to IPS (spikes, polyspikes, and spike-and-wave complexes) are clearly linked to epilepsy: Apart from those with idiopathic photosensitive occipital epilepsy (IPOE), less is known about patients with clinically evident visually triggered seizures but who have only focal occipital PPRs. These responses are most common with stimulation from 10 to 30 flashes per second.

Epidemiology of Visual Sensitivity

Most studies are retrospective and target specific patient groups. Following seizures triggered by the video game Mario World in 1992, Quirk et al.[163] prospectively studied the

incidence of visually-induced seizures and PPRs in newly diagnosed epilepsy patients in the United Kingdom. For all ages, a conservative estimate was that the incidence of epilepsy with PPRs was 1.1 per 100,000, about 2% of all new cases of epilepsy. Incidence rose to 5.7 per 100,000, or 10% of all new cases, in patients from 7 to 19 years old.

PPRs and clinical photosensitivity show marked age dependency. They are very rare before age 2 years. In Dravet syndrome (severe myoclonic epilepsy of infancy), responses may be abnormal before age 2 but without evident seizures, and Oguni et al.[148] reported a subgroup in whom myoclonic seizures and atypical absences could be triggered by constant illumination, rather than by IPS, depending on the brightness of the light. This sensitivity tended to disappear before age 5 years. Only one case has been reported of an infant aged 15 months who experienced about 20 seizures in 3 weeks when brought into a bathroom with bright white walls and shiny bright chromed plumbing; he showed the following symptoms: Motion arrest, deviation of the head and eyes to the left, jerks of the eyelids, looking afraid, and right occipital seizure on the EEG. He had no further seizures until he was 11, when occipital seizures recurred.[172]

Both PPRs and visually induced seizures show a clear female preponderance of about 60% of cases, and photosensitivity appears to peak at around puberty. Whether photosensitivity declines with age in patients is debated; several report that it declines in the third decade, while others found no decline with age.[111] PPRs occur in normal subjects, especially in children up to 16 years old, in whom a prevalence of 1.3% has been reported, and this photosensitivity declines with age. Studies in young adult male aircrew candidates in several countries yielded PPR rates of 0.5% to 0.7%.

Genetics of Photoparoxysmal Responses

Genetic studies of photosensitivity have been hampered by differences in stimulation methods and in classification of the EEG responses. The reduction of sensitivity with age, especially in asymptomatic children, also makes transgenerational studies impossible or difficult to interpret. Monozygotic twins have shown almost 100% concordance for PPRs. Waltz and Stephani reported that photosensitivity is significantly more common in 5- to 10-year-old siblings of proband offspring of a photosensitive parent (50%) than in siblings of photosensitive children without parental photosensitivity (14%). The highest risk of seizure (33%) was in photosensitive siblings of a proband with parental photosensitivity, and the lowest (4%) in nonphotosensitive siblings of probands without parental photosensitivity.[196]

A single gene for photosensitivity has not yet been identified. Three different loci have been found, one on each of chromosomes 2 (in a single family), 7q32, and 16p13, and the last two in families with prominent myoclonic epilepsy.[158] Photosensitivity occurring in some patients with identifiable epileptic syndromes (e.g., juvenile myoclonic epilepsy [JME]) is inherited separately from the other epileptic disorder.

Clinical Aspects of Visual Sensitivity

The proposed classification recognizes idiopathic photosensitive occipital lobe epilepsy and "other" visual-sensitive epilepsies as reflex epilepsy syndromes, requiring that all seizures be triggered. Other cases are classified as seizure types, which are more common, and it is not specified whether these represent generalized or focal epilepsy.

Pure Photosensitive Epilepsy

Pure photosensitive epilepsy is characterized by seizures exclusively provoked by flicker. These patients do not have spontaneous seizures. Forty percent of patients with seizures and photosensitivity studied by Jeavons and Harding, Binnie et al., and Kasteleijn-Nolst Trenité et al. are reported to fall into this group. In one study, 84% of patients had seizures reported as generalized tonic–clonic, whereas absences occurred in only 6%, partial motor seizures (possibly asymmetric myoclonus in some cases or unrecognized idiopathic photosensitive occipital epilepsy) in 2.5%, and myoclonic seizures in 1.5% of patients.[104] However, these proportions are subject to bias; patients will come to medical attention after a convulsion in front of the television but may have already had many subtle unobserved reflex seizures with brief myoclonic or absence-like events. Patient self-reporting of these triggered seizures can be extremely inaccurate: Over half of known photosensitive epilepsy patients questioned immediately after stimulation denied having had brief but clear-cut seizures induced by IPS and documented by video-EEG monitoring.[110] In laboratory studies with video monitoring, most events are myoclonic jerks[110] and patients commonly report eye pain and feelings of eyestrain. The developmental and neurologic examinations are normal.

Idiopathic Photosensitive Occipital Epilepsy

IPOE[84] is recognized as a reflex epilepsy syndrome in the proposed diagnostic scheme. IPOE is a relatively benign, age-related syndrome without spontaneous seizures. Seizures evoked by visual stimuli were formerly thought to be almost exclusively generalized despite the clear occipital localization of visual function, though asymmetric myoclonus could occur. Induction of partial seizures by visual stimulation, including typical complex partial seizures, is now well recognized.[92] Intermittent photic stimulation can induce clear-cut partial seizures originating in the occipital lobe.[81,92] As in more typical photosensitive subjects, environmental triggers include television and video games. The symptoms may remain localized to the occipital area for several minutes even after the stimulus has ceased: Visual blurring, blindness, or elementary visual hallucinations may occur.[81,169,188] The clinical seizure pattern depends on the pattern of spread. The initial reflex visual symptoms may be followed by versive movements and motor seizures. Myoclonus is not typical, but migraine-like symptoms of throbbing headache, nausea, and, sometimes, vomiting are common and can lead to delayed or incorrect diagnosis.

Photosensitive Epilepsy with Spontaneous Seizures

The remaining 60% of patients with epilepsy and photosensitivity also have spontaneous seizures, and photosensitivity gives rise to attacks precipitated by environmental visual stimulation in 33% of the total. A further 7% have demonstrable seizures during IPS but report no visually precipitated attacks in everyday life. Thus, 80% of photosensitive people with epilepsy have some form of visually precipitated seizures. These are often associated with idiopathic generalized epilepsies and especially with juvenile myoclonic epilepsy, in which 30% to 48% are photosensitive, and childhood absence epilepsy, in which 18% were reportedly photosensitive.[125,208] Typical absence seizures may be triggered by IPS: These are rare and may be resistant to treatment.[10]

Photosensitivity in Other Epileptic Disorders

Photosensitivity may be found in several epileptic disorders. It is rare in symptomatic occipital epilepsies but has been described with triggered focal occipital seizures in patients with

occipital calcifications and celiac disease.[4] It also may occur with symptomatic generalized epilepsies such as severe myoclonic epilepsy of infancy (SMEI, Dravet syndrome); with the progressive myoclonus epilepsies such as Lafora disease, Unverricht-Lundborg disease, Kufs disease; or with the neuronal ceroid lipofuscinoses, in which photosensitivity at low flash frequencies such as 1/s is typical. These syndromes are associated with photic cortical reflex myoclonus, and the patients also have clear-cut action myoclonus.

Pattern-sensitive Seizures

Pattern-sensitive epilepsy consists of seizures triggered by viewing patterns, typically stripes. The seizures are generalized convulsions, absences, or brief myoclonic attacks provoked by viewing patterns such as patterned video screen content, escalator steps, striped wallpaper, or patterned clothing.[22] Television is now the most common precipitant, reported in 41% of 73 patients.[165]

Initially described in a single child by Bickford, it was considered an interesting rarity. Bickford et al.[17] reported a low rate of EEG sensitivity to stationary pattern of 0.25% in 40,000 patients. Chatrian showed that the nature of the pattern affected its epileptogenicity, and the classic studies of Wilkins et al.[22] further described the characteristics of epileptogenic patterns. With stimuli designed for maximum effect, pattern sensitivity is more common than previously reported, found in 17% to 54% of photosensitive subjects with static patterns.[21,109,144,160] Patterns oscillating orthogonal to their line orientation are more provocative and elicit sensitivity in 60% to 70%.[21] Clinical pattern sensitivity is much less common, found in about 2% of photosensitive subjects by Jeavons and Harding[104] and in 6% by Kasteleijn-Nolst Trenité.[109] Some subjects sensitive to pattern are not sensitive to flicker.[90] Radhakrishnan et al.[165] noted this in 11% of 73 subjects, but their first EEGs were performed in 1950 and this may be partly related to different methods of IPS and age-related changes in photosensitivity.

Interictal epileptiform EEG activity has been reported in 84%. Two thirds had generalized epileptiform activity with pattern stimulation, and in one third, this was confined to posterior head regions.[165] These authors also found that 14 of 73 (19%) had JME, three had progressive myoclonus epilepsy, and one had SMEI.

Other

Some photosensitive patients are sensitive to eye closure alone. Reflex absences or brief myoclonic attacks, and visual disturbances ("scotosensitive seizures") can occur with eye closure or in darkness in patients not sensitive to intermittent photic stimulation and are thought to be precipitated in some by the abolition of central vision and fixation.[151,152] Others may not require total darkness or abolition of fixation. However, most subjects with the florid posterior epileptiform EEG activity abolished by fixation, and typical of the Panayiotopoulos and Gastaut types of idiopathic childhood occipital epilepsy, do not have reflex seizures.

Eyelid myoclonia with absences, described by Jeavons[103] and reviewed by Gobbi,[75] is characterized by eyelid jerks with eye closure in a photosensitive patient, with bilateral fast spike-and-wave EEG activity. The seizures can occur even in darkness. Some have no spontaneous seizures. Often, only the EEG change can be seen. Not all patients have absences and not all are photosensitive. It is not yet clear whether this forms a discrete clinical entity: The trigger mechanisms are complex and not well defined, and many may have another epileptic disorder such as JME. Harding and Jeavons[90] suggested that most such cases were examples of self-induction, but a detailed definition of a syndrome of eyelid myoclonia with absences has been suggested by Panayiotopoulos.[153]

Seizures reportedly triggered by eye movement[183,191] are a heterogeneous group. Some may represent scotosensitivity, and others may be cases of self-induction. Others triggered by conjugate eye movement may depend on proprioceptive input, and anterior, occipital, and parietal EEG discharges have been reported with these.

Self-induction of Visual-sensitive Seizures

Patients with all types of visually induced seizures may induce attacks with visual stimulation and may be compulsively drawn to sources of flicker or pattern stimulation such as television screens. Patients sensitive to eye closure may use a compulsively repeated eye rolling and eyelid flicker movement to self-stimulate.[47] Monitoring has shown that the stimulatory behaviors indeed trigger the seizures rather than being manifestations of the seizures. Intensely pleasurable sensations have been reported with these, and some patients induce seizures to relieve stress or to gain attention.[188] Monitoring indicates that 24% to 30%[21] engage in self-induction when placed in a well-lit environment, particularly if stressed. Diagnostic features are:[19]

1. The eye movement precedes the epileptiform EEG discharge.
2. The oculographic artifact is larger and slower than that accompanying normal spontaneous eye closure and often shows a superimposed ocular tremor at about 6 Hz.
3. The maneuver is carried out less frequently in darkness, where it fails to produce epileptiform discharge.
4. The behavior is increased by stress.
5. Patients display guilt when the phenomenon is discussed.
6. Patients admit to carrying out the maneuver, variously describing it as voluntary or compulsive.
7. A pleasant sensation is often reported; this may have a sexual component leading to orgasm in some subjects.
8. There may be a history of seizures induced by hand waving in the past, or patients may use hand waving in combination with slow eye closure to enhance or prolong the discharge, as documented on film by Ames.[5]

These can be distinguished by EEG monitoring from nonepileptic paroxysmal eyelid movements that may occur in children and adults with generalized photosensitive epilepsy. These may be mistaken for absence seizures. There is often a family history of eyelid movements.[29]

Seizures Triggered by Television and Video Displays

Reflex seizures triggered by television, computer screens, and video games have become notorious. The Pocket Monsters cartoon episode that triggered a nationwide outbreak of photosensitive seizures in Japan is a well-known example,[87,102] but broadcasting of dangerous screen content had already led to outbreaks of photosensitive seizures, and guidelines to prevent the broadcasting of screen content likely to trigger seizures were already in place in the United Kingdom. These have become more widespread since the Pocket Monsters episode. Many of these events represent pure photosensitive epilepsy with or without pattern sensitivity. Some have occurred in subjects not previously known to have epilepsy, and others have occurred in known photosensitive patients. Some were likely focal occipital visual reflex seizures with autonomic manifestations (see IPOE above). Ferrie et al.[59] found that 29% of a group of subjects with video game–induced seizures had photosensitive partial seizures. In patients with seizures recurring after an initial Pocket Monster seizure, juvenile myoclonic epilepsy was the most common diagnosis in those not known to have epilepsy before the triggered event, while those with a history of epilepsy and recurrent seizures often had frontal lobe epilepsy.[149]

P.2563

Guidelines in Japan and the United Kingdom now prohibit such program material.[91] These have been shown to successfully control potentially harmful TV screen content.[186] Special electronic filter devices are also effective in reducing PPRs induced by television.[185] Seizures associated with video screens may also have occurred by chance or in nonphotosensitive individuals in relation to other reflex seizure triggers, such as thinking, with or without manipulation of objects (action programming or praxis, see below) during computer use or game play.

Mechanisms of Visual-sensitive Seizures

Several approaches have been taken to studying human photosensitivity and seizures induced by visual stimuli. Visual stimulation resembling reported environmental stimuli such as video games can be modified and responses studied. Properties of elementary and subthreshold visual stimuli can be manipulated to enable inferences to be drawn about physiologic trigger mechanisms in both EEG and evoked potential studies and more recently in magnetic resonance and magnetoencephalography studies.

Television-induced seizures and others triggered by video displays can be understood in relation to the properties of video screens and to the images on the screen. Visual reflex seizures and the characteristics of the effective triggers have been recently reviewed.[214] Flicker rate, pattern, luminous intensity, size, location, and duration of the stimulus need to be considered. A television screen produces flicker at the alternating current (AC) frequency, effectively generating IPS at 60 Hz in North America and 50 Hz in Europe. Photosensitivity is more common at the lower frequency, with nearly 50% of patients sensitive to 50-Hz intermittent photic stimulation,[104] and television sensitivity has indeed been a greater problem in Europe than in North America. Television-induced seizures, however, are not only related to AC frequency flicker. Wilkins et al. studied patients who were not sensitive to this flicker but who responded to the vibrating pattern of interleaved lines at half the AC frequency (25 Hz in Europe and 30 Hz in North America) to which about 75% of photosensitive subjects are sensitive and which can be discerned only close to the screen.[205] Special 100-Hz television screens, marketed in Europe, reduce the risk of television-induced seizures.[169] Color is important even without luminance changes; photoparoxysmal EEG responses can be elicited in sensitive subjects by non–color-opponent stimuli even if they are isoluminant.[88] Sensitivity is greater with red stimulation at wavelengths greater than 700 nm, and red stimulation was important in the Japanese cartoon incident.[87] Red-cyan flicker, even when isoluminant, is reportedly even more provocative of epileptic discharge.[180] Thus, seizures can be triggered even at greater distances and by 100-Hz TV sets and modern noninterlaced screens without intrinsic flicker. Flashing or patterned screen content has been implicated in these. Although the 50-Hz television screen is an important determinant of screen sensitivity and 100-Hz screens reduce the ability of the screen to trigger seizures, it is important to note that all systems are equally dangerous if dangerous screen content is broadcast.

Most patients sensitive to IPS can be shown to be sensitive to pattern, and studies on pattern-sensitive patients have enabled several inferences to be drawn, based also on animal studies of single unit responses. These have recently been reviewed by Wilkins et al.[203] and can be summarized as follows:

The seizure trigger involves cortical cells. A paroxysmal EEG response occurs in the majority of patients with a history of photosensitive seizures when they are exposed to IPS. In about 30% of patients, bright, large, continuously illuminated patterns of high-contrast stripes evoke a similar, though usually less pronounced, response. The response is probabilistic and depends on the spatial and temporal properties of the visual stimuli that evoke it. Studies of length of line contour of effective patterns, pattern orientation, and the effect of binocularity indicate a cortical trigger. Further evidence comes from studies of effects of spatial frequency and of pattern motion: These suggest that the trigger involves neurons whose spatial tuning is independent of position in the visual field, and the first point at which this independence occurs is at the level of the complex cell in the visual cortex. EEG studies using patterns presented in only part of the visual field, such as hemifield stimulation, are also consistent with an occipital cortical event, and also indicate that seizure onset involves one cerebral hemisphere or both hemispheres independently. Often the response is generalized, involving many brain areas other than the visual cortex, but even in these circumstances the trigger may be cortical and unilateral because when the response is suppressed with sodium valproate, focal occipital activity can remain.[48] All these are consistent with an epileptic discharge triggered in the visual cortex, which sometimes remains within the visual cortex and sometimes spreads to involve other areas.

The triggering mechanism requires the physiologic activation of a critical area of cortical tissue. Any region of the visual cortex can evoke an epileptiform discharge, provided a sufficiently large area is stimulated. Wilkins[201] noted that the probability of a response to patterns differs in each patient, but in such a way as to indicate that each patient's threshold can be expressed in terms of the area of cortex necessary to trigger a discharge.

Synchronization of the physiologic activation is necessary for epileptogenesis. Patterns that vibrate back and forth, orthogonal to their line orientation, become more epileptogenic, but a pattern that drifts steadily in the same direction ceases to be epileptogenic. This difference suggests an important role for the synchronization of large neuronal aggregates in the induction of a discharge. When the pattern alternately changes direction, the neurons sensitive to one direction of motion should fire, followed by a period during which cells sensitive to the opposite direction of motion should fire. The very marked difference in the epileptogenic properties of drifting and vibrating patterns suggests that the synchronization that occurs with a vibrating or phase-reversing pattern is critical at the initiation of the epileptic discharge.

The trigger involves the magnocellular pathways, but the resulting discharge may be more diffuse and involve both magnocellular and parvocellular divisions. Several characteristics of epileptogenic patterns suggest this involvement. The stripes differ in brightness rather than color, and are more epileptogenic if they move in certain ways and fuse in binocular vision. They have a rather low spatial frequency. Magnocellular neurons do not generally code for color, are directionally coded, and are tuned for binocular disparity. They have a lower spatial resolution and a higher temporal resolution than parvocellular neurons. The magnocellular system is thought to be part of the “dorsal stream,” and in pattern-sensitive patients, the isolated spikes in response to a pattern tend to be most marked over parietal electrodes. The cortical hyperexcitability need not be confined to this system but the discharge may start there. Harding and Fylan[88] also provide evidence for the participation of the parvocellular system.

The visual system in visual-sensitive epilepsies is normal with respect to acuity, stereopsis, and color vision. However, evidence of visual cortical abnormality is found in pattern reversal visual-evoked potentials; these show a lack of luminance contrast gain control at low spatial frequencies in subjects with IPOE.[159] This is seen only at temporal frequencies lower than those that are typically epileptogenic. Functional magnetic resonance imaging (fMRI)[94] and magnetoencephalography

P.2564

(MEG)[154,168] also suggest regional occipital cortical hyperexcitability, regional activations, and abnormal neuronal synchronization in photosensitive subjects. MEG in photosensitive subjects showed enhanced phase synchrony in the gamma band (30 to 120 Hz) preceding those photic stimulation trials that evolve into PPR compared with trials not followed by PPR and compared with phase synchrony in nonphotosensitive controls, possibly reflecting a pathologic synchronization of gamma oscillation that mediates the transition to PPR.[154]

An important feature of most visual-sensitive seizures and of pattern sensitivity in particular is that a stimulus that activates a well-defined cortical area subserving a specific function will produce seizures usually thought of as generalized and often occurring within a typical generalized epilepsy syndrome such as JME. This paradigm will be encountered with complex reflex seizures, discussed below, and appears to operate in seizures induced by thinking and praxis and in many cases of reading epilepsy. Studies of reflex seizures suggest that cognitive triggering occurs mostly with idiopathic generalized epilepsy (IGE). These and other observations in both reflex and spontaneous epileptogenesis[20,58] suggest that the postulated cortical hyperexcitability in IGE is not necessarily uniform: Specific activities can activate specific cortical systems and produce focal discharges or partial seizures, which may generalize. This does not invalidate a diagnosis of underlying generalized epilepsy but shows that the biologic substrate of generalized epilepsy can be complicated.

Treatment of Visual-Sensitive Seizures

All reflex seizures may be treated by avoiding the triggering stimulus. This is not always practical or possible, but modification of the stimulus may reduce or eliminate its epileptogenicity. Increasing the distance from the television set, watching a small screen in a well-lighted room, using a remote control so that the set need not be approached, and monocular viewing or the use of polarized eyeglasses to block one eye should provide protection.[204] Colored eyeglasses may be useful in selected cases.[32,202] Prevention of seizures induced by video screens is effective but requires adherence to guidelines that reduce the likelihood of a visually triggered seizure or the use of special electronic filter devices, which is less practical as these would be required on all screens. A recent draft consensus developed by the Epilepsy Foundation of America[91] noted:

> "A pattern with the potential for provoking seizures contains clearly discernible stripes, numbering more than five light–dark pairs of stripes in any orientation. When the light–dark stripes of any pattern collectively subtend at the eye from the minimal-expected viewing distance a solid angle of >0.006 steradians, the luminance of the lightest stripe is >50 cd/m2, and the pattern is presented for ≥0.5 s, then the pattern should display no more than five light–dark pairs of stripes, if the stripes change direction, oscillate, flash, or reverse in contrast; if the pattern is unchanging or smoothly drifting in one direction, no more than eight stripes."

Drug treatment is needed if preventive measures are impractical or unsuccessful, if photosensitivity is severe, or if spontaneous attacks occur. The drug of choice is valproate, which in one study[89] abolished photosensitivity in 54% of patients and markedly reduced it in a further 24%. Lamotrigine, topiramate, ethosuximide, benzodiazepines such as clobazam,[34] and levetiracetam[111] also may be useful. Quesney et al.[162] proposed a dopaminergic mechanism in human epileptic photosensitivity based on the transient abolition of photosensitivity with apomorphine, and bromocriptine and parenteral L-dopa have been reported to alleviate photosensitivity.[37,139] Appropriate treatment for photosensitivity is generally successful and noncompliance or self-induction should be considered if it is not.

Startle Epilepsy

Startle epilepsy is characterized by seizures triggered by unexpected sensory stimuli, usually auditory. Startle epilepsy was described in the 1989 International Classification of Epilepsies and Epileptic Syndromes as a symptomatic epilepsy in which seizures occur with a specific mode of precipitation. The most recent proposed classification[55] includes startle epilepsy as a reflex epilepsy syndrome. The effective stimulus is usually a sudden sound.[3] Most patients are sensitive to a single sensory modality but the suddenness of the stimulation, which must be unexpected, is crucial. The seizures usually last <30 seconds and consist of a startle response followed by a brief tonic posture, which is usually asymmetric. Many subjects fall, and clonic jerks may occur. Injury is common when the seizures occur in patients who are standing or able to fall while seated, or while they are in bathtubs or similar risky locations. The seizures may be frequent but habituation is typical: If the stimulus is repeatedly presented over several minutes, it becomes temporarily ineffective. Patients with startle epilepsy usually have static cerebral lesions arising prenatally or within the first 2 years of life and intellectual handicap. Many are hemiparetic; in these, the weak side is preferentially involved in the seizure. Spontaneous seizures occur, reportedly in all cases, but may be infrequent. Startle epilepsy is typically intractable.

Brain imaging may show localized lesions (mesial hypodensity) or diffuse lesions.[2,82] The lateralized lesions usually involve sensorimotor and premotor cortex and white matter, but normal scans have been reported without neurologic deficit.[128] Such patients have precentral or perisylvian dysplastic lesions on MRI. Schizencephaly has also been found. Startle epilepsy often occurs with Down syndrome.

Scalp EEG ictal recording shows an initial vertex discharge followed by diffuse relative flattening or low-voltage rhythm at about 10 Hz. Ictal depth electrode recordings have shown an initial high-amplitude evoked response over motor areas corresponding to the vertex scalp activity, followed by ictal EEG discharge, which begins in lesioned motor or premotor cortex and spreads to mesial frontal, parietal, and contralateral frontal regions.[12,13,192] Subdural recordings in a patient with a small lesion next to the right supplementary sensorimotor area showed seizure onset in the right dorsolateral premotor cortex and the right supplementary sensorimotor area.[178]

The seizures resemble supplementary motor seizures. Localized lesions and seizure onset often involve that area or its surroundings: The epileptogenic lesion may be in the dorsolateral frontal lobe or in the perirolandic area (for a recent example with video illustration see Nolan et al.[146]).

Differential diagnosis includes startle disease (hyper-ekplexia).[6] Touch-evoked or tap seizures in children[50,212] may have a startle component, but are not startle epilepsy as currently defined. Startle stimuli can cause nonepileptic falls in Coffin-Lowry syndrome. Startle myoclonus, though not clearly startle epilepsy, has been reported in association with GM2 gangliosidosis[143] and startle epilepsy has been reported with aspartylglucosaminuria.[119] Seizures induced by sudden dousing with hot water may also have a startle component at some time in their course but are not to be confused with startle epilepsy.[15,174] Other reflex seizures, produced by cutaneous or proprioceptive stimulation, should also be distinguished from startle epilepsy.[107,192]

Startle epilepsy can be treated with drugs appropriate for focal seizures. Reports discuss carbamazepine, lamotrigine, clobazam, and clonazepam.[2,41,56,119,171] Psychological intervention has also been proposed.[136] Startle epilepsy is usually

intractable, however, and surgery has been reported to control startle epilepsy associated with infantile hemiplegia.[33,131,147]

Reading Epilepsy

Primary reading epilepsy (RE) consists of seizures triggered exclusively by reading, without spontaneous seizures.[17] The current proposed diagnostic scheme defines it as a reflex epilepsy syndrome without specifying a generalized or focal subtype.[55] Seizures usually begin in adolescence. Patients report jaw jerking or clicking and other sensations or movements in orofacial muscles, usually after reading for some time, representing partial seizures or localized myoclonus. They may thus appear to stutter.[138] If reading then continues, even for a very short time in some patients, a generalized convulsion may occur. Seizures are not induced by mental activity without reading. The developmental history, neurologic examination, interictal EEG, and computed tomography (CT) scan are normal. A family history of epilepsy is common, and familial reading epilepsy may occur.[134,209] The syndrome is relatively benign and often goes undiagnosed, mistaken for harmless tics or stuttering.

Both unilateral and bilateral orofacial myoclonus may be triggered by reading and either may be seen with unilateral or bilateral EEG discharges.[209] In an important review of 111 patients by Wolf and Inoue,[209] 77% had triggered epileptiform discharges consisting of short bursts of sharp waves, spikes, or spike-and-wave complexes that are bilateral and symmetric in 32%, bilateral but asymmetric in 38%, and unilateral or focal in 30%. Lateralization is more frequent to the language-dominant hemisphere (78%), preferentially over the temporoparietal region (80%).

Radhakrishnan et al.[164] found generalized and symmetric ictal discharges in 15 of 20 patients (75%) with RE and asymmetric or unilateral discharges in five (25%) with lateralization to the dominant hemisphere. They suggested that RE be classified among the idiopathic generalized epilepsies. Mayer and Wolf[135] found that the triggered perioral reflex myoclonus thought to be exclusive to RE was also found with bilateral spike-and-wave EEG activity in juvenile myoclonic epilepsy, and was also recorded, triggered by talking more than by reading, in patients with a variety of epileptic disorders.[211] Koutroumanidis et al.[117] monitored 17 patients with RE. During the triggered myoclonic jerks, eight had bilateral synchronous epileptic discharges. Two patients had alexia or possibly speech arrest as the only ictal manifestation, associated on the EEG with focal abnormalities over the left posterior temporal area.

Koepp et al.[115] performed [11C]-diprenorphine positron emission tomography (PET) in a patient with RE and found decreased peri-ictal opioid binding in both temporal lobes and the left frontal lobe, regions that had shown PET activation during normal reading. Archer et al.[7] performed spike-triggered fMRI in a patient with reading epilepsy. During activation tasks, spike-related activity was found in the left precentral gyrus and bilaterally in the central sulcus and globus pallidus. Comparison of fMRI activation seen during spiking with that during reading showed overlap in the posterior dorsolateral prefrontal cortex. This area was shown to be activated during specific cognitive tasks with a working memory component, and evidence for the involvement of this region in RE also comes from a patient who developed RE after removal of a left premotor arteriovenous malformation.[170] Archer postulated that the ictal activity of RE spread from working memory into nearby motor cortex. The facial myoclonus typical of RE may also be triggered by language tasks in symptomatic epilepsies.[30]

Thus, it appears that reading can activate generalized epilepsies, similar to activation by pattern sensitivity with its occipital trigger. RE is not, however, exclusively a generalized epileptic phenomenon but involves a functional system over both hemispheres. Reading requires bihemispheric cooperation, with dominant hemisphere predominance for phonologic processing and nondominant hemisphere predominance for semantic representation. Pegna et al.[155] reported a case of RE and suggested lexical and nonlexical forms of RE, and RE seems less common in Japanese, which uses a logographic writing system.

Language-induced epilepsy involves seizure precipitation by speaking, reading, and writing.[71] The seizures are similar to those of primary reading epilepsy, and patients may report one or several seizure triggers related to language (e.g., recitation or writing only).[8,93] The nosologic position of language-induced epilepsy is not clear: Reported cases most closely resemble reading epilepsy but are more heterogeneous than those of primary reading epilepsy, whose definition should probably be expanded to include them.

RE may be treated by partial avoidance of the stimulus, especially if the patient does not develop generalized seizures or has a useful delay before one occurs. Interruption or limitation of reading can then be effective. Maneuvers that briefly disrupt comprehension or increase arousal may be helpful, but social and educational handicap may arise from all of these. Audiotaped texts may be useful. Text masking may help those in whom pattern or eye movement contribute to seizure occurrence.[206] Wolf and Inoue[209] reported that valproate is the drug of choice and that clonazepam can be a useful adjunct.

Musicogenic Seizures

Induction of seizures in humans by unstructured sound apart from startle stimuli is very unusual. Musicogenic epilepsy is characterized by seizures induced by hearing certain sounds, typically music.[9,46] Patients with musicogenic seizures alone may have a reflex epilepsy syndrome, but most also have spontaneous seizures. The reflex seizures then often begin over a year after the onset of the spontaneous attacks.[198] Seizures have also been reported while the subject is exposed to the musical trigger during sleep or while thinking about it. The effective stimulus can be stereotyped for each patient. It can be restricted to a single musical work, but there is no clear common pattern among patients. An affective component of the stimulus must be present in some, yet nonmusical sounds, such as whirring machinery, can be effective triggers in others. The seizures are of simple or complex partial type, with interictal and ictal epileptiform activity recorded from either temporal region,[176] usually the right. Often, the seizure does not begin immediately and the patient must be exposed to the trigger for several seconds or minutes. Musicogenic seizures have been reported in infancy.[122] Some patients with autosomal dominant lateral temporal lobe epilepsy have reported triggering by sound or by hearing speech.[26]

A right temporal predominance for musicogenic seizures has been reported by several authors.[69,70,198] They also documented right anterior and mesial hyperperfusion during ictal single photon emission computed tomography (SPECT) of musicogenic seizures.

The mechanism of musicogenic seizures is not clear. Although cortical processing of music has been studied extensively, subjects have been normal controls or patients with lesions or intractable spontaneous seizures. Chronic temporal lobe depth electrode studies in epileptic subjects without musicogenic epilepsy suggest different lateralizations for different components of a musical stimulus.[199] Creutzfeldt and Ojemann showed that musical stimuli may have widespread effects on neuronal activity in human temporal lobes extending well

P.2566

beyond the primary auditory area,[44,121] that different components of music have different effects possibly with specialized lateralization and localization, and that the effects of music are different from those of speech. Studies of the cerebral representation and processing of music have been extended, and are reviewed in Peretz and Zatorre.[157] PET studies in patients and others[106] show predominant involvement of right hemisphere structures in networks involved in processing musical information, extending well beyond the classical auditory cortex of the Heschl gyrus. Studies in subjects with musical hallucinations show that the primary auditory cortex is not “a sufficient substrate for higher-order pattern perception.”[79]

The primate auditory cortex consists of a central core of primary cortex that receives thalamic projections, linked to several “belt” areas. Primary cortex has multiple tonotopically organized areas and is especially sensitive to pure tones. Belt regions are more sensitive to complex stimuli and are less tonotopically organized.[106] Zifkin and Zatorre also noted that more complex musical processing tasks activate more cortical and subcortical territory bilaterally but with right hemisphere predominance.[215] Thus, hyperexcitable cortical areas could be stimulated to different degrees and extents by different musical stimuli in patients sensitive to musical triggers. Gloor suggested that responses to limbic stimulation in epileptic subjects depend on widespread neuronal matrices linked through connections that have become strengthened through repeated use, of interest in considering the delay from seizure onset to the development of sensitivity to music.[73]

Musicogenic seizures can be treated by stimulus avoidance or modification in many cases, especially if there is a useful latency from stimulus onset to seizure onset or if the stimulus is very specific. If this is not possible or effective, or if spontaneous seizures occur, drugs for focal seizures are indicated and intractable cases should be assessed for surgical treatment.

Reflex Seizure Types Usually Associated with Generalized Epilepsies

Touch-evoked ("Tap") Seizures

Otherwise normal infants and toddlers may develop seizures induced by tapping, often by a single touch on the head ("tap epilepsy") or by a sudden sound.[50,212] Age of onset is usually from 6 months to 3 years. These are typically manifestations of an idiopathic generalized epilepsy and consist of an initial blink followed by bilateral myoclonic jerks mostly involving the arms, with flexion of the head and upward deviation of the eyes. If intense, they can cause a fall. They can occur isolated or in clusters. The interictal EEG is usually normal and there is no photosensitivity. The ictal EEG shows bilateral spike-and-wave EEG discharges usually predominant anteriorly. Differential diagnosis includes hyperekplexia, symptomatic disorders such as startle epilepsy and focal reflex seizures induced by cutaneous stimulation, and benign myoclonic epilepsy of infancy, which is not triggered and has somewhat later onset and longer duration of the disorder with other seizure types.[54] Imaging is normal. These seizures appear to represent an early-onset idiopathic generalized epilepsy, and many such cases remit without drug treatment. Valproate may be used when drug treatment is needed. These attacks are not remarkably different from the benign early infantile reflex absence seizures illustrated with video recording by Voskuil.[194]

Seizures Induced by Thinking and Praxis

Seizures induced by thinking[207] occur in response to higher cortical function and have been reported with a variety of stimuli, including arithmetic, drawing, playing cards or chess, decision making, solving Rubik's cube, and using the soroban (a Japanese abacus). Goossens et al.,[76] in an extensive review, have proposed this as a separate epileptic syndrome. These patients are not sensitive to reading. Although a patient may report only a single trigger, detailed testing shows that about 80% have more than one effective stimulus. Unlike those with primary reading epilepsy, most have spontaneous seizures, and the reflex and spontaneous attacks include bilateral myoclonus, absences, and generalized tonic–clonic seizures. Partial seizures have been reported but are the exception. Seizures related to "praxis," clinically and electroencephalographically similar to these,[98] have been reported, strongly associated with juvenile myoclonic epilepsy (Herpin-Janz syndrome) and at times with other generalized epilepsies. Patients with seizures induced by thinking almost always have an idiopathic generalized epilepsy syndrome but without any specific variety associated.

Seizures induced by thinking are typically associated with both spontaneous and evoked generalized bilaterally synchronous spike or multiple spike-and-wave complexes. These may reappear only after reduction of medications in some patients. Though patients often report mental arithmetic as a trigger, other effective stimuli have included parts of standard neuropsychological test batteries such as Block Design. While occasional patients have temporoparietal or frontal spontaneous nonspecific EEG abnormalities, typically over the right side, these are at times mixed with generalized epileptiform activity. Clearly localized induced epileptiform activity is very unusual.[76]

The essential component in the seizure trigger appears to be nonverbal thought, the processing of numeric or spatial information, and possibly sequential decision making. Recent studies provide more detail on the cerebral representation of calculation and spatial thought and document a bilateral functional network activated by such tasks.[181]

The term *praxis induction* was introduced by Japanese authors who described seizures triggered when subjects "are obliged to contemplate complicated spatial tasks in a sequential fashion, to make decisions, and to practically respond using a part of their body."[99] Writing is reported to be a frequent precipitating factor[98] although reading is not. Hand or finger movements without "action-programming activity" (defined as "higher mental activity requiring hand movement" and apparently synonymous with praxis) are not effective triggers. Matsuoka et al.[132,133] noted, "The dependence of hand movements in the seizure-inducing tasks differentiates the action-programming activity from the thinking activity." Reflex upper limb myoclonus occurs and may spread. This pattern occurs very predominantly in juvenile myoclonic epilepsy. It does not seem prominent in patients with thinking-induced seizures who do not also have prominent myoclonic reflex attacks. In its milder or most restricted forms, such as the morning myoclonic jerk of the arm manipulating a utensil, this phenomenon resembles cortical reflex myoclonus as part of a "continuum of epileptic activity centered on the sensorimotor cortex,"[192] and back-averaging of chess-induced spikes with unilateral myoclonia in a patient with JME has shown localization to bilateral frontocentral regions.[129] The motor component, either imagined or performed, is crucial in praxis induction, whereas seizures induced by thinking are activated by tasks such as purely mental calculation of orally presented arithmetic tasks with no motor component in either the stimulus or the response.

Seizures induced by thinking and praxis, many cases of reading epilepsy, and photosensitive epilepsy are all examples of specific brain activities involving definable cortical areas triggering generalized seizures or epileptiform EEG activity, often in the context of known idiopathic generalized epilepsy. Inoue and Kubota[97] postulated on the basis of MEG and sensory-evoked potential studies that increased, but spatially different cortical hyperexcitability operates in photosensitivity and praxis sensitivity. Binnie[20] has discussed the implications of such studies of reflex seizures for the understanding of generalized epilepsy.

Treatment of Seizures Induced by Thinking and Praxis

Avoidance of triggering stimuli is usually impractical. These seizures are almost always found as part of an idiopathic generalized epilepsy, particularly juvenile myoclonic epilepsy, and drugs appropriate for these syndromes are the treatment of choice.

Reflex Seizure Types Usually Associated with Focal Epilepsies

Seizures Induced by Eating

Eating epilepsy is characterized by seizures closely related to one or several parts of eating. Although described as eating epilepsy, seizures triggered by eating often occur in patients who also have spontaneous seizures and are not now classified as a separate epileptic syndrome but as a seizure type in the most recent proposal.[55] Some cases may be described as epilepsies characterized by specific modes of seizure precipitation.[43] A prevalence of approximately 1 per 1,000 to 2,000 epileptic patients has been reported.[142,193] The unusually high figures reported for Sri Lanka[177] may be related to ascertainment methods. Seizures induced by eating have been reported in childhood, youth, and adult life. The clinical triggers of a seizure are usually stereotyped for each patient but may have a few points in common. Thus, some patients have seizures at the very sight or smell of food, while others may have them immediately after a heavy meal. Most typically, the seizure occurs shortly after beginning to eat and does not recur during the same meal. In some, the seizures may be related to emotional or autonomic components of eating, and in others to gastric distension or to stimulation of the mouth or pharynx and with possible participation of autonomic, somatosensory, or proprioceptive afferents.

Seizures with eating are typically of complex or simple partial type, almost always related to a symptomatic localization-related epilepsy. Rémillard et al.[167] suggest that patients with temporolimbic seizures activated by eating have fewer spontaneous attacks and are more likely to have such attacks from the onset of their epilepsy than are those with extralimbic, usually suprasylvian, seizure onset who have less constant activation by eating, more obvious extratemporal structural lesions, and possible activation by specific thalamocortical afferents. The latter may also have seizures with other forms of buccal stimulation such as tooth brushing or kissing and may represent particular examples of sensitivity to somatosensory or proprioceptive stimulation. Koutroumanidis et al. reported a case of adult-onset sensitivity to tooth brushing only, with normal imaging and interictal left frontal epileptiform activity, and suggested that this was a cryptogenic reflex epilepsy.[118] The role of malformations of cortical development in reflex seizures has been recently discussed by Palmini et al.,[150] who found eating-related seizures in patients with perisylvian lesions and noted functional anatomic correlation with the reflex seizure types.

Eating epilepsy is usually associated with localized or regional epileptiform activity either from temporolimbic structures or from suprasylvian regions in association with larger lesions. Patients considered to have idiopathic generalized epilepsies are exceptional, and cases in which seizures have been shown to be generalized from the start are less frequent.[60,116]

The seizures of eating epilepsy can be affected by modifying the trigger. It is our impression that patients with eating epilepsy and extralimbic seizure onset are more sensitive to either somatosensory or proprioceptive stimuli during eating and are more likely to report that seizure induction can be prevented by altering the sensory characteristics of their food. Some will drink through a straw rather than from a cup or will avoid biting into a whole fruit by cutting it into small pieces. Such stimulus modification can reduce seizure frequency in what may otherwise be an intractable or socially disabling condition. Some patients also take advantage of a refractory period after a reflex seizure and will induce an attack in private to avoid having a seizure later in a more embarrassing setting. Some patients have prolonged periods of heightened susceptibility to reflex attacks and may then refuse to eat adequately. Drugs effective for partial seizures are usually necessary, but medically intractable patients should be recognized early and assessed for surgical treatment.

Seizures induced by eating in infancy are unusual, may present as acute life-threatening events (ALTEs), and appear to have a poor prognosis. Navelet et al.[145] reported four infants with onset before 6 months, attacks provoked by meals, cyanosis, hypo- or hypertonia, and apnea followed by clonic movements of the limbs. Gastroesophageal reflux (GER) was present in the four cases but attacks remained frequent despite anti-GER treatment and all infants developed a severe epilepsy. The first interictal EEG was normal but repeated polygraphic EEG recordings documented the seizures. The trigger in these patients is unknown and the relationship between GER, ALTEs, and epilepsy remains unclear. One of us (P.P.) studied three children with epileptic spasms beginning in the first year who developed seizures with the approach or ingestion of food at 3 to 4 years old. The triggered seizures were spasms in two cases and tonic seizures in one. The last child had cryptogenic epilepsy, the others had symptomatic epilepsy with early large opercular lesions, and all had lateralized or regionally predominant ictal and interictal EEG abnormalities. They continued to have reflex and spontaneous seizures. It is possible that a network responsible for the reflex attacks may not have matured until several years of age.

Seizures Induced by Proprioceptive Stimuli (Movement Induced)

Reflex seizures apparently induced by movement were reported before the EEG era.[78] Early reports emphasized induction by movement,[123] but later experiments showed the determinant role of proprioceptive afferents.[36,72] Thus, seizures originally described as movement induced or gait induced are usually more accurately described as "proprioceptive induced." These reflex seizures are rare[192] and may be most commonly seen as a transient occurrence with nonketotic hyperglycemia.[23]

Proprioceptive-induced seizures involve the sensorimotor area of the hemisphere contralateral to the clinical seizure onset. This has been confirmed by imaging and intensive monitoring. The supplementary motor area may also be involved. Maximum EEG electronegativity appears to be at the central vertex electrode in a published EEG of seizures induced by walking.[101] Cerebral lesions are often evident and may have occurred long

P.2568

before the onset of attacks. Acute cerebral lesions or acute diffuse encephalopathies may also be accompanied by self-limited proprioceptive-induced seizures. In nonketotic hyperglycemia or other metabolic encephalopathies, neurologic deficit related to a remote lesion may be transiently unmasked during the period of seizures.[23] New-onset proprioceptive-induced seizures thus require rapid medical and neurologic evaluation.

Reflex drop attacks elicited by walking[53] are seen rarely in patients with reflex interictal spikes evoked by percussion of the foot.[49,187] These may be a variety of seizures induced by proprioceptive stimulation. However, individuals with these evoked spikes, generally considered a benign finding, do not usually have epilepsy or reflex seizures.[120] This disorder likely represents a form of idiopathic focal epilepsy of childhood, distinct because of the parietal lobe involvement. Participation of a more elaborate network involved in motor programming cannot be excluded in some cases, especially if the effective stimulus seems restricted to activities such as walking, although "gait epilepsy"[101] is not now a recognized seizure type or epilepsy syndrome.

Seizures Induced by Somatosensory Stimuli

Seizures induced by somatosensory stimulation are typically triggered by repeatedly tapping, rubbing, or pricking part of the body. There is often a localized or regional cutaneous trigger zone. The seizures begin with a sensory aura; a sensory jacksonian seizure occurs often followed by tonic motor manifestations suggesting a supplementary motor area seizure. Generalization may occur. Consciousness is preserved at least at the onset. Ictal pain and autonomic disturbances have also been reported.[175] Compulsive somatosensory self-stimulation with self-induced epileptic spasms has also been demonstrated in children with severe developmental delay.[83] Somatosensory-induced seizures typically occur in patients with postrolandic cortical lesions that may be subtle.[192] Malformations of cortical development have also been implicated.[150] Normal MR imaging has been reported in patients with "rub" epilepsy, but detailed imaging was not described[107] and current imaging methods are more refined.

These focal-onset seizures must be distinguished from the typically more benign generalized reflex seizures induced by tapping in infants and young children (see above) that are not associated with lesions. Patients with somatosensory reflex seizures must be investigated for brain lesions and treatment is as for other symptomatic or cryptogenic focal epilepsies.

Hot Water Epilepsy

Seizures induced by immersion in or contact with hot water have until recently been reported predominantly in older children and adolescents from south India, where ritual bathing involves repeatedly pouring hot water over the head from a jug.[173,174] Indian patients are typically boys, with adolescence-onset complex partial or generalized tonic–clonic seizures during ritual bathing. Hot water epilepsy (HWE) has been thought to be a relatively benign age- and situation-related disorder akin to febrile seizures. This is often so when seizures start in infancy or early childhood. Ictal recordings are rare and interictal EEG abnormalities have been recorded over temporal areas in half of the patients. Imaging has been unremarkable in most, but focal cortical malformations have been reported.[80] Differential diagnosis includes nonepileptic events such as startle and vasovagal syncope, and startle epilepsy. Some older patients report pleasurable feelings with these events, and self-induction has been reported. Prophylactic clobazam is reportedly helpful.[52] Studies in non-Indian subjects[15,100] report onset from infancy to adult life and spontaneous seizures in 62% of patients in whom onset was after infancy. These series include younger children than in India, with complex partial seizures occurring as soon as the child is immersed in hot water rather than when hot water is poured over the head; sensitivity often diminishes with time.[100]

HWE beginning in infancy appears to have a better prognosis. Seizures begin in the first year and are always triggered by immersion in hot bath water with a temperature around 37.5°C. Parents describe some nonspecific malaise and when recorded these are complex partial seizures; general pediatricians may be unfamiliar with these seizures in such young children.

In infantile HWE, the neurologic and developmental examinations are always normal. There is no personal or family history of epilepsy. Interictal EEG is normal, including during sleep. CT scan and MRI are reported as normal, and no interictal or ictal SPECT has been reported in these infants. Treatment is by lowering the temperature of the bath. No antiepileptic drugs are needed and in more than 3 years of follow-up, no further seizures have developed in five cases we have evaluated (P.P.), some of whom were also reported by Ioos et al.[100] Differential diagnosis of HWE in infants includes gastroesophageal reflux, which, however, would be rare in the bath; syncope; startle events; and aquagenic urticaria. Sensitivity to visual stimuli such as the light reflections in the bathroom or the color of the bathtub would not be expected in otherwise normal children at this age.

A mechanism involving defective thermoregulation has been proposed.

Miscellaneous Reflex Seizures

Psychogenic seizures are triggered by specific thoughts, either self-induced attacks (e.g., by thinking sad thoughts) or those unintentionally triggered by specific mental activity.[57] This use of the term *psychogenic* does not refer to nonepileptic seizures. A report of temporal lobe seizures induced by thinking of the family home documented such seizures during monitoring and a subtle malformation of cortical development in the resected temporal structures.[130]

Seizures with extremely specific visual stimuli have been reported. Recurring self-induced brief tonic seizures triggered by looking at round objects occurred in an 18-month-old boy. Later he developed sensitivity to other patterns and secondary generalized seizures, which were difficult to control. He was not photosensitive.[25] A child with generalized seizures self-induced by looking at his own hand was reported. By 4 years of age, medications were withdrawn, and no further seizures, reflex or otherwise, occurred in 26 years of follow-up.[114] The EEG was said to be normal. A similar case has been reported.[62]

Vestibular stimuli, caloric or rotatory, have been reported to produce EEG discharges, generally nonspecific but at times in the contralateral temporal region,[14,24,31,141] but seizures induced by these stimuli, as distinguished from startle effects or syncopal events, appear to be very rare.[16,108]

Olfactory stimuli have elicited seizures in experimental animals.[140] Stevens[182] reported that strong odors increased interictal epileptiform EEG activity in 26% of patients with temporal lobe epilepsy, but triggering of seizures is much rarer.[184]

Presumed enteroceptive seizures are very unusual. Occasionally, seizures induced by eating may be shown to depend on gastric distension,[67] but this is not typical. Defecation has been reported to induce seizures, confirmed by EEG, but not immediately after emptying the rectum,[86] and was the most common trigger reported by Schubert and Cracco[175] in a case of induction by tactile stimuli.

P.2569

Summary and Conclusions

Reflex seizures have been considered interesting rarities, but are probably more frequent than we realize, especially in some relatively common syndromes that are now believed to be generalized epilepsies. Study of reflex seizures has been important in understanding some basic brain mechanisms of seizure occurrence. Neurologists, pediatricians, and family or general practitioners can expect to encounter patients with these seizures. A detailed history is the first step to proper diagnosis of seizure type and epilepsy syndrome, so that effective treatment may be prescribed.

Chapter 258

Overview: Diseases Associated With Epilepsy

Timothy A. Pedley

Introduction

Seizures and epilepsy are common manifestations of disturbed cerebral function; thus, they may be symptoms of other diseases that involve the brain and not of epilepsy *sui generis*. This association has long been recognized in the case of brain tumors and tuberous sclerosis, for example, but the modern era of brain imaging and molecular diagnosis has greatly expanded our recognition of specific disease entities in which epilepsy is a major feature. This section reviews major categories of disease that present with seizures or in which epilepsy constitutes a significant aspect of the illness. Certain presentations or evolution should always raise the question of a specific underlying disorder.

Clues from Epilepsy Syndromes

The diagnosis of infantile spasms (West syndrome; Chapter 229) or Lennox-Gastaut syndrome (Chapter 241) should always lead to a search for a specific cause. Both syndromes can occur as either idiopathic or symptomatic conditions, and therein lies one of the disadvantages of the current classification. Both are electroclinical syndromes and therefore etiologically heterogeneous. Neither is a singular pathologic entity, and cerebral malformations, perinatal asphyxia, anoxic encephalopathy from cardiopulmonary arrest, central nervous infection, postimmunization encephalopathy, and progressive degenerative or metabolic syndromes have all been implicated in individual children. Tuberous sclerosis is the most common disease entity causing infantile spasms,[7] but untreated phenylketonuria, nonketotic hyperglycinemia, and other metabolic and structural disorders are also encountered occasionally.[4] A small subgroup of children with spasms but no identifiable causes have normal developmental outcome and may represent an idiopathic condition.[3] Similar disorders are found in children with Lennox-Gastaut syndrome (Chapter 241),[1,8] and of course infantile spasms and Lennox-Gastaut syndrome are not fully independent entities: The 6-year-old child designated as having Lennox-Gastaut syndrome may well have carried a diagnosis of West syndrome as an infant. Indeed, with computed tomographic (CT) and magnetic resonance (MR) brain imaging and the availability of sophisticated and highly specific biochemical and genetic tests, the percentage of cryptogenic cases has steadily declined.

Intractable Epilepsy

Persistent seizures despite appropriate therapy are often an indication to consider medical illnesses or treatments that can contribute to or cause recurrent seizures, such as systemic lupus erythematosus, hypoglycemia, drug abuse, and theophylline toxicity (Chapters 127, 191, and 192). The use of molecular techniques to establish linkage or a gene defect has clearly demonstrated that variability in phenotype is common and that syndromic fidelity, defined traditionally by seizure semiology and electroencephalographic (EEG) features, is not invariable. Thus, older children and even adults with seemingly stable (or only very slowly progressive) neurologic abnormalities are now found to have progressive metabolic or degenerative encephalopathies due to adrenoleukodystrophy, ceroid lipofuscinosis, storage diseases such as Tay-Sachs or sialidosis, various aminoacidurias and urea cycle disorders, or one of the progressive myoclonus epilepsies. Other genetic disorders (also referred to as chromosomal abnormalities), including trisomy 13 and 21, fragile X syndrome, and Aicardi syndrome, as well as cortical malformations such as lissencephaly (e.g., Miller-Dieker syndrome) and Angelman ("happy puppet") syndrome, may present with seizures that prove to be drug resistant (Chapter 261). Associated physical abnormalities often provide clues to the diagnosis in most of these conditions.

Seizures are a common manifestation of the mitochondrial encephalopathies, although the frequency is highly variable among the different mitochondrial syndromes. Specific gene defects in many of these disorders have been identified, and they include both mitochondrial and nuclear mutations. In some cases, the type of mutation is quite different in patients that commonly present with seizures than in those in which epilepsy is rare. Thus, seizures are the rule in MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) and MERRF (myoclonus epilepsy with ragged red fibers), which are almost always associated with point mutations in the $tRNA^{Lys}$ gene.[10] However, seizures are rare in Kearns-Sayres syndrome, which is related to large deletions or duplications of mtDNA. Hirano and colleagues (Chapter 262) believe that the spatial distribution within the brain of the mitochondrial mutation underlies the association of particular mutations with epilepsy.

Seizures occur in the majority of children with Rett syndrome,[6] and these can sometimes be intractable. Some of these patients also have syncopal episodes that are occasionally misdiagnosed as epilepsy, and the characteristic stereotypic movements (e.g., hand-wringing) also may be erroneously considered to reflect seizure activity.

Importance of Brain Developmental Abnormalities

Except for major malformations such as anencephaly, holoprosencephaly, and schizencephaly, abnormalities of cortical development were largely unrecognized as a common cause of epilepsy until high-resolution MR brain imaging became widely available and part of the routine diagnostic evaluation

of patients with seizures. Cortical developmental malformations are now known to be common, especially as a cause of intractable epilepsy. They are found in up to 20% of adults[2] and >50% of children referred to epilepsy centers because of drug-resistant seizures or as possible surgical candidates.[5] Of equal interest is the growing recognition that cortical dysgenesis can be found in a wide spectrum of patients, including some without seizures, in patients with only one or a few seizures, and as associated pathology in patients with temporal lobe epilepsy due to mesial temporal sclerosis. The movement of cortical developmental abnormalities from the domain of the neuropathologist to that of the neurologist has been one of the most significant changes in modern epileptology (Chapter 259). Some critical questions are beginning to be addressed:

1. To what extent is cortical dyplasia in a given patient coincidental, an associated marker of epileptogenic mechanisms, or the direct cause of seizures?
2. Why do seizures often seem to arise from a single epileptogenic region even when the developmental abnormalities are multifocal or bilateral?
3. How do developmental malformations cause epilepsy?

Miscellaneous Considerations

Seizures are the presenting symptom in the majority of patients with astrocytomas and oligodendrogliomas, but they are also common at some point in the course of more malignant brain tumors (Chapter 264). With slowly growing neoplasms, seizures typically occur early, when there may be no other clinical symptoms or signs to suggest a tumor. CT may be normal at the time of a first seizure caused by well-differentiated, relatively benign tumors, so MRI is essential. Seizures are also common in many infectious and inflammatory diseases (Chapter 265). Parasitic, bacterial, and viral agents all cause various syndromes in which seizures or chronic epilepsy are common, including as the presenting manifestation. Both mental retardation and cerebral palsy (Chapter 263) are major risk factors for epilepsy, probably because they are markers of brain damage, and the risk for epilepsy is additive when both conditions are present. Alcohol and drug abuse are common causes of symptomatic seizures, but alcohol use itself is also a dose-dependent risk for chronic epilepsy (Chapter 268). Heroin and cocaine, but usually not marijuana, also raise the risk of unprovoked seizures, although symptomatic seizures related to acute toxic effects on the brain are far more common.

Summary and Conclusions

Certain epileptic syndromes, associated neurologic abnormalities, age at first seizure, drug resistance, and associated morphologic or systemic abnormalities should warrant a search for a specific diagnosis. High-resolution brain MR imaging will generally establish structural causes of epilepsy, including cortical developmental malformations and brain tumors, although serial scans and special imaging sequences may be necessary fully to define the abnormality. In those circumstances in which epilepsy is due to or associated with an underlying disease, proper treatment, genetic and prognostic counseling, and clinical investigation depend on accurate diagnosis.

Chapter 259

Malformations of Cortical Development

Ruben I. Kuzniecky

Graeme D. Jackson

Introduction

The development of the human brain is a long and complex process that begins with the induction of the neural plate from the undifferentiated surface ectoderm and continues after birth.[115] Any disruption of the normal mechanisms responsible for the formation of the cerebral structures can result in malformations due to abnormal cortical development.[81,85] A wide variety of genetic and environmental factors can cause disturbances in these developmental processes and can therefore lead to an abnormality in the mature brain.

Until the advent of high-resolution magnetic resonance (MR), malformative disorders of the nervous system were almost exclusively the domain of the pathologist. With magnetic resonance imaging (MRI), abnormalities of cortical development can be identified in life, and understanding these conditions, their clinical consequences, and outcome has become essential for appropriate management. The physician's goal is to diagnose these disorders accurately, using information that is available in the clinical setting. This chapter presents an approach that we believe is helpful to clinicians dealing with these disorders, especially in the setting of epilepsy.

The clinical circumstances in which these disorders are encountered are many but primarily involve developmental delay, epilepsy, skin lesions in specific neurocutaneous disorders, and associated organ malformations. From the perspective of epilepsy, there are two common presentations. First, a patient with epilepsy has an abnormal MR brain scan suggesting a malformation of cortical development (MCD). In this case, the issue is largely one of diagnosis, appropriate classification, knowledge of the relevant condition, and genetic testing, if available. This is important for prognosis, treatment, and genetic counseling. Second, a patient with epilepsy has a “normal” brain MR scan, but the clinician suspects, perhaps on the basis of family history, seizure intractability, or other findings on clinical examination, that there may be an underlying abnormality of cortical development. In this case, one is usually dealing with a subtle, localized cortical malformation, and the challenge is to identify the abnormal brain region(s). This is not an uncommon problem for epilepsy centers that deal with surgical treatment.

Clinical Presentation

Disorders of cortical development encompass many types of malformations with a comparably wide range of etiologies that produce different effects depending on the stage of brain development that is affected. Not surprisingly, then, clinical presentations are quite heterogeneous and can manifest at almost any age. As a result, the practical problem is that because there are actually many disorders of cortical development, there are no specific clinical features associated with MCDs when considered as a group.

While MCDs are a common cause of epilepsy, there are many cases in which seizures are not a feature of these disorders. Why almost identical brain abnormalities can have such variable clinical phenotypes is not known. Yet while there are no clinical features that are specific for MCDs taken as a whole, there are within this group some specific syndromes recognized on the basis of characteristic patterns of genetic, clinical, and imaging findings.

Seizure type usually reflects the topology of the malformations. That is, focal seizures occur with focal or multifocal MCD, and secondarily generalized seizures with diffuse or bilateral MCDs.

Almost any epilepsy presentation, at almost any age, can be due to an MCD. However, in focal epilepsy, some features create a strong suspicion of an underlying MCD and encourage thorough investigation to exclude this possibility if no other cause has been identified. These features include developmental delay, static focal neurologic deficits, a family history of developmental delay or epilepsy, frequent seizures from onset, and focal status epilepticus. While the presence of such elements may raise the suspicion of an MCD, it must be emphasized that none of them is specific. In surgical series of patients, such characteristics will likely lead to detailed high-resolution MRI with special techniques in an effort to define an abnormality of cortical development.

The severity of seizures in patients with MCDs also varies greatly. There are many individuals with extensive cortical malformations who have no seizures. On the other hand, some individuals with apparently small developmental malformations have severe and intractable epilepsy. The mechanisms of epileptogenesis associated with these abnormalities are complex and generally poorly understood.

Epidemiology

Few studies have addressed the epidemiology of MCDs in detail, and little information can be obtained from studies using the modalities, including MRI, that are currently available. One series based on pathology findings revealed that 46.5% of patients had developmental malformations at autopsy.[95] A case ascertainment study of lissencephaly showed a prevalence of 11.7 per million births.[40] No data are available for heterotopia, focal cortical dysplasia, or other malformations of cortical development.

Recent clinical and neuroimaging studies in special populations have suggested that cortical malformations are much more common than was previously appreciated. In children referred to epilepsy centers for intractable seizures, more than half have some type of developmental abnormality, with focal cortical dysplasia discovered in approximately 25% of those with intractable focal seizures.[79] The prevalence of these

P.2576

disorders in the adult population with intractable focal epilepsy is 15% to 20%.[6,10]

Terms and Definitions

A number of terms are commonly used in referring to patients with developmental malformations.[10] For example, *dysplasia* in this context is an encompassing term that usually means abnormalities of the cortex that have a particular histopathology and are developmental in origin. *Neuronal migration disorder* is generally used in a similar context, but this is clearly incorrect as a general term, as it describes only one embryologic stage in cortical development. We consider all of these disorders to be *malformations of cortical development* and prefer this as the general term for referring to this category of conditions. All of these disorders seem to result from disturbed organogenesis (and, hence, are malformations), and all involve cells that under normal circumstances would participate in formation of the cerebral cortex. The most common malformative disorders involve abnormal stem cell formation in the germinative zone or abnormal cortical organization. Some result from faulty neuronal migration, whereas still others are postmigratory in origin.

We believe that establishing a single nomenclature and classification system for these disorders is essential to their understanding and management. The classification proposed in the following discussion provides a means by which similar disorders can be logically grouped together.[10]

Classification Principles

MCDs can be classified according to a number of different criteria emphasizing clinical phenotype, imaging findings, pathology, and genetic defects. The overall classification scheme that we favor (Table 1) is based on the three fundamental events of cortical formation: (a) proliferation of neurons and glia in the ventricular zone and subventricular zones; (b) multidirectional migration of immature but postmitotic neurons to the developing cerebral cortex; and (c) cortical organization, which consists of vertical and horizontal organization of neurons within the cortex and elaboration of axonal and dendritic ramifications. For those malformations with abnormalities involving more than one of these processes, classification is based on the first identified abnormal step. Diffuse and focal malformations that were classified separately in the past are no longer separated since genetic studies have shown that the same gene defects can cause focal or generalized MCDs.

Table 1 Classification Scheme of Malformations of Cortical Development

I. Malformations due to abnormal neuronal and glial proliferation or apoptosis
   A. Decreased proliferation/increased apoptosis or increased proliferation/decreased apoptosis—abnormalities of brain size
      1. Microcephaly with normal to thin cortex
      2. Microlissencephaly (extreme microcephaly with thick cortex)
      3. Microcephaly with extensive polymicrogyria
      4. Macrocephalies
   B. Abnormal proliferation (abnormal cell types)
      1. Nonneoplastic
         a. Cortical hamartomas of tuberous sclerosis
         b. Cortical dysplasia with balloon cells
         c. Hemimegalencephaly
      2. Neoplastic (associated with disordered cortex)
         a. Dysembryoplastic neuroepithelial tumor
         b. Ganglioglioma
         c. Gangliocytoma
II. Malformations due to abnormal neuronal migration
   A. Lissencephaly/subcortical band heterotopia spectrum
   B. Cobblestone complex/congenital muscular dystrophy syndromes
   C. Heterotopia
      1. Subependymal (periventricular)
      2. Subcortical (other than band heterotopia)
      3. Marginal glioneuronal
III. Malformations due to abnormal cortical organization (including late neuronal migration)
   A. Polymicrogyria and schizencephaly
      1. Bilateral polymicrogyria syndromes
      2. Schizencephaly (polymicrogyria with clefts)
      3. Polymicrogyria or schizencephaly as part of multiple congenital anomaly/mental retardation syndromes
   B. Cortical dysplasia without balloon cells
   C. Microdysgenesis
IV. Malformations of cortical development, not otherwise classified
   A. Malformations secondary to inborn errors of metabolism
      1. Mitochondrial and pyruvate metabolic disorders
      2. Peroxisomal disorders
   B. Other unclassified malformations
      1. Sublobar dysplasia

2. Others

Thus, with advances in molecular genetics, we have moved from a purely phenotypic approach to a combined phenotypic/genetic classification. The basis of this change has been the recognition that malformations of varying severity can result from the same underlying processes, specifically from mutations of the same causative genes. This was shown first for classical lissencephaly[38,93,94,111,112,113,114,123] and more recently in the brain malformations associated with congenital muscular dystrophies.[15,16,17,88,89,108,132,133,134] For example, patients with large deletions and truncations of the *LIS1* and *DCX* mutations have diffuse or severe lissencephaly, while those with less severe *LIS1* mutations may only have posterior pachygyria or posterior-predominant subcortical band heterotopia. Those with less severe *DCX* mutations have anterior pachygyria or frontal subcortical band heterotopia of variable thickness,[27,49,50,51,87,92,111,114,123] or they may even have normal brain MRI scans.[57] Further support for this approach has been the recent discovery of mutations of multiple genes each causing very similar clinical syndromes, and the finding that mutations of different genes can cause the phenotype of Walker-Warburg syndrome or muscle-eye-brain disease.[123]

Developmental Malformations Associated with Epilepsy: Specific Disorders

We have restricted the following discussion to an overview of the most common and relatively distinct entities that affect patients with epilepsy.

P.2577

Focal Cortical Dysplasia

Focal cortical dysplasia (FCD) is probably the most common form of focal developmental disorder diagnosed in patients with intractable focal epilepsy.[24,67,83,86,100] The lesions consist of disruption of cortical lamination with poorly differentiated glial cell elements. Since its original description, FCD has been recognized to encompass a spectrum of changes.[130] These range from mild cortical disruption without apparent giant neurons to the most severe forms in which cortical dyslamination, large bizarre cells, and astrocytosis are present.[75,79,130] It is the presence of balloon cells that differentiates FCD type I (without balloon cells) from FCD type II (with balloon cells) and that lead to the distinction in our classification scheme (see Table 1).

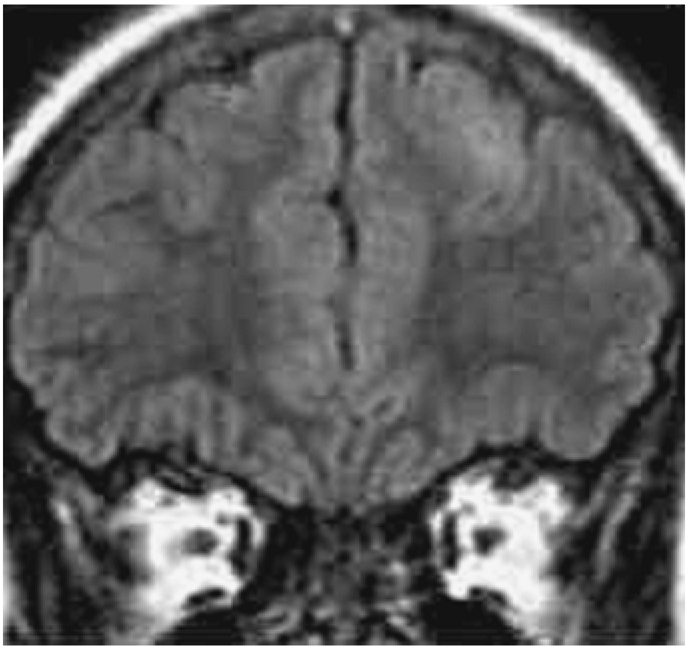

FIGURE 1. Focal cortical dysplasia (FCD). Left frontal lobe shows in this coronal fluid-attenuated inversion recovery magnetic resonance image a subtle signal abnormality and thickened cortex representing FCD. Pathology showed balloon cells.

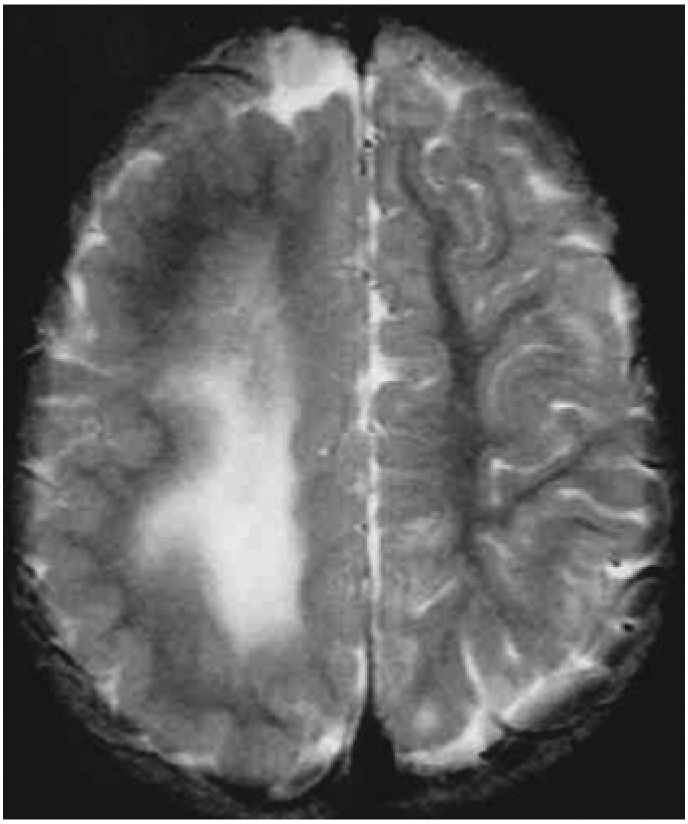

FIGURE 2. Hemimegalencephaly. Axial T2-weighted magnetic resonance image shows abnormal left hemisphere with smooth cortex and white matter changes.

The clinical manifestations of patients with cortical FCD are variable. Seizures usually begin between the ages of 2 and 10 years. Sometimes, however, seizures may be the presenting clinical problem in the second decade or even later. Focal and secondarily generalized attacks are common. Interestingly, seizures often occur in clusters, but generalized status epilepticus is rare except in patients with FCD involving the central region.[76] In our experience, the majority of patients have extratemporal cortical dysplasias that affect the pre- and postcentral regions most often. Interictal scalp electroencephalography (EEG) may demonstrate focal subclinical ictal discharges over the dysplastic lesions, underscoring the high epileptogenicity of these lesions.[103] FCD involving the frontal lobe has also been reported, and lesions can occur in both mesial and lateral neocortical structures as well.[77]

The MRI findings consist of abnormal gyral thickening with underlying T2-weighted white matter changes. These abnormalities are often circumscribed in nature, and they can sometimes be extensive, involving more than one gyrus or lobe. High-resolution MRIs with thin slices and multiplanar reconstruction are often necessary to identify these[24,25,55] (Fig. 1). Location can be quite unpredictable, as in the example of a very small lesion that was restricted to the bottom of a sulcus. Correlating clinical manifestations with the spectrum of changes seen in FCD has been limited, because histopathology is usually required before subtypes of FCD (e.g., FCD without balloon cells and microdysgenesis) can be firmly established.[10]

Hemimegalencephaly

Hemimegalencephaly is a rare malformation characterized by predominantly unilateral cerebral pathology typically associated with an enlarged hemisphere. It can be seen in isolation or in association with epidermal nevus syndrome[105] or hypomelanosis of Ito.[91,104,128] Pathologic findings are diverse and include cortical dysplasia, white matter abnormalities with abnormal cell types, or polymicrogyria usually restricted to one hemisphere. Most children with hemimegalencephaly associated with cortical malformations have not had other associated congenital anomalies.

Seizures and hemiparesis are common presenting symptoms.[101,107,118] Developmental delay is also common. Seizures usually appear within the first 6 months of life. They are often unilateral but can secondarily generalize, and they are frequently intractable to medical therapy. Continuing seizure activity is associated with the appearance or worsening of unilateral neurologic findings, such as hemiparesis and hemianopias. Occasionally there is only minimal neurologic dysfunction.

Diagnosis is based on the predominantly focal epileptic syndrome, the unilateral hemispheric EEG discharges, and the presence of unilateral neurologic abnormalities. MRI findings provide definitive diagnosis. Mild to severe enlargement of at least one lobe is present in all patients (Fig. 2). In more than half of the patients, the entire hemisphere is enlarged with thick gray

matter and broad, flat gyri.[23,83,136] The underlying hemispheric white matter usually demonstrates abnormal MRI signal intensity. Heterotopia and other malformations are sometimes detected throughout the abnormal hemisphere, and there may be ipsilateral ventricular enlargement.

Focal Transmantle Dysplasia

Transmantle dysplasia is a developmental malformation characterized by abnormal brain tissue that extends through the entire mantle of the cerebrum, from the pia to the ventricular surface.[12] On MRI brain scans, areas of signal abnormality extend radially inward from the cortical surface toward the lateral ventricle. When the imaging plane is parallel to the tract, the T2 imaging signal abnormality involves the deep cortex and subcortical white matter.

Patients with this malformation present with focal seizures at different ages. Ictal semiology and neurologic deficits resemble those that accompany FCD. EEG abnormalities are usually lateralized to the areas of cortical malformations. Mild motor signs may be present if the lesions are in close proximity to the central cortical area. This malformation likely represents a subtype of FCD as pathology obtained during resections for epilepsy show a lack of normal cortical lamination, neuronomegaly, and hypomyelination with atypical reactive astrocytosis in the white matter.

Tuberous Sclerosis

Tuberous sclerosis (TS) is an autosomal dominant, genetically determined multisystem disorder with high penetrance and variable expression.[35,36,37,71] Genetic heterogeneity is observed with gene defects reported in both chromosome 9q34 and chromosome 16p13 with genetic classification into TSC1 and TSC2.

Pathologically, TS is a disorder of cellular migration, proliferation, and differentiation, resulting in hamartomata formation that involves a large number of neural crest derivatives. Histologically, two major abnormalities are seen. Cortical tubers are characterized by cortical dyslamination, large cells (neurons and glial cells or neuroastrocytes), and abnormal neuropil with hypomyelination. Subcortically, subependymal nodules projecting into the ventricles are typical. Microscopically, densely aggregated larger cells are present, often resembling neoplasms. Electron microscopic (EM) studies of cortical tubers have demonstrated that glial cells predominate near the pial surface, whereas small neurons are more prevalent inferiorly. Underneath the tubers, a rudimentary cortical plate is seen. The presence of the most undifferentiated cell types in the subependymal zone (giant cells) and more differentiated cells in the cortical tubers with intermediate lesions between them suggest a spectrum of abnormalities in neural and glial differentiation and migration.

Seizures are the most common neurologic symptom in TS: More than 90% of patients have seizures during their lifetimes.[71,120,142] Infantile spasms and partial seizures are highly prevalent, and secondary generalization occurs more often after age 2 years. Myoclonic seizures and mental retardation are very frequent. Over time, clinical deterioration is common, with seizures becoming more frequent and difficult to treat.

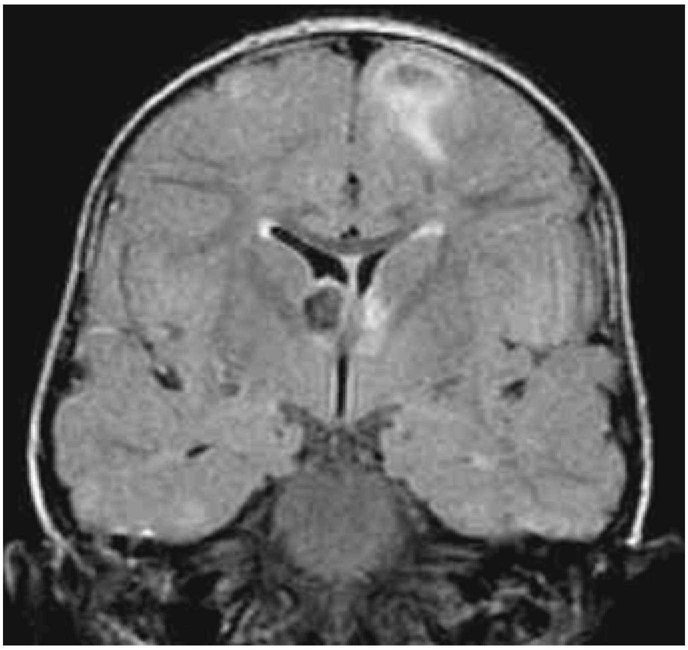

FIGURE 3. Tuberous sclerosis complex. Coronal fluid-attenuated inversion recovery magnetic resonance image shows multiple hamartomas and a large subependymal nodule.

MRI scans often demonstrate subependymal nodules with varying degrees of contrast enhancement.

Calcifications are frequent and are best demonstrated using gradient-echo sequences. Cortical tubers, ranging in size from 1 to 2 cm, are located at the gray–white matter interface. The parietal and frontal lobes are affected most often (Fig. 3). Tubers are isointense on T1 images but hyperintense using T2 sequences. Gyral core tubers may resemble an empty gyrus due to hypointensity of the white matter.[3,48,129]

The location of certain size tubers appears to correlate with EEG epileptogenic foci and prognosis. Patients with posteriorly located lesions have early onset of seizures as opposed to those with frontal lesions.[31] The presence of multiple and large cortical tubers, early onset of multiple seizure types, and multifocal EEG abnormalities correlate with unfavorable prognosis.

Lissencephalies

Lissencephaly refers to brains without normal sulcation (i.e., smooth brains).[43,72] The lissencephalies are a group of different disorders with distinct pathologic substrates and multiple causes. The major distinction is between classical lissencephaly and cobblestone lissencephaly, terms that reflect the appearance of the brain and that, in turn, derive from different genes. The various types of lissencephaly are classified according to the gene defect and associated malformations. For example, instead of classifying *LIS1* mutations and *DCX* mutations as subcategories of the isolated lissencephaly sequence, the classification includes Miller-Dieker syndrome, isolated lissencephaly syndrome, and subcortical band heterotopia as subcategories under *LIS1* mutations.[10] Instead of listing *POMT1* mutations and *FKRP* mutations under Walker-Warburg syndrome, the classification lists muscle-eye-brain disease and Walker-Warburg syndrome under *FKRP* mutations. As a result of this reclassification, many syndromes are listed more than once. For example, isolated lissencephaly sequence and band heterotopia are listed under both *LIS1* and *DCX* mutations and Walker-Warburg syndrome is listed under *POMT, FKRP,* and *FCMD* mutations.

Classical Lissencephaly

Classical lissencephaly or generalized agyria-pachygyria is a severe brain malformation manifested by a smooth cerebral surface, abnormally thick cortex with four abnormal layers,

P.2579

diffuse neuronal heterotopia, enlarged ventricles, and often hypoplasia of the corpus callosum. Mutations in the *LIS1* gene result in Miller-Dieker syndrome (MDS), isolated lissencephaly sequence (ILS), and subcortical band heterotopia (SBH). Similar phenotypes also occur with *DCX* mutations, although in patients with *DCX* mutations, the frontal lobes are most affected; whereas in patients with *LIS1* mutations, the posterior areas are more involved. Mutations of the *ARX* gene cause X-linked lissencephaly with ambiguous genitalia and anomalies of the corpus callosum.[65,69,70,127]

FIGURE 4. Lissencephaly. Miller-Dieker syndrome. *LIS1* mutation. Axial T2-weighted image shows smooth cortex.

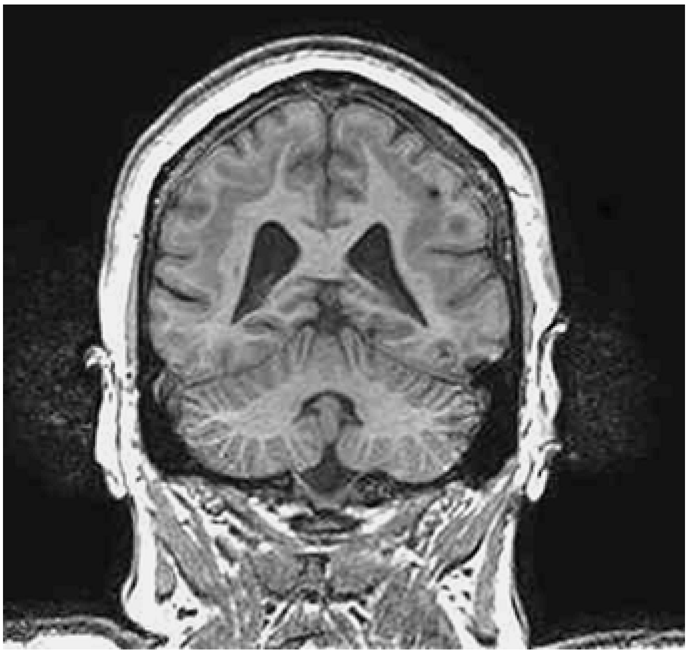

FIGURE 5. Subcortical band heterotopia (SBH). Coronal T1-weighted image shows typical subcortical band of gray matter with relative normal cortical infolding; *DCX* mutation.

Children with classical lissencephaly present with feeding difficulties or hypotonia. By 6 months of life, most of these children will have seizures, and the evolution of the epilepsy is similar in all patients. Infantile spasms with hypsarrhythmia and typical paroxysmal fast activity on the EEG appear in the first year of life. Response to treatment with adrenocorticotropic hormone (ACTH) or other anticonvulsants is variable, but most children will continue to have frequent seizures accompanied by severe developmental delay. Typical seizure types also include myoclonic, tonic, and tonic–clonic seizures. Profound mental retardation and spastic quadriplegia are present.

Diagnosis of classic lissencephaly is based on the typical clinical, EEG, and MRI features. MRI demonstrates a thickened cortex, loss of white matter, and vertical sylvian fissures, which result in the typical 8-shaped appearance of the brain (Fig. 4). Cortical thickness is in the range of 11 to 20 mm compared to 3.5 mm in normal controls.[11] In some patients there are regions of pachygyric cortex. Barkovich et al.[11] have also reported the presence of incomplete inversion of the hippocampi, a marker of arrest of neuronal migration.

Band Heterotopia (Double Cortex)

Subcortical band heterotopia or "double cortex syndrome" (Fig. 5) consists of symmetric and circumferential bands of gray matter located just beneath the cortex and separated from it by a thin band of white matter. The inner margin of the band is usually smooth, while the outer margin may be smooth or follow the interdigitations of the true cortex and white matter. Pathologic specimens have demonstrated normal lamination in cortical layers one through four; layers five and six usually cannot be seen; and layer six is merged with the U-fibers of the white matter.[90] Underneath, clusters of ganglion cells are present. Cortical thickness overlying the heterotopia is mildly increased or normal, and the temporal lobes, in particular the hippocampal structures, are normal as opposed to lissencephaly.

Band heterotopia is an X-linked recessive trait, and thus it is usually found only in females, although a few affected males have survived.[112] The risk for carrier females is high: 50% of their sons will have lissencephaly, and 50% of their daughters will have band heterotopia. Patients have mild to moderate developmental delay, upper motor neuron signs, and, in some, dysarthria. Full-scale IQs ranging from severely low to normal have been reported.[5] EEG investigations usually demonstrate frequent bilateral focal and multifocal spikes, although generalized discharges are also seen, including slow spike-wave patterns.

MRI findings are fairly stereotyped and demonstrate a circumferential band of subcortical gray matter heterotopia underlying the cortical mantle and separated from it by a thin rim of white matter. This is usually more obvious over the frontocentral parietal region. Barkovich et al. have suggested that the thickness of the heterotopic gray matter correlates with severity of the clinical syndrome.[5,66,90]

Cobblestone Lissencephaly Complex

Cobblestone lissencephaly, so called because of the pebbled appearance of the cortical surface due to leptomeningeal neuronal and glial heterotopia, is less common than classical

P.2580

lissencephaly. It is a complex brain malformation that consists of cobblestone cortex, polymicrogyria, pachymicrogyria, abnormal white matter, enlarged ventricles, small brainstem, and cerebellar vermian atrophy with cerebellar polymicrogyria.[43] It is often associated with eye malformations and congenital muscular dystrophy.

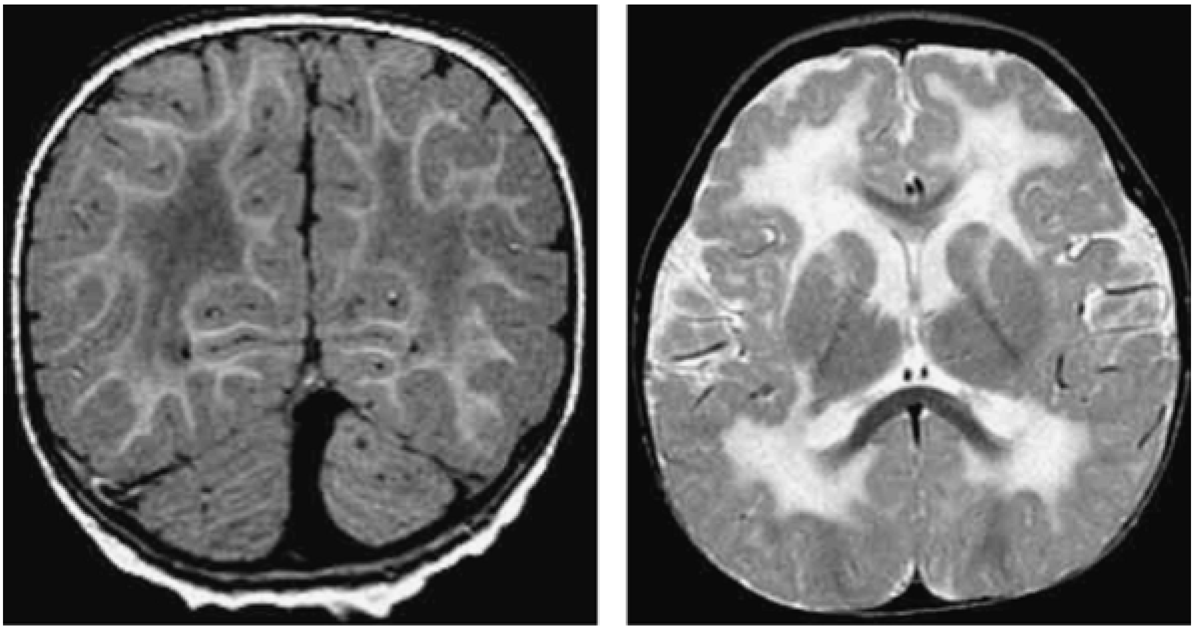

FIGURE 6. Cobblestone lissencephaly in Fukuyama congenital muscular dystrophy with *FKTN* mutation. Note white matter changes, smooth cortex, and cerebellar cyst.

Syndromes associated with cobblestone lissencephaly include Fukuyama congenital muscular dystrophy (FCMD) (Fig. 6), muscle-eye-brain disease (MEB), and Walker- Warburg syndrome (WWS). The classification of cobblestone lissencephalies changed significantly when it was discovered that congenital muscular dystrophies result from abnormalities of protein glycosylation.[2,22,143] Mutations in any of the genes involved can cause several different clinical syndromes. For example, Fukutin-related protein (*FKRP*) mutations can cause the clinical phenotypes of limb-girdle muscular dystrophy, muscle-eye-brain disease, and Walker-Warburg syndrome.[15] Fukuyama (*FCMD*) mutations can cause Walker-Warburg syndrome in addition to FCMD and MEB (Fukuyama CMD plus retinal abnormality) phenotypes.[14,124] Thus, the clinical phenotype may be related more to the severity of the mutation than to the precise gene.

Most children with cobblestone lissencephaly have severe mental retardation and hypotonia, mild distal spasticity, and often poor vision. Most patients do not survive beyond the first decade. Seizures have not been well studied.

Heterotopia

Heterotopia is, by definition, the presence of normal cells in improper locations.[8,47] In cases of epilepsy associated with MCDs, this definition usually refers to neurons within the periventricular or subcortical white matter. At the present time, there are two major groups of heterotopia that are recognized as syndromes: Periventricular nodular heterotopia (PNH) and focal subcortical heterotopia.

Periventricular Nodular Heterotopia

Periventricular nodular heterotopia, or subependymal nodular heterotopia, is the most common form of developmental disorder seen in patients with epilepsy.[8,21,44,58,68] The condition is caused by the failure of a group of neurons to either initiate or complete the migration process toward the cortical mantle. PNH can range from a few nodular clusters of neurons to diffuse lining of the ependymal regions. Bilateral periventricular nodular heterotopias (BPNHs) are usually contiguous and symmetric but occasionally are isolated and asymmetric. Ninety percent of reported patients with PNH had diffuse, narrow involvement of all subventricular regions.[44,63,84]

Patients with PNH usually have normal neurologic development. A few have had symptoms that were probably overlooked, such as headaches or psychiatric complaints, while other persons discovered during family evaluations have been asymptomatic. The majority of patients have normal intellectual and motor function or mild mental retardation. Seizures are common, and epilepsy occurs in almost 80% of cases. Interestingly, seizures usually begin in adolescence. In patients with seizures, temporal and parieto-occipital symptomatology is common. EEG findings are generally nonspecific, and interictal discharges are infrequent.[57]

Typical MRI features consist of multiple smooth ovoid nodules of cortical gray matter lining the lateral ventricles but sparing the third and fourth ventricles (Fig. 7). Approximately 75% of patients have bilateral lesions, and 30% have additional focal subcortical heterotopia. Callosal and cerebellar malformations are present in 25% of cases. Signal intensity from the nodules is isointense with gray matter in all MRI sequences, and the nodules do not enhance with contrast, distinguishing features from subependymal hamartomas seen in tuberous sclerosis. In 20% of patients, other cortical malformations may be detected.

Classic PNH can be associated with FILA (Filamin) mutation on chromosome Xq28.[46] Because it is an X-linked mutation, men are only rarely affected.[45,57,59,97] Most pregnancies carrying male fetuses terminate in spontaneous abortions.

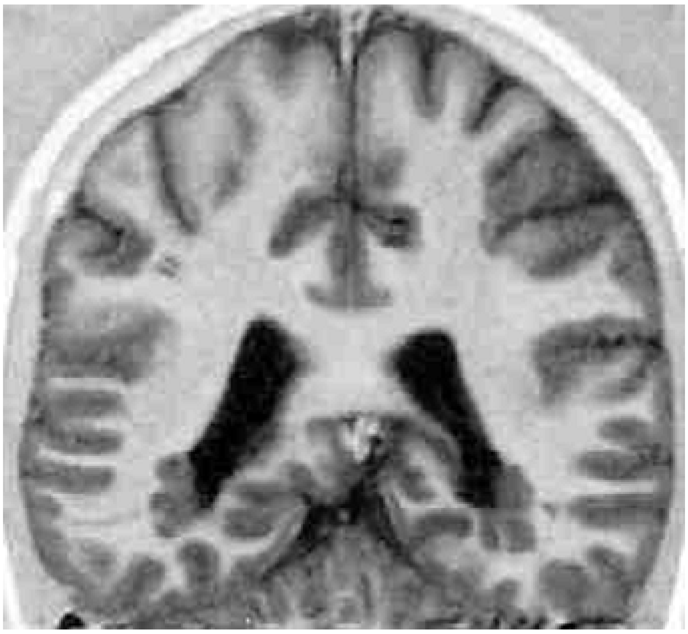

FIGURE 7. Periventricular nodular heterotopia due to Filamin 1 mutation. Note periventricular gray matter nodules.

Focal Subcortical Heterotopia

Although the majority of patients with subependymal heterotopia have diffuse nodular lesions, occasionally patients may present with few focal lesions involving one hemisphere. According to reviews,[13,45,83] the frequency of focal subcortical heterotopia is <20%. In a patient without neurologic symptoms, such lesions may be just coincidental findings, but the true incidence of seizures in these patients is unknown. Most patients have been sporadic occurrences, and subcortical heterotopias are probably secondary to mosaic mutations or to true environmental injuries.

Clinically, patients may present with normal development, but at times, depending on the size of the lesions, contralateral pyramidal signs may be present. Approximately 50% of patients with focal subcortical heterotopia are developmentally and cognitively delayed. Developmental delay is more common among patients who have concomitant callosal agenesis. Speech appears to be normal in some patients, but when lesions are extensive and involve the dominant hemisphere, speech delay is observed. Seizures in these patients are a mixture of focal motor and secondary generalized convulsions. Infantile spasms have also been described. The ultimate neurologic and seizure outcome not only depends on the type, location, and size of lesions, but also on the type of developmental disorder.

Imaging features in these patients are quite characteristic. Heterotopia appears as clusters of nodules of gray matter with irregular margins (Fig. 8). The surrounding white matter is usually normal and has normal-intensity signal. At times, the heterotopia may appear as masses with ventricular compression. On some occasions, cerebrospinal fluid (CSF) signal may be seen within these malformations. Corpus callosum abnormalities have also been reported.

Polymicrogyria

Polymicrogyria (PMG) refers to an abnormal macroscopic appearance of brain gyration that is characterized by excessive numbers of small gyri. In some cases, the gyri are shallow and very small, separated by slight sulci, whereas in other cases the gyri are wider.[1,86,108]

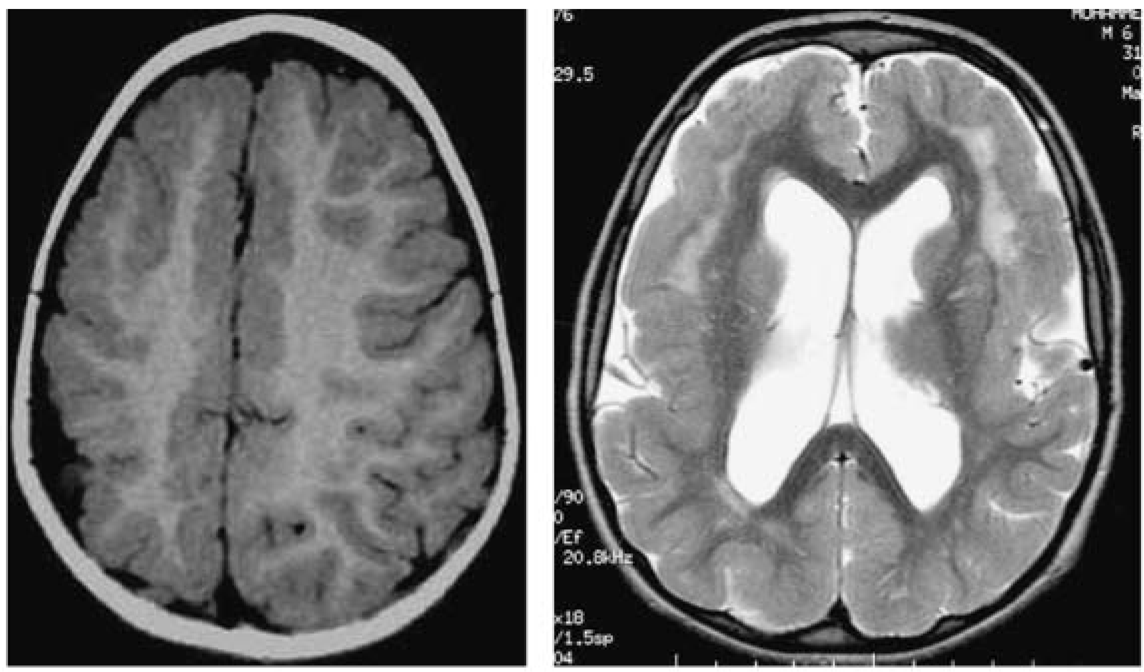
FIGURE 8. Subcortical nodular heterotopia. Axial T1-weighted magnetic resonance image shows large subcortical mass of gray matter in the mesial frontal lobe associated with partial agenesis of corpus callosum and ventricular changes.

The histologic changes in polymicrogyria are midcortical laminar necrosis in layer five resembling ischemic change. Superficial to this cortical band, the cortex consists of normal layers four, three, and two. Because late-migrating neurons reach their normal positions before laminar necrosis takes place, this type of malformation most likely originates in some cases after the 20th fetal week and is thus postmigratory in origin.

Histologic classification divides polymicrogyria into four-layered and unlayered types. Although most of the experimental data and pathologic findings in human fetuses suggest that polymicrogyria is the result of a postmigratory ischemic mechanism, this has been disputed and some investigators[1,99] have postulated that at least some forms of PMG are premigratory in origin. In fact, the best known cause in humans is intrauterine cytomegalovirus (CMV) infection, which is also usually associated with diffuse or patchy white matter changes and often diffuse or multifocal calcifications.

Several new unilateral and bilateral polymicrogyria syndromes have recently been described, and several others have had the causative genes mapped or identified. Reports of *bilateral perisylvian polymicrogyria* had commented on a significant male preponderance.[96] This was subsequently confirmed in a large series that localized a gene to Xq28.[135] Unilateral and bilateral perisylvian polymicrogyria has been observed in several chromosomal aneuploidy syndromes, most prominently with deletion of the chromosome 22q11.2 DiGeorge syndrome critical region,[18,19] and in families with presumed X-linked inheritance.[20] Additional bilateral polymicrogyria syndromes include bilateral *frontal polymicrogyria,*[60] *bilateral parasagittal parieto-occipital polymicrogyria,*[61] *bilateral lateral parietal polymicrogyria,*[7]

bilaterally generalized polymicrogyria,[30] and two distinct malformations with periventricular nodular heterotopia and overlying polymicrogyria, one with frontal-perisylvian predominance and another with posterior-temporal predominance. A recent report described a malformation designated *bilateral frontoparietal polymicrogyria* associated with abnormalities of myelination and dysplasia of the cerebellum and brainstem.[29] This has been mapped to chromosome 16q12.2-21 and subsequently associated with mutations of the *GPR56* gene.[109]



A B

FIGURE 9. A: Unilateral polymicrogyria (PMG). Note extensive atrophy and PMG cortex in the left hemisphere. **B:** Bifrontal PMG syndrome with *GPR56* mutation. Note PMG and abnormal white matter changes.

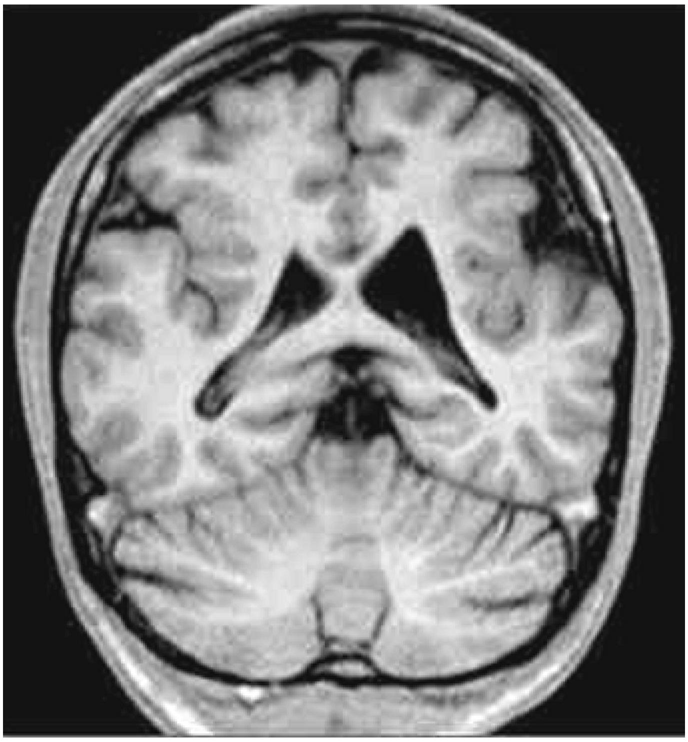


FIGURE 10. Polymicrogyria (PMG), bilateral perisylvian syndrome. Coronal T1- weighted magnetic resonance image shows bilateral perisylvian PMG.

The clinical presentation depends on the location and extent of polymicrogyria, and whether the contralateral hemisphere is involved. It is thus highly variable. Diffuse polymicrogyria may present with severe developmental delay, microcephaly, and hypotonia. Polymicrogyria can be limited to one hemisphere (*unilateral hemispheric polymicrogyria*) (Fig 9); it can also be one of the pathologic changes associated with hemimegalencephaly.

MRI findings demonstrate a seemingly thick cortex that can be interpreted as pachygyria. However, cortical thickness in polymicrogyria is less than that observed in pachygyria. The sulci are shallow, and the underlying white matter may show abnormal T2 signal. (Figs. 9 and 10).

As indicated by the foregoing descriptions, PMG syndromes have been classified by the anatomic distribution of the abnormal gyri. Some syndromes can also now be identified on the basis of clinical and imaging features. The most common of these is *bilateral perisylvian polymicrogyria,* also known as *congenital bilateral perisylvian syndrome* (CBPS).[52,56,73,74,98] Clinical features include congenital pseudobulbar paresis, intellectual delay, and characteristic bilateral lesions on computed tomography (CT) or MRI. Almost 90% of patients present with seizures, and half of them have intractable epilepsy. A unique seizure pattern consists of perioral and bilateral facial involvement. Other seizure types include atypical absences attacks, tonic/atonic seizures, and generalized tonic–clonic seizures. EEG findings include generalized spike-wave or multifocal abnormalities, but 20% have had localized epileptogenic discharges. The diagnosis can be made on the basis of the clinical features; brain MRI provides confirmation.[74] The imaging findings are distinctive with involvement of the sylvian,

P.2583

opercular, and perisylvian regions (Fig. 10). Except for unilateral hemispheric polymicrogyria, the other bilateral polymic-rogyria syndromes do not have characteristic clinical or EEG features.

Schizencephaly

Although schizencephaly has been considered a condition different from polymicrogyria, most authorities today classify them as *polymicrogyria/schizencephaly complex*. The term *schizencephaly* is used to describe clefts in the cerebral hemispheres that are lined with gray matter and extend from the pia to the ependymal lining.[42,54,64] The clefts may be in apposition to each other (closed lip or type I schizencephaly) or separated (open lip or type II schizencephaly).[126] The cortex surrounding the clefts can be normal or have underlying polymicrogyria. The gray matter lining the cleft itself is usually composed of polymicrogyric cortex. Subependymal heterotopias are common. The pathogenesis of schizencephaly is probably similar to that of polymicrogyria and porencephaly. It is, rather, the extent of cortical injury that determines if a lesion becomes polymicrogyria or schizencephaly. Injuries that extend more deeply into the cortex and destroy the superficial portions of the glial fibers produce cortical infoldings lined by polymicrogyria. When the injury involves the entire thickness of the developing hemisphere, schizencephaly results. The septum pellucidum is absent in 70% to 90% of patients.[9,117]

Schizencephaly has many features resembling those of polymicrogyria. As with polymicrogyria, schizencephaly can be bilateral or unilateral. Furthermore, bilateral lesions can be either symmetric or asymmetric. In our experience, approximately 30% to 40% of patients with schizencephaly have bilateral lesions. They are often asymmetric, however, with type I schizencephalic lesions in one hemisphere and type II lesions in the opposite hemisphere (Fig 11).

Patients with bilateral schizencephaly often have a moderate to severe spastic quadriparesis. Severe mental retardation and language disorders are also common. Infantile spasms may be the presenting seizure type in these patients, and focal motor seizures with and without secondary generalization are common. A minority of patients with bilateral lesions are controlled on drugs.

Unilateral schizencephalies are evenly distributed between the two hemispheres. The frequency of type I versus type II lesions is similar. Developmental delay, intellectual impairment, and hemiparesis contralateral to the cleft are common findings. We have not observed any significant differences in language dysfunction between left and right dominance in persons with schizencephaly, probably because these patients most likely transfer language to the more normal hemisphere. Seizures are usually focal motor, but sensory and complex partial seizures also occur. EEG investigations may reveal focal temporal discharges when the lesions are localized to the temporal-parietal convexity. However, EEG spikes may occur beyond the area of malformation, including the opposite hemisphere (see below). The location of lesions by MRI appears to be evenly distributed, with the majority located in pre- and postcentral regions.

An interesting issue concerning patients with unilateral polymicrogyria or schizencephaly is the presence of subtle cortical developmental malformations of the opposite hemisphere. The contralateral lesions are usually present in the mirror regions of the opposite hemisphere. This may explain why some patients with unilateral lesions may present with severe developmental delay. These findings underscore the possible pathogenic mechanism for cortical dysplasia, polymicrogyria, and schizencephaly.

Management of Patients with Malformations of Cortical Development

The first step is to make a correct diagnosis of the specific MCD. This is important for several reasons. First, accurate identification of the underlying MCD permits proper genetic counseling. Second, a syndromic classification assists in making rational decisions about the medical and surgical treatment for seizures. The best example of such a case is the congenital bilateral perisylvian syndrome. Third, proper diagnosis may permit assessment of ultimate prognosis. In the following section we will discuss management issues pertaining to specific problems and conditions.

Infantile Spasms and Malformations of Cortical Development

MCD is recognized with increasing frequency in children with infantile spasms (ISs) because high-resolution imaging has permitted improvement in the detection of MCDs. In fact, MCDs are the most frequent cause of ISs. However, the ultimate prognosis for these children is variable and more likely to be associated with the extent and type of underlying MCD (see Chapter 229, West Syndrome).

A number of observations have modified the treatment options in patients with ISs and MCDs.[36] It is likely that corticosteroids may be the treatment of choice in patients with focal developmental lesions and ISs associated with hypsarrhythmia. In contrast, open studies have shown that vigabatrin (VGB) is effective in patients with diffuse malformations such as TS. VGB in combination with carbamazepine or benzodiazepines is effective in TS. The response to drug treatment in patients with ISs and diffuse malformations such as lissencephaly is poor.

Surgical treatment of patients with ISs and MCDs is dependent on the underlying condition. The presence of a tumor or porencephalic cyst is usually associated with good results.[4,138] Large multifocal resections have provided improvement in a number of children with ISs and focal features.[32,33] Modified hemispherectomy is also effective in patients with ISs and hemimegalencephaly.[39,106] Callosal sections performed in some children with diffuse MCDs and ISs have given disappointing results.[140]

Other Seizure Types

Apart from the clear difference in response of TS patients with ISs to VGB treatment, there have been no randomized drug trials to prove that any particular drug regimen is superior in treating patients with MCDs.

The response to antiepileptic drugs (AEDs) is generally dismal in diffuse malformations such as Aicardi syndrome; it is more variable among patients with lissencephaly. Among patients with bilateral lesions or focal malformations, about 35% respond to AEDs.[125] It is estimated that the response rate to AEDs is approximately 35%. Valproic acid and other broad-spectrum drugs are generally chosen in patients with diffuse malformations.

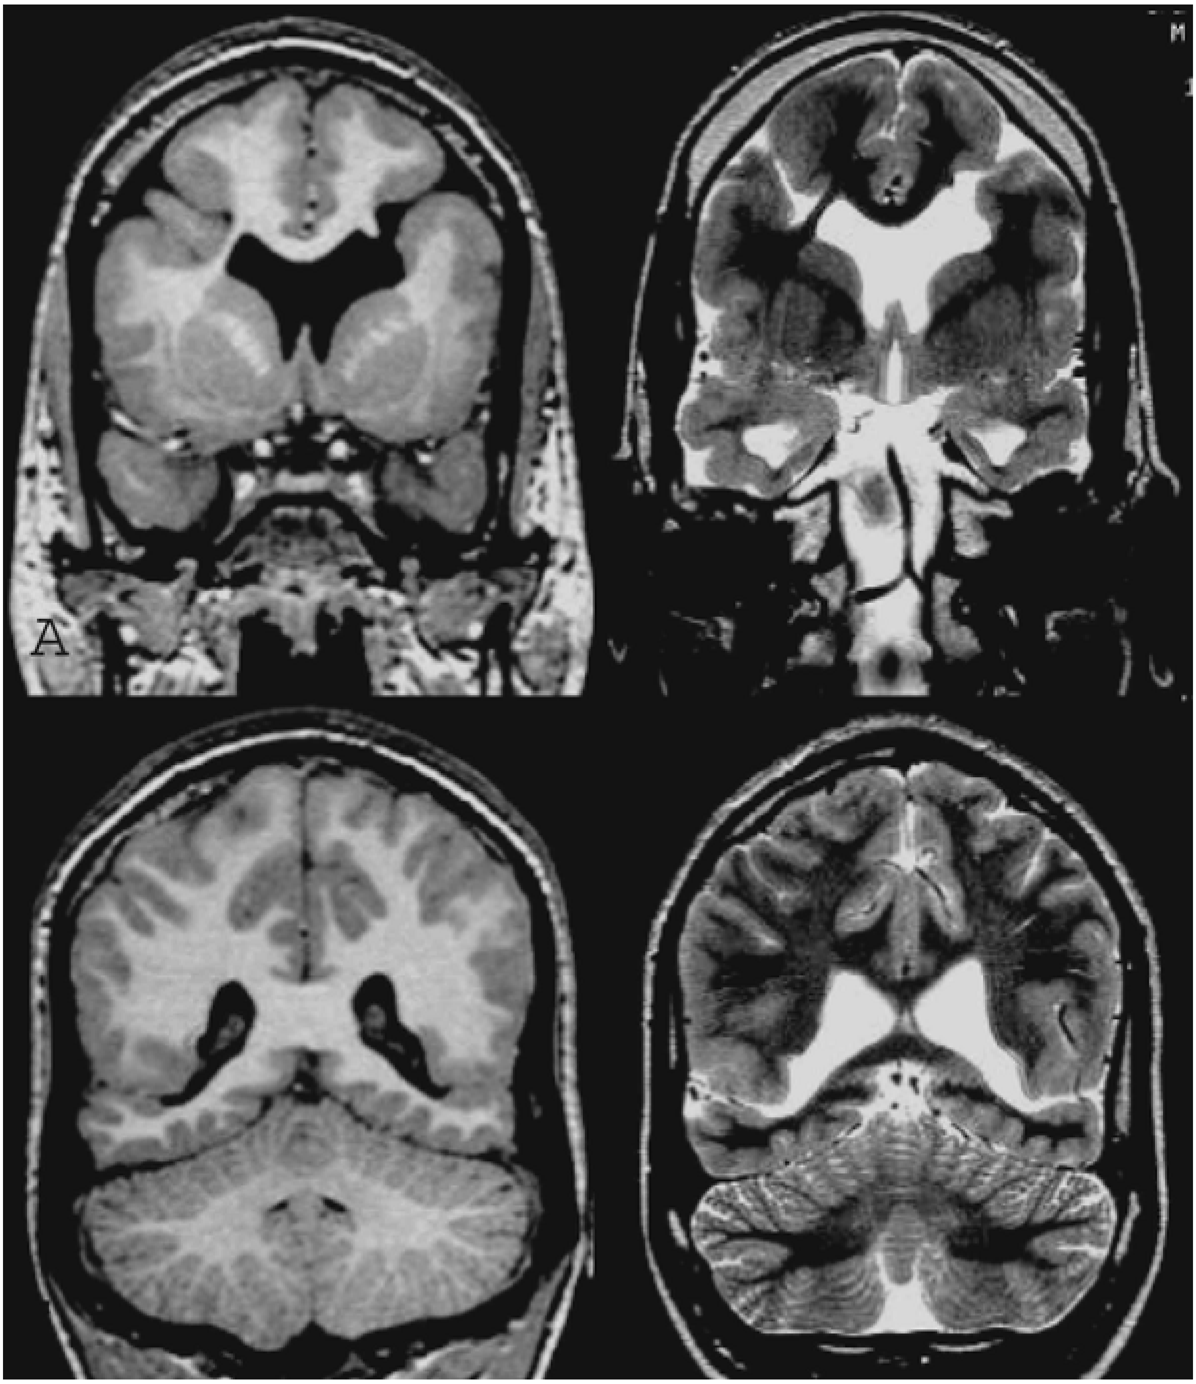

FIGURE 11. Schizencephaly/polymicrogyria syndrome, bilateral symmetric clefts involving frontal and parietal regions.

Surgical Strategies

In some cases of MCDs, depending on the specific clinical and investigative findings, surgical procedures may be appropriate

for treatment (see Chapters 178 and 179). In general, any defined abnormality (usually on MRI) is only a small part of the disturbance of the brain due to abnormal development. Therefore, resections need to extend beyond just the clearly defined abnormality; outcome is generally not as good as that following resections of focal lesions such as benign tumors or cavernomas.

Focal resections in patients with MCDs have been performed with variable results. Several groups[78,80,102,137,139,141] reported good outcome if the visualized lesions were completely resected. In our experience, the best outcome is seen among patients with small developmental abnormalities in the temporal lobe. Unfortunately, focal MCDs are commonly localized in the perisylvian region, and thus, motor or language vital cortical areas limit resections. In such cases, outcome is more variable. Recent data have indicated that 52% of patients with temporal lobe dysplasias were seizure free compared with 29% of those with frontal lobe dysplasias.[102] reported excellent outcome when ictal-like EEG activity was eliminated by surgery. Therefore, it would appear that the outcome following surgical resection of focal MCDs depends on the extent of lesion removal and elimination of highly epileptogenic discharges on EEG.

Table 2 Genetic Basis of Malformations of Cortical Development

Syndrome	Locus	Gene (Testing)	Protein
ARMCP[MCPH1]	8p23	**MCPH1** *(R)*	Microcephalin

ARMCP, autosomal recessive microcephaly; ARPHM, autosomal recessive periventricular heterotopia and microcephaly; BFPP, bilateral frontoparietal polymicrogyria; BPNH, bilateral periventricular nodular heterotopia; BPSP, bilateral perisylvian polymicrogyria; C, clinical testing available for gene; FCMD, Fukuyama congenital muscular dystrophy; ILS, isolated lissencephaly sequence; LCH, lissencephaly with cerebellar hypoplasia; MCPHA, Amish lethal microcephaly; MDC, congenital muscular dystrophy; MDS, Miller-Dieker syndrome; MEB, muscle-eye-brain disease; R, research testing available for gene; SBH, subcortical band heterotopia; SCKL1, Seckel syndrome 1; WWS, Walker Warburg syndrome.

In cases of hemimegalencephaly, high seizure-free rates have been reported with early hemispherectomy.[119] Although there has been controversy regarding the optimal timing of surgery, an increasing number of investigators advocate early surgical intervention with the aim of protecting the normal hemisphere from the damaging effects of seizures and subsequent abnormal development. Another point of contention has

related to the type of surgery. Some have argued that complete hemispherectomy is the procedure of choice,[34,119] whereas others recommend functional hemispherectomy.[28,34,131] Unfortunately, there have been no randomized trials to assess this issue. The complications of complete hemispherectomy, which include hydrocephalus and hemosiderosis, appear to be higher than with functional hemispherectomy.

Callosotomy has been used in patients with severe diffuse MCDs, but the results have been disappointing. However, benefit has been observed in some patients with specific types of malformations. For example, we previously reported good outcome in cases of congenital bilateral perisylvian syndrome,[73] although results have not been predictable. Recent experience with individual patients suggests that multiple subpial transactions may be a potential treatment for selected patients with bilateral lesions. In such cases, the surgical approach should be viewed as a palliative procedure that offers the possibility of a good outcome. Finally, vagus nerve stimulation (VNS) has been carried out in patients with various types of MCDs. Although some reports have described improved seizure control, there are no prospective studies. Our own experience indicates that outcome with VNS is unpredictable.

Genetic Counseling

MCDs often affect children, and thus, genetic counseling becomes extremely important for their families. Much has been learned about the genetics of MCDs, but diagnostic testing is available for only a few (Table 2). Among malformations of neuronal and glial proliferation/apoptosis, routine tests are only available for the two causal genes for tuberous sclerosis (*TSC1* and *TSC2*).

All forms of lissencephaly/subcortical band heterotopia are genetic, and tests are available that are applicable to at least 80% of patients, although this varies with the specific phenotype. When lissencephaly is suspected, chromosome analysis and fluorescent in situ hybridization (FISH) using a probe that contains the *LIS1* gene should be done followed by sequencing of *LIS1* and then *DCX* if *LIS1* is negative. When band

heterotopia is suspected, the order of testing should be changed to sequencing of *DCX*, followed by FISH with a probe containing *LIS1*, and finally sequencing of *LIS1*. In a child with lissencephaly whose brain imaging also reveals callosal agenesis, or whose physical examination demonstrates abnormal genitalia, *ARX* testing should be done first. When mutations of any of the aforementioned genes are found, parents should generally be tested to determine their carrier status, as this is important for genetic counseling. Parental testing is especially important for the two X-linked genes, *ARX* and *DCX*, as mothers are often carriers. The frequency of postzygotic mosaicism is high in mothers, probably at least 5%, which must be taken into account for genetic counseling. When genetic tests for lissencephaly or band heterotopia are negative, later siblings have nonetheless been affected in several instances.[41,50,82,116] Counseling should include acknowledging a 10% to 15% risk in such situations. Without testing, counseling is more difficult.

Two genes associated with PNH, *FLNA* and *ARFGEF2*, have been discovered, but no labs currently offer clinical testing. Classic PNH with cerebellar hypoplasia and no dysmorphic features occurs much more frequently in females than in males, and mutations of the X-linked *FLNA* gene account for >80% of familial PNH, ~20% of sporadic PVNH in females, and ~10% in sporadic males.[121] The large size of the gene, which would make clinical testing very expensive, probably accounts for the lack of testing by clinical labs. Among women carriers, ~50% have de novo mutations of *FLNA*, whereas the remaining 50% have inherited mutations. Although maternal transmission is much more likely, father-to-daughter transmission is possible, implying that either parent can transmit the mutation to a female proband.[62] An affected man with PNH caused by an *FLNA* mutation would be expected to transmit the mutation to all of his daughters unless somatic mosaicism is present. To date, all individuals harboring *FLNA* mutations have been found to have PNH, although they can be asymptomatic. Because germline mosaicism of *FLNA* has never been reported in PNH, the recurrence risk is probably low when a mutation is found in the proband but neither parent is a carrier. Microcephaly with PNH is a rare malformation associated with mutations of *ARFGEF2* in a few patients.[122]

So far, five genes have been identified that are associated with the cobblestone cortical malformation found in Fukuyama congenital muscular dystrophy, muscle-eye-brain disease, and Walker-Warburg syndrome (*FCMD*, *FKRP*, *LARGE*, *POMGnT1*, and *POMNT1*). Testing is not yet available clinically. However, enzyme analysis has been developed for POMGnT1 in muscle,[144] and it should be possible to use the same assay in fibroblasts. Similar assays for other enzymes in this group could be developed as well.

There are few laboratory tests to identify genes associated with malformations of late migration and cortical organization. A few patients with perisylvian polymicrogyria have had small chromosomal deletions or duplications, the most common being deletion of chromosome 22q11.2. We therefore recommend chromosome analysis, FISH using a probe from 22q11.2, and FISH using a subtelomeric probe set. The yield with the 22q11.2 probe appears to be high if the polymicrogyria is asymmetric. The causal gene for bilateral frontoparietal polymicrogyria has been identified (*GPR56*),[110] but it cannot yet be tested for clinically. Several years ago, mutations of the *EMX2* gene were reported in a few patients with schizencephaly,[26,53] but these results have not been confirmed. There is now doubt that *EMX2* is a causal gene for schizencephaly.

Summary and Conclusions

Malformations of cortical development are an important cause of drug-resistant epilepsy. High-resolution MRI now permits detection and classification of MCDs, and advances in molecular genetics are identifying causal gene mutations. It is important today to view MCDs within a coherent framework that integrates the clinical phenotype, imaging findings, and genetic cause (if known). Antiepileptic drug treatment provides benefit in some cases, and surgical intervention is useful in others. However, treatment is often frustrating and the results of various therapeutic interventions unpredictable.

Introduction

About 30 years ago, chromosomal abnormalities, as detectable by classic cytogenetics, were estimated to cause approximately 6% of central nervous system (CNS) malformations.[31] Today, the use of current techniques such as high-resolution chromosome banding, fluorescent in situ hybridization (FISH), and molecular genetics would certainly increase this percentage; it was estimated recently that genome-wide molecular cytogenetics techniques (array-CGH) can detect cryptic deletions/duplications in no less than 20% of individuals with mental retardation and dysmorphic features but apparently normal karyotype (Fig. 1).[139] It is likely that array-CGH at higher resolution will increase this percentage even further.

Most syndromes associated with chromosomal abnormalities are caused by duplications (with duplication of a segment of chromosome), deletions (absence of a segment), or breakpoint disruptions (only one or a few genes are disrupted). Virtually all known chromosomal abnormalities lead to anatomic and functional impairment of the CNS and, especially those involving autosomes, are accompanied by mental retardation. Tharapel and Summit[155] found 6.2% of cases of mental retardation to be associated with chromosomal abnormalities, as contrasted with the 0.7% rate found in controls.

The risk of epilepsy is greater in individuals with chromosomopathy than in the general population.[74] However, chromosomal abnormalities do not represent a frequent cause of epilepsy.[78]

Epilepsy as a complication of a chromosomal abnormality syndrome should be considered in a twofold perspective. First, symptomatic epilepsies have a high probability of causing intractable seizures, leading to further disability in these patients. Severe epilepsy may significantly reduce a low-IQ patient's potential for autonomy in everyday life.[64] Second, when seizures are the main manifestation of a chromosomal disorder or present with peculiar electroclinical patterns, it is important to establish whether these associations result from structural CNS abnormalities caused by the chromosomal changes or from the effect of loci that specifically affect seizure susceptibility. Careful attention to chromosomal abnormalities associated with seizures, together with detailed analysis of electroclinical patterns, may help to detect specific genes affecting seizure susceptibility.[2,142] It seems likely that the association between cryptic deletions/duplications and epilepsy will improve our ability to clone new critical genes.

Only those chromosomal abnormalities of special importance for their high frequency or association with epilepsy are considered in this chapter.

Standard Cytogenetic and Molecular Techniques for Diagnostics

Standard Karyotype and High-Resolution Chromosome Analysis

The karyotype of an individual can be ascertained from readily accessible somatic cells, such as peripheral blood lymphocytes or skin fibroblasts. Each chromosome can be identified by special staining techniques, using fluorescent dyes or Giemsa staining after treatment with a proteolytic enzyme (trypsin). A typical standard karyotype from metaphase cells contains 400 to 550 bands per haploid genome. "High-resolution" chromosome analysis makes it possible to visualize up to 2,000 bands, although a high-resolution chromosome analysis of standard quality allows the detection of about 850 bands. Given the greatly increased amount of work, the difficulty of the analysis, and the cost, high-resolution chromosome analysis should not be considered as a routine cytogenetic assay.

Molecular Karyotyping with Array-CGH

Several techniques defined as molecular cytogenetics have, over the course of the last 10 years, improved the resolution capability of the chromosome banding. The latest technology is the array-CGH, which represents a powerful modification of classical comparative genomic hybridization (CGH) based on metaphases. Using CGH, the DNA of a patient (to be tested) and the DNA of a control are labeled with green and red fluorochromes, respectively, and hybridized on metaphase spreads. The images of both fluorescence signals are captured, and the ratio of DNA intensities quantified using a dedicated software along each chromosome. The chromosome regions represented in the same amount in both DNAs (patient and control) appear yellow, the deleted regions appear red, and the duplicated regions appear green. The difficulty of obtaining sufficiently long metaphases limits the resolution power of this technique to a maximum of 3 Mb. Array-CGH technology replaces the use of chromosome spreads with clones or oligomers (targets) that cover the entire genome, and its resolution power depends only on the amount of targets and their distribution. Recently, microarrays using bacterial artificial chromosome (BAC) clones separated by 100 Kb have been used. Other platforms, using oligomers as targets, have a higher resolution that theoretically can reach up to a few hundreds of base pairs. The use of these arrays might allow the detection of deletions and duplications below the size of 1 Mb and precisely define their

P.2590

breakpoints (Fig. 1). This technology has also revealed that the human genome may harbor deletions and duplications, having an average size of 2 Mb and being devoid of phenotypic effects, which may play a role in multifactorial diseases. It seems obvious that microarray-CGH will have a crucial role in pre- and postnatal cytogenetics as well as in oncology; its potential in the etiologic diagnosis of epilepsy associated with mental disability and dysmorphic features is extremely high.

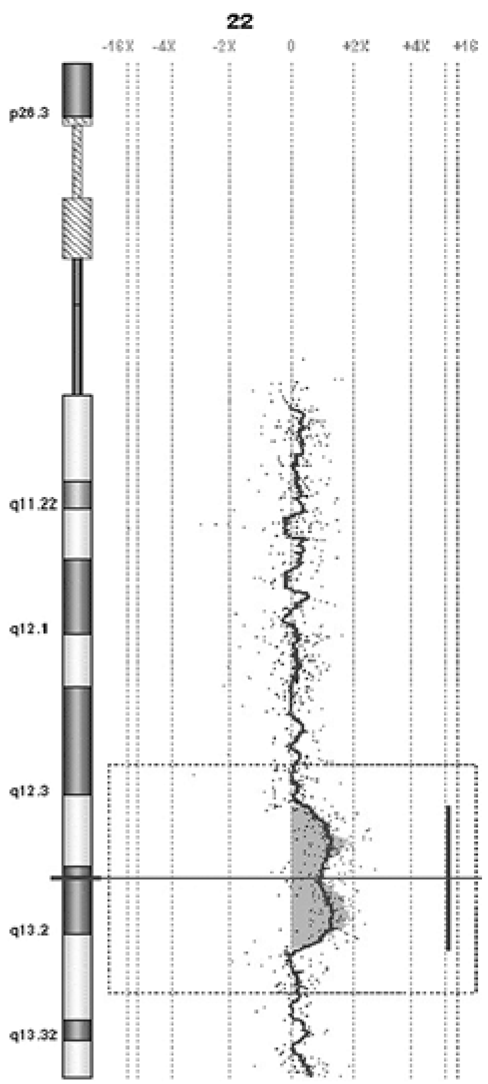

FIGURE 1. Eight-year-old girl with early-onset focal epilepsy and dysmorphic features. 6.9 Mb duplication at 22q13.1q13.2 detected through oligo-array-CGH at 75 kb resolution; log2 ratio of signals intensity is increased in the duplication region where red signals are located more proximal to the +2x line than are the remaining ones. This interstitial duplication had not been detected at conventional karyotyping nor, obviously, after FISH with subtelomeric probes. (See color insert.)

Fluorescent in Situ Hybridization

The hybridization of a labeled DNA probe for spreading metaphase chromosomes allows the detection of small deletions, duplications, or cryptic translocations involving the chromosomal segment complementary to a probe labeled with a fluorochrome. The probe signal can be visualized by fluorescence microscopy. Double or multiple hybridizations can be carried out at the same time using different fluorochromes. Although this is a sensitive technique, it allows the investigation of only a few loci in one experiment, thus it can be requested when the clinician already has a specific clinical suspicion known to be associated with the deletion/duplication of that gene/region (i.e., Angelman syndrome and 15q11–q13 deletion).

Southern Blot Analysis

Differences in the DNA sequences at the same locus in different individuals can be detected by restriction enzyme digestion and Southern blot analysis. The diversity in DNA sequences among different individuals will result in either the introduction or loss of specific restriction sites, thereby causing DNA fragments of different sizes. The DNA is subsequently electrophoresed on an agarose gel, denatured with alkali, transferred to a nylon filter, and hybridized with a radiolabeled probe. The resulting X-ray film permits a comparison among the segments of DNA from different individuals.

Polymerase Chain Reaction

Polymerase chain reaction (PCR) allows the amplification of DNA fragments of 100 to 2,000 bp in length. The reaction is carried out in the presence of oligonucleotides flanking the region of interest, free deossinucleotides, template DNA, thermostable DNA polymerase from *Thermophilus aquaticus* (TAQ), and an appropriate saline buffer. The reaction requires 25 to 35 cycles of denaturing, annealing, and synthesizing DNA strands complementary to the template, thus allowing an exponential increase in the amount of target DNA for each cycle. The PCR product can be visualized on an agarose gel stained with ethidium bromide or labeled with a radioisotope, run on a polyacrylamide gel, and detected after exposure of the gel to an X-ray film.

Main Chromosomal Abnormalities Associated with Epilepsy

Trisomy 21 (Down Syndrome)

General Clinical Findings

Down syndrome (DS) has an approximate incidence of 1 in 650 births.[144] In 95% of cases, the cause is a nondisjunction of chromosomes 21 during meiosis; in about 4% of cases, there is an unbalanced translocation. Approximately 1% of patients are mosaics and show a less severe phenotype. The region that, if triplicated, results in the typical phenotype maps to 21q22.3.[41] The risk of carrying a child with DS increases with increasing maternal age and with very young maternal age.[79]

The main clinical features of this condition include growth retardation, mental retardation of variable degree, hypotonia, flat facies, brachycephaly with flat occiput, upward-slanting eyes, epicanthal folds, small ears, speckling of the iris (Brushfields spots), simian crease, and hypogonadism. About 40% of patients have congenital heart disease. There is a marked risk of leukemia. All individuals above the age of 35 years show features of Alzheimer disease.

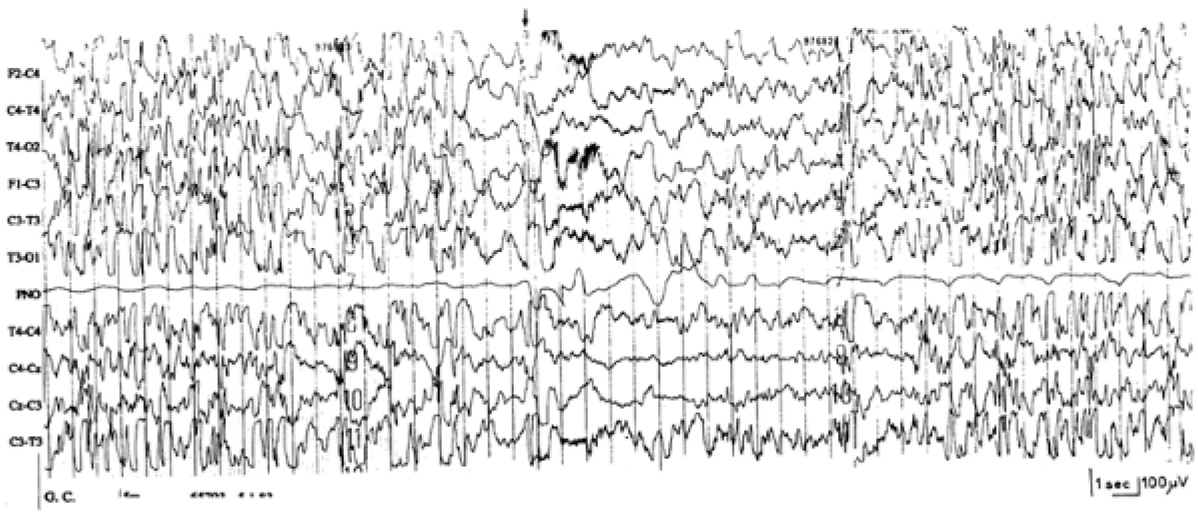

FIGURE 2. Five-month-old girl with Down syndrome and infantile spasms. Typical and symmetrical hypsarrhythmia that is interrupted after a spasm (*arrow*) initiating a cluster of spasms (not shown). Note rapid rebuilding of hypsarrhythmia after the spasm.

Epilepsy

Epilepsy in DS has been extensively investigated.[45,60,66,83,135,147] The incidence of epilepsy in children with DS was estimated to be 1.4%.[153] However, the overall prevalence of epilepsy increases with age, reaching 12.2% in patients over 35 years

of age.[159] About 40% of patients have seizures since the first year of life, and another 40% experience their first seizure during the third decade.[116] This trend seems to be related to the early medical complications of DS, such as hypoxic ischemic encephalopathy and congenital heart disease,[129] and the development of neuropathologic changes typical of Alzheimer disease[36] have a specific etiology, most often related to common medical complications of DS such as hypoxic–ischemic perinatal suffering, hypoxia from congenital heart disease, or infection. Febrile seizures have a low frequency (0.9%) in comparison with the general population.[60,93,129,153] When only cases without known causes were considered, 2.5% of patients presented with seizures, a frequency still greater than that in the general population. Although many patients in both groups had their first seizure in the first year of life, seizures occurred significantly later in infants without a known etiology. Generalized tonic–clonic (GTC) seizures predominated in both the known and unknown etiology groups. Myoclonic seizures and infantile spasms with hypsarrhythmia were also common, the latter predominating in the unknown etiology group. Partial seizures usually occurred in patients with an identifiable etiology. Prognosis for recurrent seizures varied with the etiology. Patients with seizures related to cardiovascular disease were usually well controlled by anticonvulsants. Neonates with hypoxic–ischemic injury had poor outcomes. None of the patients who developed seizures as a result of CNS infection had persistent attacks. Patients with idiopathic seizures had generally good outcomes. The authors concluded that children with DS have an increased susceptibility to seizures early in life, and superimposed systemic illness increased the risk.

In a review of studies in which population estimates were possible, infantile spasms occurred in 0.6% to 13% of children with DS, representing 4.5% to 47% of all seizures (reviewed by Stafstrom and Konkol[146]). Infantile spasms probably represent the most common seizure type in DS and, in most children, they appear without any evidence of additional brain damage.[60,113,141,146] Prognosis is usually good with regard to seizure control. Remission was obtained on conventional antiepileptic drugs (AEDs), adrenocorticotropic hormone (ACTH), or steroids, without relapse of seizures[60,113,146] or with later onset of pharmacologically controllable, age-related generalized seizure disorders[141] (Fig. 2). Conversely, spasms proved to be resistant, progressing to other forms of intractable epilepsy in most of the patients who suffered hypoxic insults.[60,146]

The occurrence of reflex seizures in the context of startle epilepsy is particularly frequent (Fig. 3).[54,66,115,130] Age at seizure onset is variable, and there is usually no evidence for etiologic factors other than DS. Most of the patients described presented "pure" forms of reflex epilepsies, with almost all seizures being precipitated by acoustic or tactile stimuli. However, the epileptic syndrome varied in type and severity, with a predominance of Lennox-Gastaut–type patterns.[66] The mechanism leading a high incidence of reflex phenomena in DS patients is unclear. A central deficit of inhibition of afferent stimuli has been proposed.[29]

Lennox-Gastaut syndrome (LGS) has been well documented in DS, but is not frequent. Quite characteristic is its de novo appearance at a mean age of 10 years, not preceded by other forms of epilepsy.[60,66]

Only a few studies have analyzed adult or late-onset epilepsy in DS, despite its high frequency.[90,159,164] Although in most late-onset epilepsies seizures appeared infrequently but were intractable,[60] no precise indications on seizure severity are available. Late-onset generalized epileptic myoclonus has also been reported.[53]

Neuropathology and Neurogenetic Basis of Seizures

Brain weight is in the lower normal range, and the gyral pattern is simplified.[39] A narrow superior temporal gyrus is observed in about 50% of patients. The insula is exposed because of hypoplasia of the inferior frontal gyrus.[86] Changes typical of Alzheimer disease appear above the age of 30 years.[51,64] Several cytoarchitectonic abnormalities have been found from birth, including a 20% to 50% decrease in the number of small granule cells, mainly inhibitory γ-aminobutyric acid (GABA)ergic interneurons, with lower neuronal density, abnormal neuronal distribution, and dysgenesis of dendritic spines.[18,81,98,127,166] The relation among these structural abnormalities and increased susceptibility to certain seizure types, particularly infantile spasms and reflex seizures, is poorly understood.

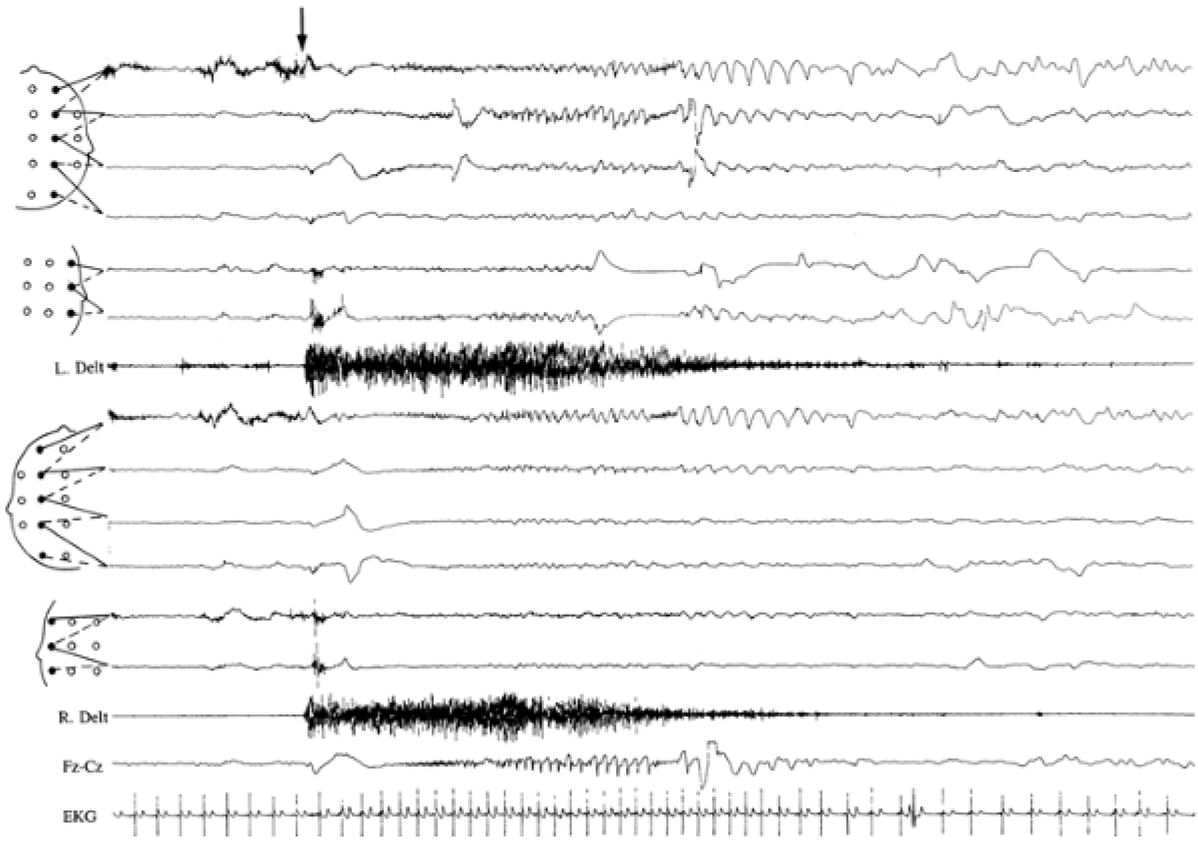

FIGURE 3. Twenty-year-old male Down syndrome patient with startle epilepsy. A sudden, unexpected noise induces a tonic seizure lasting 15 seconds, accompanied by tachycardia; the patient, who is sitting on the bed, is projected violently backward. Tonic contraction, visible on the deltoid muscles (R and L Delt), is accompanied on the EEG by a decremental event, followed by low-voltage fast activity, with increasing amplitude and decreasing frequency, well recognizable over the vertex and frontocentral electrodes, more on the right.

Diagnostic Evaluation

Most patients have a free trisomy 21, detectable on standard chromosome analysis. In such circumstances, chromosome study in the parents is not indicated. Parents should be given a 1% recurrence risk, based on the calculation of the recurrence of DS in a sibship. This slightly higher recurrence risk, when compared to the expectation based on the maternal age is likely due to a germinal mosaicism present in a few parents or to a general failure in the chromosomal disjunction mechanisms normally occurring at meiosis.[110]

If DS results from a translocation, this usually occurs between acrocentric chromosomes, termed a *robertsonian translocation*. In such circumstances, one of the parents might be a balanced carrier of the translocation, and a chromosomal study is strongly indicated for both parents. The most common robertsonian translocation found in healthy carriers involves chromosomes 14 and 21. Virtually all the (21;21) translocations are de novo. The involvement of chromosome 21 in translocations with nonacrocentric chromosomes[101] is very rare. The calculation of the recurrence risk for DS in the carriers of robertsonian translocation is based on the gender of the transmitting parent and the chromosome involved.

Fragile-X Syndrome

General Clinical Findings

Fragile-X syndrome has an approximate incidence of 1 in 1,500 males[163] and is the most common chromosomal abnormality associated with heritable mental retardation. Both genders may be affected, but the phenotype is notably more severe in males. It is estimated that 1 in 1,000 females are carriers.[23] The X-chromosome of patients affected with the syndrome shows a "fragile" site at Xq27.3 when cells are grown in a folic-deprived medium. The condition results from a dynamic mutation in heritable unstable DNA,[124] because of variation in the copy number of a trinucleotide repeat p(CCG)n within the *FMR1* gene. This fragile site is termed *FRAXA*. The disorder has an unusual mode of inheritance. About 20% of males who carry the mutation are clinically and cytogenetically normal (normal transmitting males). About 30% of female carriers have mental impairment. Transmission is consistent with an X-linked semidominant condition. The main clinical features include moderate mental retardation, poor language, hypotonia, growth retardation, macrocephaly, prominent forehead, long, narrow facies, large ears, macroorchidism, pectus excavatum, a floppy mitral valve, and hyperactive or autistic behavior.[50,165]

Epilepsy

The prevalence of epileptic seizures is approximately 25%.[167] Seizures usually appear before the age of 15 and tend to disappear during the second decade of life.[65,167] In most patients, seizures are fairly rare or are controllable with simple drug regimens.[59,65,105,167] The most frequently mentioned seizure types are generalized tonic–clonic seizures.[50,165] However, no specific epilepsy syndrome is observed.[65] Background electroencephalographic (EEG) activity is slow.[105,167] An EEG pattern of midtemporal spikes, possibly age related, similar to the waveform of benign rolandic epilepsy, has been described in some affected males, with or without seizures.[104] This EEG pattern has been confirmed by other investigators, but only in a minority of cases.[60,167] The fragile-X locus has been excluded as the candidate gene for benign rolandic epilepsy.[118]

Neuropathology and Neurogenetic Basis of Seizures

The variety in seizure types in the fragile-X syndrome may reflect extreme clinical polymorphism as a consequence of the variability of amplification of the trinucleotide repeat among patients.[52] A somatic variation in DNA amplification during development is also possible.[168] Little is known of the neuropathology. Anomalous synapses and abnormal development of dendritic spines have been observed using Golgi impregnation.[129,167] Neuroimaging studies have shown hypoplasia of the cerebellar vermis[121] and periventricular heterotopia in rare patients.[103]

Diagnostic Evaluation

The fragile site at Xq27.3 is not expressed in cell culture media employed for standard karyotypes. The induction of the fragile site in stimulated lymphocytes can be achieved using culture media free of folic acid and thymidine. The fragile site is detected only in a proportion of metaphase cells, with most fragile-X males expressing their fragile site in only 5% to 50% of their lymphocytes. Normal transmitting males usually do not express the fragile site. Fragile-X females with mental impairment express their fragile site, but in a lower proportion of cells than do fragile-X males. The majority of female carriers do not express the fragile site, but some of them might show an expression in 5% or less of their cells. The fragile-X syndrome is due to the expansion of a p(CGG)n repeat within the 5′ untranslated region of the *FMR1* gene. Normal chromosomes are polymorphic, containing 6 to 52 copies of this repeat, whereas males with more than 200 copies have the disease (full mutation). Normal transmitting males have 50 to 200 copies (premutation). Females bearing the premutation are phenotypically normal and do not express the fragile site. Females with more than 200 copies may be normal or mentally retarded and can show facial features of fragile-X syndrome. Premutations tend to expand when transmitted to offspring through female carriers, and the risk of expansion to a full mutation correlates with the size of the premutation.[52,73] In association with the full mutation, the promoter region of the *FMR1* gene is hypermethylated, and the transcription of the gene is repressed.[112,160] DNA studies have improved the accuracy of testing for fragile-X syndrome. By looking at the size of the trinucleotide repeat segment, as well as the methylation status of the *FMR1* gene, the genotype can be determined for both affected individuals and suspected carriers. Two main approaches are used: Polymerase chain reaction (PCR) and Southern blot analysis. PCR analysis utilizes flanking primers to amplify a fragment of DNA spanning the repeat region. Thus, the sizes of the PCR products are indicative of the approximate number of repeats present in each allele of the individual being tested. The efficiency of the PCR reaction is inversely related to the number of CGG repeats, so that large mutations are more difficult to analyze and may fail to yield a detectable product in the PCR assay. An additional limitation to the PCR approach is due to the fact that it provides no information about *FMR1* methylation. On the other hand, PCR analysis permits accurate sizing of alleles in the normal and premutation size ranges. *FMR1* analysis by Southern blotting allows both size of the repeat segment and methylation status to be assayed simultaneously. A methylation-sensitive restriction enzyme that fails to cleave methylated sites is used to distinguish between methylated and unmethylated alleles. Southern blot analysis is more labor intensive than PCR and requires larger quantities of genomic DNA. Southern blot accurately detects alleles in all size ranges, but precise sizing is not possible. Many laboratories can use both methods, and choose the type of analysis that is most appropriate to the circumstances. A few patients with fragile-X harboring deletions in the *FMR1* have been described.[117,152]

Two additional fragile sites reside in the distal Xq, termed *FRAXE* and *FRAXF*. Although *FRAXF* is not clearly associated with a specific phenotype, those with *FRAXE* show mental impairment, usually milder than that observed in patients with *FRAXA* mutations. Because no clinical overlap occurs between patients with mutations at the *FRAXA* and the *FRAXE* loci, other than mental retardation, the details about the diagnostic procedures for identifying *FRAXE* will not be discussed here.

Del 4p (Wolf-Hirschhorn) Syndrome

General Clinical Findings and Genetic Background

Wolf-Hirschhorn syndrome (WHS) is a multiple congenital anomalies/mental retardation syndrome[34] with a frequency of 1 in 50,000 births and a female:male predilection of 2:1.[57,96] It is caused by partial loss of material from the distal portion of the short arm of chromosome 4. The minimal deleted segment causing the phenotype is 4p16.3.[96] Although about 75% of patients have a de novo deletion[96] of preferential paternal origin,[38,157] about 12% have an unusual chromosome abnormality (such as ring 4), and about 13% have a deletion of 4p16 resulting from an inherited unbalanced chromosome rearrangement from a parent with a balanced rearrangement. The main features of monosomy 4p are the typical "Greek warrior helmet appearance of the nose," microcephaly, pre- and postnatal growth delay, congenital hypotonia, severe mental retardation, and seizures.[13] In at least one-third of cases, death occurs during the first year of life because of severe systemic malformations, cardiac failure, or pulmonary infection.

Epilepsy

Seizures constitute a major medical concern during the first years of life, and occur in 50% to 100% of patients.[10,13,32,40,68,149] Seizure onset usually occurs within the first 2 years of life, with a peak incidence around 9 to 10 months of age. These seizures may be clonic or tonic, unilateral with or without secondary generalization, or generalized tonic–clonic from the onset.[5,8,9,10,11,12,13,47,108,119] They are frequently triggered by fever, may be prolonged, and often occur in clusters.[5,11,12,136,171] More than 50% of the patients experience early unilateral or generalized clonic or tonic–clonic status epilepticus (SE), despite adequate treatment.[13] Two-thirds of the subjects develop, between 1 and 5 years of age,

P.2594

atypical absences, often accompanied by a mild myoclonic component, mainly involving the eyelids and axorizomelic muscles.[5,11,12,13,14,136] Such episodes are accompanied by generalized slow spike-and-wave complexes. The interictal EEG shows high-amplitude, fast spikes, polyspikes, and wave complexes over the posterior third of the head on eye closure. Other seizure types have been described in a minority of patients (Fig. 4).[80,171]

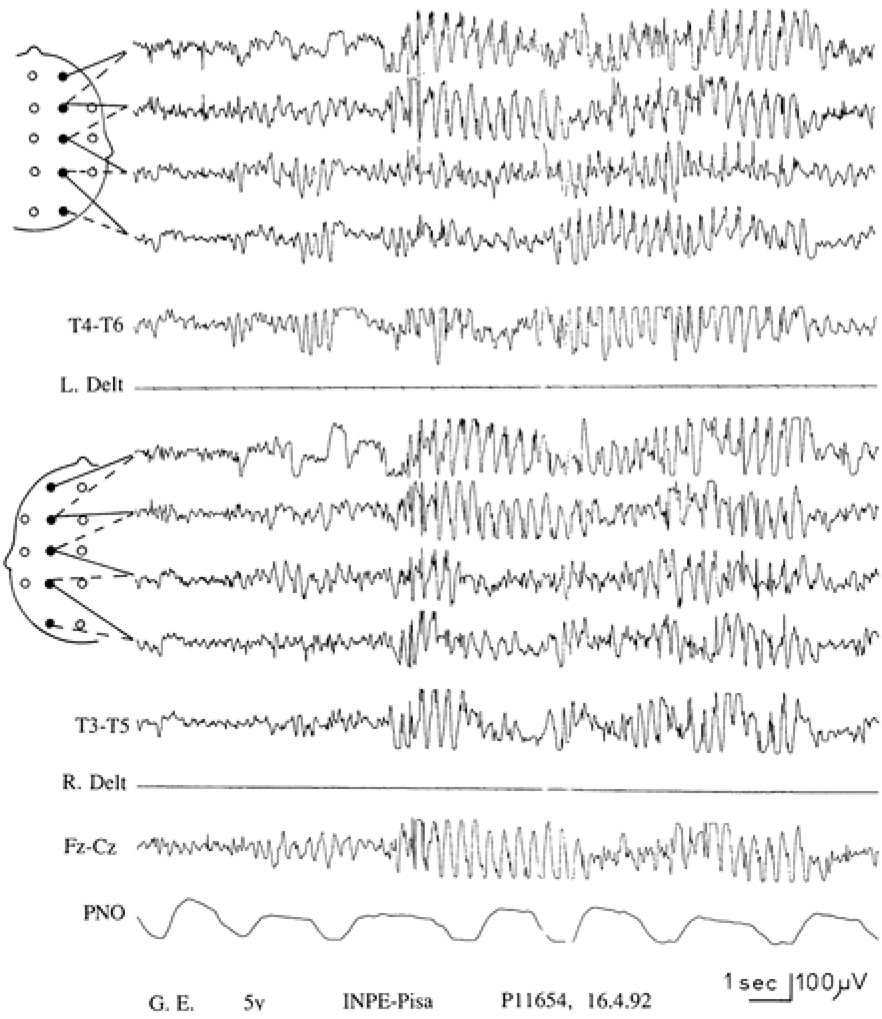

FIGURE 4. Five-year-old girl with 4p- syndrome. An atypical absence seizure is accompanied by diffuse atypical slow spike-and-wave complexes. Interictal EEG preceding the episode shows multifocal spikes and spikes and spike-and-wave complexes.

In our experience, the seizures observed in WHS can be effectively controlled by valproate alone or associated with ethosuximide and, in patients who continue to have seizures, add-on benzodiazepines are usually effective. Carbamazepine may cause seizure worsening. Despite early severity, the long-term outcome of epilepsy is relatively good, because seizures tend to disappear with age.[7,10]

Neuropathology and Neurogenetic Basis of Seizures

Corpus callosum hypoplasia is the most frequent brain abnormality (rarely associated with decreased white matter volume) and hypoplasia or agenesis of the posterior lobe of the cerebellum also is seen. Hypoplastic brain with narrow gyri, heterotopia, and dysplasia of nuclear structures has been described in some cases.[58,92]

The *$GABA_A$* receptor gene maps proximal to the critical deletion region (WHSCR), specifically, 4p12–p13[27] and is probably not involved in epileptogenesis in this condition. *LETM1*, a gene possibly involved in calcium (Ca^{2+})

signaling or homeostasis, seems to be a good candidate for seizures and neuromuscular problems in WHS.[46,158] Initially, *LETM1* was suggested to flank the WHSCR,[13,46] but a recent report implies that it falls within the newly proposed critical region of WHS nearer the telomere.[173]

Diagnostic Evaluation

Standard cytogenetics detects about 60% to 70% of deletions, whereas FISH (using the WHSCR probe) detects more than 95%. Subtelomeric FISH analysis can be useful to determine if a deletion is the result of an unbalanced translocation.[14]

Partial Monosomy 15q (Angelman Syndrome)

General Clinical Findings

Angelman syndrome (AS) has a prevalence of about one in 12,000 to 20,000 of the population,[148] accounting for up to 6% of all cases with severe mental retardation and epilepsy.[87] The main clinical features of AS may not be apparent early in life. All patients have developmental delay, which becomes apparent by 6 to 12 months of age, microcephaly, severely impaired expressive language, ataxic gait, tremulousness of limbs, and a typical behavioral profile including a happy demeanor, hypermotoric behavior, and low attention span. About 90% have epilepsy.[3,161,174]

Seventy percent of patients show a deletion involving the maternally inherited chromosome 15q11–q13, encompassing a cluster of GABA receptor subunit genes; 5% show chromosome 15 paternal uniparental disomy (UPD); 5% harbor a mutation in the imprinting center (IC), a transcriptional regulatory element; and 10% harbor intragenic mutations of the *UB3A*

gene. A few patients have no detectable genetic abnormality. The rare cases of familial recurrence of AS show either IC or *UBE3A* mutations.[62]

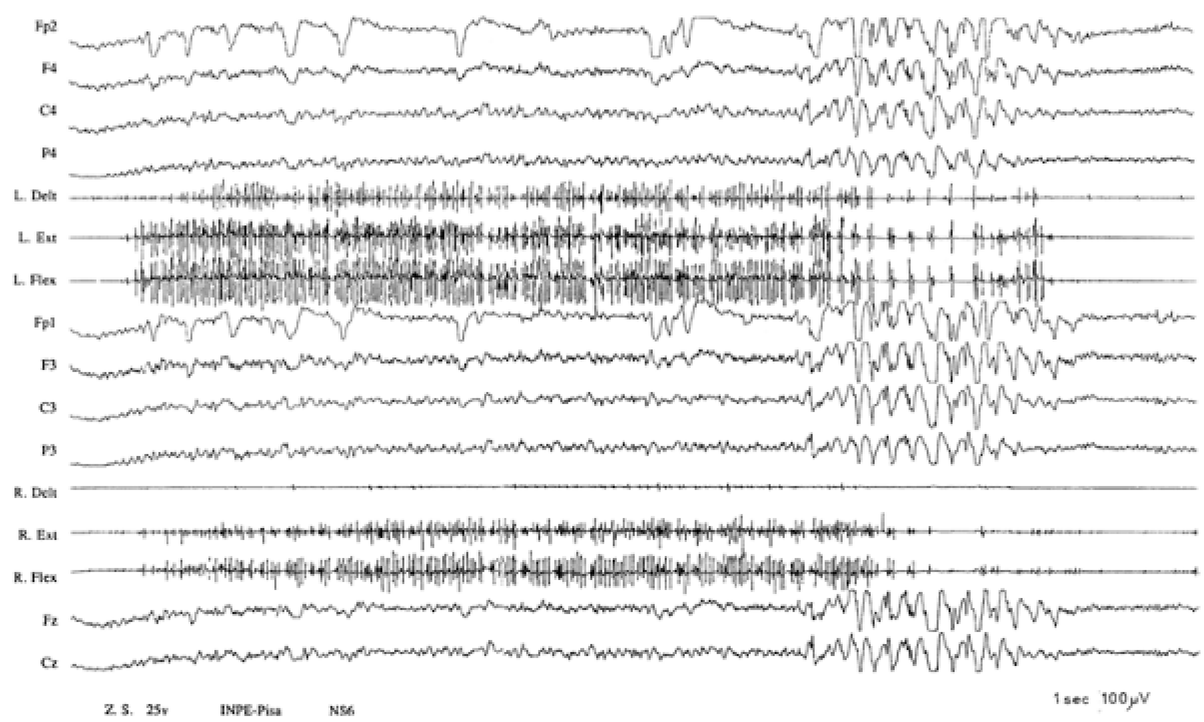

FIGURE 5. Twenty-five-year-old female patient with Angelman syndrome and 15q11–13 deletion. Polygraphic

recording. Rhythmic 12- to 15-Hz myoclonus (fast-bursting cortical myoclonus) involving all muscles recorded, is accompanied by 5- to 7-Hz rhythmic activity recorded from all EEG electrodes. A discharge of generalized, irregular polyspike-and-wave complexes lasting 3 seconds is accompanied by rhythmic bursts of two or three myoclonic potentials; each burst is time-locked with the spike component of the discharge. Clinically, the fast-bursting cortical myoclonus resembles tremor. The generalized spike-and-wave discharge is accompanied by a short myoclonic absence.

Epilepsy

It is estimated that about 90% of patients have epilepsy.[174] Viani et al.[161] reviewed 155 published patients, of whom 130 (84%) had experienced seizures. Viani's review[161] and subsequent reports suggest that the first seizures occur between the ages of 3 months and 20 years,[63,100,150,161,174] although onset is in infancy or early childhood in most. The first seizures are often precipitated by fever.[100,150] Infantile spasms are exceptional. Complex partial seizures with eye deviation and vomiting, possibly indicating occipital lobe origin, were estimated to occur frequently.[161] Atypical absences, myoclonic seizures, GTC, and unilateral seizures are among the main seizure types.[63,100,150,161] Over half of the patients suffer from episodes of decreased alertness and hypotonia lasting days or weeks, described as nonconvulsive SE.[100,150] Often there is concomitant mild jerking, rhythmic or not,[37,63] typical of myoclonic status. Polygraphic recordings reveal diffuse, slow, irregular spike-and-wave complexes at about 2 Hz, accompanied in some patients by myoclonic potentials that are time locked to the EEG spikes (Fig. 5). This clinical and EEG pattern has also been described by Dalla Bernardina et al.[37] as *myoclonic status* in nonprogressive encephalopathies. In other patients, myoclonus may remain erratic, showing no apparent relation with EEG discharges. Myoclonic jerks typically cease during sleep.[63,161] Myoclonic status is rare after the age of 6 years. In addition to myoclonic seizures or status, AS patients exhibit quasicontinuous rhythmic cortical myoclonus at about 11 Hz, mainly involving hands and face, and producing a mild jerking or twitching, easily mistaken for tremor (see Fig. 5).[63]

Individuals with chromosome 15q11–q13 deletions have more severe impairment and are more prone to develop severe epilepsy. Uniparental disomy, IC, and *UB3A* mutations are associated with a milder phenotype.[62,102]

Although seizures are generally difficult to treat in infancy and early childhood, they are usually less severe in later childhood,[174] although complete seizure remission is rare.[89] The exact percentage of patients continuing to suffer seizures as adults is unknown.

Episodes of myoclonic status and of nonconvulsive status are usually stopped with intravenous benzodiazepines,[63,161] although they frequently relapse.[100] Chronic treatment using benzodiazepines achieve fairly effective control of myoclonus. Particularly effective is the association clobazam-valproate for the long-term treatment of epilepsy.[63,161] Valproate and ethosuximide in association are also effective in patients presenting recurrent myoclonic status.[37] Worsening of myoclonus and absence seizures may be produced by carbamazepine or vigabatrin.[85,161] If cortical myoclonus is particularly disabling, generous doses of piracetam are often effective in reducing it.[63]

Neuropathology and Neurogenetic Basis of Seizures

Neuroimaging does not disclose conspicuous CNS abnorm- alities.[63,174] Available neuropathologic data derive from the study of the brains in two patients in whom the AS had not

P.2596

been confirmed by genetic analysis. Jay et al.[77] found cerebellar atrophy with loss of Purkinje and granule cells and extensive Bergman gliosis. Neurochemical study of the cerebellar cortex demonstrated markedly reduced GABA content, possibly related to failure to develop or a loss of Purkinje cells and inhibitory GABAergic interneurons. Kyriakides et al.[88] reported small temporal and frontal lobes with disorganized and irregular gyri, irregular distribution of neurons in layer 3, and minor cell heterotopia in both the cerebrum and cerebellum. There is some evidence that the motor cortex in AS is hyperexcitable. Because the deletion involving the maternal 15q11–13 chromosome eliminates a cluster of $GABA_A$ receptor genes (β3, α5, γ3), it has been suggested that cortical hyperexcitability might result from reduced GABAergic inhibition.[63] A 60% to 80% reduction in benzodiazepine binding has been shown in most brain regions of a mutant mouse exhibiting a deletion involving a chromosomal region that is syntenic to the AS region.[106] The antiabsence and antimyoclonic action of benzodiazepines, which is based on their GABAergic properties, is confirmed in AS.[62]

Diagnostic Evaluation

About 80% of cases are detected through the CpG methylation at 15q11.q13 genes through "bisulfite" tests, which allows the detection of deletions, UPD, and IC mutations. The test is based on the different parentally derived methylation patterns at specific loci. If the methylation test is abnormal, a FISH assay should be run in the search of a 15q11–q13 deletion. If the FISH assay is normal, a UPD study should be performed to distinguish UPD from an IC mutation. If an IC mutation is suspected, the case should be referred to a research laboratory for the identification of the IC mutation. Mutation analysis of the *UBE3A* gene should be performed in those cases matching the clinical criteria for AS in the presence of a normal methylation test. This analysis is not 100% sensitive, because mutations involving the promoter or intronic regions might remain undetected.

The results of genetic testing have important implications for genetic counseling, because de novo deletions and UPD can be assigned a very low recurrence risk, whereas IC mutations and *UB3A* mutations can be inherited in a dominant fashion and may be causative disease mutations according to the gender of the transmitting parent. It is important to point out that about 5% of patients do not show any molecular or cytogenetic abnormality. Most such cases are sporadic but, due to the few reported familial cases, recurrence risk in siblings may be as high as 50%.

Ring Chromosome 20 Syndrome

General Clinical Findings and Genetic Background

Ring chromosome 20 (r20) is a rare chromosomal disorder, of which epilepsy is a striking feature. Although some patients may have microcephaly, mild to moderate mental retardation, and behavioral abnormalities,[114] the lack of specific phenotypic features in most individuals makes diagnosis difficult. Dysmorphic signs are exceptional. Psychomotor development tends to be initially normal. The description of about 50 cases has drawn attention to the uniqueness of the electroclinical presentation,[142] which should always prompt a request for karyotype. The chromosomal abnormality can occur in mosaic. Most cases are sporadic, but a few are familial.[30] The severity of cognitive impairment seems to correlate with the percentage of mosaicism, whereas that of epilepsy does not.[76]

Epilepsy

Seizures occur in almost all subjects, with onset between infancy and age 17 years, and these seizures are usually refractory to treatment.[142,175] The typical presentation is with repetitive episodes of confusional state, lasting from several minutes to 30 minutes, also described as "complex partial" or "nonconvulsive" status, during which patients appear to be confused and unresponsive to a variable degree. Motionlessness and staring or, conversely, complex automatisms or wandering have been described.[76,142] Perioral jerking and eyelid myoclonus are often observed.[30,76,91,111,142] Such episodes often occur daily and are accompanied on the EEG by long bursts or trains of rhythmic θ-waves and high-amplitude, 2- to 3-Hz rhythmic, notched slow waves with frontal predominance.[30,76,111] Typical spike-and-wave discharges are rarely seen. Hyperventilation, specific mental activities, or adverse psychological situations can act as triggers in some children.[128] Frontal lobe ictal-onset was shown by means of subdural electrodes during typical confusional episodes.[76] On the basis of ictal single positron emission computed tomography (SPECT) studies, a possible role of subcortical structures has been hypothesized in the genesis of such a characteristic ictal pattern. Mainly in young children, the prolonged seizures are misinterpreted as behavioral nonepileptic manifestations, unless video-EEG recording is available.[76] Partial motor and generalized tonic–clonic seizures have also been reported. Interictal EEG, normal in some individuals, can show spikes over both frontotemporal areas in others.

Diagnostic Evaluation

A standard karyotype should be performed examining at least 100 mitoses, considering that the percentage of lymphocytes carrying the chromosome rearrangement may be low.[128] In most cases, the locus of fusion between the deleted short and long arms in the ring chromosome was p13q13, p13q13.3, or p13q13.33.[76,142] The loss of telomeric material on both arms of chromosome 20 is usually identified by FISH.[26] Cases with a mosaicism for r20 have also been observed.

Del 1p36 Syndrome

General Clinical Findings and Genetic Background

The incidence of del 1p36 syndrome is estimated to be 1 in 5,000 to 1 in 10,000, with a female predilection of 1.5:1.[17,71,137] About 100 cases have been reported.[71,97] It appears that 1p36 deletions account for as much as 0.5% to 0.7% of "idiopathic" mental retardation.[56] Intrauterine growth retardation and/or postnatal growth deficiency,[19,21,55,69,82,97,120,125,138,143,170] as well as obesity and hyperphagia[48,82,132,138] have been observed.

The craniofacial features represent a hallmark of the disorder, and are characterized by microbrachycephaly, large and late-closing anterior fontanel, prominent forehead, straight eyebrows, deep-set eyes, short palpebral fissures, broad/flat nasal bridge, midface hypoplasia, pointed chin, abnormal ears, and short hands and feet.[17,71,120,138] Moderate to profound mental retardation and very poor language skills are observed in most individuals.[17,71,137,138]

Epilepsy

Seizures occur in over 50% of patients.[17,71] Different seizure types, such as infantile spasms, simple and complex partial seizures, generalized tonic–clonic, myoclonic, and absence seizures, have been reported.[21,55,82,84,120,125,138,143] Infantile spasms associated with a hypsarrhythmic EEG are observed in about 50% of cases and are usually responsive to ACTH.[4] In about 30% of patients, complex partial seizures or tonic

P.2597

seizures may occur, often having a favorable outcome.[17,48,143] Seizure onset is usually within the third year of life. Background EEG shows poverty of the usual rhythmic activities. Interictal EEG abnormalities are variable, including hypsarrhythmia, focal and multifocal spikes, generalized slow spike-and-wave complexes.[15]

Neuropathology and Neurogenetic Basis of Seizures

Cerebral atrophy, ventricular dilatation, hydrocephalus, delay in myelination, focal cortical dysplasia, and a leukodystrophic picture have been documented on brain neuroimaging.[6,17,49,69,72,82,125,138,143,170] A severe seizure phenotype has been associated with hemizygosity for the voltage-gated potassium (K^+) channel β-subunit gene, *KCNAB2*.[72]

Diagnostic Evaluation

Monosomy 1p36 may be the result of pure terminal deletions, interstitial deletions,[169] derivative chromosome 1, and more complex rearrangements.[6,17,71] Conventional cytogenetics may not detect these different rearrangements, particularly those that are derivative chromosomes. FISH analysis with subtelomeric region-specific probes is necessary in most cases. CGH microarray can be used as an alternative. Determination of the parental origin has provided discordant results.[17,71] Overall, deletions of paternal origin seem to be larger than deletions derived from the maternally inherited chromosome.[17,71]

Other Chromosomal Disorders Associated with Seizures

Inv Dup(15) or Idic(15) Syndrome

The chromosome region 15q11–q13 is known for its instability,[43] and many rearrangements may occur in this imprinted segment, such as deletions, translocations, inversions, and supernumerary marker chromosomes formed by the inverted duplication of proximal 15. Interstitial duplications and triplications are much less frequent. The inv dup(15) accounts for about 60% of supernumerary marker chromosomes.[35] Of the two identified cytogenetic types, one is a metacentric chromosome, smaller or similar to a G group chromosome, not containing the PWS/AS critical region (PWS/ASCR); it is found in children without dysmorphic features who are usually studied because of mild mental retardation or behavioral abnormalities.[75] However, a normal phenotype is also possible. The second type of inv dup(15) is as large as or larger than a G group chromosome, contains the PWS/ASCR,[22,126] and is associated with an abnormal phenotype.[16] Its cytogenetic description is dic(15)(q12 or q13). Most dic(15)(q12 or q13) derive from the two homologous maternal chromosomes at meiosis and are associated with increased maternal age at conception. The presence of large inv dup(15) results in tetrasomy 15p and partial tetrasomy 15q. Incidence at birth is estimated to be 1 to 30,000, with an equal sex ratio.[133]

Patients with large inv dup(15), extending to q15, usually have severe epilepsy, mental retardation, autistic-like behavior, and minor dysmorphic features.[16,25,28,151] A clinical presentation of infantile spasms in children with minor dysmorphic features has been reported in some patients, whereas LGS with very poor outcome has been observed by several authors.[16,28,151,156] Focal epilepsy has also been reported.[25] Milder presentations with mild mental retardation, generalized epilepsy with onset in adolescence of absence seizures, and an interictal pattern of generalized spike-and-wave discharges have been reported even in patients with large duplications.[33]

Various genetic mechanisms have been hypothesized to explain clinical heterogeneity (beyond the size of chromosomal duplication), including dosage effect of genes located within the duplication.[33,156] Considering that a mild epilepsy phenotype is possible, it has been suggested that inv dup(15) be ruled out as a possible, although rare, cause of “cryptogenic” or seemingly idiopathic generalized epilepsy.[33]

To distinguish between inv dup(15)s and the other supernumerary marker chromosomes, the simple distamycin A/4′-6′-diamidino-2-pheylindole hydrochloride (DA-DAPI) staining technique is sufficient, but FISH or array-CGH may be useful, although more expensive. The majority of inv dup(15)s are dicentric, with one centromere inactivated; these are also referred to as *pseudodicentric chromosome 15* or *SMC(15)*. By conventional cytogenetics, they can be classified into two main groups: (a) small SMC(15)s, which are metacentric chromosomes without euchromatic material; and (b) large SMC(15)s, which are acrocentric chromosomes containing two copies of the 15q11–q13 region. Small SMC(15)s can be familial or de novo. In contrast, large SMC(15)s are almost always de novo in origin, maternally derived, and associated with an abnormal phenotype that includes severe mental retardation, developmental delay, behavioral problems, and epilepsy. For this reason, it is important to discriminate between small and large inv dup(15), especially in prenatal diagnosis. To this aim, FISH performed on a gene within the critical Prader Willi/Angelman syndrome region allows the precise discrimination of whether the supernumerary chromosome is harmful or without any effect. However, the molecular confirmation that inv dup(15) belongs to the “small” category is not sufficient to exclude that the fetus will be affected by Prader Willi or Angelman syndrome, because cases have been reported with small inv dup(15) associated with uniparental disomy for chromosome 15 or with 15q11–q13 deletions.[94]

Ring Chromosome 14

Ring chromosome 14 (r14) is a rare chromosomal abnormality consistently associated with epilepsy. Reviews of reported cases suggest that early onset epilepsy, which is often intractable, is a constant feature of the syndrome, but does not have typical clinical or EEG features.[142] Generalized tonic–clonic seizures, myoclonic, and complex partial seizures have been reported.[95,134] General clinical features include moderate to severe mental retardation, microcephaly and facial dysmorphism with narrow elongated face and retrognathia.[122] Ocular abnormalities involving cataract and retinal pigmentation have been observed in about 50% of cases.[172] Most patients show a mosaic chromosomal abnormality. Familial occurrence is possible.[99] There is no indication of the brain histopathology that underlies such severe neurologic presentation, and neuroimaging seems to be of little help.[109]

Trisomy 12p and Tetrasomy 12 (Pallister-Killian Syndrome)

Trisomy of the short arm of chromosome 12 can be caused either by a malsegregation of a balanced parental chromosomal rearrangement or can occur de novo.[1]

Trisomy 12p is characterized by severe mental retardation, early hypotonia, turricephaly, flat occiput, short neck, round facies with prominent cheeks, prominent forehead, hypertelorism, epicanthal folds, and other dysmorphic facial features. Lateralized microgyria, internal hydrocephalus, cortical dysplasia, and ectopic glial tissue in the leptomeninges have been reported.[107]

Particularly striking was the finding of generalized 3-Hz spike-and-wave discharges in four patients, three of whom had childhood onset myoclonic absences or myoclonic seizures that appeared well controlled by AEDs.[44,61] It is of interest that three voltage-gated K^+ channel genes are clustered together, probably in the 12p13 band.

Pallister-Killian syndrome (PKS) is a rare, sporadic disorder caused by a mosaic supernumerary isochromosome 12p (i[12p]). The i(12p) is infrequently present in peripheral lymphocytes, but it is found in cultured fibroblasts and other tissues such as bone marrow and lungs. Children present with peculiar dysmorphic features including coarse and flat facies, prominent forehead, scarcity of scalp hair over frontal and temporal regions, hypertelorism, broad nasal bridge, small nose with anteverted nostrils, highly arched palate, microretrognathia, cupid bow-shaped upper lip, and low-set ears.[20,70,123] A combination of these features, with severe to profound cognitive impairment and epilepsy, characterizes the syndrome.[20,70,123,145,162] Seizures have been reported in 40% of 67 cases,[20] but their frequency is probably underestimated because most patients had a short follow-up.[20,123,145,162] For the same reason, no information is available on the seizure semiology and electrophysiologic correlates of epilepsy in these patients. Epileptic spasms have been reported in some patients.[131]

Klinefelter Syndrome (XXY Syndrome)

The prevalence of seizures in Klinefelter syndrome ranges from 2% to 10% in major series.[67] Some patients have been reported with generalized epilepsy with absence seizures or generalized tonic–clonic seizures, and a 3-Hz spike-and-wave EEG pattern.[24] However, the most common profile of patients with Klinefelter syndrome and seizures includes mental retardation, behavioral problems, epileptiform EEGs, and generalized tonic–clonic seizures. In one series, the seizures of six of 11 patients with epilepsy were well controlled with AEDs; the electroclinical spectrum was heterogenous, and outcome with AED treatment was often favorable.[154]

Partial Monosomy 17p (Miller-Dieker Syndrome)

The main clinical and genetic findings of Miller-Dieker lissencephaly are discussed in Chapter 228. We present here some guidelines for diagnostic evaluation of patients with both Miller-Dieker syndrome (MDS) and lissencephaly related to chromosome 17p (more severe in the posterior part of the brain). More than 90% of the MDS patients show a cytogenetically visible or a submicroscopic deletion involving the 17p13.3 band. About 40% with the LIS1-type lissencephaly show a submicroscopic deletion at the same chromosomal locus. Because these deletions are not observed under standard chromosome banding analysis, they are referred to as “submicroscopic.” *LIS1*, a gene mapping to 17p13.3 and encoding for the noncatalytic 45-Kd subunit of the platelet-activating factor (PAF) acetylhydrolase, is the lissencephaly causative gene, based on the finding of subtle mutations involving this gene in some patients with LIS1-type lissencephaly.

FISH using commercial probes containing the *LIS1* gene is required in all patients in whom a chromosome 17 lissencephaly is suspected on the basis of the appearance of magnetic resonance imaging (MRI).[42] In particular, it is recommended that a FISH study be performed using the *LIS1*-specific probe PAC 95H6. The search for point mutations consists of the direct sequencing of the *LIS1* gene, following PCR amplification of the entire coding region. About 25% of patients with classic lissencephaly show an intragenic mutation of *LIS1*. Gene sequencing is not 100% sensitive because the promoter and transcription regulatory regions of the gene are not routinely investigated, and a mutation in these regions could be missed. Southern blot analysis reveals gross rearrangements of the *LIS1* gene, which can be detected in about 4% of patients. The recent demonstration of mosaic mutations of the *LIS1* gene in individuals with posterior band heterotopia-pachygyria[140] suggests that a highly sensitive technique, such as denaturing high pressure liquid chromatography (DHPLC), can be useful in identifying low-level mosaicism that may escape recognition by direct sequencing or other standard techniques.

Summary and Conclusions

Chromosomal abnormalities are relatively common, genetically determined conditions that increase the risk of epilepsy. However, the likelihood of developing seizures varies greatly among the different chromosomal disorders. Chromosomal abnormalities almost constantly result in rearrangements or deletions/duplications that affect the function of more than one gene. As a consequence, even when very high-resolution techniques, such as microarray-CGH, are used, patients with chromosomal abnormalities always have a combination of clinical features and only exceptionally have isolated epilepsy. The ring chromosome 20 syndrome represents the most striking example in which a highly specific epilepsy phenotype can be the only expression of the chromosomal disorder. Most often, mental retardation and dysmorphic features, even subtle, coexist with epilepsy. Although some conditions are associated with a risk for epilepsy only slightly greater than that of the general population, others carry a risk of close to 100%, and the epilepsy is part of the phenotype. Some chromosomal abnormalities result in intractable seizures, whereas others have a more favorable epilepsy prognosis. Susceptibility to developing epilepsy does not necessarily correlate with the severity of structural abnormalities in the brain or with the extent of the chromosomal derangement. Depending on the specific genes involved, seizure susceptibility is more likely to be related to factors that alter cortical excitability, such as gene dosage effect in genes involved in ion channel and neurotransmitter function or neural development. Awareness of the associations between syndromes due to chromosomal abnormalities and epilepsy, together with knowledge of their response to treatment and the expected outcome, should be of help in planning rational treatment and counseling families.

Chapter 261

Inherited Metabolic Disorders

Douglas R. Nordli Jr.

Darryl C. De Vivo

Introduction

There are a wide variety of disorders of metabolism, approximately 50 of which are associated with seizures or epilepsy. From the epileptologist's perspective, many present similarly, with indistinguishable seizure semiology and electroencephalographic (EEG) findings. The clinical presentation may be influenced more by the age of the child than the specific etiology. In some children with inborn errors of metabolism and recurrent seizures, the epilepsy can be categorized into one of the recognized epileptogenic encephalopathies, such as early myoclonic epilepsy or West syndrome. In other cases, precise syndromes are lacking and terms like “generalized symptomatic epilepsy, not otherwise specified” and “epilepsies with focal and generalized features” are used. Clearly, more work needs to be done to accurately identify children with inborn errors, and we suspect that there are novel epilepsy syndromes yet to be described in this interesting group of patients. In the meantime, useful clues sometimes present that might alert one to the correct diagnosis. In some cases, this might be a relatively unique clinical feature, in others a characteristic of the epilepsy, and, finally, in some, a particular detail of the interictal EEG (Table 1). We have tried wherever possible to include these details, but we recognize that these definitive features seldom present themselves. For this reason, it is usually necessary to consider a relatively broad differential diagnosis. To organize the thought process, it is useful to think in terms of the age of the child and broad characteristics of the presentation. These have been organized into a table for ready reference (Table 2). The differential can be refined with the use of judiciously chosen screening tests. The results of these tests further guide the selection of definitive enzyme studies or genetic testing.

The acquisition of genetic information is proceeding at an exciting pace. Although this is stimulating to the neurologist, it presents a challenge for the traditional textbook format to contain up-to-date information. For this reason, we include a reference number from the Online Mendelian Inheritance of Man (OMIM) Web site so that the interested reader can quickly obtain the most current data (this source also links to Medline references). Wherever applicable, the OMIM number is given in parentheses in each heading. Another useful site is http://www.genetests.org, which provides a comprehensive listing of gene tests and the associated laboratories.

Metabolic Disorders of The Neonatal Period

The neonatal period comprises the first month of postnatal life, and a number of metabolic disorders that appear at this time include seizures as a major clinical feature.

Nonketotic Hyperglycinemia (#605899)

In this condition, glycine accumulates in the central nervous system and elsewhere in the body because of a primary biochemical defect involving the glycine cleavage system. There are four enzymes that cleave glycine: (a) P protein, a pyridoxal phosphate–dependent glycine decarboxylase (GLDC), (b) T protein, a tetrahydrofolate-requiring enzyme (GCST), (c) H protein, a lipoic acid–containing protein (GCSH), and (d) L protein, a lipoamide dehydrogenase. Disease can be caused by defects in any of these enzymes, although mutations involving GLDC and GCST are most common. Mutations that involve the pore region of the T protein appear to particularly impair function. [7] The mode of transmission is autosomal recessive, with an estimated prevalence of 1/250,000. Neonatal nonketotic hyperglycinemia (NKH) is characterized by an initial variable symptom-free interval of 1 to 42 days. Clinical symptoms are at first lethargy, poor feeding, apneic spells, altered muscular tone, and intermittent ophthalmoparesis that occasionally progresses to bilateral external ophthalmoplegia. Erratic myoclonus is another major symptom that may appear early; hiccups and coma follow. The electroencephalogram (EEG) demonstrates a suppression-burst pattern that correlates with brainstem-evoked potential abnormalities and intrinsic brainstem pathology seen on postmortem examination (Fig. 1).[54] Similar EEG abnormalities are characteristic of phenylketonuria, maple syrup urine disease, and molybdenum cofactor deficiency (Table 2). Clinical seizure patterns include infantile spasms and generalized tonic seizures. Progressive brain atrophy, delayed myelination, incomplete development of the corpus callosum, gyral malformations, cerebellar hypoplasia, and culpocephaly are common. Elevated glycine concentrations in the cerebrospinal fluid (CSF) during the first hours of life and a partial suppression-burst EEG pattern detected as early as 30 minutes after delivery in an asymptomatic patient indicate that the abnormal glycine metabolism has been present prenatally. A CSF-to-plasma glycine ratio >0.08 is diagnostic of nonketotic hyperglycinemia. The disease usually has a severe outcome, but milder cases have been reported. Some of these are due to abnormal splicing with slightly preserved enzyme function. [72] Transient nonketotic hyperglycinemia is associated with similar clinical and biochemical findings initially, but glycine concentrations normalize between 2 and 8 weeks of life, and the prognosis is generally more favorable. [10]

Treatment of NKH has focused on three compounds: (a) glycine, (b) benzoate, and (c) carnitine. Glycine is known to stimulate the *N*-methyl-D-aspartic acid (NMDA) receptor, and dextromethorphan is a noncompetitive agonist of this same receptor, which has been used with some clinical success. High doses of benzoate can lower the CSF concentration of glycine, and there are anecdotal reports of responses. Carnitine deficiency has been documented in patients treated with benzoate,

P.2604

P.2605

P.2606

and therefore supplementation with L-carnitine has been advocated in patients receiving benzoate. Despite prompt administration of these treatments, some children may still suffer lasting neurologic sequelae.[8]

Table 1 Metabolic disorders in late infancy

Disorder	Seizure frequency	Seizure type	EEG	Dysmorphism	Neuroimaging	Laboratory findings	Treatment
Metachromatic leukodystrophy	++/+++	P	Diffuse slowing; asymmetric, slow-wave activity	Absent	White-matter lesions	High CSF protein; arylsulfatase deficiency	Not available (bone marrow transplant)

Schindler disease	+++	GTC, M	Multifocal spike-and-wave complexes	Absent	Severe atrophy of cerebellum, brainstem, and cervical spinal cord	Abnormal oligosaccharide pattern; α-*N*-acetylgalactos-aminidase deficiency	Not available
Mucopoly-saccharidoses	++	G	No specific pattern	Present	Cortical atrophy; ventricular dilation	Abnormal oligosaccharide pattern; several enzyme defects	Bone marrow transplant
CDG syndrome	+++	IS (CDG type III), P	Focal slow activity; hypsarrhythmia	Absent	Cerebellar atrophy; pons atrophy; demyelination (type III)	Low thyroxine-binding protein; abnormal serum and CSF disialotransferrin; phosphomannomutase deficiency	Not available

+, 0%–25% seizure activity; CDG, carbohydrate-deficient glycoprotein; CSF, cerebrospinal fluid; EEG, electroencephalogram; G, generalized; GTC, generalized tonic–clonic; IS, infantile spasms; M, myoclonic; P, partial.

Table 2 Metabolic disorders in the neonatal period

Disorder	Seizure frequency	Seizure type	EEG	Dysmorphism	Neuroimaging	Laboratory findings	Treatment
Urea cycle	++	P	Theta/delta waves; suppression-burst	Absent	Cerebral edema	High ammonia; low plasma urea	Dietary and pharmacologic
Nonketotic hyperglycinemia	++++	M, G, IS	Suppression-burst	Absent	CNS malformations	High CSF/plasma glycine ratio	Symptomatic
Maple syrup urine disease	++	M, P	Suppression-burst; comblike rhythm activity	Absent	Cerebral edema	Elevated Leu, Ile, Val; abnormal OA pattern	Dietary
Pyroxidine dependency	++++	P, G, M, IS	Multifocal spikes	Absent	Normal	Low CSF GABA	Pyridoxine

+, 0%–25% seizure activity; CNS, central nervous system; CSF, cerebrospinal fluid; EEG, electroencephalogram; G, generalized; GABA, γ-aminobutyric acid; IS, infantile spasms; M, myoclonic; OA, organic acids; P, partial; VLCFA, very-long-chain fatty acids.

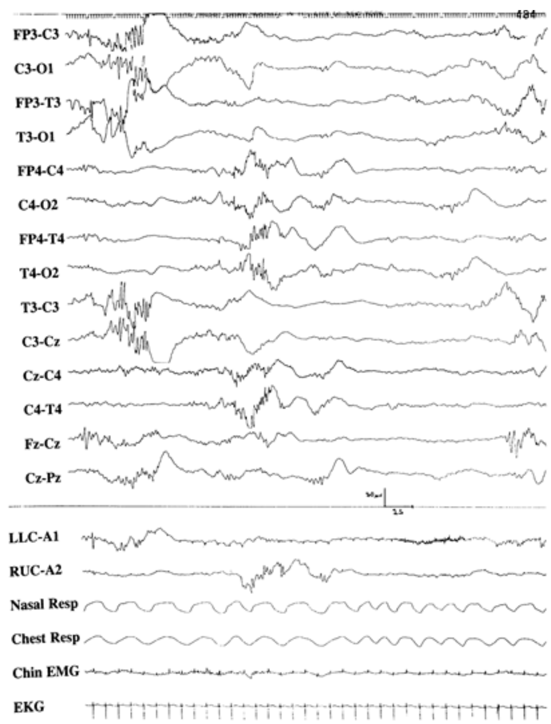

FIGURE 1. Suppression-burst electroencephalogram with interhemispheric asynchrony in a newborn. The sup- pression-burst pattern is characteristic of a variety of disorders, including nonketotic hyperglycinemia, phenylketonuria, maple syrup urine disease, and molybdenum cofactor deficiency. EKG, electrocardiogram; EMG, electromyogram; Resp, respiration.

Pyridoxine-dependent Epilepsy (#266100)

This disorder, transmitted as an autosomal-recessive trait, was previously believed to be due to a defect involving glutamic acid decarboxylase, but linkage studies have excluded this enzyme and implicated other pathways that do not appear to be primarily involved with this reaction. [5] Instead, mutations in an enzyme, antiquitin, in the lysine degradation pathway are responsible for the condition. An accumulated substrate inactivates pyridoxal 5-phosphate by forming a Knoevenagel condensation. The diagnosis can be suspected by finding elevated pipecolic acid in the blood, urine, or CSF. [41]

Typically, recurrent and long-lasting seizures occur in the neonatal period that are refractory to treatment with conventional antiepileptic drugs. The seizure types vary, and include persistent partial seizures with variable preservation of consciousness, recurrent status epilepticus, generalized myoclonic and atonic seizures, and infantile spasms. Progressive irritability, restlessness, and vomiting often precede seizures. The EEG may be diagnostic, showing an unusual paroxysmal pattern consisting of bursts of diffuse but asynchronous high-vol- tage delta activity intermixed with spikes or sharp waves. Other EEG findings include focal and multifocal spikes, bursts of generalized delta waves, and paroxysmal complexes of sharp and slow waves.[40] Intravenous administration of pyridoxine usually produces rapid control of seizures, but some cases may require several days of oral administration to show clinical effect. Patients remain dependent on pyridoxine supplementation to maintain seizure control and normal neurologic development.

Atypical cases of pyridoxine dependency have been described. Onset may be delayed into early infancy. As a rule, all infants of this age who have idiopathic seizures should be given a test dose of pyridoxine (75–100 mg) to determine responsiveness. Occasionally, a patient with vitamin B6–dependent conditions will become apneic after the test dose is administered, and so it is important to anticipate the need for transient respiratory support. Decreased concentration of γ-aminobutyric acid (GABA) in the CSF is the defining biochemical abnormality. This finding, coupled with elevated CSF concentration of glutamate and response to administration of pyridoxine, is diagnostic.

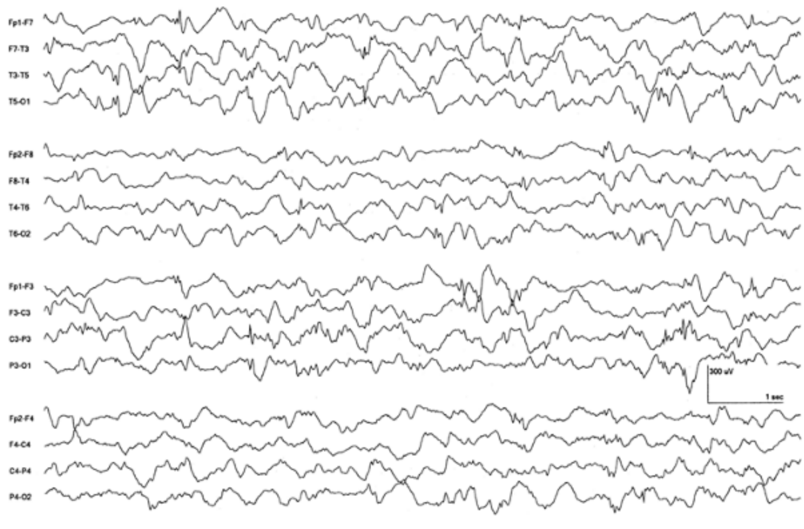

FIGURE 2. Electroencephalogram (EEG) in a patient with dihydropyrimidine dehydrogenase deficiency. The infant is 6 months old. Note the background slowing, the asymmetry with reduced complexity on the right, and the presence of multifocal spikes. A prior EEG had shown reduced complexity on the left, indicating that this feature presents with shifting laterality. (Courtesy of Dr. Kent R. Kelley.)

Some patients with neonatal encephalopathies do not respond to B6 but do respond to pyridoxal phosphate. [9,67] Pyridoxal phosphate is the biologically active form of the B6 vitamins, but the defect in these patients is not precisely known. Some advocate giving neonates or infants with intractable seizures and encephalopathy a test dose of pyridoxal phosphate (either 50 mg for a neonate or 30–50 mg/kg/d for infants) for 2 weeks because of these rare cases of pyridoxine resistance

P.2607

and the observation that pyridoxal phosphate appears to be superior to B6 in idiopathic epilepsies. [4,68]

Dihydropyrimidine Dehydrogenase Deficiency (#274270)

Dihydropyrimidine dehydrogenase (DPD) is used in the first step of the pyrimidine degradation pathway, converting uracil and thymine to ß-alanine and the R-enantiomer of ß-aminoisobutyric acid. This conversion primarily takes place in the liver, and DPD is the rate-limiting enzyme of the catabolism. This enzyme is absent in the brain, but it is believed that alanine may be converted from carnosine owing to the presence of tissue carnosinase in brain. There is a wide range of clinical presentation, but nearly all children present with neurologic abnormalities, including hypertonia, hyperreflexia, tremor, seizures, and developmental delay. Severely affected children present as newborns with hypertonia, stiffness, and feeding difficulties.[2] Details of the EEG features and characteristics of the seizures have yet to be described. In our own patient, erratic myoclonias were present. The EEG showed bursts of semirhythmic delta and attenuation of the expected background complexity over either hemisphere with shifting laterality. Multifocal interictal epileptiform discharges were present (Fig. 2). No treatment has been shown to be effective.

Molybdenum Cofactor Deficiency (#252150)

This condition is exceedingly rare. Molybdenum is a trace element that serves as an essential cofactor for the reactions of three different enzymes: (a) sulfite oxidase, (b) xanthine dehydrogenase, and (c) aldehyde oxidase. Deficiency of molybdenum cofactor can result from mutations in four separate genes: *MOCS1*, *MOCS2* (which codes for molybdopterin synthase), *MOSC3*, and *GEPH* (which codes for gephyrin).[36] Absence of hepatic molybdenum cofactor results in a combined enzyme deficiency. A progressive encephalopathy develops in affected infants, with recurrent and refractory seizures appearing shortly after birth. Focal seizures, diffuse tonic seizures, and erratic myoclonic jerks are common. Jitteriness, abnormal cry, and intermittent irritability are other neurologic findings. Dysmorphic features, ectopia lentis, and hepatomegaly are associated somatic manifestations. The EEG is characterized by multifocal paroxysms and a suppression-burst pattern. Brain magnetic resonance imaging (MRI) demonstrates initial signal changes consistent with white matter edema, then curvilinear signal changes in the gray–white junction suggestive of hemorrhage and laminar necrosis, and ultimately multiple subcortical cystic areas scattered throughout the brain. [16]

Isolated sulfite oxidase deficiency is clinically and pathologically indistinguishable from molybdenum cofactor deficiency, suggesting that decreased sulfite oxidase activity is central to the clinical syndrome.[59] In both conditions, the serum concentration of uric acid is abnormally low, and sulfur-containing

P.2608

products are evident in the urine. Serum urate may be the more sensitive screening test. [3] There is no effective treatment for this condition. Recent work suggests that sulfites might have a direct impact on glutamate dehydrogenase function, thereby reducing the adenosine triphosphate (ATP)-producing capacity of cells. [75] In theory, a severe impairment of energy production could account for the MRI appearance and the burst-suppression pattern apparent on EEG tracings.

Peroxisomal Diseases

These disorders are invariably associated with seizures in the neonatal period. Zellweger (cerebrohepatorenal) syndrome (ZS) is the prototype of this group of conditions. Neonatal adrenoleukodystrophy and infantile Refsum disease are progressively milder presentations. Most cases of ZS are caused by mutations in the *PEX1* gene, and the severity of the mutation correlates with the clinical severity, although to an imperfect degree. [66] Severe encephalopathy with failure to thrive, hypotonia, hyporeflexia or areflexia, and seizures are the major features. Seizures develop in the neonatal period in 80% of patients. Seizure types include focal, myoclonic, and atypical flexor spasms. The EEG shows multifocal spikes or, less frequently, hypsarrhythmia. Dysmorphic features are distinctive and often permit diagnosis by inspection. These include a high, prominent forehead; shallow orbital ridges; high palatal arch; deformities of the external ear; micrognathia; presence of epicanthal folds; low, broad nasal bridge; and redundant skin folds of the neck. Cataracts, glaucoma, pigmentary retinopathy, optic nerve dysplasia, and amaurosis are usually present, as are hepatomegaly, polycystic kidneys, and calcific stippling of the patellae. Laboratory abnormalities include absence of peroxisomes on liver biopsy and high levels of very-long-chain fatty acids in the serum.

Disorders of the Urea Cycle

These conditions involve 1/30,000 live births.[24] Except for ornithine transcarbamoylase deficiency, which is transmitted as an X-linked dominant trait, the other five urea cycle disorders are autosomal-recessive diseases. Hyperammonemia, respiratory alkalosis, absence of ketoacidosis, and decreased blood urea nitrogen concentrations are laboratory findings that strongly suggest a urea cycle disorder. The concentrations of citrulline and argininosuccinic acid in the plasma and of orotic acid in the urine help to differentiate among six different enzyme defects of the urea cycle.

Approximately 60% of infants with urea cycle defects become symptomatic within 24 to 72 hours of birth. Symptoms include progressive lethargy, vomiting, hypothermia, and hyperventilation. Seizures are not usually seen initially but are manifested later, as cerebral edema develops. The EEG is characterized by low-voltage, asymmetric delta and theta activity. A suppression-burst pattern may develop, and the duration of intervals between bursts may correlate with the degree of hyperammonemia. Brain imaging reveals cerebral edema with small ventricles, and intracranial hemorrhage has been reported. Primary treatment is dietary, with various drugs administered to lower the blood and tissue concentrations of ammonia.

Maple Syrup Urine Disease (#248600)

There are five subtypes of maple syrup urine disease (MSUD), but the classic severe neonatal form presents with poor sucking, lethargy, and coma, beginning sometime between the fourth and seventh days of life. Intermittent hypertonus and opisthotonus, gross tremor, myoclonic jerks, and repetitive flexion–extension movements of the limbs are common. It is the result of a defect of the branched-chain α-ketoacid dehydrogenase complex, and mutations in at least four different genes can cause the clinical syndrome. This mutation is expressed as an autosomal-recessive trait, with an estimated prevalence of 1/200,000 live births. The branched-chain amino acids (leucine, isoleucine, and valine) accumulate together with the α-ketoacid derivatives. Clear focal seizures, seizures with diffuse clinical expression, and uncontrolled cerebral edema are common in untreated subjects. A mu-like rhythm characterized by bursts of 7- to 9-Hz spindle-like sharp waves of moderate amplitude is distinctive. [18] Fast rolandic rhythms have also been described.

Organic Acidurias

The disorders of organic acid metabolism comprise a large number of inborn errors, including isovaleric aciduria and several ketotic hyperglycinemic syndromes (propionic acidemia, methylmalonic acidemia, and β-ketothiolase deficiency).

Symptoms develop during the neonatal period in approximately 50% of children who have isovaleric aciduria (#243500), with poor feeding, vomiting, dehydration, and a progressive encephalopathy manifested by lethargy, tremors, seizures, and coma. Cerebral edema is present, and seizures are most often focal motor or diffuse tonic posturing. The EEG shows dysmature features during sleep. Distinctive biochemical findings include metabolic acidosis, ketosis, lactic acidosis, hyperammonemia, and transient bone marrow suppression. Isovalerylglycinuria is diagnostic. The disorder is due to a defect in isovaleryl CoA dehydrogenase. It is of note that recent newborn screening has led to the identification of asymptomatic individuals with identical genetic mutations. This is important information for genetic counseling. [44]

The symptoms of propionic acidemia (#606054) also appear during the neonatal period, and 20% of affected newborns have seizures as the first symptom. The defect is in propionyl-CoA carboxylase. Again, both focal seizures and manifestations that appear more diffuse have been reported. The EEG shows diffuse delta wave activity, with generalized or focal temporal spikes during the encephalopathic phase. Intractable epilepsy may develop. In 40% of affected children, generalized convulsions and myoclonic seizures develop in later infancy, and older children may have atypical absence seizures. A recent workshop showed that modern mortality rates are about one in three, but the degree of dietary protein restriction used as treatment varies considerably among centers worldwide. [65] Biochemical findings include metabolic acidosis, ketosis, and elevation of branched-chain amino acids and propionic acid.

Methylmalonic acidemia is the metabolic signature of several biochemically distinct entities, all of which show decreased activity of methylmalonyl-CoA mutase. [48] Stomatitis, glossitis, developmental delay, failure to thrive, and seizures are the major features. Diffuse tonic postures and focal seizures with apparent secondary generalization are the most frequently described seizure types. Methylmalonic acidemia also occurs in association with homocystinuria. Seizures involve repetitive clonic eyelid blinking and simultaneous upward deviation of the eyes. Lesions of the globus pallidus on computed tomography (CT) or MRI are classic. [57]

Defects of carnitine palmitoyltransferase types I and II may be manifested in the newborn period by diffuse neurologic signs and seizures. [39] Hypsarrhythmia has been described in one case. Deficiency of carnitine acylcarnitine translocase also may produce seizures, apnea, and bradycardia in the neonatal period, and seizures may occur in other defects of fatty acid oxidation. [28]

P.2609

Pyruvate Dehydrogenase Deficiency (#312170) and Pyruvate Carboxylase Deficiency (#266150)

The clinical manifestations of pyruvate dehydrogenase (PDH) deficiency are extremely heterogeneous. The spectrum ranges from neonatal lactic acidosis with severe neurologic dysfunction to a slowly progressive, chronic neurodegenerative disorder. [6] Structural abnormalities, such as agenesis of the corpus callosum, are frequently revealed by brain imaging. Mutations most often affect the E_1 α subunit gene located on the short arm of chromosome X. [11] The pyruvate dehydrogenase complex catalyzes the irreversible conversion of pyruvate into acetyl-CoA. The PDH complex is composed of multiple copies of three enzymes: E1 (PDHA1), dihydrolipoyl transacetylase (DLAT or E2), and dihydrolipoyl dehydrogenase (DLD or E3). The E1 enzyme is made up of two α and two β subunits. The E1 α subunit contains the active site and plays a key role in the function of the PDH complex. Complex malformations of the nervous system are common in girls with neonatal onset, and seizures are a frequent feature, including infantile spasms and myoclonic seizures. Electroencephalographic abnormalities are usually severe and include multifocal slow spike-and-wave discharges. Patients with defects in E2 have been recently reported. The clinical expression is quite different, and affected individuals may present with episodic dystonia and few or none of the classical features of PDH deficiency. [26] Patients are treated with the ketogenic diet because use of ketone bodies for oxidative metabolism bypasses the primary defect. A zebrafish model was developed that demonstrates the effectiveness of this approach. [60]

Pyruvate carboxylase deficiency also may be devastating in the neonatal period, being associated with severe lactic acidosis, hypotonia, failure to thrive, and seizures. [11] The combination of lactic acidosis and ketosis is a distinctive metabolic disturbance, and when hyperammonemia, citrullinemia, and hyperlysinemia are also present, it is diagnostic of the disorder. Seizures are related to the associated hypoglycemia and failure of the Krebs cycle. Treatment with adrenocorticotropic hormone (ACTH) can worsen infantile spasms associated with this disorder, and treatment with the ketogenic diet can be lethal. [52]

Other disturbances of mitochondrial function have been linked to Leigh syndrome (LS) and Alpers syndrome. Symptoms of these two syndromes, which appear in infancy, include convulsions. Leigh syndrome is better understood and may be related to various biomolecular defects. [14] Maternally inherited Leigh syndrome (MILS) is frequently associated with convulsions and pigmentary retinopathy. The common mutation associated with MILS is a thymine–guanine transition at nucleotide position 8993 in complex V of the mitochondrial genome. Other mitochondrial DNA mutations may produce the MILS phenotype. Leigh syndrome associated with deficiency of pyruvate dehydrogenase is characterized by convulsions about 50% of the time. In contrast, convulsions occur infrequently (7% of cases) in LS associated with cytochrome *c* oxidase.

The pathophysiology of Alpers syndrome is more obscure. This condition is transmitted as an autosomal-recessive trait and is invariably associated with convulsions. Liver failure with cirrhosis follows in the Huttenlocher variant. [27] Whether Alpers syndrome is mitochondrial in origin had been a subject of debate. [24] Mutations in the POLG gene have been reported. [45]

Disorders of Carbohydrate Metabolism

Hypoglycemia in the neonatal period is often caused by an inborn error of gluconeogenesis, such as deficiency of fructose-1,6-bisphosphatase. Fifty percent of affected children show symptoms during the first week of life, including periodic hyperventilation, hepatomegaly, irritability, apnea, somnolence, and coma. Other patients become symptomatic during the early infantile period. Seizures are common, and the initial EEG reveals diffuse slowing and low-amplitude background activity with intermittent bursts of fast activity. Less frequently, there are multifocal sharp waves and spikes. Profound hypoglycemia, lactic acidosis, ketosis, elevated plasma concentrations of alanine, and presence of abnormal urinary organic acids with glycerol and glycerol-3-phosphate are characteristic biochemical findings. The diagnosis can be made using cultured lymphocytes, thereby eliminating the need for a liver biopsy. [31] Neurologic symptoms and permanent brain damage can be avoided by preventing hypoglycemia.

Other disorders are caused by abnormalities of fructose and galactose metabolism. Galactosemia can be caused by defects in the products of three genes. The most commonly involved enzyme is galactose-1-phosphate uridyltransferase (#230400). Deficiency occurs in 1/62,000 births. The precise cause of the neurologic disability is not known. Despite prompt recognition and appropriate dietary management, long-term disability may still result. [55] Hyperchloremic metabolic acidosis, hyperaminoaciduria, albuminuria, abnormal liver function, and elevated blood concentrations of galactose are diagnostic of this condition. Neonatal screening can be performed.

Disorders of Biotin Metabolism

These conditions may produce seizures in the neonatal period (Table 2).[7] Holocarboxylase synthetase binds biotin covalently to four apocarboxylases (propionyl-CoA carboxylase, pyruvate carboxylase, β-methylcrotonyl-CoA carboxylase, and acetyl-CoA carboxylase) (#253270). The gene map locus is 21q22.1. Biotinidase, in turn, cleaves biotin from biocytin, a short biotinylated peptide that is formed during the proteolytic degradation of the holocarboxylases. Holocarboxylase synthetase deficiency is also known as early-onset multiple carboxylase deficiency, and biotinidase deficiency is also termed late-onset multiple carboxylase deficiency. Symptoms of holocarboxylase synthetase deficiency appear in the neonatal period; diffuse tonic seizures, brief focal motor seizures, and multifocal myoclonic jerks develop in 25% to 50% of cases. In addition, Thoene et al.[61] reported lactic acidosis, alopecia, keratoconjunctivitis, and perioaral erosions. Seizures are usually refractory to treatment with antiepileptic drugs but may improve with large doses of biotin. The EEG shows a suppression-burst pattern and multifocal spikes (Fig. 1).

Metabolic Disorders of Early Infancy

Several inborn metabolic errors of which seizures are a manifestation become symptomatic after the first month of life. All patients with GM_2 gangliosidosis, disorders of folate metabolism, glucose transporter protein deficiency, fumarase deficiency, and Menkes disease have seizures as part of the clinical picture. In the other metabolic disorders of early infancy, seizures occur in 25% to 75% of cases (Table 3).

Lysosomal Disorders

GM_2 gangliosidosis is a lysosomal disorder that invariably includes seizures as a prominent feature. The infantile form of GM_2 gangliosidosis includes Tay-Sachs disease (#272800), caused by deficiency of hexosaminidase A, and Sandhoff disease, caused by deficiency of hexosaminidase A and B. Classic

P.2610

P.2611

Tay-Sachs disease is characterized by developmental regression, paralysis, blindness, seizures, and death in the second or third year of life.[46] An exaggerated startle response, often associated with myoclonic jerks, is one of the earliest neurologic signs, and is a distinctive feature of this disorder. Focal and atypical absence seizures have been described and respond poorly to antiepileptic drugs. The EEG shows central spikes with a very sharp morphology (Fig. 3). The classic cherry red spot is present in the ocular fundi of nearly all patients. One report in the literature based on autopsy findings suggested an exaggerated sensitivity to phenytoin neurotoxicity.[42] Nonetheless, phenytoin should be avoided in patients with Tay-Sachs disease because of the high incidence of myoclonus and the availability of other agents effective against multiple seizure types.

Table 3 Metabolic disorders in early infancy

Seizure disorder	Seizure frequency	type	EEG	Dysmorphism	Neuroimaging	Laboratory findings	Treatment
GM_2 gangliosidosis	++++	SM, P, M	Multifocal paroxysms	Absent	Progressive ventriculomegaly	Abnormal urinary oligosaccharide pattern; hexosaminodase A deficiency	Not available
Krabbe disease	+++	M, SM, IS	Asynchronous spike-polyspike paroxysms	Absent	White-matter demyelination	Increased CSF protein; galactosylceramidase deficiency	Not available
Biotinidase deficiency	+++	G, M, IS	Suppression-burst; spike-and-slow-wave paroxysms	Absent	Nonspecific	Abnormal urinary OA pattern	Biotin
Folate disorders	+++/++++	IS, M, P	Multifocal paroxysms; hypsarrhythmia	Absent	Cortical atrophy; leukoencephalopathy; calcifications	Abnormal amino acid pattern: homocystinuria, low methionine, normal or low CSF folate	Folate, betaine
Glucose transporter protein deficiency	++++	M, A	Normal	Absent	Normal	Low CSF glucose and lactate; normal serum glucose	Ketogenic diet
Branched-chain organic acidurias	+++	P, G, M, IS	Generalized or focal delta slowing	Present (3-OH-isobutyric aciduria)	Cerebral edema; hypodensity BG; heterotopias; cerebral dysplasia	Ketonuria or hypoketosis; hypoglycemia; abnormal urinary OA	Dietary, carnitine
Fumarase deficiency	++++	P, IS, M	Multifocal spikes; spike-and-wave complexes; hypsarrhythmia	Absent	CNS malformations	Lactic acidosis; fumaric aciduria	Symptomatic
Hyperpheny-alninemias	+++	G, P, M, IS	Generalized or focal paroxysms; hypsarrhythmia	Absent	White-matter lesions; cerebral atrophy	High phenylalanine; abnormal CSF biopterin ratio	Dietary, biopterin

Fructose-1, 6-biphosphatase deficiency	+++	P, G	Diffuse slowing; intermittent burst; fast activity	Absent	Normal	Hypoglycemia; lactic acidosis; ketosis	Dietary
HHH syndrome	+++	G, P, M, IS	Spike-and-wave complexes; diffuse slowing	Absent	Normal	Increased orotic acid, glutamate, alanine; homocitrullinuria; hyperammonemia	Dietary
Urea cycle	++	P, G	Generalized theta-wave paroxysms	Absent	Cerebral edema; white-matter lesions	Hypera- mmonemia; abnormal amino acid pattern	Dietary, phenylbutyrate
Menkes disease	++++	M	Multifocal paroxysms	Absent	Cerebral, cerebellar atrophy; focal areas of necrosis	Low serum copper and ceruloplasmin	Symptomatic
Histidinemia	+++	M, IS, SM	Atypical hypsarrhythmia	Absent	Normal	High histidine	Symptomatic, histidine restriction
Hyper-prolinemia	++	P, IS	Slow delta-wave activity	Absent	Normal; leukodystrophy (1 case)	High proline	Symptomatic

+, 0%–25% seizure activity; BG, basal ganglia; CNS, central nervous system; CSF, cerebrospinal fluid; EEG, electroencephalogram; G, generalized; IS, infantile spasms; M, myoclonic; OA, organic acids; P, partial; SM, startle myoclonic.

FIGURE 3. Electroencephalographic tracing showing very fast central spikes in an infant with Tay-Sachs disease.

Other lysosomal disorders occurring at this age include globoid-cell leukodystrophy (Krabbe disease; #245200), caused by a deficiency of galactocerebrosidase. Presentation in early infancy is characterized by developmental regression, increasing irritability, progressive spasticity, and opisthotonic posturing. [20] Myoclonic jerks, startle myoclonus, and extensor spasms are common, and infantile spasms with hypsarrhythmia have been reported in several cases. The EEG is usually characterized by increasingly severe bilateral, symmetric delta activity and asynchronous spike-polyspike discharges. Increased CSF protein and peripheral neuropathy are distinctive features of this disease of white matter. In contrast to what is observed in most classic white-matter diseases, seizures occur early in the course of 50% to 75% of infants with Krabbe disease. Bone marrow transplantation has been used and is most promising in the presymptomatic newborns. [17,70]

Disorders of Vitamin Metabolism

Disorders of vitamin metabolism with symptoms that appear in early infancy include biotinidase deficiency (#253260) and disorders of folic acid. As described in a previous section, biotinidase deficiency produces multiple carboxylase deficiency. Thirteen different mutations have been described in the gene. [73] Seizures occur in 50% to 75% of patients and are the presenting clinical symptoms in one third of cases. Apparently generalized clonic seizures, infantile spasms, and myoclonic seizures are seen. Electroencephalographic findings may include a suppression-burst pattern, absence of physiologic sleep patterns, poorly organized and slow waking background activity, and frequent spike and spike-and-slow-wave discharges. A deficiency of biotinidase is diagnostic, and patients respond dramatically to supplementation with high-dose biotin. Newborn screening is used to make the diagnosis, but not all individuals identified will develop clinical symptoms. [74]

Methelyne tetrahydrofolate reductase deficiency (#236250) is the most common inborn error of folate metabolism, with a clinical spectrum from early neurologic deterioration and death to asymptomatic adults, even within the same family. [25] In affected individuals, a progressive neurologic syndrome develops with

P.2612

regression in infancy. Clinical features include acquired microcephaly and seizures. Intractable infantile spasms, generalized atonic and myoclonic seizures, and partial motor seizures are seen. Electroencephalographic findings vary from diffuse slowing of background activity to continuous spike-and-wave complexes or multifocal spikes. The early-onset form differs from the late-onset form. The latter presents with progressive motor deterioration, schizophrenia-like psychiatric symptoms, and recurrent strokes; seizures are uncommon. Homocystinuria and elevated serum concentrations of homocystine and methionine are the main biochemical features. Treatment with folate can reverse white matter lesions, but this response may be variable, even within families of affected members. [58]

Defects in methionine biosynthesis are also associated with seizures. Convulsions are frequent and are predominantly generalized, although myoclonic seizures with a hypsarrhythmia on the EEG have been reported. Diagnostic laboratory findings are megaloblastic anemia, homocystinuria, decreased methionine, and normal folate and cobalamin concentrations in the absence of methylmalonic aciduria.

Seizures are common in congenital folate malabsorption, a rare condition that is believed to be caused by a defect in the folate transporter system. Folate is concentrated in the nervous system, and the CSF concentrations of folate are higher than serum concentrations. Sometimes, calcifications form in the occipital lobes and basal ganglia. Without folate supplementation, a slowly progressive encephalopathy develops with refractory seizures. Other clinical features include megaloblastic anemia, diarrhea, mouth ulcers, and failure to thrive. High-dose folate or folinic acid may improve seizure control.

Inherited defects of vitamin B12 metabolism also may produce severe megaloblastic anemia in early infancy. Generalized tonic convulsions occur almost invariably and are refractory to conventional treatment. Methylmalonic aciduria without homocystinuria suggests this diagnosis.

Glucose Transporter Type 1 Deficiency Syndrome

The glucose transporter type 1 deficiency syndrome is a prototypic example of a defect in energy supply. [12,64] Affected infants become encephalopathic, with seizures and delayed motor and mental development. Seizures typically begin after the second month of life and are of diverse types but are probably multifocal in origin. Later, generalized nonconvulsive seizures, myoclonic jerks, and atypical absence seizures are common. Developmental clumsiness, impaired early language and behavioral development, and deceleration of head growth with acquired microcephaly are additional findings. Low CSF glucose and lactate concentrations in the presence of a normal blood sugar concentration are diagnostic. The EEG is often normal early in the course or may show scattered multifocal interictal epileptiform discharges (Fig. 4B). As the child matures, bursts of generalized spike-and-wave discharges are seen in about one third of patients (Fig. 4A).[35] Another useful EEG clue to the diagnosis is the marked enhancement of the interictal epileptiform abnormalities in the fasting state and, in turn, the marked improvement of the EEG after a meal. [29] The disease can be diagnosed by assaying glucose transport in isolated intact erythrocytes. Seizures generally respond well to a ketogenic diet, but they tend to be refractory to conventional antiepileptic drugs. Phenobarbital should be avoided because of its potential to interfere with transport of glucose into the nervous system. [34]

Early infantile seizures can be seen in other disorders of carbohydrate metabolism, including hereditary fructose intolerance, d-glyceric aciduria, and galactokinase deficiency.

Congenital Disorders of Glycosylation

Congenital disorders of glycosylation (CDGs) are caused by deficiencies in glycoprotein biosynthesis and usually result in severe cognitive dysfunction. CDG type I (CDG-I) disorders are an increasingly expanding group of conditions caused by disturbances in the synthesis of the lipid linked glycan precursor or in the attachment of glycans to proteins. CDG-II disorders are caused by impairments of either the trimming of the protein-bound oligosaccharide or the addition of sugars. Seizures can be seen in infants with CDG-IE and CDG-IL. Patients with CDG-IE have had onset of seizures within the first year of life. Additional features are development delay, hypotonia, and acquired microcephaly. Laboratory evaluations showed hypoglycosylation on serum transferring and cerebral spinal fluid β-trace protein. The disorder is due to dolichol phosphate mannose synthase (DPM1) mutations.[32] Detailed descriptions of the seizures and EEG features are not available. CDG-IL is caused by deficiency of the ALG9 α1,2-mannosyltransferase enzyme and results in delay, seizures, hypotonia, diffuse brain atrophy with delayed myelination, failure to thrive, pericardial effusion, cystic renal disease, hepatosplenomegaly, esotropia, and inverted nipples. Detailed descriptions of the seizures are lacking. One report stated that the initial EEG shortly after onset of seizures was normal.[71] Febrile seizures are a common feature of CDG-IA, but afebrile seizures are only variably seen in this disorder. [33]

Organic Acidurias

Seizures in early infancy may be the presenting symptom of branched-chain organic acidurias. These include isovaleric aciduria, 3-methylcrotonyl-CoA carboxylase deficiency, 3-methylglutaconic aciduria with normal 3-methylglutaconyl-CoA hydratase, and 3-hydroxy-3-methylglutaryl CoA lyase deficiency (#246450).[76] In the latter condition, the urine has been observed to smell like a cat. The common mutation associated with this condition may alter the three-dimensional structure of the enzyme. [50] Seizures, including convulsions and infantile spasms, tend to be prominent in 3-methylcrotonyl-CoA carboxylase deficiency. The typical abnormal organic acid includes 3-hydroxyisovaleric acid and 3-methylcrotonyl glycine. Serum concentrations of free carnitine are very low.

Severe developmental delay, progressive encephalopathy, and seizures are the most common features of 3-methylgluta- conic aciduria, but the biochemical features can also be identified in asymptomatic individuals. [1,19] Seizures occur in one third of cases, and infantile spasms have been reported early on. The typical organic acid abnormality includes marked elevations of 3-methylglutaconic acid and 3-methylglutaric acid in the urine.

Seizures are the presenting symptom in 10% of patients with 3-hydroxy-3-methylglutaric aciduria, a metabolic disorder caused by a deficiency of the lyase enzyme that mediates the final step of leucine degradation and plays a pivotal role in hepatic ketone body production.

Infantile spasms have been reported in patients with 3-hydroxybutyric aciduria. Facial dysmorphism and brain dysgenesis are prominent manifestations. The enzyme deficiency causing this condition is unknown. Urinary excretion of 3-hydroxyisobutyric acid in the absence of ketosis is diagnostic.

Glutaric acidemia type I is a more common autosomal recessive disorder of lysine metabolism that is caused by a deficiency of glutaryl-CoA dehydrogenase. Seizures often are the first clinical signs of metabolic decompensation following a febrile illness. Valproate and carnitine with a low-protein diet and riboflavin supplementation are recommended.

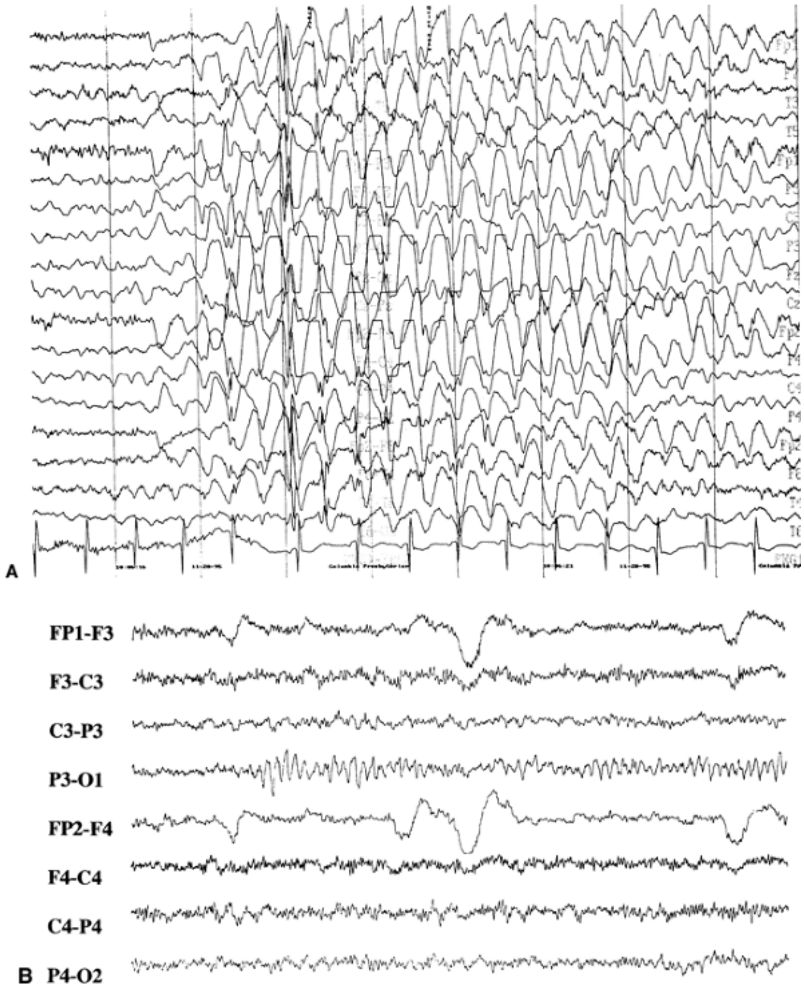

FIGURE 4. Typical electroencephalogram from a patient with glucose transporter type 1 deficiency syndrome. **A:** Bursts of generalized irregular spike-and-wave discharges and runs of rhythmic delta activity are associated with altered responsiveness. Similar discharges have been encountered in approximately one third of patients with glucose transporter protein deficiency. In other patients (not shown), multifocal spikes with very sharp morphology, rapid repetition, and a proclivity for the posterior head regions have been seen. **B:** Electroencephalogram showing a depression of the alpha rhythm on the right, consistent with a focal disturbance of cerebral function in the right posterior head region.

Aminoacidurias

Phenylketonuria (PKU; #261600) is typical of several disorders of amino acid metabolism whose symptoms appear in early infancy.[2] Phenylketonuria is caused by phenylalanine hydroxylase deficiency and is associated with mental retardation, microcephaly, psychotic behavior, and seizures.[47] Generalized seizures occur in 25% of patients. The majority of children with classic PKU who are treated early will have normal EEGs.[51] Focal and generalized slowing and epileptiform discharges have been reported in patients with abnormal EEGs. Increased delta activity may occur with oral phenylalanine loading. PKU may be successfully treated by dietary restriction of phenylalanine.

A hyperphenylalaninemic state may be the consequence of disorders of phenylalanine metabolism or tetrahydrobiopterin (BH_4) homeostasis. A disorder of BH_4 recycling produces severe neurologic regression and epilepsy that is refractory to antiepileptic drugs. Recurrent episodes of status epilepticus have been reported during the first year of life. The EEG may show hypsarrhythmia in early infancy. The typical biochemical profile is hyperphenylalaninemia, associated with decreased urinary and CSF biogenic amines.

A disorder of BH_4 synthesis secondary to deficiency of guanosine triphosphate cyclohydrolase (#233910) produces

P.2613

early developmental regression and infantile spasms. Control of seizures and improvement in the clinical condition can follow BH_4 replacement. Central replenishment of dopamine and serotonin can also lead to further improvement. The EEG of a patient followed at our institution revealed diffuse background slowing and multifocal spikes (Fig. 5). Deficiency of 6-pyruvoyal tetrahydrobiopterin synthase is characterized by progressive encephalopathy, pyramidal and extrapyramidal signs, and myoclonic seizures. Treatment with BH_4 and central neurotransmitter precursors controls seizures and normalizes the EEG.

Inborn errors of tyrosine metabolism cause seizures in patients of this age group. Tyrosinemia type III (4-hydroxy- phenylpyruvate dioxygenase deficiency) was reported in a newborn with recurrent seizures and in children in whom infantile spasms developed. Electroencephalographic findings included generalized voltage attenuation with single-spike and polyspike discharges in the parietal-occipital areas.

FIGURE 5. A 9-year-old child with guanosine triphosphate cyclohydrolase deficiency. Note severe background slowing with admixed multifocal spikes.

Mental retardation and seizures occur with histidinemia or histidase deficiency. Infantile spasms and myoclonic seizures are frequent. Delayed development and an exaggerated startle response are additional features. Seizures are refractory to the

P.2614

usual drugs, and only one patient has responded to a diet low in histidine. A few patients with hyperprolinemia type I (proline oxidase deficiency) have mental retardation, seizures, and severe encephalopathy. Hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome is manifested by ataxia, myoclonus, chorea, spasticity of gait, mental retardation, and seizures.[15] Infantile spasms have been reported in association with this defect of intramitochondrial ornithine transport. Restriction of protein and supplementation with ornithine, arginine, and citrulline are recommended as treatment.

Defects of the Urea Cycle

Presenting symptoms of disorders of the urea cycle and disorders of branched-chain amino acid and keto acid metabolism can appear either in the neonatal period, as discussed previously, or during infancy.

Disorders of γ-Aminobutyric Acid Metabolism

4-Hydroxybutyric aciduria is an example of an inborn error of GABA metabolism that results from a defect in succinic semialdehyde dehydrogenase function (#271980).[30] Psychomotor retardation, language delay, hypotonia, and ataxia develop in affected children between the ages of 6 months and 11 years. Seizures may be the presenting symptom in about 50% of patients. Accumulation of 4-hydroxybutyric acid in urine, plasma, and CSF and variable elevations of glycine are characteristic. Valproic acid is effective in controlling the seizures. Although it should theoretically work, our personal experience with vigabatrin treatment in one case was very disappointing. Others have also found lack of a good effect.[20,22]

Menkes Disease

This is an X-linked inherited disorder that results from a defect in the Cu^{2+}-transporting ATPase α polypeptide.[39] As a result, copper-dependent enzymes, including cytochrome *c* oxidase, are catalytically less active. The disturbance in cerebral oxidative metabolism is reflected in elevated CSF concentrations of lactic acid. Affected infants have a progressive encephalopathy with characteristic facial features, abnormalities of the hair, and various skin manifestations, including cutis laxa, seborrheic dermatitis, recurrent rash, and hypopigmentation. Myoclonic seizures are common during the first 2 months of life and are generally refractory to treatment. The EEG shows multifocal epileptiform discharges. Details regarding the EEG findings are not often reported, but evolution to infantile spasms has been observed.[56] Copper histidinate, the only available treatment, may be effective if begun in the presymptomatic phase.

Metabolic Disorders of Late Infancy

In general, metabolic diseases that cause seizures in late infancy are disorders affecting the structural components of the nervous system. These conditions are inexorably progressive, and the most important ones are lysosomal (Table 1).

Metachromatic Leukodystrophy

Metachromatic leukodystrophy is the result of a deficiency of arylsulfatase A. There are at least five allelic forms, including the characteristic late-infantile variant. Gait disorder and ataxia are the most common presenting symptoms, which are followed by a progressive decline in mental and motor skills.[21]

P.2615

Partial seizures develop late in the clinical course in 25% of patients with the late-infantile form of metachromatic leukodystrophy and in 50% to 60% of patients with the juvenile-onset form. Electroencephalographic findings include diffuse high-voltage slowing and occasional bursts of spikes. Slow-frequency activity may be asymmetric. Focal interictal epileptiform discharges predominate in the late-infantile form.[69]

Schindler disease (#609241) results from a deficiency of α-*N*-acetylgalactosaminidase and is an extraordinarily rare condition.[62] Affected patients appear normal at birth, but progressive neurologic decline becomes evident after 1 year of age. Manifestations include spasticity, cerebellar signs, and extrapyramidal dysfunction. Generalized tonic–clonic seizures and myoclonic jerks are common. Electroencephalographic abnormalities include multifocal spikes and spike-and-wave complexes.

Mucopolysaccharidoses

The mucopolysaccharidoses are a family of lysosomal storage disorders caused by the deficiency of several enzymes involved in the degradation of glycosaminoglycans. The various mucopolysaccharidoses share many clinical features, including a chronic and progressive course, multisystem involvement, organ enlargement, dysostosis multiplex, and abnormal facial features. The most frequently occurring mucopolysaccharidosis is Sanfilippo syndrome; four different subtypes have been described, each associated with a different enzymatic defect. Generalized seizures develop in about 40% of patients with Sanfilippo syndrome, but these are often easily controlled by antiepileptic drugs. Progressive dementia and severe behavioral disorders are other features. Bone marrow transplantation has been successful in several cases.

Neuronal Ceroid Lipofuscinoses

The neuronal ceroid lipofuscinoses (NCL) are a group of diseases with the common feature of storage of lipopigments in the brain and other tissues. At least seven clinical subtypes as well as additional rare atypical forms have been reported, and virtually all these are transmitted as autosomal-recessive traits.[53] Infantile NCL (#256730), also referred to as Santavuori-Haltia-Hagberg disease, is particularly common in Finland, with an incidence of 1/13,000 live births. The disease is caused by a defect in palmitoyl-protein thioesterase (PPT). Infants are normal in the neonatal period, but at about 1 year of age, rapid neurologic deterioration with ataxia occurs. Initially, patients may be given a misdiagnosis of Rett syndrome because of the deceleration of head growth and stereotypic abnormal hand movements. However, myoclonic jerks become increasingly evident, and the appearance of macular and retinal degeneration with optic atrophy allows cases of infantile NCL to be distinguished clinically from cases of Rett syndrome. The electroretinographic findings are abnormal, and the EEG shows progressive slowing and loss of amplitude. Some cases of Lennox-Gastaut syndrome have been caused by NCL. Symptoms of the late-infantile form of NCL, known as Jansky-Bielschowsky disease (#204500), appear in late infancy or early childhood, and epilepsy is the dominant clinical manifestation. This is due to a mutation in the CLN2 gene. Other features are ataxia and dementia. The EEG shows multifocal spikes and slow background rhythm and a highly characteristic response to photic stimulation. Stroboscopic light flashed at rates of <4/s produce high-voltage spike discharges over the posterior scalp regions. Visual-evoked potentials and somatosensory-evoked potentials are also of very high voltage. A pseudoperiodic pattern with absence of sleep spindles may be highly suggestive of the disorder in the early stages of presentation.[63] Seizures are difficult to control, and the diagnosis may be hard to establish. Skin or conjunctival biopsy specimens demonstrate abnormal cytosomes containing curvilinear bodies.

Metabolic Disorders of Childhood and Adolescence

Numerous metabolic disorders make their presence known in later childhood or adolescence. These conditions largely represent variants of disorders discussed in the preceding sections. Seizures may occur, but not invariably, as shown in Table 4.

Homocystinuria

Disorders of transulfuration include cystathionine β-synthase deficiency, the most frequent cause of homocystinuria (#603174). Some patients respond to pyridoxine administration. Mental retardation, behavioral disturbances, and seizures are manifestations of nervous system involvement; ectopia lentis, osteoporosis, and scoliosis are other common clinical findings. Generalized seizures occur in about 20% of patients with pyridoxine-nonresponsive homocystinuria and in 16% of patients with the pyridoxine-responsive form. Electroencephalographic abnormalities are more common than seizures and may consist of either mild diffuse background slowing or focal interictal epileptiform discharges. These abnormalities may not respond to B6 administration.[13] Thromboembolism, malar flush, and livedo reticularis reflect vascular system involvement. Biochemical abnormalities include homocystinemia, methioninemia, decreased cystine concentration, and homocystinuria.

Diabetes Mellitus

Diabetes mellitus is the most common metabolic disorder. Seizures are generally not a feature except during metabolic crisis with ketoacidosis and cerebral edema. Nonketotic hyperosmolar diabetic coma has a high mortality, and generalized or partial seizures are common in this setting. Epilepsia partialis continua has been reported with nonketotic hyperglycinemia. Generalized tonic–clonic seizures have also been reported in a patient with diabetes mellitus who had an intracerebral hemorrhage during ketoacidosis.

Adrenoleukodystrophy

There are seven different clinical presentations of adreno- leukodystrophy (#300100).[43] It is caused by mutation in the *ABCD1* gene, which encodes an ATPase-binding-cassette protein. Symptoms of the X-linked form of adrenoleukodystrophy classically appear in early childhood. Partial motor seizures, often with secondary generalization, and generalized tonic–clonic seizures are common in this peroxisomal disorder. Status epilepticus has been the initial presenting symptom, and epilepsia partialis continua has also been reported. The EEG is characteristic, with high-voltage polymorphic delta activity and loss of faster frequencies over the posterior regions.[38]

Lysosomal Disorders

An example of this group of diseases is neuraminidase deficiency (#256550), characterized by progressive loss of vision, presence of a macular cherry red spot, and progressive and

P.2616

P.2617

disabling myoclonus but relative preservation of cognition. The condition is also known as the cherry red spot-myoclonus syndrome. Generalized seizures are common, and the EEG is characterized by low-voltage, fast background activity and positive spikes that correlate with massive myoclonic jerks. This form of neuraminidase deficiency is referred to as sialidosis type I. Sialidosis type II is subdivided into two groups, an infantile form with early onset and a juvenile form with early normal development.[37] The infantile form is characterized by progressive encephalopathy, visceromegaly, course facial features, dysostosis multiplex, and presence of macular cherry red spots. Seizures are uncommon. Symptoms of the juvenile form appear in childhood, and include progressive mental regression, myoclonus, short stature, dysostosis multiplex, course facial features, and cherry red spots. The EEG is abnormal in 50% of patients, with an irregular slow background activity and spike-and-wave complexes.

Table 4 Metabolic disorders in childhood and adolescence

Disorder	Seizure frequency	Seizure type	EEG	Dysmorphism	Neuroimaging	Laboratory findings	Treatment
Tyrosinemia type I	+/++	G	Slow-wave acitvity in acute phase	Absent	Cerebral edema (rare)	Hyponatremia; aminoaciduria; high tyrosine; abnormal coagulation profile	Dietary, liver transplant
Homocystinuria	+/++	GTC	No specific abnormalities	Marfan-like; ectopia lentis	Normal	High methionine and homocysteine; low cystine; homocystinuria	Pyroxidine
Diabetes mellitus	++	P, EPC (nonketotic hyperglycemia), GTC	Diffuse or focal slow activity; focal paroxysms (sharp/slow wave)	Absent	Cerebral edema	Hyperglycemia; hyponatremia; hyperosmolarity	Mannitol therapy; fluid restriction

Pyrimidine disorders	+++	GTC, A	Generalized paroxysms; photic response	Absent	Hypoplasia CC; BG calcifications	High thymine and uracil	Symptomatic
X-linked adrenoleukodystrophy	+++	P, GTC, SE, EPC	Slow theta-delta waves of large amplitude	Absent	White-matter lesions	High VLCFA	Symptomatic; immuno-suppression; bone marrow transplant
Sialidosis	+++ (type 1)	M	Abnormal background	Present (type II)	Cerebral, cerebellar atrophy	Abnormal urinary oligosaccharide pattern	Symptomatic
Niemann-Pick type C	++	GTC, P, akinetic	Diffuse theta slowing; bursts of spike-and-wave complexes; multifocal spikes	Absent	Cerebellar atrophy; large fourth ventricle; white-matter lesions	Accumulation of unesterified cholesterol; normal or elevated sphingomyelinase activity	Drug therapy
Gaucher disease	+++	P, GTC	Slow background; spike-and-wave paroxysms	Absent	Normal	Glucocerebrosidase deficiency	Enzyme replacement; bone marrow transplant
Krabbe disease	++	M, atonic, RSE	No specific pattern	Absent	White-matter lesions; enhancement of the splenium CC; low-density gray matter	Galactosylceramidase deficiency	Not available
Galactosialidosis	+++	M, GTC	Multiple spike-and-slow-wave paroxysms	Present	Normal	Abnormal oligosaccharides; combined β-galactosidase and neuraminidase deficiency	Not available
GM_2 gangliosidosis	++	P, GTC, M, gelastic	Spike-and-wave complexes; slow waves (anterior region)	Absent	Cerebellar atrophy	Abnormal oligosaccharides; hexosaminidase A deficiency	Not available

+, 0%–25% seizure activity; BG, basal ganglia; CC, corpus callosum; EEG, electroencephalogram; EPC, epilepsia partialis continua; G, generalized; GTC, generalized tonic-clonic; M, myoclonic; P, partial; RSE, recurrent status epilepticus; SE, status epilepticus; VLCFA, very-long-chain fatty acids.

Niemann-Pick disease type C is an autosomal recessive lipidosis caused by a defect in cholesterol esterification (#257220), specifically a mutation in either the *NPC1* or *NPC2* gene.[49] The sphingomyelinase activity is normal or elevated. Neurologic manifestations are striking and include a progressive ataxia, supranuclear vertical gaze palsy, progressive extrapyramidal symptoms, and seizures.[27] Complex partial seizures, partial seizures with secondary generalization, and primary generalized tonic–clonic convulsions occur frequently. Akinetic seizures, often precipitated by sudden laughter, are less frequent but suggestive of the disorder. Conventional antiepileptic drugs are rarely effective.

Gaucher disease is another lysosomal disorder; it results from a deficiency of acid β-glucosidase. There are three clinical types. Type I (#230800) is characterized by hepatosplenomegaly, hypersplenism, and bone lesions. Type II (#230900) involves the nervous system, with early onset of progressive encephalopathy and visceromegaly. Type III (#23100) represents an intermediate form, characterized by early normal development, ocular apraxia, and slowly progressive mental and motor deterioration with ataxia. Complex partial seizures and generalized tonic–clonic seizures occur almost invariably. Some patients have early progressive myoclonus. Current treatment is enzyme protein replacement and bone marrow transplantation.

Finally, GM_2 gangliosidosis may appear in early to late childhood as a progressive ataxic syndrome associated with mental and motor deterioration and seizures. Partial complex seizures and generalized tonic or tonic–clonic seizures are particularly common. Generalized atonic seizures and gelastic seizures also have been described. Seizures are generally refractory to treatment.

Diagnostic Investigation

The diagnosis of genetically determined metabolic diseases is straightforward in many instances but complicated in others. For example, the classic aminoacidopathies and organic acidurias, once suspected, can be easily diagnosed by appropriate blood or urine measurements. Conversely, the diagnosis of an obscure condition, such as the carbohydrate-deficient glycoprotein syndrome, may require specific isoelectric focusing of the serum sialotransferrin isoform pattern in a specialized research laboratory.[23] Before obtaining appropriate metabolic, biochemical, or tissue specimens, the physician must have a reasonable differential diagnosis. Age of onset, clinical findings, family history, and neurologic examination continue to be the cornerstones of diagnosis. Experienced neurologists can often diagnose many of the disorders discussed in this chapter at the first clinical encounter. In such situations, laboratory studies serve only to confirm the clinical diagnosis. The presence of macular cherry red spots, abnormal appearance of the hair, or a peculiar distribution of fat over the posterior flanks or thighs immediately suggests the diagnosis of Tay-Sachs disease, Menkes disease, or the carbohydrate-deficient glycoprotein syndrome. Deceleration of head growth during infancy with consequent acquired microcephaly implies a defect of energy metabolism, the infantile form of NCL, or Rett syndrome, among other possibilities. Dislocated lenses and a seizure followed by a stroke are virtually diagnostic of homocystinuria.

Genetically determined metabolic diseases often have a saltatory historical pattern, in contrast to neurodegenerative diseases, which are inexorably progressive.

A complete blood cell count with differential and platelet count should be obtained in every case. Bone marrow depression occurs in the ketotic hyperglycinemic syndromes. A review of the peripheral smear may reveal important clues, such as a macrocytic anemia or vacuolated lymphocytes. A complete serum chemistry profile will uncover carbohydrate and electrolyte disturbances or specific organ dysfunction. Calcium and magnesium concentrations should be determined in every case. Low uric acid concentration raises the possibility of molybdenum cofactor deficiency, and low blood urea nitrogen suggests a defect involving the urea cycle. Quantitative measurement of plasma and urinary amino acids is necessary to identify the various aminoacidopathies. A urinary organic acid profile should be obtained based on the first morning urine specimen.

A lumbar puncture is required to measure various CSF metabolites. Elevated CSF protein concentration is characteristic of metachromatic leukodystrophy and globoid-cell encephalopathy. Low CSF glucose concentration is consistent with hypoglycemia caused by a defect of gluconeogenesis or a defect in the transport of glucose across the blood–brain barrier (glucose transporter type 1 deficiency syndrome). Low CSF folate concentration suggests a defect involving folate metabolism. The presence in CSF of amino acids, specifically glycine, glutamate, and GABA, may be diagnostic of nonketotic hyperglycinemia or pyridoxine-dependent epilepsy. Lactate and pyruvate values are elevated in CSF in disorders of cerebral energy metabolism, including pyruvate dehydrogenase deficiency, pyruvate carboxylase deficiency, numerous disturbances of the respiratory chain, and Menkes disease. A low CSF lactate value may be seen in the glucose transporter protein deficiency syndrome. Abnormal findings on measurement of CSF biogenic amine and measurement of biopterin metabolism suggest several disorders associated with the hyperphenylalaninemic state.

Tissue biopsy specimens also provide important information in establishing a diagnosis. Specimens of skin, conjunctiva, rectum, peripheral nerve, and skeletal muscle may provide useful clues. Only rarely would a brain biopsy be necessary.

Electroencephalographic abnormalities are frequently helpful in establishing a diagnosis. A suppression-burst pattern is characteristic of nonketotic hyperglycinemia, phenylketonuria, maple syrup urine disease, and molybdenum cofactor deficiency. Distinctive EEG features include the comblike rhythm with 7- to 9-Hz central activity in maple syrup urine disease, vertex positive spikes in sialidosis type I, bioccipital polymorphic delta activity in X-linked adrenoleukodystrophy, and 14- to 22-Hz invariant activity with infantile neuroaxonal dys- trophy.

Structural brain imaging provides important information, although findings are frequently nonspecific. Progressive atrophy is characteristic of NCL. White-matter signal abnormalities are characteristic of metachromatic leukodystrophy, globoid-cell encephalopathy, phenylketonuria, some mitochondrial diseases, Canavan disease, and some organic acidurias. Calcification of the cerebral cortex and basal ganglia is seen with many inherited metabolic diseases. Magnetic resonance spectroscopy

may demonstrate elevated concentrations of lactate in brain tissue in various mitochondrial diseases or elevated concentrations of *N*-acetylaspartic acid in Canavan disease.

Treatment

The treatment of seizures associated with inherited metabolic diseases should focus primarily on the metabolic disturbance whenever possible. For example, seizures associated with a hypoglycemia are correctly treated with administration of glucose to maintain a normal blood glucose concentration. Similarly, seizures associated with hyponatremia, hypocalcemia, or hypomagnesemia respond best to correction of these electrolyte disturbances. Dietary treatment is appropriate for many inherited metabolic diseases, including defects of the urea cycle, defects of fatty acid oxidation, gluconeogenic defects, aminoacidopathies, organic acidurias, and the glucose transporter deficiency syndrome. The ketogenic diet is effective in controlling seizures in patients with the glucose transporter protein deficiency syndrome, and it provides some benefit in the management of patients with pyruvate dehydrogenase deficiency. Phenylketonuria can be well treated with a diet low in phenylalanine. Protein restriction is recommended for defects of the urea cycle, and fat restriction is advised for defects involving fatty acid oxidation. Pyridoxine-dependent epilepsy and other vitamin-responsive syndromes can be cured by early diagnosis and prompt administration of the specific vitamin or cofactor. Enzyme protein replacement has proved to be effective in Gaucher disease. Bone marrow transplantation has been used effectively to treat patients with mucopolysaccharidoses and adrenoleukodystrophy. Conventional antiepileptic drugs are useful adjuncts to these more direct therapeutic interventions but are often ineffective by themselves. Patients with certain inherited metabolic diseases (e.g., defects of fatty acid oxidation) may be less tolerant of some antiepileptic drugs, notably valproic acid, particularly because it interferes with fatty acid oxidation and depletes tissue stores of carnitine.

Summary and Conclusions

Seizures often are part of the clinical picture of inherited metabolic disorders, particularly when these conditions first appear in the neonatal period or during infancy. Why seizures commonly accompany some metabolic diseases and are infrequent in others is incompletely understood, but certain correlations are intuitively obvious. Defects of energy metabolism commonly are associated with seizures—witness the hypoglycemic syndromes and defects involving pyruvate metabolism, the Krebs cycle, and the respiratory chain. In addition, seizures frequently accompany inherited metabolic disorders that affect neurotransmission, such as nonketotic hyperglycinemia and pyridoxine-dependent epilepsy. A more fundamental common mechanism may be operative in many of these conditions. For example, an alteration in the ratio of glutamic acid to GABA may exist in conditions associated with cerebral energy failure and in conditions affecting the GABA shunt. Any inherited metabolic condition in which the extracellular glutamate concentration is elevated and the extracellular GABA concentration is lowered would lower the seizure threshold. Recent studies have confirmed this speculation in cases of symptomatic hypoglycemia, nonketotic hyperglycinemia, and pyridoxine-dependent epilepsy.

In contrast, defects of fatty acid oxidation are less likely to be associated with epilepsy. Fatty acids do not serve as oxidizable fuels for brain metabolism. Brain function is compromised principally when the patient is subjected to fasting and hypoketotic hypoglycemia develops. Under these conditions, the brain is deprived of its two primary fuels—glucose and ketone bodies. Disturbed consciousness and seizures may occur under these circumstances.

All infants and young children seen with unexplained seizures should be evaluated for an inherited metabolic disorder. A positive family history may provide an important clue, and careful studies of blood, urine, and CSF may uncover important diagnostic clues. Primary correction of the metabolic disturbance is the optimal treatment of the associated seizure disorder, even though conventional antiepileptic drugs may blunt the expression of the seizure disorder. In certain situations, antiepileptic drugs are ineffective, as is the case with the glucose transporter protein deficiency syndrome. Providing an alternative fuel source for brain metabolism by placing the patient on a ketogenic diet is effective in controlling seizures in this syndrome, whereas conventional antiepileptic drugs are ineffective.

It can reasonably be assumed that seizures in the neonatal period or infancy have a metabolic basis until it is proved otherwise. Careful study of this patient population will continue to identify novel inherited metabolic disorders and lead to more direct and effective treatments of these conditions.

Chapter 262

Mitochondrial Diseases

Michio Hirano

Wolfram S. Kunz

Salvatore DiMauro

Introduction

Since the initial discovery of mitochondrial DNA mutations in 1988, our understanding of the mitochondrial encephalomyopathies has advanced at an astoundingly rapid pace. Numerous scientific and clinical reports have documented the discoveries, while review articles[19,23] and even several books[20,104] have summarized much of this progress. The purpose of this chapter is not to describe the mitochondrial encephalomyopathies comprehensively, but rather, to illustrate some of the fundamental clinical and scientific themes in these diverse disorders that often manifest epilepsy.

Mitochondria are vital organelles, because they (a) produce energy in the form of adenosine triphosphate (ATP) through oxidative-phosphorylation of carbohydrates, fats, and amino acids,[57,70,128] (b) are essential for intracellular calcium homeostasis,[28] (c) contribute to the synthesis of important metabolic precursors [e.g., uridine,[54] amino acids, and iron-sulfur (Fe-S) clusters[34]], and (d) finally, participate in cell death pathways.[39] Much has been learned about the functions of these organelles, and defects of specific processes provide an elegant and rational biochemical classification system of the mitochondrial diseases (Table 1). A prime example of a specific biochemical defect of mitochondria is carnitine palmityl transferase (CPT) II deficiency.[21] Transport of fatty acids through the mitochondrial membranes is impaired by specific mutations in CPT II. By contrast, mitochondrial respiratory chain disorders often do not conform to single-enzyme defects because multiple enzymes can be affected; therefore, this biochemical classification scheme has limitations.

Molecular genetics provides an alternative perspective of mitochondrial diseases. One can gain a better understanding of mitochondrial disorders by considering the several unique genetic characteristics of mitochondria. Mitochondria are unique mammalian organelles because they possess their own genetic material, mitochondrial DNA (mtDNA), which is a small (16.5 kilobases) circular molecule encoding 13 polypeptides, 22 transfer RNAs (tRNA), and two ribosomal RNAs (rRNA).[4] The mtDNA-encoded polypeptides are vital subunits of the respiratory chain. In addition, more than 1,000 mitochondrial proteins are encoded in the nuclear DNA (nDNA). Because mitochondria are the products of two genomes, defects in either genome can cause mitochondrial dysfunction. To date, most of the respiratory chain defects that have been characterized at the molecular genetic level are due to mtDNA mutations.[19,20,23]

An important principle of mtDNA genetics is *heteroplasmy.* Each mitochondrion contains two to ten copies of mtDNA and, in turn, each cell contains multiple mitochondria; therefore, there are hundreds to thousands of mtDNA molecules in each cell. Alterations of mtDNA may be present in some of the mtDNAs (heteroplasmy) or in all of the molecules (*homoplasmy*). As a consequence of heteroplasmy, the proportion of a deleterious mtDNA mutation can vary widely. An individual who harbors a large proportion of mutant mtDNA will be more severely afflicted by the mitochondrial dysfunction than a person with a low percentage of the same mutation. As a consequence, a given mtDNA mutation can produce a diverse spectrum of clinical severity among patients.

A second factor that can influence the expression of a mtDNA mutation in a person is the *tissue distribution* of that mutation. The best example of tissue distribution variation is offered by large-scale mtDNA deletions. Infants with a high proportion of deleted mtDNA in their blood can develop Pearson syndrome, a sideroblastic anemia often accompanied by exocrine pancreatic dysfunction.[68,92] Presumably, these infants have a high proportion of deleted mtDNA in the bone marrow stem cells. Some children survive the anemia with blood transfusions and subsequently recover, because the stem cells with a high proportion of deleted mtDNA are eliminated through a negative selection bias. Later in life, however, those children may develop the multisystem mitochondrial disorder Kearns-Sayre syndrome (KSS), characterized by ophthalmoplegia, pigmentary retinopathy, and cardiac conduction block.[53,93] Thus, variable tissue distribution broadens the clinical spectrum of pathogenic mtDNA mutations.

The third factor that determines clinical expression of a mtDNA mutation is tissue *threshold effect*. Cells with high metabolic activities are more severely affected by relatively lower levels of mtDNA mutations; therefore, these disorders tend to affect disproportionately the brain and muscles (encephalomyopathies).

A fourth unusual characteristic of mtDNA is *maternal inheritance*. During the formation of the zygote, the mtDNA is derived exclusively from the oocyte. Thus, mtDNA is transmitted vertically in a nonmendelian fashion from the mother to both male and female progeny. A single exception to this rule has been described; a man with exercise intolerance and two base-pair deletions in the mitochondrial-encoded gene for subunit 2 of complex I (nicotinamide adenine dinucleotide [NAD] dehydrogenase 2 [ND2]) showed paternal inheritance of mtDNA in skeletal muscle.[56,108] Because paternal inheritance of mtDNA appears to be exceedingly rare,[29,109,122] maternal inheritance is important to recognize in determining whether a family is likely to harbor a mtDNA mutation. A caveat to this principle is the fact that maternal relatives who have lower percentages of a mtDNA mutation may have fewer symptoms (oligosymptomatic) than the proband, or they may even be asymptomatic. Therefore, in taking the family history, it is important to ask about the presence of subtle symptoms or signs in maternally related family members who might be oligosymptomatic.

Table 1 Biochemical classification of mitochondrial encephalomyopathies

1. **Defects of transport**
   a. CPT deficiency
   b. Carnitine deficiency
   c. Defects of FAD uptake (?)
2. **Defects of substrate utilization**
   a. Pyruvate carboxylase deficiency
   b. Pyruvate dehydrogenase complex deficiency
   c. Defects of β-oxidation
3. **Defects of the Krebs cycle**
   a. Fumarase deficiency
   b. α-Ketoglutarate dehydrogenase (dihydrolipoyl dehydrogenase) deficiency
4. **Defects of oxidation-phosphorylation coupling**
   a. Luft syndrome (loose coupling of muscle mitochondria)
5. **Defects of the respiratory chain**
   a. Complex I deficiency
   b. Complex II deficiency
   c. Complex III deficiency
   d. Complex IV deficiency

e. Complex V deficiency
f. Combined defects of respiratory chain components

From DiMauro S, et al. Mitochondrial encephalomyopathies. *Neurol Clin*. 1990;8:483–506, with permission.

These peculiar features of "mitochondrial genetics" contribute to the clinical complexity of human mitochondrial

disorders. Variable heteroplasmy of mtDNA mutations produces an extensive range of disease severity, whereas tissue distribution and tissue threshold of mtDNA mutations explain the frequent but variable involvement of multiple organ systems.

In addition to mtDNA mutations, nuclear DNA (nDNA) defects can also cause mitochondrial dysfunction. In fact, nDNA encodes most of the components of the respiratory chain and, since 1995, many nDNA mutations associated with defects in oxidative-phosphorylation have been identified.[19,20] In this chapter, we review the major mitochondrial encephalomyopathy syndromes associated with seizures. We will not quote or summarize the vast literature on mitochondrial encephalomyopathies; rather, we will try to convey some of the principles of evaluation, diagnosis, and treatment of these disorders with emphasis on epilepsy.

Clinical Description

The mitochondrial encephalomyopathies comprise a heterogenous group of multisystem disorders that typically affect infants, children, or young adults. Among these diverse conditions, specific clinical syndromes were recognized. Because clinicians are confronted with patients, the clinical classification of the mitochondrial disorders is of pragmatic significance in guiding the diagnostic evaluation, determining prognosis, and in directing therapy. The discovery of distinct mtDNA and nDNA mutations has demonstrated that, in general, clinical phenotypes have specific genotypes; however, some patients do not fit into any clinical syndrome, or they have an atypical presentation for a particular mutation.

Table 2 Seizure incidence in specific mitochondrial encephalomyopathy syndromes

Syndrome	Incidence	Percent	References
MERRF	62/62	100	44
MELAS	97/102	96	43
KSS	5/156	3	44

MERRF, myoclonus epilepsy with ragged-red fibers; MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; KSS, Kearns-Sayre syndrome.

Common to all mitochondrial disorders with prominent epilepsy is involvement of the central nervous system (CNS), particularly the cortex. Imaging techniques have confirmed that gray matter involvement is an early feature of myoclonus epilepsy with ragged-red fibers (MERRF) and of mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS); white matter abnormalities are also seen at later stages, but usually not in isolation.[15] Maternal inheritance is pathognomonic of mtDNA point mutations, whereas patients with single large-scale rearrangements tend to be sporadic. In addition, phenotypic variability in families is the general rule rather than the exception with pathogenic mtDNA point mutations.

Mitochondrial Encephalomyopathies Associated with mtDNA Mutations

Kearns-Sayre Syndrome

Rowland and colleagues defined Kearns-Sayre syndrome (KSS) by the obligate triad of ophthalmoplegia, pigmentary retinopathy, and onset before age 20, with at least one of the following additional features: Cardiac conduction block, ataxia, and cerebrospinal fluid (CSF) levels of greater than 100 mg/dL.[93] The existence of KSS as a clinical entity is supported by the fact that more than 150 patients with these characteristics have been reported.[43] About 90% of the KSS patients have single large-scale rearrangements of the mtDNA, either deletions, duplications, or both.[72,85] Typically, KSS patients are sporadic, because the mtDNA rearrangements seem to originate in oogenesis or early zygote formation. Despite the clear evidence of encephalopathy (dementia, basal ganglia calcifications, and spongy changes of the brain white matter), seizures are uncommon in KSS (5/156 patients) (Table 2).[43]

Myoclonus Epilepsy with Ragged-Red Fibers Syndrome

In contrast to KSS, MERRF includes epilepsy as a defining clinical feature. In addition, these patients have myoclonus, ataxia, and ragged-red fibers in the muscle biopsy.[32] Other common clinical manifestations associated with MERRF are hearing loss, dementia, peripheral neuropathy, short stature, exercise intolerance, lipomas, and lactic acidosis.[118] The majority of MERRF patients have a history of affected maternally related family members, although not all have the full syndrome.

In 1990, Shoffner et al. identified a mtDNA A-to-G transition mutation at nucleotide (nt) 8344 of the $tRNA^{Lys}$ gene[113]; that mutation has been found in about 90% of MERRF patients tested.[118] This mutation was the first molecular genetic defect to be associated with a hereditary epilepsy syndrome. A second mutation in the same gene at nt-8356 was identified in a pedigree with typical MERRF[117] and in another family with overlap features of MERRF and MELAS.[134] In addition, a mutation at nt-611 in the $tRNA^{Phe}$ gene has

P.2623

been also associated with MERRF.[63] Within families with a MERRF proband, oligosymptomatic and asymptomatic members harbor the same mtDNA mutation, but the phenotype is presumably attenuated by heteroplasmy and tissue distribution of the mtDNA mutation.[118]

Table 3 MtDNA mutations associated with epilepsy

Table 4 Mitochondrial encephalomyopathies with epilepsy due to nuclear DNA mutations

Biochemical defect	Clinical phenotype	Defective gene or gene product
1. *Mutations in genes encoding structural subunits of respiratory chain enzymes*		
Complex I deficiency	Encephalomyopathy or Leigh syndrome	*NDUFS1, NDUFS2, NDUFS3, NDUFS4, NDUFS6, NDUFS7, NDUFS8, NDUFV1, NDUFV2*
Complex II deficiency	Leigh syndrome	Flavoprotein subunit of SDH
2. *Mutations in genes encoding assembly factors for respiratory chain enzymes*		
Complex I deficiency	Encephalopathy	*B17.2*
Complex III deficiency	Encephalopathy, tubulopathy, and hepatopathy	*BCS1L*
Complex IV deficiency	Leigh syndrome	*SURF1*
	Infantile cardioencephalopathy	*SCO2*
	Infantile encephalopathy	*SCO1, COX10*
3. *Defects of intergenomic communication*		
Autosomal recessive	MNGIE	Thymidine phosphorylase
	arPEO	*POLG1*
	ARCO	Unknown

PEO with multiple Δ-mtDNA		
Autosomal dominant PEO with multiple Δ-mtDNA	adPEO	*ANT1*, Twinkle, *POLG1*
MtDNA depletion	Infantile encephalopathy and hepatopathy	dGK
	Alpers disease	*POLG1*
	Infantile encephalomyopathy	ADP-forming succinyl-CoA synthase
4. *Defects of the mitochondrial membrane*		
Coenzyme Q10 deficiency	Myoglobinuria, encephalopathy, ragged-red fibers	Unknown
	Cerebellar ataxia	Unknown
	Infantile encephalomyopathy nephropathy	COQ2

Mitochondrial Encephalomyopathy, Lactic Acidosis, and Stroke-like Episodes Syndrome

MELAS is another maternally inherited disorder whose defining clinical features include (a) stroke-like episodes at a young age (typically before age 40); (b) encephalopathy manifest as seizures, dementia, or both; and (c) mitochondrial dysfunction with lactic acidosis, ragged-red fibers, or both.[44,82] Other commonly encountered manifestations include normal early development, migraine headaches, myopathic weakness, exercise intolerance, myoclonus, ataxia, short stature, and hearing loss.[44,82] It is uncommon for more than one family member to have the full MELAS syndrome; in most pedigrees, there is only one MELAS patient with oligosymptomatic or asymptomatic relatives in the maternal lineage.

Other Mitochondrial Encephalomyopathies with Epilepsy Caused by mtDNA Point Mutations

In addition to the three aforementioned common and well-defined phenotypes of mitochondrial diseases, several other epilepsy syndromes have been associated with point mutations of mtDNA (Table 3). These mutations reside predominantly in mitochondrial tRNA genes.[50,64,78,86,99,106,114,115,125] Although less common, mutations in polypeptide-coding mitochondrial genes have also been reported in patients with epilepsy.[11,13,17,65,75,124,130] Some of these mutations are associated with multisystem disorders such as maternally inherited Leigh syndrome (MILS),[17,115] neuropathy ataxia retinitis pigmentosa (NARP),[13] or Leber hereditary optic neuropathy

(LHON).[11] In addition to epilepsy, other common manifestations include dementia, cardiomyopathy (typically hypertrophic) skeletal myopathy, and hearing loss.[99,120]

Mitochondrial Encephalomyopathies Associated with Nuclear Mutations

Leigh Syndrome

Subacute necrotizing encephalomyelopathy was originally described in 1951 by Dr. Denis Leigh, who reported a 6.5-month-old infant presenting with developmental regression that progressed quickly and led to death 6 weeks later.[61] At autopsy, Dr. Leigh observed multiple symmetric foci of spongy degeneration with microvascular proliferation in the brainstem tegmentum, thalami, cerebellum, posterior columns of the spinal cord, and optic nerves. He astutely noted that the neuropathologic alterations resembled those of Wernicke syndrome but spared the mamillary bodies, a consistent feature that distinguishes the two disorders.

The clinical presentations of Leigh syndrome (LS) are heterogeneous, due to variations in age-at-onset, rates of progression, frequency of epilepsy, and presence or absence of pigmentary retinopathy. The onset is often acute and may coincide with a febrile illness or may follow a seizure. Most LS patients present in infancy with psychomotor regression, whereas some present in childhood or adolescence. Adult-onset LS is uncommon. In infants with LS, in addition to developmental regression, generalized hypotonia, feeding problems, progressive vision loss due to optic neuropathy or pigmentary retinopathy, progressive external ophthalmoplegia, hearing loss, nystagmus, ataxia, and seizures are typical manifestations. In addition, failure to thrive, dysarthria, vomiting, and diarrhea are common manifestations. Respiratory dysfunction is often prominent and frequently causes death. Most infantile-onset LS patients die before age 2 years. In older infants or young children, LS may begin with ataxia, dystonia, or intellectual decline.

The clinical diagnosis of LS is usually made by brain magnetic resonance imaging (MRI) scans, which reveal increased signals in the basal ganglia and brainstem on T2-weighted or FLAIR images. The lesions are typically symmetric and commonly affect the putamen, globus pallidus, caudate, thalami, substantia nigra, inferior olivary nuclei, periaqueductal gray matter, and brainstem tegmentum. Magnetic resonance spectroscopy (MRS) scans reveal decreased N-acetylaspartate and increased lactate in the affected brain regions.

The causes of LS are biochemically heterogeneous and, to an even greater extent, genetically diverse (Table 4). LS has been associated with defects of pyruvate carboxylase, pyruvate dehydrogenase complex (PDHC), and mitochondrial respiratory chain complexes I, II, IV, and V.[10,98,126,129,135] The inheritance pattern depends on the specific mutated gene, but may

be autosomal recessive, X-linked recessive, or, as previously mentioned, maternally inherited.

Alpers Syndrome

Alpers or Alpers-Huttenlocher syndrome was reported in 1931 by Bernard Alpers, who described a previously healthy 3-month-old girl, who developed intractable seizures, blindness, and became stuporous before dying at age 4 months.[3] Neuropathology revealed widespread degeneration of the cortex and basal ganglia. Huttenlocher et al. described the pathologic findings in liver, which included microvesicular steatosis, proliferation of bile ducts, and cirrhosis.[48] Clinically, Alpers syndrome is characterized by autosomal recessive inheritance, normal early development, episodic neurodegeneration with psychomotor regression, seizures that become intractable, and hepatopathy. The occipital lobe is frequently affected, leading to cortical blindness. Onset is usually in infancy or childhood, but can be as late as 25 years. In patients with Alpers disease, valproic acid should be avoided because this drug can precipitate fulminant hepatopathy.

Ultrastructurally abnormal mitochondria in cerebral neurons suggested that the disease might be a mitochondrial encephalomyopathy[97]; this notion was confirmed by the identification of mtDNA depletion in association with pathogenic mutations in the gene encoding the catalytic subunit of mitochondrial DNA polymerase-γ (*POLG1*).[77]

Coenzyme Q_{10} Deficiency

Coenzyme Q_{10} (CoQ_{10}) is a small lipophilic molecule located in the inner mitochondrial membrane and composed of a quinone group and a poly-isoprenoid tail.[127] CoQ_{10} transfers reducing equivalents from complexes I and II to complex III. Deficiency of CoQ_{10} in skeletal muscle has been associated with four major phenotypes. A predominantly myopathic form is characterized by the triad of recurrent myoglobinuria, ragged-red fibers, and encephalopathy with seizures, ataxia, or mild mental retardation.[81] A more common ataxic form presents with cerebellar ataxia and atrophy with variable involvement of the peripheral nerves, muscle, and other CNS functions.[59,74] The third variant is a rare infantile encephalomyopathy with nephropathy.[92,96] Finally, a pure myopathic variant without epilepsy exists.[58] Presumably, all the CoQ_{10} deficiencies are due to defects of biosynthesis. The first mutation directly affecting CoQ_{10} biosynthesis was identified in a pair of siblings with the infantile form; the homozygous missense mutation resides in the *COQ2* gene, which encodes *para*-hydroxybenzoate-polyprenyl transferase.[87] It is important for clinicians to recognize patients with CoQ_{10} deficiency because the syndrome responds dramatically to CoQ_{10} supplementation (150–3,000 mg daily in adult patients).

Epileptic Seizures

Seizures are a common manifestation of mitochondrial encephalomyopathies (Table 2). As with other clinical features, the frequency and severity of seizures varies with the syndrome and even among affected individuals within a family with a single mtDNA point mutation.

Kearns-Sayre Syndrome

Seizures have been rarely described in KSS. Of 156 reported patients, only five (3%) were noted to have seizures and, in four of these, epilepsy was attributed to electrolyte imbalance secondary to hypoparathyroidism.[43] The infrequency of epileptic seizures in KSS illustrates an important clinical point; although seizures are a common feature of MELAS and a defining symptom of MERRF, their relative absence in KSS reinforces the concept that distinct clinical syndromes do exist although overlap features sometimes occur. It is very likely that the spatial distribution of the mitochondrial defect in the CNS is the responsible factor that determines the association of certain mtDNA mutations with epilepsy.[56,123] This seems to be in line with the fact that KSS is a white matter disorder affecting preferentially brainstem tegmentum, white matter of cerebellum and cerebrum, cervical spinal cord, basal ganglia, and diencephalon,[56] which are brain areas with low epileptogenicity.

Myoclonus Epilepsy with Ragged-Red Fibers

Myoclonus epilepsy with ataxia comprises a classical neurologic triad originally described by Ramsey Hunt as *dyssynergia cerebellaris myoclonica*.[47] We now label idiopathic cases of that triad as Ramsey Hunt syndrome, which is one form of progressive myoclonus epilepsy (PME).[6] PME syndromes include a well-characterized set of disorders that are described earlier in this volume. Since 1980, when Fukuhara et al.[32] first defined MERRF, this syndrome has been increasingly recognized as a major form of PME.

Symptoms and signs in isolated MERRF patients may be clinically indistinguishable from other PME disorders such as Unverricht-Lundborg disease and Lafora body disease. The myoclonus typically affects limbs, and can be severe enough to interfere with normal voluntary functions such as writing, speaking, or walking.[7,32,91] The myoclonus can be virtually constant,[91] but is usually spontaneous and intermittent, and it may be photosensitive.[60] In one unusual patient, the myoclonus correlated with EEG spikes: Both manifestations were seen with eyes closed and disappeared when the patient opened her eyes.[33]

Patients with MERRF typically have generalized tonic–clonic seizures, which are responsive to conventional antiepileptic therapy. Focal clonic and akinetic seizures have been reported.[7,60] Visual or somatosensory auras may precede the generalized seizures.[7] Both myoclonus and seizures may be precipitated by photic stimulation, such as watching television.[33,91]

Mitochondrial Encephalomyopathy, Lactic Acidosis, and Stroke-Like Episodes

Patients with MELAS frequently manifest seizures, myoclonus, and ataxia; therefore, they may closely resemble individuals with MERRF. In a review of 110 reported MELAS patients, myoclonus was noted in 38% (23/72), seizures in 96% (97/102), and ataxia in 33% (23/70)[44]; however, stroke is the distinguishing clinical feature of MELAS.

Seizures are extremely common in MELAS patients and are not infrequently the initial clinical manifestation (28% in one series).[44] The seizures are sometimes associated with stroke-like episodes. It is possible that the increased metabolic demands imposed by the seizures provoke some MELAS strokes, and it is likely that the cerebral lesions cause the seizures, thus establishing a vicious cycle. Sometimes, febrile episodes accompany the seizures, raising the hypothetical possibility that the added metabolic stress of the febrile illness can precipitate seizures.

Information about seizures was available in 42 of the 110 reported MELAS patients we identified.[44] Of those patients, 26 had both generalized and partial seizures, and 10 had generalized epilepsy (including one patient with absence seizures).[22,31,46,49,66,67,80,103]

P.2626

Partial seizures were predominantly motor, (21 patients), and, less commonly, visual (six patients), temporal (three patients), auditory (one patient), or sensory (one patient).[22,31,46] At least six individuals developed status epilepticus.[22] Myoclonus is generally less common and less severe in MELAS patients than in MERRF patients.[44]

Other Mitochondrial Encephalomyopathies with Epilepsy Due to mtDNA Point Mutations

In addition to the common clinically delineated mitochondrial conditions, atypical or overlap encephalomyopathy syndromes with epilepsy—atypical MELAS, atypical MERRF, MELAS/MERRF, or MERRF/KSS—have been reported in association with mutations in genes encoding $tRNA^{Ser}$,[86] $tRNA^{Leu}$,[78] $tRNA^{Lys}$,[125] $tRNA^{Asp}$,[115] $tRNA^{His}$,[123] and the polypeptides ND3[124] and ND5.[75] Epileptic seizures have been also described in patients harboring mtDNA mutations that typically cause clinical syndromes without epilepsy, such as LHON.[11] Although more frequently caused by nDNA mutations, LS can be a manifestation of mtDNA point mutations[13,17,115] and is often associated with epilepsy. Furthermore, mitochondrial encephalomyopathies with recurrent episodes of epilepsia partialis continua have been linked to mutations in $tRNA^{Ser}$ genes[50,106] and subunit 1 of cytochrome C oxidase (COX) (CO1).[130]

Mitochondrial Encephalomyopathies Associated with Nuclear Mutations

Leigh Syndrome

Seizures are common in LS, but are particularly frequent in patients with MILS due to the T8993G or T8993C NARP mutations or with PDHC deficiency.[98] In contrast, seizures are less prominent in LS due to COX deficiency.

Alpers Syndrome

In Alpers syndrome, seizures are a clinical hallmark and include simple and complex partial, generalized tonic–clonic, epilepsia partialis continua, and status epilepticus. The seizures typically become intractable. EEGs often reveal very slow activity (≤1 Hz) of high-amplitude (0.2–1 mV) with polyspikes of lower amplitude.[41] In patients with this condition, valproic acid should be avoided because this drug can precipitate fulminant hepatopathy.

Coenzyme Q_{10} Deficiency

Seizures have been observed in three of the four clinical phenotypes associated CoQ_{10} deficiency: The predominantly myopathic form, the ataxic form, and the infantile encephalomyopathy with nephropathy.[59,74,81,92,96] Although detailed descriptions of the epileptic syndromes in CoQ_{10} deficiency are lacking, complex partial and generalized seizures have improved with oral CoQ10 supplementation.[18,74,96]

Diagnostic Investigation

Clinical Issues

As with any patient with a neurologic disorder, one must begin with the clinical evaluation. These disorders are typically multisystemic and clinically variable. The wide clinical diversity provides diagnostic challenges even for experienced neurologists. In obtaining the medical history of patients suspected to have a mitochondrial encephalomyopathy, clinicians should inquire about the following clinical features: Normal infancy and early development, premature exercise-induced fatigue, migraine headaches, diabetes mellitus, short stature, and hearing loss. Multiple lipomas are not uncommon in MERRF syndrome and hypoparathyroidism in KSS. Family history is important, but may be very subtle when dealing with a mtDNA point mutation. For example, in families with MELAS syndrome, relatives in the maternal lineage may have migraine-like headaches or diabetes mellitus as the only manifestation of the genetic defect.

A careful physical examination may reveal subtle clues to the correct diagnosis. Patients are often short and thin. Multiple lipomatosis can be disfiguring in patients with MERRF or in their maternal relatives.[7] Dementia can be a prominent finding in KSS, MELAS, and MERRF.[43] Cranial nerve functions may be impaired and affect particularly extraocular muscles, with ptosis and progressive external ophthalmoplegia (PEO), which are necessary to diagnose KSS, but are sometimes seen in MELAS patients. Funduscopy may reveal pigmentary retinopathy in KSS and, less commonly, in MELAS and MERRF. Optic atrophy is sometimes detected in MERRF patients. Peripheral neuropathy is frequent in MERRF and MELAS. Sensorineural hearing loss is common in many mitochondrial encephalomyopathies.

Clinical Laboratory Tests

The laboratory evaluation should begin with routine blood tests, including complete blood count, serum electrolytes (including calcium and phosphate), liver function tests, blood urea nitrogen, creatinine, lactate, and pyruvate. These tests may reveal parathyroid, kidney, or liver dysfunction. Lactate and pyruvate at rest are commonly elevated in patients with mitochondrial encephalomyopathies, and these values may increase dramatically after moderate exercise.

Electrocardiograms may reveal preexcitation in MELAS or MERRF, and heart block in KSS or MELAS. Lumbar puncture may show elevated CSF protein, especially in KSS patients, in whom it is often greater than 100 mg/dL. CSF may also reveal elevated lactate and pyruvate levels. Electromyography and nerve conduction studies are typically consistent with a myogenic process, although neurogenic changes may be detected in MERRF or MELAS. Brain imaging with CT or MRI scans may reveal basal ganglia calcifications and atrophy in all three major syndromes. In MELAS patients, neuroimaging often reveals lesions compatible with strokes that typically affect the posterior cerebrum and generally do not conform to the distribution of major arteries.[1,2,67]

Electroencephalogram findings are usually not specific. Of 27 MELAS patients with seizures, EEG demonstrated diffuse slowing in 20 individuals and focal slowing in seven; epileptic activity was diffuse in 12 patients and focal in 15.[22] One MELAS patient had clinical and radiologic evidence of a left occipital stroke and a normal EEG.[67]

In 62 reported MERRF patients, we were able to identify descriptions of 32 EEGs; all were considered ab-normal.[7,9,25,27,30,32,33,44,60,62,76,84,89,90,91,110,118,119,132] Although details of the EEGs were not available in all cases, 13 showed slowing (12 generalized, one focal and generalized) and 14 revealed epileptiform activity

(12 generalized, one focal, one bitemporal). Photic stimulation was elicited in seven of nine MERRF patients, whereas hyperventilation produced epileptiform activity in one of three patients. The relationship of myoclonus and EEG discharges was unclear in several

cases.[119] As in other forms of progressive myoclonus epilepsy, somatosensory evoked responses typically reveal giant cortical evoked responses.[119]

Special Laboratory Tests

Clinical research has contributed greatly to our understanding of mitochondrial disorders and to our diagnostic capabilities. Specialized evaluation for oxidative-phosphorylation defects has evolved from laboratory research and includes histology (particularly skeletal muscle), measurement of oxidative-phosphorylation enzyme activities, and molecular genetic analyses.

Histology

Histology has focused on skeletal muscle, but mitochondrial changes have been noted in other tissues. In the mid-1960s, Shy, Gonatas, and Perez described the typical ultrastructural alterations seen in mitochondrial myopathies.[116] These changes include (a) an overabundance of ultrastructurally normal mitochondria ("pleoconial myopathy"), (b) enlarged mitochondria with disoriented cristae ("megaconial myopathy"), and (c) "paracrystalline" and "osmiophilic" inclusions within mitochondria.[116] Engel and Cunningham developed a modified Gomori trichrome stain,[24] which has been commonly used to identify fibers with subsarcolemmal accumulations of mitochondria, which are commonly referred to as "ragged-red fibers."

Histochemical stains for mitochondrial enzymes are also used to identify excessive mitochondrial proliferation and to demonstrate specific enzyme defects. These stains include succinate dehydrogenase (SDH), nicotinamide dehydrogenase-tetrazolium reductase (NADH-TR), and cytochrome *c* oxidase (COX). Immunohistochemical techniques are used to identify defects in specific mitochondrial polypeptides.

In KSS, MELAS, and MERRF, RRF with ultrastructurally abnormal mitochondria are almost always identified in skeletal muscle by the Gomori trichrome stain. SDH histochemistry reveals mitochondrial proliferation as hyperintense staining in subsarcolemmal regions of muscle fibers. In MELAS patients, excessive SDH staining often occurs within blood vessel walls, so-called strongly SDH-reactive vessels or SSVs.[42,94] Another characteristic of skeletal muscle from MELAS patients is the relative preservation of COX staining in RRF, in contrast to muscle from KSS and MERRF, which generally shows an abundance of COX-negative RRF on serial or double-stained (SDH and COX) sections. Nevertheless, histologic abnormalities in skeletal muscle biopsies are absent in some patients with MERRF[113] or other mitochondrial disorders.[45,46]

Unfortunately for clinicians, the histologic abnormalities described are neither specific nor sensitive enough to define all mitochondrial diseases. Morphologically abnormal muscle mitochondria have been detected in many conditions that are not primary oxidative-phosphorylation defects, for example, inflammatory myopathies[14] and myotonic dystrophy.[26] Conversely, some conditions with defects of respiratory chain enzymes do not have morphologically abnormal mitochondria, including LHON, LS, and Alpers syndrome.

Biochemistry (Enzyme Assays)

Activities of mitochondrial respiratory chain enzymes can be measured in vitro using crude extracts or isolated mitochondria. In KSS, MELAS, and MERRF, one can detect various combinations of respiratory chain enzyme deficiencies; however, the pattern is often not consistent, and normal enzyme activities have been reported. Factors influencing the activities of mitochondrial respiratory chain enzymes are the degree of heteroplasmy[37] and the distribution pattern of the mutation within the skeletal muscle biopsy sample.[38]

Molecular Genetics

Since the initial discoveries of the first mtDNA point mutation and large-scale deletions in 1988,[45,131,133] there has been an outburst of information relating molecular genetic defects to human disorders. Numerous mtDNA mutations have been identified including duplications, depletion, single and multiple deletions, and more than 100 pathogenic point mutations.[19,20,23]

Holt et al. first identified large-scale mtDNA deletions in mitochondrial myopathy patients[45] and, soon thereafter, Zeviani et al. pointed out the specific association with KSS.[133] Approximately 90% of KSS patients have large-scale mtDNA deletions, duplications, or both.[72,85] The mtDNA deletions generally range from about 2.0 to 10.4 kb in length,[45,72] and are mainly confined to an 11-kb region that does not include the origins of mtDNA replication or mtDNA promoter regions. About one-third of the mtDNA deletions involve an identical 4,977 base pair (bp) segment, which is often referred to as the "common deletion."[72] The majority of the mtDNA deletions are flanked by direct DNA sequence repeats, which suggests that they may originate from homologous recombination events.[45,51,69,105,112] The large-scale mtDNA deletions are often undetectable in leukocytes, so that molecular diagnosis requires muscle biopsy.

MERRF was the first multisystemic disorder to be associated with a mtDNA point mutation, specifically, A8344G in the transfer RNA lysine ($tRNA^{Lys}$) gene.[113] A second $tRNA^{\mathrm{Lys}}$ mutation at nt-8356 was associated with both MERRF and MERRF-MELAS phenotypes,[117,134] and a $tRNA^{\mathrm{Phe}}$ mutation at nt-611 has been associated with MERRF.[86] These point mutations can be easily identified in blood leukocytes from patients.

MELAS was also associated with a specific mtDNA point mutation, an adenine-to-guanine transition in the $tRNA^{Leu(UUR)}$ gene at nt3243 (A3243G). About 80% to 90% of MELAS patients have been found to harbor this mutation. Fifteen other mtDNA mutations have been identified in patients with MELAS, and a large number of other mtDNA point mutations have been associated with epilepsy (Table 3). As in MERRF, blood leukocytes can be screened for epilepsy-associated mtDNA point mutations.

Although the identification of mtDNA mutations has simplified diagnosis in most cases of mitochondrial encephalomyopathies, it has created new dilemmas. Genetic counseling of patients and their maternal relatives is difficult because heteroplasmy and variability of mutation loads in different tissues make clinical outcome predictions tenuous. Similarly, prenatal diagnosis is also perilous. The molecular genetic information should be handled carefully, because it can adversely affect medical insurability, employment opportunities, and the emotional status of patients.

Treatment

The medical management of mitochondrial myopathy has lagged behind research and diagnostic knowledge. Treatment can be divided into two types: Symptom management and metabolic therapy.

Symptom Management

Seizures in MERRF and MELAS typically respond to conventional antiepilepsy drugs[119]; however, they may be difficult to

control in the setting of metabolic disarray. There have been reports that valproate therapy can cause adverse effects in certain patients with mitochondrial encephalomyopathies and particularly in individuals with Alpers syndrome.[8,107] The electrolyte disturbances related to hypoparathyroidism and diabetes mellitus should be corrected. Thyroid hormone replacement will alleviate the hypothyroidism. Cardiac pacemaker placement can prolong life in KSS patients with cardiac conduction defects.

Metabolic Therapy

Treatments aimed at the primary biochemical defects in mitochondrial encephalomyopathies have been tried; however, the evidence of efficacy has been anecdotal. We generally recommend CoQ_{10}, 50 to 200 mg t.i.d. and L-carnitine, 1,000 mg t.i.d. Idebenone, a related quinone, has also been administered to patients and has the theoretical advantage of better crossing the blood–brain barrier.

Dichloroacetate, a lactate-lowering agent, was shown to cause or exacerbate peripheral neuropathy, which overshadowed potential benefit in a randomized double-blind placebo-controlled trial in MELAS patients.[52]

Vitamins that may donate electrons directly to COX include phylloquinone (vitamin K_1), menadione (vitamin K_3), and ascorbic acid (vitamin C).[111] Vitamin C has also been used as an antioxidant because the impaired oxidative-phosphorylation pathway may generate increased amounts of free radicals. Nicotinamide and riboflavin have been used to improve electron chain functions.[83]

In cultured human cells, ketone body treatment reduced the amount of deleted mtDNA.[101] This finding, coupled with the fact that ketogenic treatment has been effective in children with intractable epilepsy,[55] suggests that a ketogenic diet may be an effective treatment for patients with heteroplasmic mtDNA mutations and seizure disorders, but clinical trials have not yet been conducted to demonstrate safety and clinical efficacy.

Summary and Conclusions

Since the seminal publications of the first pathogenic human mtDNA mutations in 1988, the field of mitochondrial encephalomyopathies has expanded at a rapid rate. Molecular genetic research has led the way through the identification of numerous mutations including more than 100 different mtDNA point mutations, numerous single mtDNA large-scale deletions and duplications, multiple mtDNA deletions, mtDNA depletion, and a growing number of nuclear DNA mutations. Seizures are common manifestations, and the first epilepsy syndrome to be defined at the molecular genetic level was MERRF.[113] Modern histology with histochemistry, immunohistochemistry, and ultrastructural analysis has provided further insight into the pathogenesis of these disorders. Correlations of genotypes and phenotypes revealed general relationships between specific mutations and clinical syndromes; however, we learned that there can be wide variability of the clinical manifestations of a given mtDNA mutation. Due to this clinical complexity, neurologists must carefully evaluate patients with suspected mitochondrial encephalomyopathies to reach the correct diagnosis. Genetic counseling is important, but is imprecise in families with heteroplasmic mtDNA point mutations. Treatment is primarily symptomatic, and seizures are generally amenable to conventional antiepileptic agents. Clearly, there is a large gap in our understanding of how the mtDNA defects lead to human disease; however, as our knowledge expands, more rational and specific therapies may develop.

Chapter 263

Cerebral Palsy

John B. P. Stephenson

Introduction

Understanding epilepsy is a necessary part of the management of individuals with cerebral palsy.[45] Epilepsy is common in all types of cerebral palsy and, in some varieties, it is the rule.

Definitions

The definitions of *epileptic seizures, symptomatic epileptic seizures*, and *epilepsy* are the same as those used in other chapters throughout this book. The definition of *cerebral palsy* (CP) is a little more difficult, insofar as some variation occurs in the way in which the term is used between different authors and different studies. The most frequent definition of *cerebral palsy* is "a disorder of posture and movement due to a static lesion of the developing brain." Most authors include cerebral malformations as examples of static lesions of the brain but, in at least one study, cerebral malformations were excluded.[20] Many authors include the aftereffects of acute cerebral insults and injuries in infancy and even in early childhood, whereas others would exclude from the CP definition any condition presumed not to have been present before the age of 4 weeks.[20] There is considerable force in the argument for limiting the definition of cerebral palsy in this way, insofar as the prognosis with respect to epilepsy differs between those whose brain lesion is of perinatal or prenatal origin and those children with unequivocally postnatal cerebral insults.

A new definition of cerebral palsy was proposed in 2005[5]: "Cerebral palsy (CP) describes a group of disorders of the development of movement and posture, causing activity limitation, that are attributed to nonprogressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of cerebral palsy are often accompanied by disturbances of sensation, cognition, communication, perception, and/or behavior, and/or by a seizure disorder." From the point of view of this chapter, it is disappointing to see the term "seizure disorder" employed. This sloppy and ambiguous term deserves to be deleted from scientific discourse.[38]

Authors have exhibited some variability on the definition of the various subtypes of CP but, on the whole, these differences in classification do not materially affect the understanding of epilepsy in the context of CP. The main divisions in the Edinburgh classification were[23]: (a) hemiplegia, (b) bilateral hemiplegia, (c) diplegia (which might vary from virtually paraplegic to tetraplegic), (d) ataxic CP (including ataxic diplegia and ataxia), (e) dyskinesia (including dystonia and athetosis), and (f) any other form of CP, including mixed forms. Many authors now include ataxic diplegia within the diplegia categories. Certainly, for the purposes of discussion of epilepsy, dystonic CP should be strongly distinguished from athetoid CP, insofar as the liability to epilepsy may be high in the former and low in the latter type. The group described by the Edinburgh School as bilateral hemiplegia will have severe mental retardation, as discussed in the section Risk Factors for Epilepsy.[13]

Recent studies[31,37] of the etiology of CP (with or without epilepsy) have shown a much higher diagnostic yield than was thought likely in the past. This should make one wary of the CP label without firm foundation.

Problems in Diagnosis of Cerebral Palsy

Many conditions can masquerade as cerebral palsy but turn out to be something else.[21,40] Most such conditions are individually rare, but parents do not commonly judge the rarity of a condition as a justification for pediatricians or neurologists to make an incorrect diagnosis. Fortunately for the present issue, cerebral palsy imitators complicated by epilepsy or epileptiform attacks are few. Pelizaeus-Merzbacher disease is one such confusing condition.[6] One might argue that this is actually an example of cerebral palsy but, of course, the important point is that it is an X-linked disorder and may recur in a future male child.

Another condition with an unequivocally progressive cerebral pathology is the Aicardi-Goutières syndrome.[39] Affected children may behave much like patients with cerebral palsy without regression.[39] Confirmation of the diagnosis of Aicardi-Goutières syndrome depends on finding elevated cerebrospinal fluid (CSF) and serum α-interferon in the absence of any congenital viral infection.

Another confusing condition is hyperekplexia[47] in which affected neonates may be very stiff and troubled by severe nonepileptic convulsions. When a family history of dominantly inherited startle disease is present, the diagnosis presents no difficulty, but in sporadic cases it can be difficult.

Rare, potentially treatable inborn errors of metabolism leading to cerebral palsy and epilepsy have been described. These include defective serine biosynthesis[24] deficiency,[4] and GAMT deficiency.[28a]

New conditions will continue to be recognized, and it behooves the child neurologist to question the diagnosis in every patient with “cerebral palsy.” This is particularly so in so-called *ataxic cerebral palsy*, which some have suggested should not be called cerebral palsy at all,[26] insofar as genetic etiologies abound.

Problems in Epilepsy Diagnosis

Having cerebral palsy is no insurance against exhibiting or suffering from the various nonepileptic attacks that may affect the general population.[38] We suspect that children with cerebral palsy are more at risk of having epilepsy misdiagnosed in this way because epilepsy is common in cerebral palsy and so expected to be seen. For example, a young child with spastic diplegia may have what we term *reflex anoxic seizures*[38] after falling over and bumping his head just like anyone else who is similarly genetically predisposed. In addition, patients

P.2632

with cerebral palsy may have a predilection for various movements having a superficial resemblance to epileptic seizures. In all these situations, keen clinical judgment must be used. The interictal electroencephalogram (EEG) cannot be relied on to assist in the differential diagnosis. Although it has been attested that spikes or epileptiform discharges are more common in children with cerebral palsy who have epileptic seizures, cerebral palsy individuals who have never had epileptic seizures may not uncommonly show spike discharges also.[35] When an individual with cerebral palsy has had one or more previous epileptic seizures, it is even less rational to expect that an EEG examination will help to diagnose a new unexplained paroxysmal event.[38] On the other side of the coin, those with startle epilepsy[36] may not show spikes at all in the ictal EEG; however, such individuals always have other epileptic seizures without the startle provocation.[28]

Nonepileptic Paroxysmal Disorders in Sleep

It is particularly important not to mistake nonepileptic paroxysmal phenomena associated with sleep for epileptic seizures. Repetitive sleep starts are serial, sleep-related nonepileptic jerks or spasms that may occur in young neurologically impaired children.[16] As these children may *also* have epilepsy,[16] the recognition of these nonepileptic sleep starts is necessary to avoid needless increases in antiepileptic therapy.

Second, because of their cerebral palsy, affected individuals may have obstructive sleep apnea with tonic nonepileptic seizures, easily misdiagnosed as the expected nocturnal epileptic seizures.[3]

In both these clinical situations polygraphy during sleep may be necessary, recording EEG, electrocardiogram (ECG), respiration, and electromyogram (EMG).[3,16]

Anoxic-Epileptic Seizures: Epileptic Seizures Induced by Syncope

Epileptic seizures induced by syncopes—what we call anoxic-epileptic seizures—may not be rare in children.[22]

When this occurs in cerebral palsy, diagnosis may be exceptionally difficult. A recent report describes a boy with Cornelia de Lange syndrome diagnosed as having symptomatic epilepsy until it was realized that his clonic and hemi-clonic epileptic seizures—including status epilepticus—were always triggered by obstructive apnea[29] and ceased without the need for antiepileptic medication once recurrent upper airways obstruction was prevented.[29]

Problems in Combined Cerebral Palsy and Epilepsy Diagnosis

The Special Case of Glucose Transporter Deficiency

It has become apparent that one of the most important etiologies of "cerebral palsy" and epilepsy or "epilepsy" is the genetic disorder of glucose transport now known as GLUT-1 deficiency syndrome or GLUT1DS.[46] The importance lies not in the frequency of this disorder but in its potential treatment by ketogenic diet, albeit such treatment is not universally successful.[25] Affected individuals mostly—but not always[34]—have epilepsy, and many have a motor disorder that could be described as cerebral palsy. Presumed nonepileptic movement disorders and other paroxysmal events are also seen.[46] Insofar as the ketogenic diet is potentially useful for the treatment of these various phenomena, clinicians should consider this disorder early and make careful simultaneous measurements of fasting blood and CSF glucose when in doubt.[46]

Risk Factors for Epilepsy

The early studies of Ellenberg and Nelson[14] indicated that knowledge of the etiology of epilepsy not associated with cerebral palsy was very limited. A number of later studies have addressed such a question in various ways.

Goulden et al.[20] studied a cohort of mentally retarded individuals born in Aberdeen, Scotland, between 1951 and 1955. By 22 years, 15% of these had epilepsy. With their definition of *cerebral palsy* as "having a presumed prenatal or perinatal onset," the cumulative risk for epilepsy was 28%, 31%, and 38% at 5, 10, and 22 years of age, respectively. This compared with a much lower risk for individuals with mental retardation and no associated disabilities, and a much higher risk of epilepsy in those with postnatal brain injury (defined as a significant brain insult after 28 days of life which might reasonably account for the child's later functioning). This particular study included a separate group with cerebral malformations but, in fact, the only malformation determined was described as an occipital meningocele.

A careful Italian study[9] focused on the risk factors for the co-occurrence of partial epilepsy, cerebral palsy, and mental retardation. In a studied population of 64 children with these three conditions, neuroimaging identified 32 with cerebral malformations and 32 without but with encephalomalacia, periventricular leukomalacia, or diffuse atrophy. These two groups were compared with a much larger population of normal children. The definitions in this study were as follows:

Partial epilepsy met the International League Against Epilepsy (ILAE) criteria. Such seizures had to have begun in the first 3 years of life. Apparently generalized seizures at onset did not exclude a child if persistent partial motor or complex partial seizures appeared within the first 3 years, but partial seizures in West syndrome or Lennox-Gastaut syndrome excluded a child from this study. *Cerebral palsy* was defined as "a disorder characterized by abnormal control of movement or posture starting early in life and without any recognized underlying progressive disease." *Mental retardation* was defined as an IQ of less than 70.

Significant relative risks were found for both familial factors and for maternal and neonatal factors. Any kind of epilepsy occurred in 0.5% of first-degree relatives of controls, whereas in both the groups with cerebral malformation and without cerebral malformation, the epilepsy risk in first-degree relatives was over 7% (95% confidence interval did not include one). Similarly significant maternal and neonatal factors for both groups (with and without cerebral malformation) were: Maternal diseases in the 2 years before pregnancy (such as diabetes, heart disease, hyperthyroidism, and gynecologic disorders), placental pathology, prematurity with delivery later than 31 weeks' gestation in those who were small for their gestational age, and neonatal convulsions. An enormously increased risk was found for those born at or before 31 weeks' gestation, all of these from the group without cerebral malformation. The need for cardiopulmonary resuscitation in the neonatal period, used as a measure of presumed asphyxia, was a high risk factor in the group without cerebral malformation, but not a risk factor in those with cerebral malformation. The findings of this study indicate that a number of genetic and prenatal risk factors interact in the genesis of early partial epilepsy with cerebral palsy and mental retardation.

P.2633

Ottman et al.[32,33] looked at the etiology of epilepsy from a different perspective. In this study of about 2,000 individuals, all had epilepsy but none had severe mental retardation. Of these, 80% had either idiopathic or cryptogenic epilepsy; 18% had postnatal symptomatic epilepsy, defined as having had a cerebral insult 7 or more days before the first unprovoked seizure. Of interest in the present context was the smallest group with neuro deficits (1%). This group consisted of 28 individuals with cerebral palsy and one with mild intellectual impairment. Although the 95% confidence intervals did not include one because of small numbers, the standard morbidity ratios for epilepsy or for idiopathic or cryptogenic epilepsy was 3 or over in the group with neuro deficits from birth. This was no different from the standard morbidity ratios in the case of those with idiopathic or cryptogenic epilepsy, but different from the situation in postnatal symptomatic epilepsy, where the standardized morbidity ratio was 1.

These studies are consistent with other results such as those of Aicardi[1] in demonstrating that, whereas postnatal brain damage is frequently the cause of subsequent epilepsy, similar genetic and prenatal factors underlie both cerebral palsy not of postnatal origin and epilepsy when it coexists.

The relationship of mental retardation is complex. Those with mental retardation are more likely to have epilepsy if they also have cerebral palsy, and those with cerebral palsy are more likely to have epilepsy if they are mentally retarded. To a certain extent, these relationships reflect a common etiology, but by no means is enough known. A simple method of demonstrating the relationship of neurologic deficit severity to IQ has been proposed for individuals with childhood hemiplegia.[19]

The risk of epilepsy in different subtypes of cerebral palsy also varies. It is highest[13] in those with what some call *double hemiplegia* and some *quadriplegia*, perhaps not surprisingly. Those with dystonic cerebral palsy who may not be easily distinguishable from those in the former group will also have a high incidence. In those with spastic hemiplegia, the relative incidence is intermediate,[42] with the lowest frequency in those with preterm related diplegia or athetoid cerebral palsy.

Clinical Features of the Epilepsy

Considerable difficulties arise in classifying the epilepsies in individuals with cerebral palsy, according to the previous international classification. It might be argued that the epilepsies in cerebral palsy ought to be either partial or localization-related, or secondarily generalized. However, there is no *a priori* reason why genetic epilepsy, such as the primary generalized epilepsies, or even benign partial epilepsy, such as benign rolandic epilepsy,[27] should not occur in those with cerebral palsy, with or without mental retardation. For instance, typical absences with 3 per second spike-and-wave can be seen in children with cerebral palsy,[1] and one cannot on clinical and EEG grounds say whether that individual has secondary generalized absences or whether there is coincident primary generalized absence epilepsy. This applies to many of the epilepsies in the context of cerebral palsy. Perhaps the argument is specious insofar as, as indicated earlier in the sections Problems in Combined Cerebral Palsy and Epilepsy and Risk Factors for Epilepsy, a common genetic etiology may exist for the cerebral palsy and the epilepsy.

Certain seizure types, such as infantile or juvenile spasms (otherwise called *periodic spasms*[17]), or atonic or startle seizures,[36] may be more likely to occur in those with cerebral palsy, but almost any type of epileptic seizure is possible.[1,2] It is important to recognize that although normal intellect may be preserved when cerebral palsy and epilepsy are combined (see Case 2) even with startle epilepsy,[30] intellectual stagnation or decline may occur (see Case 4).

A study from London[44] showed that in children with hemiplegic cerebral palsy and overall intelligence within normal limits, the presence of epileptic seizures in the first 5 years of life was associated with defects of cognition, language, and memory. In this study, when hemiplegia was unaccompanied by early seizures, nonverbal functions were almost exclusively impaired. The authors inferred that language displaced spatial abilities. By contrast, when hemiplegia was accompanied by early seizures, nearly all measures of psychologic function were affected, nonverbal and verbal alike. The presence of seizures seemed to be more important than the presence of EEG discharges. Furthermore, the presence of early seizures was more important than the size of the lateralized lesion on imaging: Children with severe neuroradiologic deficits and no seizures did better on verbal IQ, memory quotient, and third-trial paired associate learning than did those with mild neuroradiologic deficit and early seizures. Case 4 provides a more extreme example with documented regression and loss of skills.

Therapy of the Epilepsy and of the Cerebral Palsy

The principles of medical therapy of the epilepsies complicating cerebral palsy are generally similar to those that pertain in other clinical contexts. Little has been written about the use of corticosteroid, but this is alluded to in a case example below (Case 4). The use of rectal diazepam or buccal midazolam has become widespread in the management of children with cerebral palsy and epilepsy, perhaps in part because of the frequency of long hemiclonic seizures.

The place of epilepsy surgery in cerebral palsy has remained rather small, despite impressive reports on the value of hemispherectomy in refractory epilepsy with complicating hemiplegia (see Chapter 178). Section of the corpus callosum and subpial transection are discussed elsewhere (see Chapters 180 and 182). An impressive recent report from Utrecht has shown that epilepsy surgery in children and adolescents with or without prior spasticity does not harm motor performance.[43]

Baclofen by intrathecal route has increased in popularity as a treatment for spastic and other forms of cerebral palsy. There has been concern that this use of baclofen—insofar as it is a GABA-B antagonist—might be epileptogenic. However, a recent controlled study concluded that in children with spasticity of cerebral origin intrathecal baclofen does not seem to aggravate or induce epilepsy.[7]

Prognosis

The prognosis of the neurodevelopmental features, in particular cognitive function and the development of mental retardation, has been discussed earlier in "Risk Factors for Epilepsy." This section focuses on the prognosis for the epilepsy, with brief mention of mortality.

Prognosis of the Epilepsy

Clinical impression of the intractability and unremitting continuation of epileptic seizures in many children with cerebral palsy is undoubtedly biased by patient referral and differential follow-up of those with good and bad outcomes. In a report[11] from Dallas, around 25% (531 of 2,086 children with cerebral palsy actively followed) had epilepsy at the time of writing or previously had epilepsy. Since 1985, only 69 or 13% of these children with cerebral palsy and epilepsy had been seizure free for 2 years or more. These children were studied prospectively

on antiepileptic drug withdrawal. Electroencephalography was done before the antiepileptic drug discontinuation. In all children, therapy was tapered off by 15% to 20% every 2 weeks. Four were lost to follow-up, but the remaining 65 were followed after antiepileptic drug discontinuation until seizure relapse or until at least 2 years without seizures. In the event, the seizure relapse rate was about 41% (i.e., the remission rate was about 60%). Many factors appeared to have no significant effect on whether remission would or would not take place, although, as the authors point out, nonsignificance means only that we are yet unable to state with a high degree of confidence that the factor does have prognostic value. Paradoxically, there is a higher frequency of relapse in those with normal mental development than in those with mental retardation, but this was likely due to the higher incidence of epilepsy relapse in those with hemiplegic cerebral palsy. In this study spastic hemiparesis was the only factor identified that significantly increased the risk of epilepsy relapse after discontinuation of antiepileptic drug therapy. These hemiplegic individuals were more likely to have normal intelligence than were those having other forms of cerebral palsy.

Thus, the vast majority of children with cerebral palsy do not become seizure free, but of those who do, the majority will be able to discontinue antiepileptic drugs. Children with hemiplegic cerebral palsy seem to be an exception to this rule.

Mortality

Epilepsy significantly increases the mortality rate in those with mental retardation,[15] and it has been shown[8] that independent predictors of this increased mortality are: The type of cerebral palsy (spastic quadriplegia and double hemiplegia having the worst prognosis); the presence of epilepsy (of any type); and the presence of severe or profound mental retardation. In remote symptomatic epilepsy as a whole mortality is increased,[10] seizure severity seemingly a factor.[41] By contrast, the prognosis for survival in those with hemiplegic cerebral palsy and epilepsy but without mental retardation is excellent (96% at 30 years).[8]

Case Examples

For those who appreciate the value of detailed clinical observations on individual children, four case studies are provided in this section. One child represents a condition that successfully masquerades as cerebral palsy but has different implications. The other three case studies are of three children with congenital left spastic hemiplegia, with different trajectories and outcomes. These clinical studies may suggest to others further ways of refining the excellent type of epidemiologic studies referred to earlier.

Case 1: Progressive “Cerebral Palsy”

A girl was born at term in 1991 to unrelated parents who had two previous normal children. She presented at age 10 weeks because she was not holding up her head and did not smile. Her left limbs jerked repetitively as she fell asleep. Her development was very slow, but her parents and medical attendants did not observe loss of skills. She smiled once at 3 months and then more so at 9 months, smiling very readily at age 3 years. Initial hypotonia changed to spastic tetraplegia from her second year of life. Seizures consisting of extension of her limbs with quivering for about a minute occurred daily in infancy, at which time the EEG was normal, but diminished to once a week at age 3 years, EEG then showing a considerable quantity of slow spike-and-wave activity. Chilblains (pernio) were prominent, particularly on her toes. The only clinical evidence of a progressive disorder was failure of head growth. Initially, head circumference was on the mean, albeit 2 cm below that expected from her parental and sibling head circumferences, but after age 4 months, growth further declined; by 4 years of age, head circumference was 4 standard deviations below the mean.

Computed tomography head scans demonstrated progressive encephalopathy with periventricular calcifications, later also in basal ganglia and dentate locations, associated with white matter hypointensity. Cerebrospinal fluid contained 40 lymphocytes/mm^3. There was no evidence of viral infection, and the huge level of cerebrospinal fluid α-interferon confirmed the diagnosis of autosomal recessive Aicardi-Goutières syndrome.[35a,39]

Comment

Epilepsy, yes; cerebral palsy, no!

Case 2: Hemiplegic Cerebral Palsy, West Syndrome, and Good Outcome

A first-born male did not show signs of asphyxia after a long labor but was very jumpy at noise at the age of 2 hours and from age 2 days had a tendency to tenseness of his left limbs, with his fontanel bulging when he was upset. Thereafter, his behavior and development seemed normal except that there was a tendency for his left hand to be fisted.

When he presented at the age of 7.5 months, his parents said that about a month previously he had lost his happy disposition and had become lethargic, docile, and unsmiling. At about the same time, he had begun to have runs of spasms five or so times a day, with ten or more spasms in each run about 10 seconds apart. On admission to the hospital, runs of spasms were observed, sometimes with a degree of asymmetry. His head circumference was on the second percentile, and his skull transilluminated excessively on the right. He had a left hemianopia and absent optokinetic nystagmus when the drum or tape was moved to his right. His left hand did not have full voluntary control, only briefly retaining an object. Brain imaging was not done at that time, but years later showed infarction in the right middle cerebral territory. Electroencephalography showed hypsarrhythmia without convincing asymmetry.

He was treated with adrenocorticotropic hormone (ACTH) gel, 40 units daily for 2 weeks, and nitrazepam 1 mg twice daily. He had no further infantile spasms after the first dose of ACTH, and 3 days later he was smiling and taking an interest in his toys again. Repeat EEG after 2 weeks showed no discharges but reduced rhythmic activity over the right.

He received nitrazepam in the same dose until the age of 2 years. He developed intellectually, having a verbal comprehension at the age of 1.5 years of more than 2 standard deviations above the mean. He had left spastic hemiparesis and required lengthening of his Achilles tendon at the age of 3 years. An additional medical complication was an atrial septal defect, which was closed without use of blood at the age of 9 years.

From the age of 4 years, he had occasional episodes of altered consciousness, sometimes with some motor disturbance on the left. These tended to be preceded by a "funny feeling in his tummy"; instances of "sick tummy" were more frequent. Antiepileptic therapy for these simple and complex partial seizures was not required until the age of 11 years, when carbamazepine was introduced. At the age of 12 years, he replied to a letter sent to his parents inquiring about him: "Thank you

for the letter of interest. My Mum and Dad thought that it would be appropriate for me to write because I am the person you are so considerate of…" At about age 15 years, he began to have startle-induced alterations in the tone of his left limbs, lasting 15 to 30 seconds, the startle stimulus being solely an accidental scuffing of the toe of his left foot on the ground. He was improved by an increase of carbamazepine dose in the sustained release form. At the age of 17 years, he had two episodes of left limb stiffness without startle, but since the addition of vigabatrin, 500 mg daily, he has remained seizure free.

When he was aged 17 years, he discovered that he would have difficulty obtaining a driving license because of his left hemianopia. However, the combination of a life-long habit of frequently shifting his gaze to the left and training in blind sight in his left visual field has enabled him to drive commercially and to achieve complete independence.

When in his 20s, he suffered several attacks of loss of consciousness, preceded by a funny feeling in his abdomen. These were misdiagnosed as a return of his epilepsy, and an EEG was inappropriately requested. In fact, his mother had a long history of vasovagal syncopes with an identical abdominal aura.[38]

Comment

Aside from illustrating determined human qualities, this case illustrates that neither symptomatic West syndrome nor epilepsy complicating hemiplegic cerebral palsy are bars to intellectual achievement and success in life.[18]

It is also a powerful reminder that individuals who have had epilepsy may have syncopes as well.

Case 3: Congenital Hemiplegia with Secondary Generalized Myoclonic Epilepsy

This boy's mother sustained a motor vehicle accident in pregnancy at 22 weeks' gestation, after which she was unconscious for 2 hours and required an infusion to maintain her blood pressure. He was born normally at term, but a left hemiparesis became apparent later in the first year of life. His development appeared to be otherwise normal.

At age 3.5 years, he first had simultaneous head nods with right arm jerk. Soon after, he had one clonic epileptic seizure from sleep. At age 4 years, jerks became very frequent daily. They appeared to involve head nodding and abrupt dropping of the right upper limb, suggesting negative myoclonus (although surface EMG polygraphy was not undertaken). Interictal EEG showed very frequent runs of high-voltage 2/sec spike-and-wave; this slow spike-and-wave was generalized but of even higher voltage on the right. Computed tomography brain scan showed a smaller right cerebral hemisphere with abnormal gyration and a deep cleft consistent with polymicrogyria. His attentiveness varied with the frequency of his seizures but intellectual assessment showed normal intelligence.

Carbamazepine was associated with worsening of his seizures, and sodium valproate with or without lamotrigine had no consistent beneficial effect. A 2-week course of betamethasone led to marked reduction in seizures and an increase in attentiveness; he went into normal school and has continued on lamotrigine monotherapy with only occasional jerks.

Comment

An example of prenatal origin hemiplegic cerebral palsy with intelligence in the normal range despite severe secondary generalized epilepsy, probably negative myoclonic.[7a] Selective learning difficulties were expected to become more apparent in school years.

Case 4: Congenital Hemiplegia with Epileptic Encephalopathy

After an uneventful pregnancy, this girl was born at term by emergency cesarean section because of a maternal straight sacrum. There was said to be fetal distress with meconium staining and type 2 dips in labor. The APGAR score was 3 at 1 minute, and she was intubated at 3 minutes for 2 minutes. However, she was well as a neonate except that when about 1 week old, it was noted that whenever she fought out of her shawl or cot covers, it was always with the right hand. Thereafter, although she developed evidence of a left spastic hemiparesis (shown later to be due to a large right middle cerebral infarct), her general development was distinctly advanced, and she spoke many meaningful words, including “what's that?” before the age of 1 year.

Just after the age of 2.5 years, she had an episode of staring with left hand twitching. At the age of 3.5 years, she had a bilateral clonic seizure of at least 25 minutes' duration. At the age of 4 years, she began to have blanks, which increased in frequency and began to be described as periods of confusion. EEG from before the age of 4 years showed runs of generalized spike-and-wave discharges, which were nearer to 2 per second but were often at 2.5 to 3 per second with blinking and probable absence. By the age of 5 years, there was also bifrontal slow activity. She received sodium valproate in a dose of 400 mg daily from 4 years 4 months, and 800 mg daily from 4 years 8 months, changing to ethosuximide 500 mg daily, 2 months later.

Cognitive and behavioral decline was noticed by her mother from about the age of 4 years 4 months. Although there was some fluctuation, the girl would no longer sit down and draw people and faces if requested but would run about most of the time. Professional evaluation confirmed the decline. At the age of 4 years 2 months, her expressive language was well above average, and her verbal comprehension not less than 4 years 9 months (the ceiling had not been reached in the tests). By 4 years 11 months, both expressive language and verbal comprehension had dropped to 2 years 6 months. She had also become disorientated and declined in nonverbal skills, and had various behavioral abnormalities.

Short courses of betamethasone initially reduced spike-and-wave activity on EEG and were associated with improved cognition and behavior such that, for example, her Stanford-Binet intelligence was raised from 2 years 11 months at 5 years 2 months up to 3 years 11 months at 5 years 5 months, but such improvements became less and of shorter duration after each successive betamethasone course. In due course, although the atypical absences were eliminated by the betamethasone, her cognition and behavior did not much improve. Over the next 5 years, these atypical absences fluctuated and were often not observed. Very occasional night seizures, possibly tonic–clonic, were reported, but there have been no further seizures of any type observed since the age of 10 years on ethosuximide monotherapy. At the age of 15 years, she has just begun to read but has no road sense, is too friendly with strangers, and has other behavioral difficulties.

Comment

In this previously very intelligent girl with hemiplegic cerebral palsy, severe cognitive and behavioral decline was associated with rather subtle epileptic manifestations. Although cortico-steroid administration at first led to improvement, this was temporary, and she is now not likely to be able to live independently, despite remission of her epilepsy. Whether more modern medical or surgical antiepileptic approaches might have prevented this dismal prognosis remains speculative. A good discussion of cognitive and behavioral disturbances as epileptic manifestations is to be found elsewhere.[12]

Summary and Conclusions

It is essential to make sure that the diagnosis of cerebral palsy is correct and that the diagnosis of the epilepsy is correct. In the case of cerebral palsy diagnosis, both genetic disorders with high recurrence risk and rare treatable cerebral disorders should be excluded. In the case of the epilepsy diagnosis, special attention should be paid to nonepileptic events in patients with cerebral palsy that masquerade as epileptic seizures. Even epileptic seizures do not always imply epilepsy, as the section on anoxic-epileptic seizures has illustrated. Obviously, antiepileptic therapy should be avoided when it is not appropriate.

It appears that cerebral palsy and epilepsy are linked both by etiology and prognosis. The outlook is not universally bad, but we have little evidence on which to make improvements. Especially terrible are regressions in mental capacity linked in some way to the epileptic component of the cerebral palsy.

Chapter 264

Neoplastic Diseases

Lawrence D. Recht

Glantz Michael

Introduction

Seizures are frequently the first symptom in patients with brain tumors, and they represent an important cause of potentially preventable morbidity. They thus present a clinical problem requiring specific treatments that do not necessarily affect the course of the brain tumor but that generally improve quality of life.

Historical Perspectives

The first reports of a relationship between brain tumor and epilepsy were published before the 18th century, and a number of clinicians, including J. Russell Reynolds, drew attention to this problem in the early 19th century. Hughlings Jackson, however, was the first to point out a direct association between partial epilepsy and tumors.[40] Jackson also recognized the relationship between epileptogenicity and tumor involvement of the cortical gray matter.[40,41]

Since then, the evolution of neurosurgical techniques and the development of new imaging techniques have greatly facilitated the management of tumor-associated epilepsy. Nevertheless, controversy over optimal pharmacologic and surgical therapies persists, and seizures still represent one of the more commonly encountered problems in neuro- oncology.

Epidemiology

Although neoplasms of the brain account for only 1% of cases of epilepsy, seizures occur in approximately 50% of children with supratentorial tumors,[4,39,50] and seizures develop in approximately 35% to 40% of adults with brain tumors.[48] The rate is much lower for tumors of the infratentorial or pituitary region, and consequently even higher for supratentorial lesions. Furthermore, because physicians who are not neurologists are apt to miss seizures with other than motor manifestations, these figures are probably underestimates.

In the majority of patients with supratentorial low-grade gliomas, seizure is the initial manifestation.[47,66] Seizures occur especially commonly in association with oligodendrogliomas. A recent retrospective study found seizures to be the first symptom in three quarters of patients with oligodendrogliomas.[91] Seizures are also commonly encountered in patients with meningiomas. Although earlier workers reported that seizures were less frequently encountered in cases of more malignant glial neoplasms,[27] recent studies demonstrate that up to 60% of patients with malignant gliomas experience seizures at some time during their clinical course.[57] In contrast, the incidence of seizures in patients with cerebral metastasis is much lower; most reports suggest an incidence of 20% at time of presentation.[18,28,63,96]

Clinical Presentation

Clinical Correlates of Tumor-Associated Epilepsy

Despite the variable frequency of seizures as a function of histologic subtype, the most important factor associated with the development of seizure is probably tumor location.[44,52] Seizures occur much more frequently in supratentorial (22%–68%) than infratentorial (6%) lesions.[31,64,78] Moreover, the incidence of seizures increases as the site of tumor approaches the rolandic fissure.[90] As the distance from the central sensorimotor region increases, early-onset seizures are less likely to occur.[65] Similarly, superficial and cortical tumors are associated with a much higher incidence of epilepsy than are noncortical deep lesions (63% vs. 29%), and lesions entirely within the white matter infrequently produce seizures.

Other factors aside from location are also probably important determinants. Both the chronicity of tumor growth and patient age affect the incidence of epilepsy in intra-axial supratentorial neoplasms.[23,24,25,30,31,34,54,64,69,70] Slowly growing tumors, such as gangliogliomas and dysembryoplastic neuroepithelial tumors, are overrepresented in patients with brain tumors who have seizures, whereas more rapidly growing tumors are less often epileptogenic. Thus, a seizure incidence of 70% is reported for astrocytoma, but only 37% for glioblastoma multiforme.[4,70,90] Young age also is correlated with the presence of epilepsy.[91]

Seizure Types in Tumor-Associated Epilepsies

Since Jackson first noted, at the end of the last century, the relationship between uncinate seizures and tumors of the frontotemporo-orbital regions, many reports have documented the important relationship between the type of seizure and the presence of tumor. Despite occasional disagreement,[48,86] a correlation between a specific seizure type and either a particular neoplasm or specific tumor location has been commented on repeatedly. In an analysis of psychomotor attacks in 80 untreated patients with and without tumor, for example, olfactory and gustatory hallucinations were very suggestive of tumor.[43,52] Muller (cited in Jackson[40]) noted olfactory hallucinations, increasing frequency of attacks, and random variations in the type of attack (especially of motor seizures) to be particularly characteristic of tumor. For children, the probability of diagnosing an underlying tumor is higher in those with complex partial seizures (10%–46%) than in those with other seizure types.[7,82,90]

In a recent series of patients with oligodendroglial tumors, seizures were approximately equally divided between generalized, partial, and mixed types.[91] In contrast, localization-related motor seizures, characterized by a clonic jerking of

the face or one extremity, are often characteristic of patients with intracranial metastases or malignant gliomas,[44,48] and these seizures are almost always seen in association with focal neurologic abnormalities.[57] Multifocal or bilateral neoplasms more often produce seizures than solitary neoplasms do,[57] and seizures tend to occur more frequently with lesions of the central nervous system (CNS) caused by metastatic melanoma, because these lesions involve gray matter and tend to be multiple.[11] Furthermore, partial seizures in patients with brain tumors are clinically significant, because they are rarely falsely localizing and thus provide a clue to tumor location.[1] Following partial or secondarily generalized seizures, many patients with underlying brain tumors exhibit a significant Todd's paralysis; although usually transient, this may be permanent.[56]

Diagnostic Evaluation

Because seizures are a presenting complaint in approximately 20% of patients with newly diagnosed brain metastases,[68] neuroimaging, preferably magnetic resonance imaging (MRI), is required in every patient with cancer in whom seizures develop. Since seizures also occur in up to 40% of neutropenic patients with infectious meningitis,[51] are a common manifestation of leptomeningeal carcinomatosis, and have been reported as an early manifestation of limbic encephalitis, a spinal fluid analysis with careful assessment of the patient's prior clinical course for possible epileptogenic drugs and metabolic aberrations is always indicated.

Before the advent of modern neuroimaging, the significance of a seizure as a first manifestation of brain tumor was insufficiently recognized, and the average delay between first seizure and tumor diagnosis was about 3 years.[16,44,89] In recent years, however, scanning with computed tomography (CT) and MRI has made it possible to document that many low-grade gliomas have relatively benign pathologic features and, although they produce chronic epilepsy, tend to be associated with long survival.[26,71] Furthermore, low-grade gliomas are serendipitously noted in up to 20% of resected surgical specimens from the brains of patients with chronic temporal lobe epilepsy.[10,58,79,84] Therefore, it is the authors' recommendation that all patients with a first seizure have a CNS imaging study, preferably an MRI scan, at the time of presentation.

Electroencephalography (EEG) is also useful in assessing these patients. Findings correlate with tumor location, and in approximately 40% of patients, the EEG abnormalities are lateralized to the side of the tumor.[17] On the other hand, in the authors' experience,[32] EEG does not predict in which patients with supratentorial lesions late seizures will develop. Nevertheless, because EEG is relatively inexpensive and helps to localize the epileptogenic foci by a method different from neuroimaging, it remains a useful test for attempting to localize the physiologic seizure focus.

Differential Diagnosis

In patients with established cancer, the differential diagnosis of either isolated or multiple seizures includes more than just mass lesions, and the appropriate work-up must be designed accordingly. Although the differential diagnoses of a seizure in cancer patients are similar to those in patients without cancer, certain etiologies are specific to or more frequent in a patient with preexisting cancer. For example, hyponatremia, hypomagnesemia, and hypocalcemia all occur more frequently in patients with cancer owing to a number of factors, including dehydration and chemotherapy. These metabolic aberrations in turn predispose to seizures. Similarly, the immunosuppression associated with cancer and its treatment predisposes patients to meningitis, often with less common etiologic agents, such as *Listeria* and *Cryptococcus*. A partial list of potential causes of seizures in patients with cancer is given in Table 1.

Treatment and Outcome

Pharmacotherapeutic Aspects of Tumor-Associated Epilepsy

Seizures can be especially detrimental to patients with tumors because they can lead to breakdown of the blood—brain barrier[61] and subsequent formation of brain edema. This process is probably related to seizure-induced arterial hypertension. Because the increase in blood flow and blood volume may worsen elevated intracranial pressure, leading to focal ischemia and sometimes infarction, the Todd's paralysis that frequently follows these seizures tends to be more protracted (even permanent on occasion) than that occurring in patients with partial seizures and no tumor. This potential complication alone justifies instituting aggressive antiepileptic measures for these patients once a seizure has occurred.

As in the treatment of idiopathic seizures and secondary seizures not related to tumor, however, the efficacy of anticonvulsant therapy for tumor-associated epilepsy falls well short of complete control. Tumor-associated epilepsy tends to be relatively refractory to antiepileptic drugs (AEDs), and significant remission of seizures is rare.[34,57,78] Primary tumors tend to be more difficult to control than metastatic lesions (M. Glantz, *unpublished observations*), but seizures with onset late in a patient's clinical course tend to be easier to control than those that are an initial manifestation of tumor.[57]

A number of unique problems also complicate the use of AEDs in cancer patients. For example, a rash develops in approximately 25% of patients taking either phenytoin or carbamazepine, a figure twice the reported incidence in the population without tumors.[57] Even more serious, both of these agents have been reported to cause Stevens-Johnson syndrome, particularly in patients who receive radiation therapy while taking a decreasing dose of steroids.[19]

Moreover, it is difficult to maintain therapeutic levels of conventional AEDs (e.g., phenytoin, carbamazepine, phenobarbital) in cancer patients. A number of chemotherapeutic agents, including bischloroethylnitrosourea (BCNU), cisplatin, carboplatin, and Taxol, cause antiepileptic drug levels to decrease, either because of induction of microsomal enzymes or decreased absorption.[9,22,29,36,60] Complex mutual interactions of these agents with the commonly coadministered dexamethasone also exist; as a result, corticosteroid requirements are increased[15,38] and phenytoin levels are decreased, necessitating close monitoring of antiepileptic drug levels.[93] To compensate for lower AED levels, dosages may have to be increased, only to have the level overshoot into the toxic range. Toxicity, in turn, may mimic the symptoms of brain tumor progression, including seizure.[12,81] Lethargy and cognitive dysfunction do not occur only as manifestations of drug toxicity; they can also occur when drug levels are in the therapeutic range. Finally, in approximately 20% of patients with brain tumor who are taking phenobarbital, pain and dysfunction develop in the shoulder and sometimes the entire upper extremity (shoulder-hand syndrome) on the tumor-affected side.[83]

Table 1 Causes of seizures other than tumor masses in cancer patients

Etiology	Setting	Comment
Metabolic	Hypomagnesemia	Occurs 2–7 days after cisplatin chemotherapy.
	Hyponatremia	Often occurs after craniotomy. Usually caused by hydration with hypotonic fluids. Sometimes occurs with vincristine chemotherapy.
	Hypocalcemia	Occurs after cisplatin chemotherapy.
Drug-induced	Methotrexate	Especially with concurrent RT and in patients with abnormal CSF flow.
	Cisplatin	May be caused by electrolyte disturbance.
	Ifosfamide	Especially common in setting of renal failure.
	BCNU (high-dose), IL-2, VP-16 (high-dose)	Uncommon.
	Anticonvulsants	Associated with abrupt decreases or increases; frequently caused by interactions with other drugs.
Intracranial hemorrhage	Coagulopathy	Also occurs with chemotherapy-induced thrombocytopenia.
Radiation	Radiation necrosis	May mimic recurrent tumor.
Infectious	Meningitis	Especially *Listeria*; occurs frequently in patients with ventricular reservoirs.

Neoplastic	Leptomeningeal carcinomatosis	
Paraneoplastic	Limbic encephalitis	Most common with small-cell cancer of lung; very rare.

RT, radiation therapy; CSF, cerebrospinal fluid; BCNU, bischloroethylnitrosourea (carmustine); IL-2, interleukin-2; VP-16, etoposide.

Furthermore, AEDs address only a minority of the possible pathophysiologic mechanisms purported to be important in generating tumor-associated epilepsy. Specifically, these agents tend to act on excitatory mechanisms by blocking and inactivating Na^+ or Ca^{++} channels or on inhibitory ones through

P.2639

increasing γ-aminobutyric acid (GABA)ergic activity.[21] They do not address other possible causative factors such as morphological changes, altered receptor and connexin patterns and changes in cytokine expression.[73]

To complicate matters even further, no published studies address whether AEDs prevent further seizures in patients with brain metastases or whether any one epileptic agent is superior. In earlier work, Posner[68] recommended phenytoin as an initial agent, followed by carbamazepine, phenobarbital, and valproate. However, because brain tumor patients with epilepsy suffer from a number of neuropsychological and psychological problems that are aggravated not only by the severity of epilepsy, but also by the intensity of treatment,[46] use of some of the newer agents such as levetiracetam, which has less allergenicity and fewer medical interactions, seems an attractive alternative that is more frequently being recommended.[85] However, no agent has been proven clearly superior, and the failure of one agent does not predict failure of another.

Should Patients with Brain Tumors Receive Prophylactic Antiepileptic Drugs?

Although the risk for perioperative seizures after neurosurgical procedures is 10% to 15% in the first week,[20,55] this does not necessarily justify the long-term use of prophylactic antiepileptic drugs in patients with brain tumors. Only one study suggests that prophylactic administration of antiepileptic drugs can prevent seizures in patients with glioma.[8] Other retrospective studies have failed to demonstrate decreased seizure frequency in patients with brain metastases or gliomas treated with antiepileptic drugs.[18,53,57] Recently, two prospective studies also failed to indicate a difference in the frequency of first seizures in patients having either primary or metastatic tumors treated with either phenytoin or valproic acid.[32,88] A similar recommendation was made for patients with malignant gliomas by Moots et al.,[57] who recommend that these agents be withheld except for patients at high risk (multiple or hemorrhagic lesions). This has led to a general consensus that was published as an American Academy of Neurology practice parameter that prophylactic drugs not be prescribed in this situation,[33] a recommendation further supported by a subsequent controlled study on the topic.[24]

The practice of the authors therefore has been not to prescribe antiepileptic drugs until a seizure occurs. On the other hand, prophylactic antiepileptic drugs have proved effective in at least one specific instance: Prevention of contrast-induced seizures at the time of CT. Five to ten milligrams of diazepam given orally 30 minutes before contrast administration decreases the likelihood of seizures.[62]

Surgical Treatment of Tumor-Associated Epilepsies

Tumor-associated epilepsies can also be ameliorated by resection. Even a lesion in or near the sensorimotor or language cortex is not an absolute contraindication to surgery.[34] Intractable seizures can often be controlled by gross total removal.[13,34,79] Of patients with low-grade gliomas, for example, 40%

P.2640

become seizure-free and another 30% have a marked reduction in seizure frequency after surgery.[48] Tumor removal or lesionectomy alone provides effective relief in many patients. In numerous series, from 30% to 60% of patients with brain tumors are rendered seizure free after surgery,[3,13,14,25,34,35,39,74] even though up to 35% of these patients retain their auras after surgery.[80] When surgery failed to control seizures, incomplete resection of the lesion was usually found.

The most favorable seizure-free outcomes following lesionectomy have been reported for patients with indolent glial neoplasms. Complete seizure remission can be obtained in 65% to 80% of these patients, and doses of antiepileptic drugs can be tapered in half of them.[13,14,39] When surgery involves subtotal lobectomy and removal of the medial temporal or frontal structures, at least a 95% reduction in seizure frequency is seen in virtually every patient.[79] Best results are seen in patients undergoing extensive resections soon after the development of epilepsy.[2,94,95] Results are poorer, however, for patients with meningiomas and malignant gliomas.[48] Seizures in patients with brain tumors can also be reduced using either radiation therapy[34,72] or chemotherapy.

Lesionectomy Versus More Extensive Surgery

Although lesionectomies are generally effective, many investigators feel that more extensive surgery produces better results. This contention is supported by the frequent finding on intraoperative electrocorticography in patients with low-grade gliomas of epileptogenic foci remote from the tumor nidus that are devoid of tumor infiltration.[6] Furthermore, a statistically significant decrease in both GABA and somatostatin neurons has been noted in epileptogenic tissue not infiltrated by tumor, compared with nonepileptic cortex not infiltrated by tumor.[37] These findings suggest that cortex surrounding a slowly growing tumor may become isolated, lose inhibitory neurotransmitters, and develop into an independent, tumor-free epileptogenic cortical focus. The not infrequent persistence of seizures following complete tumor resection further suggests that the epileptogenic zone responsible for the initiation and propagation of seizures is sometimes separate from the area of tumor-involved brain removed during lesionectomy.

Whether resection of separate seizure foci, using intraoperative electrocorticography, in addition to radical resection of tumor optimizes seizure outcome remains controversial. Penfield et al.[64] demonstrated a seizure-free outcome in only 21% of patients undergoing lesionectomy and therefore subsequently recommended electrocorticography and more extensive surgery.[65] Many other workers have since reported optimal results when both tumor and epileptogenic foci are identified and removed. If the region of epileptogenicity involves the amygdala-hippocampal complex, results can be improved even further.[5,42,45,67] Furthermore, others[3,34,39,91,92] have reported that routine tumor resection performed without electrocorticography is inferior to more monitored procedures in terms of attaining postoperative seizure control, but this issue remains unsettled.

Part of the difficulty in attaining remission of epilepsy associated with brain tumor can be attributed to progressive, reactive changes taking place in the brain surrounding the lesion, in contrast to the regressive neuronal changes commonly found in seizure foci in idiopathic epilepsies. Thus, failure to control seizures is usually related to persistent disease. In some patients, an initially satisfactory result is followed by a relapse; second surgeries tend to be ineffective.[91] In this situation, if electrocorticography is used, large contiguous and noncontiguous areas of brain surrounding the lesion are found to be dysrhythmic. Paradoxically, however, in patients whose focal neurologic deficits become worse, seizure disorders frequently become easier to control, presumably because of progressive neuronal loss in previously epileptogenic brain.[91]

Prognosis

Although the Brain Tumor Cooperative Group (BTCG) trials for patients with malignant gliomas did not demonstrate a correlation between the occurrence of seizures at diagnosis and improved survival,[77,87] a number of other observations suggest that at least for patients with primary brain tumors, presentation with a seizure is a favorable prognostic sign. In the era before CT, for example, reports of cases of long-standing seizures in patients with benign tumors of the temporal lobe abound. List[49] and Penfield et al.[64] both felt that the prognosis of patients with brain tumors who had seizures was better, because less aggressive neoplasms are commonly seen in these patients. This observation has been substantiated in recent years. Convulsions tend to occur more frequently and earlier in patients with lower-grade gliomas, whereas more malignant tumors tend to produce other signs first. Tumor calcification, which occurs more frequently in lower-grade neoplasms, also correlates with seizure frequency.[76] In fact, a number of recent studies have identified presentation with a seizure as a favorable prognostic sign.[59,75,78] Possible explanations for this observation include relative surgical accessibility (because tumors tend to have a cortical location), earlier detection and diagnosis, and overrepresentation of lower-grade tumors. Interestingly, although most glial neoplasms producing intractable epilepsy are not clinically aggressive, almost 20% have anaplastic histologic features.[26]

Summary and Conclusions

Seizures are frequently the first symptom in patients with brain tumors, or seizures develop later in the clinical course. Thus, they represent an important cause of potentially preventable morbidity in these patients. Determining the cause of the seizure using neuroimaging and other diagnostic tests is critical, because multiple potential etiologies exist in patients with cancer. Unfortunately, pharmacologic therapies are often ineffective in the absence of surgery or other antitumor therapy, and no one antiepileptic drug is clearly superior in terms of efficacy. Furthermore, antiepileptic drugs probably do not prevent seizures from occurring in those patients with brain tumors who have not yet had a seizure. Therefore, for most patients, prophylactic antiepileptic drugs are not recommended. In contrast, surgery, either lesionectomy or more extensive epilepsy-type surgery, frequently produces long-lasting remission of epilepsy, especially in patients with lower-grade primary tumors of the brain.

Chapter 265
Infection and Inflammatory Diseases

Oscar H. Del Brutto

Introduction

Infectious and inflammatory diseases of the central nervous system (CNS) cause a wide range of clinical manifestations, including decreased level of consciousness, behavioral changes, increased intracranial pressure, focal neurologic deficits, and seizures. The latter may occur as the primary manifestation of the disease or as part of a diffuse encephalopathy. Pathogenesis of the seizure disorder varies widely from one disease to another. In some of these conditions, seizures appear in close temporal association with the acute disease process, although in others, seizures may occur from several weeks to months later, and tend to recur over the following years. Recognition of infectious- or inflammatory-related acute or remote symptomatic seizures has important therapeutic and prognostic implications. Here, we review the most common CNS infectious and inflammatory disorders associated with seizures.

Parasitic Infections

Neurocysticercosis

Neurocysticercosis (NCC) is defined as the infection of the CNS by the larval stage of *Taenia solium*. The disease occurs when humans become intermediate hosts in the life cycle of this cestode after ingesting its eggs in contaminated food or by the fecal–oral route in individuals harboring the adult parasite in the intestine. Although the former was previously considered the most common form of transmission, recent studies showing clustering of NCC patients around taeniasic individuals have changed previous concepts crediting food and the environment as the main sources of human contamination with *T. solium* eggs.[21] *Taenia* carriers are contagious sources of cysticercosis, endangering everyone coming into contact with them. Human cysticercosis must be considered a disease resulting from contagion from an infected human; therefore, the patient's close environment should be investigated to eradicate the source of contagion.

NCC constitutes a threat to millions of people in Latin America, sub-Saharan Africa, and Asia. Massive immigration of people from endemic areas has also caused a recent increase in the prevalence of this parasitic disease in the United States and some European countries.[68] NCC is a leading cause of late-onset epilepsy and a major cause of seizures in developing countries, where the prevalence of active epilepsy is twice that seen in industrialized nations. Indeed, population-based studies have shown that NCC accounts for up to 30% of this excess fraction of epilepsy in the developing world.[14,39,41] It is estimated that 50,000 deaths due to NCC occur every year, and many times that number of patients survive but are left with irreversible brain damage. Despite the magnitude of these numbers, they are but the “tip of the iceberg” because the actual prevalence of NCC is not known.

Pathophysiology

Cysticerci may be located in brain parenchyma, subarachnoid space, ventricular system, and spinal cord. After entering the CNS, cysticerci elicit few inflammatory changes in the surrounding tissues. In many patients, cysticerci remain in this vesicular stage for years. In others, parasites enter, as the result of the host's immune attack, in a process of degeneration. Stages of involution through which cysticerci pass during this process are called colloidal, granular, and calcified. Inflammatory reaction around cysticerci induce pathological changes in the CNS serving as a substratum for the further development of seizures. Within the brain parenchyma, such a reaction is usually associated with edema and reactive gliosis. At the subarachnoid space level there is thickening of the leptomeninges with entrapment of cranial nerves and blood vessels located at the base of the skull. Luschka and Magendie's foramina may be occluded with the subsequent development of hydrocephalus. Ventricular cysticerci elicit a local inflammatory reaction if they are attached to the ventricular wall. In such cases, ependymal cells proliferate and may block cerebrospinal fluid (CSF) transit at the level of the cerebral aqueduct or Monro's foramina; this process of granular ependymitis causes obstructive hydrocephalus.[49]

Epilepsy is more frequently observed in patients with cysticerci located in the brain parenchyma or in the depth of cortical sulci. Cysticerci in all stages of involution may induce seizures, although the mechanisms of epileptogenesis are different. Vesicular cysts cause seizures due to compression of the surrounding brain parenchyma and colloidal cysts cause seizures due to acute inflammatory changes. In contrast, granular and calcified cysticerci cause seizures due to the intense astrocytic gliosis that usually surrounds these lesions.[44]

The concept that cysticerci play a role in epileptogenesis comes from epidemiological studies showing a correlation between populations with increased prevalence of both cysticercosis and epilepsy, and from neuroimaging studies showing NCC in patients with epilepsy in the absence of other etiologies. Also, the episodic appearance of edema surrounding cysticerci after a seizure episode unquestionably links cysticerci with seizures (Fig. 1). This phenomenon occurs not only in patients with living cysts but also in those with calcifications, suggesting that calcified cysticerci should not be seen as inert lesions causing no symptoms.

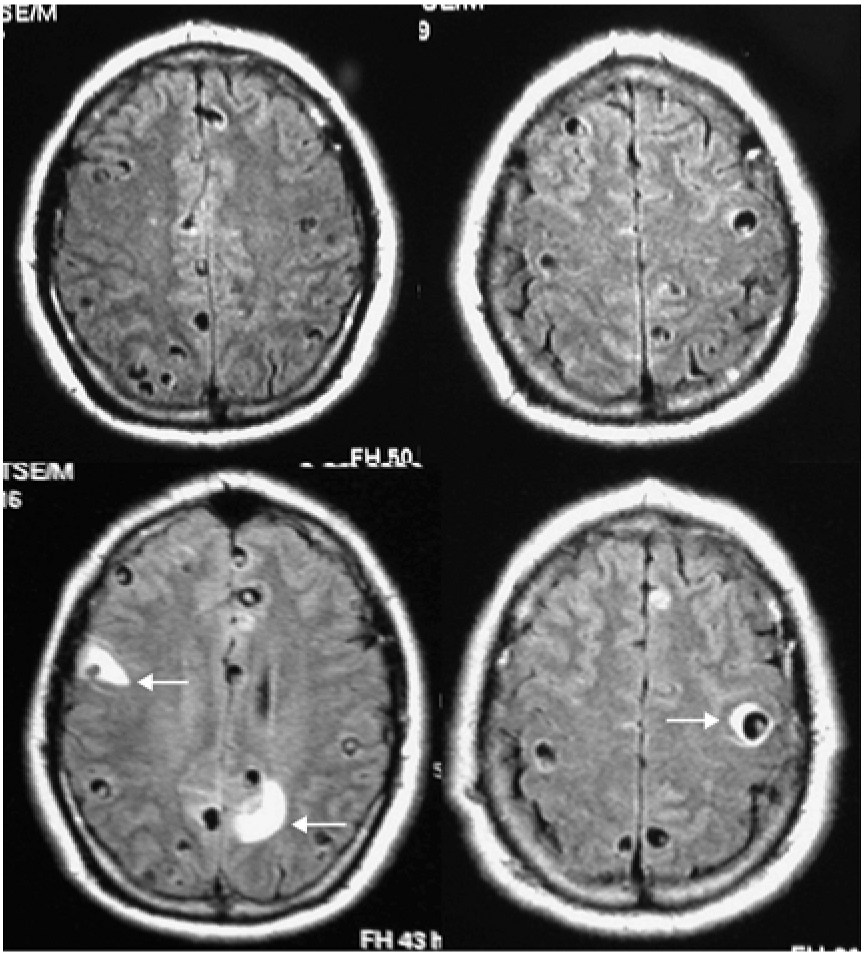

FIGURE 1. Fluid attenuated inversion recovery MRI of patient with parenchymal NCC before (*upper panel*) and 6 hours after (*lower panel*) a seizure episode, showing new hyperintense areas in brain parenchyma, some of which are surrounding cystic lesions (*arrows*).

The pathogenesis of edema around calcified cysticerci is not fully understood.[44] One hypothesis is that periodic remodeling of calcifications exposes the host's immune system to residual antigens still present in these lesions. Direct calcium toxicity is another possibility as it has been suggested that brain lesions that calcify are associated with increased seizure activity compared to those that fail to calcify. It is also possible that brain gliosis left during the death of the parasite explain recurrent

P.2644

seizure activity. Another hypothesis is that edema is not the cause but the result of the seizure, as has been documented in a few patients after a cryptogenic partial status epilepticus. However, this is improbable because the magnetic resonance imaging (MRI) pattern of perilesional edema in cysticercosis is most consistent with vasogenic edema resulting from breakdown of the blood–brain barrier, and does not have the imaging appearance of cytotoxic edema resulting from cell swelling associated with prolonged seizures.

Clinical Manifestations

NCC is highly pleomorphic owing to individual differences in the number and location of the lesions. Seizures, focal deficits, cognitive decline, and increased intracranial pressure are common manifestations of NCC. Seizures occur in more than 70% of NCC patients.[15] Most of these patients have a normal neurologic examination, and differ from patients with epilepsy due to other cerebral lesions, who usually present with focal signs.

Seizures due to NCC are most commonly simple partial or generalized tonic-clonic, although some patients may present with complex partial or myoclonic seizures. The seizure type has been considered to be related to the number and location of the parasites, whereby patients with a single lesion present with partial seizures, although patients with multiple lesions have generalized seizures.[15] However, other studies have shown no difference in the frequency of partial seizures in patients with single cysts as compared with those with multiple cysts.[40] It is possible that most NCC patients with generalized seizures actually have partial seizures with rapid secondary generalization, an assumption based on the fact that focal brain lesions rarely course with genuine generalized seizures. Not all NCC patients with seizures develop epilepsy. Indeed, there are some patients with a single colloidal cyst who after a bout of two or three seizures remain free of seizures even without antiepileptic drug (AED) therapy.[53] Nevertheless, if we consider the population of patients with NCC-related seizures at large, the vast majority actually have epilepsy because the epileptogenic focus is already developed when the patient is first seen.

Diagnosis

NCC is often diagnosed on the basis of information provided by neuroimaging studies and serology. Both computed tomography (CT) and MRI give objective information on the number and location of lesions as well as on the stage of evolution of cysticerci.[19] Although MRI has better accuracy than CT, it may miss some small calcifications and has the shortcoming of being less available in endemic areas for NCC. From the many immune diagnostic tests, current evidence favors the use of serum immunoblot using purified glycoprotein antigens.[21] A major problem using the immunoblot is that almost 50% of patients with a single intracranial cyst may test negative, and that some patients with taeniasis (but not NCC) may test positive. A set of diagnostic criteria has been proposed to homogenize the diagnosis of NCC.[13] Proper interpretation of these criteria permit two degrees of diagnostic certainty, definitive or probable (Table 1).

Table 1 Diagnostic criteria for neurocysticercosis

DIAGNOSTIC CRITERIA

Absolute Criteria:

- Histologic demonstration of the parasite from biopsy of a brain or spinal cord lesion.
- Cystic lesions showing the scolex on CT or MRI.
- Direct visualization of subretinal parasites by funduscopic examination.

Major Criteria:

- Lesions highly suggestive of neurocysticercosis on neuroimaging studies.
- Positive serum immunoblot for the detection of anticysticercal antibodies.
- Resolution of cystic lesions after therapy with albendazole or praziquantel.
- Spontaneous resolution of small single enhancing lesions.

Minor Criteria:

- Lesions compatible with neurocysticercosis on neuroimaging studies.
- Clinical manifestations suggestive of neurocysticercosis.
- Positive CSF enzyme-linked immunosorbent assay (ELISA) for detection of anticysticercal antibodies or cysticercal antigens.
- Cysticercosis outside the central nervous system.

Epidemiologic Criteria:

- Evidence of household contact with *T. solium* infection.
- Individuals coming from or living in an area where cysticercosis is endemic.
- History of frequent travel to disease-endemic areas.

DEGREES OF DIAGNOSTRIC CERTAINTY

Definitive Diagnosis:

- Presence of one absolute criterion.
- Presence of two major plus one minor and one epidemiologic criteria.

Probable Diagnosis:

- Presence of one major plus two minor criteria.
- Presence of one major plus one minor and one epidemiologic criteria.
- Presence of three minor plus one epidemiologic criteria.

Treatment

Characterization of NCC according to the viability and location of lesions is important for a rational therapy, which usually includes a combination of symptomatic and cysticidal drugs, surgical resection of lesions, or placement of ventricular shunts.[20] Albendazole and praziquantel have changed the prognosis of most patients with parenchymal brain and

P.2645

subarachnoid cysts presenting with seizures. However, because pioneer studies of NCC therapy focused on the number of cysts before and after the trial, some authors affirmed that cyst disappearance did not necessarily mean improved clinical outcome. Thereafter, two studies showed a strong association between cysticidal treatment and fewer seizures in NCC patients, a finding that was also questioned due to the non-randomized design of these studies.[15,66] During the past few years, placebo-controlled trials have shown that the use of cysticidal drugs not only results in better resolution of lesions but in a lesser risk of seizure recurrence in patients with NCC, providing Class I evidence favoring therapy in these cases.[2,22]

The control of epilepsy in NCC patients not only depends on the use of cysticidal drugs, but on the chronicity of the disorder and the presence of brain calcifications. These patients must be treated with an AED regardless of the use of cysticidal drugs. The optimal length of AED therapy has not been settled. A prospective study showed that up to 50% of NCC patients had relapses after AED withdrawal.[11] Such patients had been free of seizures during two years, and their brain cysts had been successfully destroyed with albendazole. Prognostic factors associated with seizure recurrence included the development of calcifications, and the presence of both recurrent seizures and multiple brain cysts before cysticidal drug therapy.[11,52] Calcified cysticerci are potentially active epileptogenic foci that may cause recurrent seizures after AED withdrawal. Although epilepsy due to NCC may be easily controlled with AEDs, a seizure-free state without medications cannot always be achieved.

Cerebral Malaria

Of the four species of malaria parasites, only *Plasmodium falciparum* invades the CNS and causes cerebral malaria. Because all species may cause fever associated with delirium or seizures, definition of cerebral malaria requires all of the following conditions to be present: unarousable coma, evidence of acute infection with *P. falciparum*, and no other identifiable cause of coma.[69] Humans acquire the infection when parasites are inoculated through the skin during a blood meal by a female *Anopheles* mosquito. Malaria is a public health problem around the world. Up to 500 million people are infected by *Plasmodium spp*. every year, with 3 million fatal cases, most of which occur in African children. Due to increased travel, many cases of cerebral malaria have also been recently recognized in developed countries.[63]

Pathophysiology

The brain of patients dying from cerebral malaria shows diffuse swelling and small ring hemorrhages in the subcortical white matter. These are related to extravasation of erythrocytes resulting from endothelial damage which, in turn, is caused by the liberation of cytokines and vasoactive substances. Another common neuropathologic finding in cerebral malaria is the plugging of capillaries by parasitized erythrocytes due to an increased adherence of these cells to the endothelium. This causes brain damage as a result of obstruction of the cerebral microvasculature, increased concentrations of lactic acid, and ischemic hypoxia.[53]

Clinical Manifestations

Cerebral malaria is an acute encephalopathy characterized by headache, seizures, somnolence or agitation that rapidly progresses to stupor and coma, and extensor posturing. Seizures occur in up to 70% of cases, and are most often tonic-clonic generalized, although some patients present with partial seizures.[54] Pulmonary edema, renal failure, hypoglycemia, and disseminated intravascular coagulation are common during the acute phase of the disease. Most patients who do not die during the first few days recover without sequelae. Some others are left with hemiplegia, blindness, psychiatric symptoms, speech disturbances, recurrent seizures, and extrapyramidal manifestations.[69]

Diagnosis

P. falciparum may be seen by examining blood smears with Giemsa stain; repeated examinations may be needed, because parasitemia is cyclic. Dipstick antigen-capture assay may be of diagnostic value in patients with low levels of parasitemia.[67] Although the cytochemical analysis of CSF is normal in these patients, a spinal tap is mandatory to exclude other causes of encephalopathy. Neuroimaging studies may show brain swelling,

P.2646

hypodense areas in the thalamus or cerebellum, small hemorrhages, or dural sinus thrombosis.[36]

Treatment

Because of chloroquine-resistant strains of *P. falciparum*, quinine is the drug of choice for cerebral malaria.[6] The association of quinine plus pentoxifylline may be better than quinine alone for therapy of cerebral malaria in adults. Mefloquine is effective against *P. falciparum* but has not been evaluated in patients with cerebral malaria. Recent evidence favors the use of artemether as a first-line therapeutic agent for cerebral malaria.[43] Symptomatic therapy includes fluid replacement, sedatives, and osmotic diuretics. Corticosteroids are harmful to comatose patients with cerebral malaria and should be avoided. Although phenobarbital is often used to treat malaria-related seizures in endemic areas, the common loading dose of 20 mg/kg may be deleterious for children with cerebral malaria. A recent study suggested that an initial dose of 15 mg/kg followed by two doses of 2.5mg/kg after 24 and 48 hours is safe and effective in these patients.[30] Despite therapy, up to 25% of patients with cerebral malaria die. Factors adversely affecting the prognosis include coma, retinal hemorrhages, recurrent seizures, renal failure, disseminated intravascular coagulation, respiratory distress, arterial hypotension, severe anemia, hypoglycemia, altered liver function tests, presence of malaria pigment in peripheral white blood cells, high levels of parasitemia, and co-infection with HIV.[8,69]

Other Parasitic Diseases of the Central Nervous System

Almost any parasite invading the CNS may cause seizures. These may occur as the result of the pressure effects of a parasite growing within the brain parenchyma (as in the case of cerebral hydatid disease or coenurosis), due to the irritative effects of a larva migrating through the brain (as in gnathostomiasis or sparganosis), or as part of a diffuse encephalopathy (as in patients with cerebral amebiasis or African trypanosomiasis). In any case, seizures may occur during the acute phase of the disease or as a chronic sequelae of the infection.[12,58] AED therapy should be promptly started in these cases to stop seizures and to avoid recurrences, irrespective of the specific therapy used for each of these conditions. Duration of AED therapy and the risk of seizure recurrence after AED withdrawal will vary depending on the severity of the initial infection and the occurrence of residual structural brain damage.

Bacterial Infections

Pyogenic Meningitis

Causal agents of pyogenic meningitis vary according to the age and the immune status of the patient, and the route by which the infection gains access to the CNS. *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae* are the most common pathogens causing this condition. Bacteria may reach the subarachnoid space by the hematogenous route from a remote infection, or by contiguity from an infection of paranasal sinuses or ears.[56]

Pathophysiology

Pyogenic bacteria induce the formation of a purulent exudate within the subarachnoid space related to migration of neutrophils and other immune cells.[53] Such exudate, together with direct effects of bacterial toxins, may cause seizures by a number of pathogenetic mechanisms, including: (a) occlusion of small pial arteries with the subsequent development of cortical infarctions, (b) venous thrombosis, (c) diffuse brain swelling, (d) toxic effects of bacteria accumulation within the subpial space, and (e) acute metabolic changes.

Clinical Manifestations

Pyogenic meningitis is an acute disease mainly characterized by fever, headache, cloudiness of consciousness, and seizures. Neurologic examination usually shows neck stiffness or other signs of meningeal irritation. Less common signs include cranial nerve palsies, papilledema or focal deficits. Acute symptomatic seizures occur in up to 40% of patients and are more often of the tonic-clonic generalized type, although some patients present with partial seizures. Only a few patients develop chronic epilepsy after the acute infection. In two large series of children with pyogenic meningitis, epilepsy occurred in 2% and 7% of cases, and was most often associated with the occurrence of permanent neurologic deficits.[50,64]

Diagnosis

A spinal tap usually shows a turbid CSF under increased opening pressure. CSF examination reveals increased polymorphonuclear cells (>1,000 mm^3), decreased glucose levels (<20 mg/dL), and high protein contents (from 100–500 mg/dL). Gram stains and cultures are helpful for identifying the offending microorganism but may be negative in some patients, especially in those receiving antibiotics prior to admission. Polymerase chain reaction (PCR) amplification techniques are useful for detecting bacterial antigens in patients with partially treated infections.[17] CT or MRI should be performed to rule out a cerebral abscess.

Treatment

Patients must be treated with antibiotics according to the causal agent. When the etiology is not know, antibiotics should be chosen according to the age of the patient and the suspected portal of entry of bacteria.[56] Current knowledge does not favor the routine use of corticosteroids in most cases. Acute seizures should be treated with intravenous phenytoin of fosphenytoin; most of these patients will not need long-term AED therapy. However, patients with late seizures should be managed according to the guidelines of treatment of symptomatic epilepsies. Some patients, particularly those developing mesial temporal sclerosis as a late sequela may course with intractable epilepsy, and may require surgery for seizure control.[33]

Brain Abscess

Abscesses are localized infections occurring as the result of invasion of the brain parenchyma by pyogenic bacteria. Most common causal agents include *Bacteroides spp.*, *Staphylococcus aureus*, *Streptococcus spp.*, *Proteus spp.*, and *Enterobacter spp*. These lesions are most often related to the direct spread of bacteria from an adjacent focus of infection (paranasal sinuses, ears, orbits, or teeth), but may also be the result of hematogenous spread of microorganisms from distant foci of infection, usually located in the heart and lungs.[7]

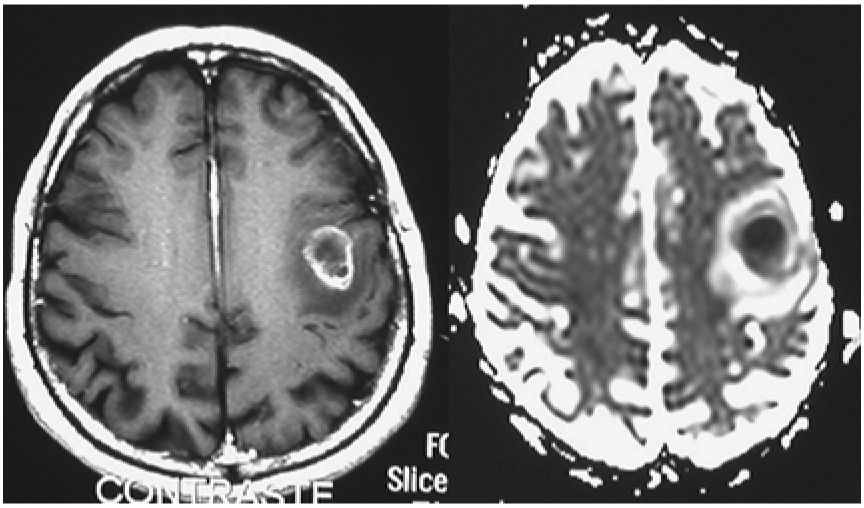

FIGURE 3. Gadolinium-enhanced, T1-weighted MRI (*left*) and apparent diffusion coefficient (ADC) map (*right*) of patient with brain abscess. Reduced ADC helps to differentiate abscesses from brain tumors (courtesy of Dr. Julio Lama, Guayaquil, Ecuador).

Pathophysiology

Most abscesses are located in the cerebral hemispheres at the cortico-subcortical junction. These lesions evolve into four stages: Early cerebritis (days 1–3), late cerebritis (days 4–9), early capsule formation (days 10–13), and late capsule

P.2647

formation (after 14 days). Once fully developed, an abscess consists of a necrotic center and a capsule composed of fibro-blasts, macrophages, and collagen fibers. The surrounding brain parenchyma shows severe swelling and gliosis, providing a substrate for the occurrence of seizures.[31]

Clinical Manifestations

A brain abscess may cause fever, signs and symptoms of increased intracranial pressure, and focal deficits that vary according to the location of the lesion.[7] Fever may be lacking, especially in the elderly or immunosuppressed patients. Seizures occur in more than 50% of patients during the acute phase of the disease, and almost 40% of survivors are left with residual epilepsy. A retrospective series showed that brain abscesses located in the temporal lobe were associated with the highest risk of developing late epilepsy.[31]

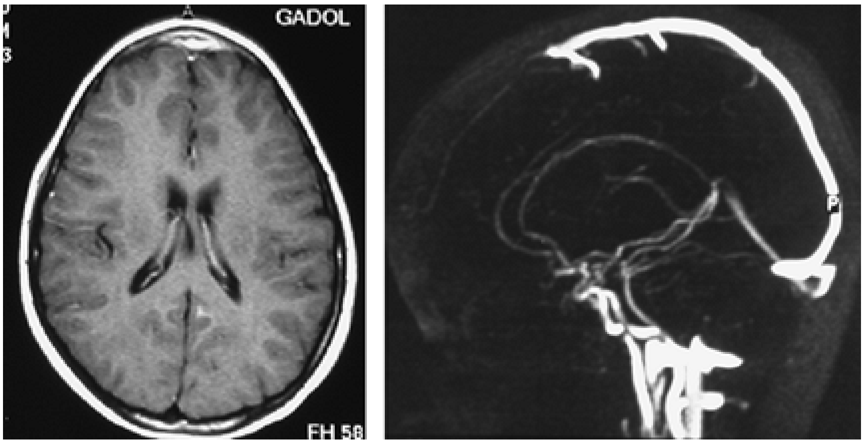

FIGURE 4. Gadolinium-enhanced, T1-weighted MRI (*left*) and MR angiography (*right*) showing epidural empyema and occlusion of anterior half of superior sagittal sinus in patient presenting with tonic–clonic generalized status epilepticus.

Diagnosis

Abscesses appear on CT and MRI as ring enhancing lesions surrounded by edema. The rim of enhancement is usually thicker at the cortical than at the ventricular side of the abscess. Lesions may be multilobulated, due to the formation of the so-called “daughter abscesses” (Fig. 2). New MRI techniques such as MR spectroscopy, diffusion-weighted imaging, and apparent diffusion coefficient (ADC) maps have been shown to be of value in the differentiation of abscesses from other space-occupying brain lesions such as brain tumors and tuberculomas.[24] The purulent center of a brain abscess has a reduced ADC as opposed to necrotic or cystic brain tumors presenting with elevated ADC values (Fig. 3).

Treatment

Patients usually require a combination of medical and surgical management. Antibiotics must be started without knowing the causal agent and their spectrum of action should cover both aerobic and anaerobic bacteria.[4] Increased intracranial pressure should be treated with mannitol or corticosteroids; the latter may reduce the concentration of antibiotics in the necrotic center of the lesion. Seizure prophylaxis is indicated as soon as a brain abscess is diagnosed, and most patients will require prolonged AED therapy.

FIGURE 2. Gadolinium-enhanced, T1-weighted MRI of patient with brain abscess showing multilobulated ring-enhancing lesion displacing midline structures.

Empyemas

Empyemas are collections of purulent material at the subdural and epidural spaces. They occur as the result of direct spread from an adjacent focus of infection and, in cases of brain abscesses, empyemas are most often caused by anaerobic bacteria.[28]

Pathophysiology

Empyemas distend the dura and cause septic thrombosis of intracranial dural sinuses. Cortical veins may also be occluded with the subsequent development of cortical infarctions. Seizures may occur as the result of these infarctions or due to direct irritation of the cerebral cortex by the infectious process, as occurred in patients with meningitis.

Clinical Manifestations

Intracranial hypertension and seizures are common manifestations of empyemas.[16] Focal neurologic deficits occur in patients with cortical venous infarctions. Careful examination usually reveals an infectious process of paranasal sinuses, orbits, or ears.

P.2648

Diagnosis

Neuroimaging studies usually allow the visualization of the empyema and the extent of compromise of intracranial dural sinuses (Fig. 4). A spinal tap is contraindicated in these patients due to the high risk of cerebral herniation.

Treatment

Most patients require surgical drainage of the purulent collection.[4,60] Broad-spectrum antibiotics should be given for several weeks, especially if osteomyelitis is present. AEDs should be started in all cases due to the high risk of seizures during the acute disease. The need of long-term AED therapy will be guided by the development of cortical infarctions.

Tuberculosis of the Central Nervous System

Tuberculosis is most often caused by *Mycobacterium tuberculosis*, an acid-fast bacillus that enters the body through the respiratory tract, settles in the lungs, and then reaches the CNS by the hematogenous route. The first step of brain invasion is the formation of small parenchymal brain tubercles called Rich foci. Then, tubercles may rupture into the subarachnoid space to cause meningoencephalitis or may grow in the brain parenchyma to form tuberculomas.[23]

Pathophysiology

Tuberculous meningitis is characterized by the formation of a thick exudate that encroaches cranial nerves and subarachnoid blood vessels causing arterial narrowing and cerebral infarctions. Luschka and Magendie's foramina may be occluded with the subsequent development of hydrocephalus. Also, damage of the cerebral cortex adjacent to areas of subarachnoid exudate may occur. These pathological changes are responsible for the occurrence of seizures as well as other manifestations of the disease.[47] Intracranial tuberculomas are space-occupying lesions composed of a core of caseation necrosis and a capsule of collagen tissue and inflammatory cells. The surrounding brain parenchyma shows edema and astrocytic proliferation, providing a substrate for the occurrence of seizures.[10]

Table 2 British Medical Research Council classification of severity of tuberculous meningitis

STAGE I

- Fully conscious and rational patient, who does not have any neurologic sign.

STAGE II

- Confused but not comatose patient, who may present with some focal neurologic signs such as hemiparesis or a single cranial nerve palsy.

STAGE III

- Stuporous or comatose patient, who has hemiplegia, paraplegia, or multiple cranial nerve palsies.

Clinical Manifestations

Tuberculous meningitis is a subacute disease characterized by fever, malaise, behavioral changes, headache, seizures, focal neurologic signs, and stupor or coma. The disease has been classified into three stages according to its severity (Table 2). Seizures occur in approximately 20% of cases, are more common in children than in adults, and may represent a predictor of poor outcome.[26,65] Intracranial tuberculomas present as mass lesions, with increased intracranial pressure, focal signs, and seizures.[23]

Diagnosis

Data provided by CSF analysis and neuroimaging studies usually allows a correct diagnosis of tuberculous meningitis.[23] The CSF shows lymphocytic pleocytosis, low glucose levels, and increased protein contents. Acid-fast bacilli may be seen in less than 50% of cases, but cultures are positive in 80%. PCR detection of mycobacterial antigens is of diagnostic value in doubtful cases. CT and MRI show hydrocephalus, abnormal leptomeningeal enhancement, and small cerebral infarctions.[45] In contrast, diagnosis of intracranial tuberculomas is more complex because they resemble other space-occupying lesions on neuroimaging studies, and CSF examination is most often unrevealing. On MRI, some tuberculomas are visualized with a hypointense center surrounded by concentric rims of different intensities (Fig. 5).

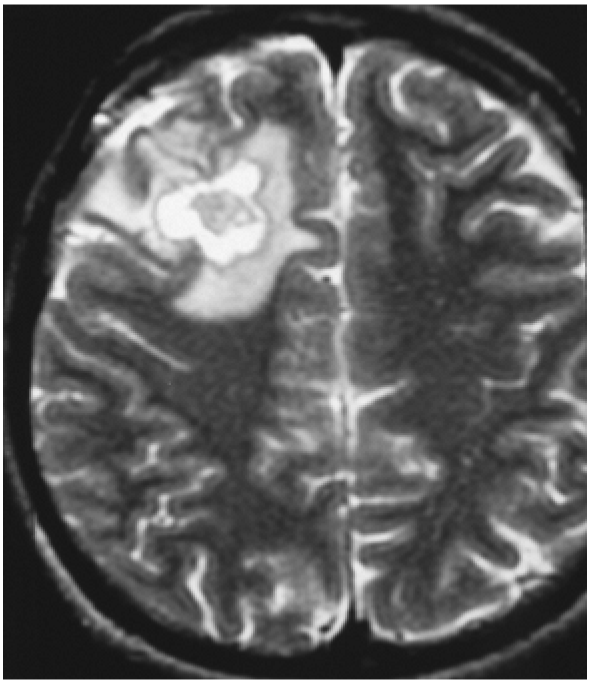

FIGURE 5. T2-weighted MRI of patient with intracranial tuberculoma showing characteristic "target" appearance of lesion.

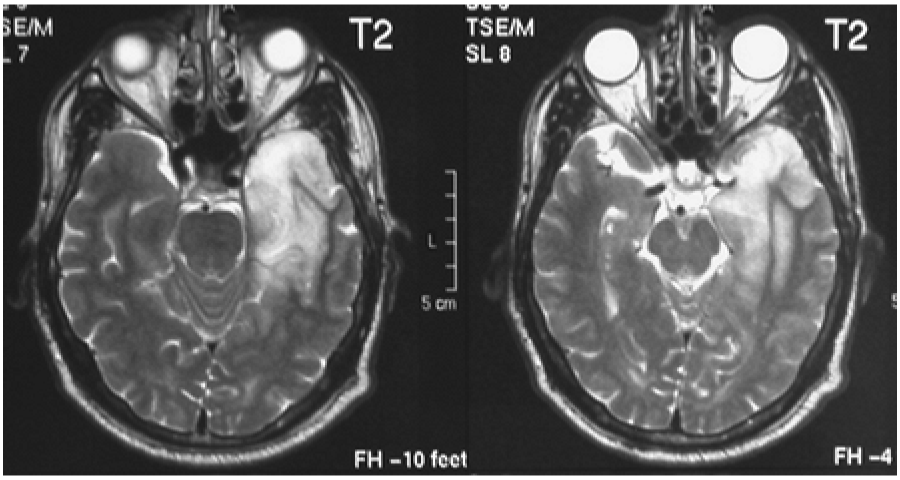

FIGURE 6. T2-weighted MRI of patient with herpes simplex virus type 1 encephalitis showing hyperintense lesion in left temporal lobe.

Treatment

Prompt therapy with antituberculous drugs is associated with decreased morbidity and mortality in patients with meningitis. Corticosteroids ameliorate the inflammatory reaction and reduce the risk of angiitis. Tuberculomas should also be treated medically because of the risk of disseminated disease after surgery. AED therapy is indicated in patients with seizures.

Viral Infections

Viral Encephalitis

A number of viruses may cause encephalitis, defined as a diffuse inflammation of the brain parenchyma.[57] Some of these conditions are mosquito-borne, whereas others are transmitted by rodents, ticks, non-human primates, or by direct human-to-human contagion. Some encephalitides result from direct viral invasion of the CNS, whereas others are related to the occurrence of postinfectious immune disorders. In some other cases, reactivation of a latent viral infection may cause encephalitis. Viral encephalitis may occur sporadically or in epidemic bouts, and some are cosmopolitan whereas others are restricted to certain areas. Herpes simplex virus type 1 (HSV-1) is the most common cause of sporadic viral encephalitis worldwide. Of the geographically restricted viral encephalitis, the most important are Japanese B encephalitis, Venezuelan equine encephalitis, Eastern equine encephalitis, and West Nile virus encephalitis, a formerly restricted disease that is currently spreading from Africa to Europe and America.[38]

Pathophysiology

Once in the CNS, viruses spread to involve the cerebral cortex, basal ganglia, cerebellum, and brainstem. Severity of brain damage is influenced by both the virulence of the offending agent and the immune status of the host. Pathological abnormalities in the brain parenchyma of patients with viral encephalitis include diffuse swelling, vascular congestion, demyelination, inflammatory infiltrates of mononuclear cells, microglial proliferation, formation of glial nodules, and diffuse necrosis of the cerebral cortex and basal ganglia. These changes explain clinical manifestations of viral encephalitis, including seizures.

Clinical Manifestations

Viral encephalitides usually have an acute or subacute onset followed by a rapidly progressive course that may kill the patient in a few days. Occasionally, encephalitis evolves over months, causing a slowly progressive brain damage. Clinical manifestations include fever, seizures, behavioral changes, cloudiness of consciousness, rigidity, and focal neurologic deficits related to the development of cerebral infarctions.[1,29] Some patients present myalgias, sore throat, conjunctivitis, skin rash, bleeding diathesis, and respiratory dysfunction.[9,29] Seizures may be generalized or partial, are most often recurrent, and may persist after the acute disease, especially in patients left with permanent brain damage.

Diagnosis

Viral encephalitis is diagnosed on the basis of virus isolation or detection of specific antibodies in serum, in the proper epidemiological context.[62] CSF examination is abnormal in about 90% of patients, and usually shows a lymphocytic pleocytosis associated with mildly increased protein contents and normal glucose levels.[57] Neuroimaging studies most often show diffuse brain swelling or multiple small cerebral infarctions. In some conditions, MRI findings may suggest the diagnosis by showing hyperintense lesions in the temporal lobe, as in the case of HSV-1 encephalitis (Fig. 6), or bilateral necrosis of the thalamus and striatum, as in patients with Japanese B and other flaviviruses encephalitis.[18,51]

Treatment

Antiviral agents are of value in some conditions such as in HSV-1 encephalitis (acyclovir or foscarnet), cytomegalovirus

P.2650

encephalitis (ganciclovir and foscarnet), and Lassa fever (ribavirin). Other viral encephalitides as well as those in which the etiology cannot be established may be treated initially with acyclovir and then with foscarnet if the patient deteriorates despite therapy.[29] Seizures must be aggressively treated with intravenous AEDs.

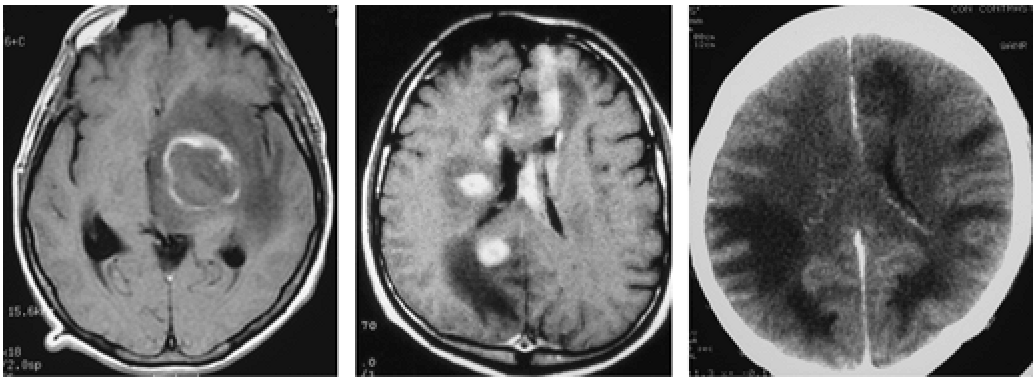

FIGURE 7. Neuroimaging findings in AIDS patients with seizures. Gadolinium-enhanced, T1-weighted MRI showing toxoplasma brain abscess (*left*) and intracranial lymphoma (*center*), and contrast-enhanced CT showing progressive multifocal leukoencephalopathy (*right*).

Acquired Immunodeficiency Syndrome

Acquired immunodeficiency syndrome (AIDS) affects millions of people worldwide. It represents the late stage of infection with the human immunodeficiency virus (HIV), a nononcogenic retrovirus that is acquired by sexual contact, blood transfusions, needle sharing, or vertically from the mother to the fetus. Neurologic complications of AIDS are protean, and may be caused by the HIV itself or by a number of opportunistic microorganisms or neoplasias.[37] Seizures may occur as the result of different pathogenetic mechanisms, including direct neuronal damage induced by HIV, the presence of space-occupying infectious or tumoral lesions within the brain, metabolic abnormalities, or even as a collateral effect of antiretroviral therapy.[55] Seizures may be the presenting symptoms of CNS involvement or may occur late in the course of the disease. It has been estimated that seizures occur 10 times more frequently in HIV-positive patients than in the general population.[25] In most cases, neuroimaging studies show toxoplasma brain abscesses, lymphomas, or progressive multifocal leukoencephalopathy (Fig. 7). Some patients presenting with seizures and no discernible mass lesion develop HIV-related encephalopathy in the short-term.[25,70]

HIV-positive patients with seizures must be treated with AEDs because of the high risk of recurrences. However, traditional AEDs should not be used. Phenytoin is associated with an increased prevalence of cutaneous reactions, valproic acid may favor HIV replication, and carbamazepine or phenobarbital interact with protease inhibitors.[25,27,42] Newer AEDs, such as topiramate or gabapentin, are the preferred drugs in these patients.[55]

Noninfectious Inflammatory Disorders

Rasmussen Encephalitis

Rasmussen encephalitis (RE) is a sporadic focal encephalopathy of unknown cause. A viral etiology has been postulated but never proved, and it has been suggested that the disease may be related to autoimmune mechanisms or to depletion of cellular immunity.[5] These hypotheses are supported by the fact that most patients had an infectious disease before the start of symptoms.

Pathophysiology

The brain of patients with RE shows astrocytic gliosis, microglial nodules, spongy degeneration, and perivascular inflammation. Pathological changes are always localized to the cerebral cortex of one hemisphere.[46] There is no sound pathogenetic mechanism explaining these findings, although it has been suggested that antibodies against subunit 3 of the inotropic glutamate receptor (GluR3) cause brain damage.[5] Those antibodies would be produced after an infectious process, and would enter the brain through a focal breach in the blood–brain barrier, thus explaining the unilateral nature of RE.

Clinical Manifestations

The disease most often affects children and has an acute onset characterized by partial seizures, followed by progressive hemiparesis and cognitive decline. Epilepsia partialis continua is common, with many patients dying with severe intellectual deterioration a few years after the onset of symptoms.[59]

Diagnosis

RE should be considered in children with a typical clinical picture in whom neuroimaging studies show unilateral cerebral atrophy. Electroencephalograms (EEGs) may show delta waves or multifocal spikes in the affected cerebral hemisphere. CSF examination reveals a mild mononuclear pleocytosis associated with increased protein contents.

Treatment

Antiviral agents, interferon-α, immunoglobulins, plasmapheresis, and corticosteroids have been empirically used in some cases. Many patients develop intractable seizures despite aggressive AED therapy, and will require cerebral hemispherectomy.[48]

Neurosarcoidosis

Sarcoidosis is a systemic granulomatous disease that more often affects African-American, middle-aged women. Although the etiology is unknown, it is accepted that exposure to certain infectious agents or environmental toxins triggers, in a susceptible host, a severe inflammatory response leading to noncaseating granuloma formation.[71] Sarcoidosis usually affects the lungs, the liver, and the eyes. CNS involvement occurs in 5% of cases, and does not necessarily occur in patients with systemic manifestations of the disease. Neurosarcoidoses usually present with cranial nerve palsies, peripheral neuropathy, or diabetes insipidus. Seizures may occur in patients who develop parenchymal brain or subdural granulomas.[34,61] Children are more prone to develop seizures than adults

(15% vs. 40% of cases, respectively).[3,32] Diagnosis is difficult in patients who do not have systemic disease, and is often disclosed after a brain biopsy.[34] Therapy includes corticosteroids and AEDs. The risk of developing recurrent seizures is related to the occurrence of fibrotic scars in the brain parenchyma after granuloma resolution.

Summary and Conclusions

Almost any infectious agent invading the CNS, and a number of inflammatory conditions affecting the brain parenchyma, may cause seizures. In this setting, seizures may be related to the pressure effects of a focal infection growing within the brain, to the irritative effects of a given infectious agent, or as part of a diffuse encephalopathy. In any case, seizures may occur during the acute phase of the disease or as a chronic sequelae of the infection. Initial therapy should be directed to stop seizures and to treat the specific infection. In many cases, AEDs must be given for years to avoid seizure recurrences irrespective of the successful management of the infectious process. Duration of AED therapy and the risk of seizure recurrence after AED withdrawal vary according to the severity of the infection and the occurrence of structural brain damage.

Chapter 266

Connective Tissue Diseases

Barbara S. Koppel

Introduction

Seizures occur in several connective tissue diseases, most frequently systemic lupus erythematosus (SLE), and in forms of vasculitis that involve the brain. Often, however, seizures are not due to the primary disease process itself, but rather to secondary conditions. For example, seizures may occur in the setting of hypoxic or metabolic encephalopathy. Chronic hypertension and accelerated atherosclerosis, even in the absence of antiphospholipid syndrome or cerebral vasculitis, increase the risk of stroke and hemorrhage, which in turn predispose to seizures. Both the underlying disease and its treatment with immunosuppressive drugs increase the risk of brain or meningeal infection, which can cause seizures. Finally, some therapeutic agents used in the management of collagen-vascular disease or vasculitis, such as tacrolimus and cyclosporine, cause an encephalopathy of which seizures are a manifestation.[29]

This chapter reviews the incidence of seizures in connective tissue and vasculitic diseases; when in the course of these illnesses, and under what circumstances, seizures can be expected; and pathophysiology, diagnostic testing, and treatment guidelines. The role of antiepileptic drugs in causing chemical and clinical signs of lupus is also discussed briefly.

General Principles of Autoimmunity in Epilepsy

Seizures occur in autoimmune disorders of the brain such as Hashimoto encephalopathy, Rasmussen encephalitis, paraneoplastic limbic encephalitis, and probably Landau-Kleffner syndrome.[87] In addition, in the absence of structural pathology, antibodies against membranes or ion channels have been proposed as causes for some cases of epilepsy. Some antibodies that are found may be just disease markers, but if there is a clinical response to treatments that lower antibody levels, or if animals immunized with the target antigen develop signs similar to those of the human disease, pathogenesis due to an immune reaction to a targeted antibody is confirmed.[105] In a study of 139 epilepsy patients, 26 had known autoimmune diseases (most often SLE and antiphospholipid syndrome) with antibodies to nuclear antigens. Although these antibodies did not correlate closely with seizure frequency, patients with antibodies against voltage-gated potassium channels and glutamic acid decarboxylase (GAD) generally had more seizures. This suggests a role for these antibodies in causing seizures, especially given that antibodies to voltage-gated calcium channels, gangliosides, glutamic receptor 3, and cardiolipins were not found.[70]

Systemic Lupus Erythematosus

Clinical Manifestations

Collagen-vascular disorders, including SLE, rarely present with seizures. Seizures almost always appear later in the course of active disease, especially during flares of systemic and central nervous system (CNS) lupus.[79] SLE is one of the most common autoimmune diseases, with an annual incidence of 1.8 to 7.6/100,000 and a prevalence of 39 to 51/100,000.[79] Onset is most common in early adult life, women account for 80% of patients, and non-whites (Asians and African-Americans) are disproportionately affected.[62,81] In addition to the nervous system, SLE affects, in order of frequency, joints, mucous membranes and skin (discoid lupus, malar rash, photosensitivity, alopecia), kidneys, pleura, heart, and bone marrow. Neurologic or neuropsychiatric complications have been reported in all series since Kaposi[53] first described them in 14% to 75% of patients >100 years ago.[2,13,46,71] Psychiatric symptoms include depression and psychosis. Neurologic syndromes include dementia, aseptic meningitis, seizures, stroke, movement disorders (especially chorea), myelopathy, and peripheral neuropathy.[2,14,37] Headache can be prominent due to benign intracranial hypertension, aseptic meningitis, and venous thrombosis.[46,61] Even in the absence of dementia or depression, neuropsychological testing reveals high frequencies of cognitive dysfunction.[46,47,71,72] Neurologic complications are a common cause of hospitalization in patients with SLE[89] and the second leading cause of death.[14,107] Early neurologic involvement, especially stroke, has a worse prognosis, but seizures also contribute to poor outcome when they occur in children with arthritis.[90] Seizures double the rate of mortality when found with nephritis in adults.[107]

Both partial and generalized seizures occur in SLE. Generalized seizures can be the sole evidence of brain involvement in diffuse CNS lupus [the term “cerebritis” is no longer used by the American College of Rheumatology (ACR) due its lack of specific pathologic findings], or they may occur as part of hypertensive or metabolic encephalopathy. Status epilepticus also occurs, especially in critically ill patients, in whom it may be a preterminal event.[109] Partial seizures can be a manifestation of cerebrovascular complications (hemorrhage, ischemic stroke, venous thrombosis), abscess, or meningitis.[110] Reflex epilepsy induced by acoustic and patterned visual stimuli has been reported,[16] as has photosensitive myoclonic epilepsy,[74] both in children with SLE. Psychiatric symptoms, especially psychosis and delirium, commonly coexist with seizures[14] and are reported to occur at some time in up to 50% of patients. Partial complex (nonconvulsive) status epilepticus presents with confusion, delirium, or hallucinations; electroencephalographic

P.2654

monitoring is often necessary to confirm the diagnosis,[14,86] which suggests that it may have been missed in the past.

Because of the multiple causes of neuropsychiatric symptoms, it is difficult to obtain meaningful incidence figures for seizures occurring in SLE. However, the fact that seizures are listed first on the SLE activity index devised by the ACR,[12] even after this was updated to separate persistent from acute symptoms,[40] indicates their importance in this condition. In one series of 91patients with SLE, 22% experienced generalized seizures and an additional 5% had partial seizures.[37] Multiple factors, including renal failure, coagulopathy, and hypertension, contributed to seizure occurrence, whereas 3 patients had seizures completely unrelated to SLE. Of interest, 2 patients had seizures only during flares of their SLE, and 8 of the 14 patients who had had strokes experienced seizures during the course of their illness. Most series do not provide sufficient detail to conclude whether the reported seizures are due to SLE or to other conditions.

Diagnostic Tests

In patients with seizures, brain imaging should be done promptly to look for evidence of intracranial hemorrhage (parenchymal or subarachnoid), cerebral infarction, or other structural pathology. Hemorrhage is associated with vasculitis, which occurs in only a minority of patients with SLE.[78] Cortical atrophy is a frequent finding[46,49] and may relate to either long-term steroid use or disease duration.[41] Abnormalities detected by brain magnetic resonance imaging (MRI) scans have been reported in up to 75% of patients with active disease, but the findings are frequently nonspecific subcortical and periventricular punctuate areas of increased T2 signal that most likely reflect small-vessel disease or, possibly, demyelination with gliosis.[41,92] In patients with chronic SLE, abnormal MRI scans were found in 57% of cases; many of the findings were clinically silent.[41] SLE patients with neuropsychiatric symptoms have increased cerebral atrophy and more T1- and T2-weighted lesions compared to both controls and SLE patients without such symptoms.[3] However, only 4 of 43 patients had seizures in this study. Similar lesions have been reported in neurologically asymptomatic patients.[13] Acute inflammatory lesions are enhanced with gadolinium, and in symptomatic patients, serial MRI scans can document loss of enhancement or complete resolution as clinical improvement occurs.[71,110] MR venography and computed tomography (CT) angiography are useful in detecting thrombosis, especially given the dangers of invasive angiography in patients with anticardiolipin antibodies. Transcranial Doppler can be used to follow ischemic changes over time.[57]

Functional brain imaging modalities that have been used in patients with SLE include single photon emission computed tomography (SPECT), positron emission tomography (PET), and MR spectroscopy.[27,92,108] SPECT is abnormal in patients with ischemic stroke, showing focally reduced perfusion in areas that correlate well with both CT and clinical findings. At times, SPECT may be an even more sensitive indicator of cerebral ischemia than MRI, with hypoperfusion preceding clinical symptoms in patients undergoing serial scans.[50,111] Loss of the vascular response to acetazolamide detects marginally perfused areas that are at risk for infarction.[43] In patients with psychosis, SPECT has revealed decreased perfusion in the frontal lobes.[56] PET scans using fluorodeoxyglucose (FDG) demonstrate hypometabolic areas in regions of ischemia or infarction.[22,92]

Serologic markers have been studied in both generalized and CNS lupus. Positive antinuclear antibody (ANA) is found in 95% of patients with SLE, and anti–double-stranded DNA is found in 30% to 75%.[76] Although anti-Sm (smith) antibody is found in <30% of patients, it is specific for SLE. Other laboratory abnormalities that are useful in following active disease are elevated CSF complement 3 and 4,[52] and anti–single- or anti–double-stranded RNA.[33] Serum markers of autoantibodies, especially antiphospholipids (aPL), are increased in SLE patients with neuropsychiatric symptoms compared to those without them.[110] The tests most often used to distinguish among the different connective tissue disorders and types of vasculitis are summarized in Table 1. Anticardiolipin antibody levels, especially immunoglobulin G (IgG), correlate with the occurrence of seizures,[48] whereas antiribosomal P seems to be a marker of psychosis without other neurologic symptoms or signs.[14,33,113] The presence of antibodies to native DNA rather than to the histone complex favors idiopathic rather than drug-induced lupus.[16,21,36,79] Although antineuronal antibodies reflect diffuse pathology and have been reported in 60% of patients with neuropsychiatric SLE, they are also found in patients without neurologic symptoms, raising doubt as to their role in "cerebritis."[27,71,99]

In patients with cerebral ischemia or infarction, the following findings on blood tests can be helpful: The presence of anticardiolipin antibodies, of which IgG is more significant for stroke[79,116] protein S or C deficiency (this is sometimes caused by the nephrotic syndrome[61] when kidney damage is prominent); thrombocytopenia; and lupus anticoagulant using kaolin clotting time or lupus anticoagulant (LAC)-prolonged activated partial thromboplastin time (aPTT). Echocardiography can assist in determining whether there is a cardiac source for cerebral emboli, although marantic (Libman-Sacks) endocarditis is only rarely responsible for stroke in SLE.[46]

Lumbar puncture is required whenever infection is suspected, although significant thrombocytopenia or other clotting abnormalities need to be corrected before it can be performed to avoid producing a lumbar epidural hematoma. Up to one third of patients undergoing a lupus flare with CNS involvement have nonspecific findings in the cerebrospinal fluid (CSF) including increased numbers of white cells (usually lymphocytic) and elevated protein levels.[46] CSF antiribosomal-P and anticardiolipin antibodies correlate with disease activity,[112] but they can also be related to vascular damage that produces breakdown of the blood–brain barrier. Similarly, CSF interleukin-6 (IL-6), a regulator of autoantibody production, can be elevated in patients with infection and is thus best viewed as a nonspecific inflammatory marker.[46,103,112] CSF antineuronal antibody, oligoclonal bands (seen in 25% of one series, produced locally in half),[72] and IgG levels decline with treatment,[110] suggesting that they play a role in the pathogenesis of neuropsychiatric symptoms.

Electroencephalographic abnormalities have been reported in up to 65% of patients with SLE,[69] including those without symptomatic cerebral involvement.[110] The most common finding is generalized slowing, which correlates better with cognitive dysfunction than with the occurrence of seizures.[14,46] For example, in one series of 42 patients, 11 of whom had seizures, EEG recordings did not reveal epileptiform activity in any, although focal slowing was present in 29%, and diffuse slowing was seen in 26%.[49] In contrast, however, a study of 120 patients with SLE found that epileptiform activity occurred in one third, but none of these patients had seizures.[69] Monitoring critically ill SLE patients using continuous EEG is useful in discovering reversible causes of altered mental state or coma, including seizures and metabolic encephalopathy.[86]

Pathophysiology

There are diverse causes of seizures in patients with SLE. Cerebral involvement by lupus itself results in seizures through immune, vascular, and inflammatory mechanisms. Generalized seizures, often accompanied by neuropsychiatric symptoms

P.2655

P.2656

and headache, are associated with increased titers of antineuronal antibodies, elevated levels of CSF IgG, and oligoclonal bands,[72] as well as cytokine production.[46] Whether these are simply markers of cerebral lupus or are actually pathogenic is not known,[110] although loss of self-tolerance leading to increased cytokine and T- and B-cell production undoubtedly plays some role. Antibodies against brain reactive antibodies,[99] synaptosomes,[46] and gangliosides[67,88] are also increased, especially in patients with seizures or psychosis.[99] Anticardiolipin antibodies from patients with SLE reduce γ-aminobutyric acid (GABA)-mediated chloride currents in snail neurons, a finding that may be relevant to development of seizures.[64]

Table 1 Features of Syndromes with Primary or Secondary Vasculitis

	Patients (%)					
Disease	**CNS**	**Seizures**	**When**	**Vessel size**	**Laboratory**	**Radiology**
PACNS	95	30	Anytime	Small, medium, large; granulomata, stenosis, beads	CSF: > 10 WBC, Pro > 100; culture, Ag, Ab, + oligoclonal bands	MR: subcortical ↑signal T2, meningeal enhancement, mass lesion +/-MRA, SPECT changes
SLE	11–75	12–50	Early or with flares	Small artery vein, capillary Rare stenoses in large arteries (vasculitis rare)	Pancytopenia, +ANA, +/- anticardiolipin, + n-dsDNA (homogeneous), + Sm or RNP (speckled) + RNA (nucleolar), antiribosomal P, ↓complement during flare; CSF: ↑protein, few lymphs, ↑IgG, oligoclonal bands	Hemorrhage with vasculitis; CT, MRI: nonspecific ↑signals; wm, resembles hypertensive; rare abnormal angiogram; MRA; atrophy (diffuse involvement) PET ↓ metabolism
APA			With CVA	Rare vasculitis, medium, large, thrombosis	+ Antiocardiolipin Ab (IgG, IgM), +LA or ↑pTT, ↓plt	Multiple cortical and subcortical strokes, SPECT diffuse and focal ↓ uptake
WG	3		Late	Arteriole, venule, rare medium large	Anti-cANCA>>pANCA; kidney, lung, sinus involvement	Sinusitis
RA	Rare	<1	Anytime	Any size, near involved meninges	+RF	Enhanced meninges, granuloma, or pachymeningeal plaque,

						hemorrhage
SS	Rare	<1	Anytime	Small outside CNS	Anemia, ↑ESR, +RF, +ANA, anti- Ro(SSA), La(SSB), hyperyglobulinemia	MS-like lesions
Behçet	5–20	<1	With flare	Capillories, veins, often brainstem	Mucous membrane lesions, uveitis, CSF: few L or N, sl ↑ Pro, oligoclonal bands	Meningeal thickening; small irregular lesions brainstem; spinal cord, deep wm
Cogan	3–5	<1	Rare	Aorta, any	Eye findings, CSF lymphs	Rare cavernous sinus thrombosis
PAN	3–28	1.5	Rare	Small, medium, branch-point aneurysms	↑ESR, ↑WBC, anemia + HepB, HepC, HIV, pANCA	Single or multiple strokes, often normal, irregular vessels with aneurysms on angiogram
MPA	8	<1	Rare	Small artery, capillary, venule	+pANCA, no Hep B	CXR pulmonary hemorrhage, normal CNS studies usually
TA	1.5	<1	Anytime	Medium, large carotid (external) rare intracranial	↑ESR, ↑CRP	Rare infarct, angiogram beading

Ab, antibody; ANA, antinuclear antibody; APA, antiphospholipid antibody; cANCA, cytoplasmic-staining antineutrophil cytoplasmic autoantibody; CNS, central nervous system; CRP, C-reactive protein; CSF, cerebrospinal fluid; CT, computed tomography; CVA, cerebrovascular accident; CXR, chest x-ray; ESR, erythrocyte sedimentation rate; GA, granulomatous angiitis; HepB, hepatitis B; HepC, hepatitis C; IgG, immunoglobulin G; IgM, immunoglobulin M; L, lymphocyte; LA, lupus anticoagulant; La(SSB); MPA, microscopic polyangiitis; MR, magnetic resonance; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; MS, multiple sclerosis; N, neutrophil; n-dsDNA, non double stranded DNA; PACNS, primary angiitis central nervous system; PAN, polyarteritis nodosa; pANCA, perinuclear staining antineutrophil cytoplasmic autoantibody; PET, positron emission tomography; plt, platelet; Pro, protein; PT, prothrombin time; pTT, partial thromboplastin time; RA, rheumatoid arthritis; RF, rheumatoid factor; RNP, ribnonuclear protein; Ro(SSA); sl, slight; SLE, systemic lupus erythematosus; Sm, Smith antibody; SS, Sjogren syndrome; SPECT, single photon emission computed tomography; TA, temporal arteritis; WBC, white blood cells; WG, Wegener granulomatosis; wm, white matter

After brain involvement by lupus itself, the next-most-common cause of partial and secondarily generalized seizures is cerebral infarction. Infection may also occasionally be a cause. Infarcts can occur from vasculitis caused by immune-complex deposition, emboli from Libman-Sacks endocarditis, enhanced platelet aggregation—due either to endothelial damage or antiphospholipid antibodies—and hypercoagulable states.[14,37,61,109] Cerebral hemorrhage is associated with hypertension, renal failure, and vasculitis. Ironically, accelerated atherosclerosis in patients receiving long-term corticosteroid therapy also contributes to increased risk of cerebrovascular disease, although the role of inflammation promoters (cytokines, proteases, adhesion molecules) is probably paramount.[66] Cerebral ischemia of any cause can be associated with seizures, either at the time the infarct occurs (acute symptomatic seizures) or much later (remote symptomatic seizures). Microinfarcts due to vasculopathy contribute to generalized seizures and depression of mental status.

Seizures can occur as symptoms of a metabolic encephalopathy that is most often related to uremia[109] or as a consequence of lupus-related cardiac disease causing heart block with secondary cerebral ischemia.[75] Because multiple potential causative factors can contribute to seizures even in individual patients, it is frequently difficult to identify SLE as the primary cause. For example, in a review of 91 SLE patients with neurologic dysfunction, more than one third of those with seizures had had a stroke, 2 patients had probable idiopathic epilepsy, and 1 had posttraumatic seizures.[37] Two patients had seizures only during lupus flares.

Treatment

Antiepileptic drug (AED) therapy is not always needed, especially in circumstances in which underlying causes, such as metabolic abnormalities, hypertension, or infection, can be quickly and successfully treated.[93] Seizures occurring with systemic lupus exacerbations often respond to intravenous pulsed methylprednisolone alone. When seizures are frequent, short-term treatment with AEDs is necessary until the lupus flare is suppressed. Seizures occurring in the context of neuropsychiatric symptoms without other factors indicate cerebral parenchymal involvement by lupus and require immunosuppression.[79] Children with SLE who have depression or behavior problems almost always respond to corticosteroids, which suggests that immune-mediated neuronal dysfunction, not a reactive psychiatric condition, is responsible.[62] The incidence of steroid-induced psychosis is often exaggerated. Most patients who develop hallucinations and other psychotic symptoms require increased doses of steroids, not a decrease.[25,55] In addition to oral and intravenous steroids, other immunosuppressive drugs in common use include cyclophosphamide, azathioprine, and cyclosporine.[102] Cyclosporine must be used with caution in patients with seizures both because it can provoke seizures and because it interacts with antiepileptic drugs that are hepatic enzyme inducers. Intravenous immunoglobulin has also been effective.[101] Stroke prevention includes anticoagulation, with or without antiplatelet aggregants.[79,81] Patients with remote-symptomatic seizures generally require long-term antiepileptic drug therapy.

Drug-Induced Lupus

SLE has been attributed to almost all anticonvulsant drugs, as well as to other medications such as procainamide, chlorpromazine, isoniazid, and hydralazine.[7,21,32,39] Clinical manifestations are mild, appear only when the suspected medication is being used, and subside quickly after it is discontinued. Symptoms and signs are usually limited to the skin and joints with accompanying fever and malaise. Visceral, kidney, and CNS involvement is extremely rare. The immune mechanisms underlying drug-induced lupus have been reviewed recently.[117] Although antibodies to the histone complex of DNA are present in 90% of drug-induced cases, they are also found in up to one third of idiopathic SLE patients. Other laboratory abnormalities that drug-induced cases share with idiopathic SLE include cytopenia, positive ANA, prolonged PTT, and rheumatoid factor.[32] Antibodies to single-stranded DNA are common in drug-induced lupus, but antibodies to native double-stranded DNA do not occur. Complement levels are normal.[36] Symptoms resolve soon after the offending drug has been withdrawn, although antibody production may persist for months. In patients with SLE and seizures, AEDs should be prescribed as clinically indicated without undue concern about exacerbating the underlying condition, because only isolated cases of drug-induced lupus attributed to AEDs have been reported.[15,36,110]

Cerebral Vasculitis: Clinical Syndromes

Vasculitis with CNS involvement occurs alone or in combination with several diseases, all of which produce symptoms by inflammatory mechanisms that create structural damage to blood vessels that may lead to ischemia or hemorrhage. In addition to primary autoimmune processes, vasculitis is seen with several collagen-vascular diseases, infections, tumors, or paraneoplastic syndromes, as a consequence of amphetamine, cocaine, or other stimulant use, and with other drugs. The annual incidence of vasculitis is about 4/100,000.[78] Ischemia results from several pathologic processes, including deposition of antigen–antibody complexes in vessel walls, infiltration of blood vessel walls by inflammatory cells, and formation of antibodies to platelets and other cell-mediated immune mechanisms.[17,63,78,115,116] Different conditions affect blood vessels of a particular size and at various sites.[111] Some types of vasculitis affect the brain primarily; others are systemic and involve multiple organs, including the brain. In addition to ischemic strokes, hemorrhage can occur, especially in the presence of aneurysm.[78,80] When many small blood vessels become occluded, diffuse encephalopathy and even coma results. Other symptoms include fluctuating level of consciousness and systemic signs such as fever, diffuse muscle or joint pains, weight loss, anemia, and headache.[17,78] An international consensus group recently updated the classification of the various forms of vasculitis.[98] Several types (polyarteritis nodosa, Churg-Strauss syndrome, temporal arteritis) mainly involve the skin, peripheral nerves, and muscle.[59] Seizures occur as complications of cerebral infarction, metabolic encephalopathy related to hepatic or renal failure, or steroid encephalopathy.[59] Seizures occur in about 4% of patients with polyarteritis nodosa.[28] Although brain involvement is common in Behçet disease, seizures are rare.[23,80] Electroencephalography may be necessary to exclude subclinical

P.2657

seizures in patients with confusion, behavioral changes, and depressed levels of consciousness.[4,86] Some authors have suggested that a vasculitis may be the cause of Landau-Kleffner syndrome,[87] although the evidence for this is weak (see Chapter 242). In general, children who have cerebral vasculitis are less likely to have seizures than are adults.[8]

Connective tissue diseases are among the causes of secondary CNS vasculitis that can lead to seizures. Arteritis is also a complication of some infections (most notably cytomegalovirus, tuberculosis, herpes simplex, herpes zoster, and aspergillosis), vasoactive drugs (phenylpropanolamine, ergotamine, amphetamines, and cocaine), malignancies (lymphoma), and drug hypersensitivity reactions.[17,45,98,114] In these conditions, patients usually have a subacute or chronic course characterized by headache, behavioral or psychiatric symptoms, confusion and altered mentation, as well as generalized seizures. Large-vessel ischemia produces prominent focal neurologic signs and partial seizures. The presence of systemic signs such as fever, nausea, weight loss, and fatigue is variable.

Granulomatous Angiitis (Primary Central Nervous System Angiitis)

Seizures are most often a feature of primary (isolated) granulomatous angiitis of the brain: They occur in 20% to 44% of patients.[1,17,19] Seizures are less often encountered in a recently described “benign” form of granulomatous angiitis that often lacks angiographic evidence of vasculitis and is associated with a better outcome.[20] The incidence of seizures is much higher than can be accounted for by stroke alone, which occurs in no more than 15% of cases, usually those with medium- and large-vessel involvement. Onset of the disorder is subacute, and the course is consistent with a progressive encephalopathy. Focal signs are common but can be transient. Children with primary angiitis have seizures, cumulative neurologic deficits, and headache due to granulomatous invasion of small cerebral vessels.[60] Laboratory findings include CSF pleocytosis and high protein content with normal glucose.[17,114] Meningeal or brain biopsy is required for definitive diagnosis because similar clinical and arteriographic findings can occur in other inflammatory and neoplastic diseases.[17,114]

Diagnostic Tests

When cerebral vasculitis is suspected as a cause of seizures, laboratory testing should be directed to obtaining evidence of an autoimmune disorder and to determining whether there is systemic as well as brain involvement. Blood tests should include erythrocyte sedimentation rate (ESR), C-reactive protein,[66] autoantibody titers (antinuclear, antineutrophil, anticardiolipin), complement levels, creatinine, liver enzymes, and creatine phosphokinase.[98] In granulomatous angiitis, the ESR is normal in 30% of patients.[45,78] Cerebrospinal fluid should be obtained for evidence of inflammation and to exclude infection and neoplasia. In up to 80% of patients with granulomatous angiitis, the CSF shows a lymphocytic pleocytosis, elevated protein, and normal glucose.[45] Brain MRI may show findings consistent with small-vessel disease and stroke,[111] gyral or parameningeal enhancement and edema, and mass lesions in 10% of cases that may mimic abscess or sarcoid.[79,111] Cerebral angiography, although insensitive for changes affecting smaller vessels, can sometimes be helpful and generally should be performed.[45,54,106] Brain and meningeal biopsies are necessary for definitive diagnosis,[31] although these have a false-negative rate of about 25%.[17,114]

Treatment

Treatment of cerebral vasculitis is based on immunosuppression using corticosteroids or cytotoxic agents such as cyclophosphamide.[1,18,44,45,77,98] There is little evidence, however, that these drugs are effective in primary granulomatous angiitis of the brain. When vasculitis is secondary to an infection or neoplasia, the underlying disease must be treated. Plasmapheresis has helped in some cases of steroid failure.[26] Seizures can generally be controlled by carbamazepine or phenytoin; there is less experience with newer AEDs. Because encephalopathy is usually present, benzodiazepines and barbiturates, which can further depress mental status, should be avoided.

Wegener Disease

Wegener granulomatosis results from immune-mediated necrotizing granuloma formation in the mouth, nose, ears, upper and lower respiratory tract, and sinuses, sometimes accompanied by vasculitis and glomerulonephritis.[84] Neurologic complications occur in one third of patients. Cranial or peripheral neuropathies are most common, but stroke and seizures are not rare.[84] Multifocal myoclonus has been described in one child.[44] Wegener granulomatosis is associated with seizures in up to 10% of patients.[84] Vasculitis involving small and medium blood vessels is the presumed etiology of both strokes and seizures, although renal hypertension is associated with cerebral hemorrhage. Direct intracranial extension of the granulomatous pathology can occur from involved sinuses. Seizures are also seen as a preterminal event in patients with severe pulmonary or renal disease, sepsis, and disseminated intravascular coagulation.[104]

Diagnosis of Wegener granulomatosis is based on demonstration of oral ulcers or purulent, bloody nasal discharge, pulmonary involvement with a characteristic X-ray picture, microhematuria, and biopsy demonstrating perivascular granulomatous inflammation. The condition is classically associated with antineutrophil cytoplasmic antibodies (ANCA) in many but not all patients.[42] Cytoplasmic antibodies (cANCA) are more frequent than perinuclear antibodies (pANCA).[51] ANCA titers decline following immunosuppressive treatment but do not correlate reliably with disease activity. CT or MRI of the brain may show meningeal disease or parenchymal destruction consistent with stroke.[100] The most common MRI finding is diffuse white matter hyperintense signals on T2-weighted images[44] that are maximal posteriorly.[85] Treatment includes corticosteroids and cyclophosphamide, with immune globulin reported as having helped one child.[97]

Behçet Syndrome

Behçet syndrome is a form of vasculitis that affects small, medium, and large vessels; both arteries and veins can be involved. This disease occurs mainly in young adults, men more often than women, and classically manifests with the triad of mouth ulcers, genital ulcers, and inflammatory iritis, uveitis, or keratoconjunctivitis. The brain, especially the brainstem, is involved in about 5% of cases.[23] The picture is one of meningoencephalitis. Cranial nerve palsies, focal cerebral signs (aphasia, hemiparesis), encephalopathy, and seizures have been reported. Neurologic dysfunction appears late in the course, although rarely it is the presenting problem.[73] In one study, seizures

occurred in 4.5% of 223 patients with CNS involvement.[9] Half of these patients had other risk factors for seizures, such as insertion of ventriculoperitoneal shunts, brain biopsy, or unrelated surgical interventions. Patients with seizures had a high mortality rate, attributable to the underlying meningoencephalitis.

Rheumatoid Arthritis

Rheumatoid arthritis is an inflammatory disease that produces erosive arthritis of many joints; the viscera are occasionally involved. Neurologic manifestations, although uncommon, sometimes occur in patients with long-standing disease. Cases of polyneuropathy, myopathy, atlantoaxial dislocation with spinal cord compression, myelopathy caused by rheumatoid nodules in the spinal dura, meningitis, and, rarely, rheumatoid nodules in the brain parenchyma[15] have been described in addition to secondary complications of vasculitis.[24,83] Seizures are extremely rare, and when they occur, they are most often a consequence of stroke caused by immunoglobulin, complement, or amyloid deposition in arterioles. Seizures have also been attributed to parenchymal rheumatoid nodules.[15] Rheumatoid cerebral involvement is treated by immunosuppressive therapy such as cyclophosphamide.[79] When seizures are present, AEDs are usually required.

Sarcoidosis

The nervous system is involved in approximately 5% of patients with sarcoidosis.[91,96] Neurologic symptoms usually appear within the first 2 years following diagnosis, although in Sponsler et al.'s review of the literature, they occurred late in the course in almost one third of patients.[95] Seizures occur in about 20% of patients with CNS sarcoidosis. Partial seizures suggest a mass lesion.[58,95] Most, however, are secondarily generalized.[96] Generalized seizures accompanying meningitis or hydrocephalus are associated with a poor prognosis and increased mortality,[30,58] a correlation that presumably reflects more severe parenchymal involvement. Focal seizures that are related to isolated mass lesions have a better prognosis.[95] Seizures occur at higher frequency in children <13 years of age (38% of one series) than in adults[10] without deleterious effect on prognosis. Seizures may also be symptomatic of hyponatremia due to hypothalamic dysfunction or inappropriate antidiuretic hormone (ADH) secretion due to lung disease.[96] Patients with sarcoid are at risk for opportunistic infections and malignancies that may also cause seizures.

Angiotensin-converting-enzyme (ACE) levels are usually elevated in the serum and may be increased in the CSF as well.[94] Brain MRI demonstrates inflammatory changes and granulomata in the majority of patients with neurologic symptoms or signs.[94] Oligoclonal bands are found in the CSF in about one half of these patients.[72]

Patients with sarcoidosis who have seizures require treatment with AEDs, but seizures are often refractory until the underlying disease remits.[30,65]

Scleroderma

Neurologic manifestations of scleroderma (also known as *progressive systemic sclerosis*) are uncommon and usually limited to myopathy and neuropathy. Seizures or other manifestations of brain involvement are rare,[11,49] probably because the antigenic targets in scleroderma are components of collagen, which in the brain occurs only in the basement membrane of some blood vessels and in the leptomeninges.[49]

In the few published case reports, seizure etiology has been unclear but may have been stroke related, due to carotid or intracranial arteritis, or due to hypoperfusion secondary to cardiac involvement.[82]

Sjögren Syndrome

Sjögren syndrome is common and often complicates other connective tissue diseases.[118] Diagnostic criteria include dry mouth (xerostomia), lack of tearing (keratoconjunctivitis sicca) causing dry eyes (xerophthalmia), and characteristic pathologic findings in a salivary gland biopsy. It has been estimated that Sjögren syndrome affects 3% of adults, mostly women.[5] The most common neurologic complications are peripheral neuropathy and polymyositis. CNS manifestations are rare,[34,49] although meningitis and cerebral involvement with cognitive impairment and mental symptoms were seen in 15% of patients with Sjögren syndrome at one tertiary referral center.[5]

Seizures have been estimated to occur in up to 1.5% of patients and are most often partial or secondarily generalized. They are usually attributed to vascular involvement,[6] although autopsy findings in one patient with partial seizures were limited to leptomeningeal lymphocytic infiltrates and laminar cortical necrosis and gliosis without evidence of vasculitis.[38]

MRI scans are abnormal in up to 80% of patients with Sjögren syndrome who have CNS symptoms.[68] Findings include multiple, small, T2-weighted signal abnormalities in the subcortical white matter and periventricular areas (similar to findings in multiple sclerosis), as well as cerebral infarcts and cortical atrophy. The white matter lesions do not resolve with treatment. Cerebral angiography demonstrates changes consistent with arteritis in about 20% of CNS cases.[5] EEG abnormalities are common, and both epileptiform and nonspecific changes have been described.[5,49] Patients with CNS involvement frequently have anti-Ro antibodies in serum.

The pathophysiology of the neurologic manifestations of Sjögren syndrome is unknown, although immune-mediated damage to blood vessels is hypothesized.[5] Vasculitis is commonly presumed to be present, although neither immune-complex deposition nor vasospasm has been excluded as possible mechanisms. Anti-Ro (SSA) antibodies have been implicated; antineuronal antibodies have not been found. Treatment includes corticosteroids, plasmapheresis, and monthly injections of cyclophosphamide.[34]

Sneddon Syndrome

Sneddon syndrome was identified in 1965 in patients who had livedo reticularis (a fishnet-like mottling of the skin) and vasculitis involving medium-sized cerebral blood vessels.[35] About one half the patients have antiphospholipid (aPL) antibodies, which are associated with strokes in patients <45 years of age, headache, and chorea. Seizures have been reported to occur more often in aPL-positive patients (14%–37%) than in aPL-negative patients (0%–11%). They have not been associated with clinical or MRI ischemic events, which suggests an immune etiology. Some patients with Sneddon syndrome have features of SLE. Treatment with steroids can worsen vascular complications; antiplatelet agents have been as effective as anticoagulation with warfarin in aPL-positive patients.[35]

Summary and Conclusions

Seizures can occur in many connective tissue diseases and vasculitis syndromes, although the incidence varies considerably across the different disorders. Seizures are seen most often as a feature of SLE and primary granulomatous angiitis of the brain. Generalized seizures are usually associated with signs of

encephalopathy reflecting diffuse brain involvement by the vasculitis or metabolic or infectious complications. Partial seizures usually indicate ischemic complications or, less often, inflammatory lesions. An infectious cause must always be considered before starting or intensifying immunosuppressive regimens. AED therapy must be individualized, based on usual clinical practice. Drug-induced lupus is rarely serious or permanent.

Chapter 267

Electrolyte, Sporadic Metabolic, and Endocrine Disorders

Giuseppe Gobbi

Salvatore Grosso

Gianna Bertani

Antonella Pini

Introduction

Acute and chronic metabolic, electrolyte, and endocrine disorders may cause dysfunction or impairment of the central nervous system, including epileptic seizures.

Occasional seizures resulting from metabolic and electrolyte imbalances are typical and well-recognized events in neonates. However, seizures may develop in later childhood and adulthood as the presenting symptom of an endocrine or metabolic disturbance, and these have been reported with increasing frequency, sometimes in newly recognized clinical conditions such as primary magnesium deficiency. Metabolic disorders in which seizures are one of the main symptoms also occur with liver and kidney transplantation.[4]

Epilepsy as an initial and prominent symptom of unrecognized gastrointestinal disease has been described in cases of gluten intolerance.[11,31,88202] Finally, there have been anecdotal reports of patients affected by concomitant endocrine, metabolic, and gastrointestinal disorders in whom seizures were the presenting manifestation.

In this chapter, the main metabolic, endocrine, and gastrointestinal disorders in which seizures or epilepsy may occur are reviewed based on the literature. The following conditions are considered:

- Electrolyte disorders of sodium (hyponatremia) and magnesium (hypomagnesemia).
- Renal failure (uremic encephalopathy, aluminum encephalopathy, dialysis disequilibrium syndrome, dialysis encephalopathy syndrome).
- Endocrine disorders, including pituitary disorders, hypothalamic hamartoma, thyroid disorders (primary hyperthyroidism, primary hypothyroidism, Hashimoto encephalopathy), parathyroid disorders (hypoparathyroidism, hyperparathyroidism), pancreatic disorders (diabetes mellitus or nonketotic hyperglycemia, diabetic and nondiabetic hypoglycemia), and reproductive disorders.
- Gastrointestinal diseases (celiac disease, orthotopic liver transplantation).

Electrolyte Disorders

Electrolyte disorders can be associated with seizures especially in neonates, but also in children and adults. Seizures may be the presenting symptom of an isolated disorder or of a disorder associated with renal or endocrine disease. Seizures may be present in cases of sodium, magnesium, and calcium imbalance. Seizures associated with sodium and magnesium imbalance are described in this section on electrolyte disorders; disturbances of calcium balance are discussed in the section on endocrine disorders.

Sodium Electrolyte Disorders: Hyponatremia

General Findings

Hypotonic hyponatremia is an electrolyte disturbance characterized by low plasma osmolality (<280 mosm/kg).[29] Hyponatremia may be mild (serum sodium concentration <130 mEq/L) or severe (serum sodium concentration <120 mEq/L). Mild hyponatremia commonly occurs in about 3% to 5% of hospitalized patients[14] and in 1.5% of hospitalized children.[37] Usually, it is asymptomatic and requires no specific therapy. Severe hyponatremia is rare (occurring in only 0.2%),[37] but it must be corrected immediately because of the risk for severe neurologic sequelae.[14] Hypotonic hyponatremia may be hypovolemic, euvolemic, or hypervolemic (Table 1).

The clinical consequences of hyponatremia uncommonly manifest primarily as neurological symptoms but may occur in cases of *acute (symptomatic) hypotonic hyponatremia*. In this condition serum sodium concentration falls rapidly (in <24 hours) to levels <120 mEq/L, without the brain having time to adapt to the electrolyte disturbance. When an osmotic gradient occurs in the brain within a few hours, equilibrium is restored by movement of water molecules into both extracellular fluid and cells. Cerebral edema consequently develops, inducing convulsions followed by tentorial herniation, respiratory arrest, and death. The rate of change is a key element in the appearance of convulsions, and is more important than the degree of hyponatremia. The same mechanism causes seizures during rapid rehydration in cases of hypernatremia.[17] Some authors[18] have suggested that the ability of the brain to adapt to hyponatremia is gender related and that androgens may augment such adaptation. In children, in whom hormonal concentrations are minimal or absent, no gender difference has been found.[19] Of course, the pathogenesis is complicated, and there may be other contributing factors, such as concomitant hypomagnesemia,[180] a combination of hypokalemia and elevated levels of antidiuretic hormone (ADH) (diuretic-induced hyponatremia), a combination of excessive water intake and impaired renal excretion of free water caused by inappropriate secretion of ADH syndrome (SIADH),[19] increased tubular sensitivity to ADH (e.g., in psychotic patients taking neuroleptics),[52] and a combination of extensive extrarenal loss of electrolyte-containing fluids and intravenous replacement with hypotonic fluids in the presence of ADH activity (as in postsurgical patients).

Table 1 Classification of hypotonic hyponatremia

Hypovolemic hypotonic hyponatremia	Extrarenal losses	Vomiting, diarrhea, sweating, pancreatitis, peritonitis, ascites, burns, muscle trauma	Low urinary sodium concentration (<20 mEq/L)	Loss of sodium exceeds loss of water
	Renal losses	Primary renal disease, drug- and hormone-induced renal dysfunction	High urinary sodium concentration (>20 mEq/L)	Loss of sodium exceeds loss of water
Euvolemic hypotonic hyponatremia		Excess of ADH (SIADH), reset osmostat, water	High urinary sodium concentration	Near-normal total body sodium and

	intoxication, endocrine disturbances	(>20 mEq/L)	slightly increased extracellular fluid volume
Hypervolemic hypotonic hyponatremia	Acute renal failure, chronic renal failure	High urinary sodium concentration (>40 mEq/L)	Water retention markedly exceeds sodium retention
	Congestive heart failure, cirrhosis of the liver, nephrotic syndromes	Low urinary sodium concentration (<20 mEq/L)	Water retention exceeds sodium retention

ADH, antidiuretic hormone; SIADH, syndrome of inappropriate secretion of ADH.

Epileptic seizures have been reported in cases of *diuretic-induced acute hyponatremia*, *SIADH acute hyponatremia*, and *acute water intoxication*.

P.2662

Diuretic-induced acute hyponatremia may be caused by a thiazide or a combination of hydrochlorothiazide and amiloride.[141]

The syndrome of inappropriate secretion of ADH (SIADH) is a form of chronic hyponatremia sustained by constant or intermittent secretion of ADH that is inappropriate in relation to both osmotic and volume stimuli.[37] SIADH is characterized by hyponatremia without extracellular dehydration and edema and by plasma hypo-osmolality without urinary hypo-osmolality. Renal, thyroid, or adrenal insufficiency is absent. Causes of SIADH may be any of the following: Central nervous system disorders (infections, trauma, tumor, sarcoid psychosis), tumors (leukemia; lymphosarcoma; and carcinoma of prostate, ureter, pancreas, or duodenum), drugs (vincristine, vinblastine, carbamazepine, oxcarbazepine, barbiturates, amitriptyline), or pulmonary diseases (infection, tumors, asthma, pneumothorax).[37] In particular, acute hyponatremia and generalized tonic–clonic seizures have been observed in infants with respiratory syncytial virus bronchiolitis. Therefore, fluid therapy in these vulnerable infants should be tailored to reduce the risk of hyponatremia.[93] The syndrome has also been observed in postoperative patients with water retention caused by heart, liver, or kidney failure and in cases of excess salt depletion, as occurs in adrenal insufficiency, malnutrition, or diuretic therapy. Seizures have been reported only in cases of SIADH acute hyponatremia associated with *Salmonella* infection,[47] ingestion of 3,4-methylenedioxymethylamphetamine (MDMA, "ecstasy"), or febrile convulsions.[178]

Acute water intoxication is a rare condition occurring in a variety of clinical settings, all of which involve excessive and rapid intake of free water resulting in a sudden fall of serum sodium levels to <120 mEq/L. Acute oral water intoxication is increasing in frequency, especially in infants <6 months of age, in whom it follows inappropriate administration of low-solute formula or excessive administration of water to infants who are denied formula or breast-feeding.[140] In some cases, water had been given because of mistaken ideas about the correct management of diarrhea in infants or because of infant irritability (perhaps caused by neglect).[140] The risk for this problem may be increased among infants of parents living in poverty. Oral water intoxication is rarer in children (0.4%) and adults (1%–4%); it has been reported in cases of children being forced to drink water or swallowing swimming pool water[114] and of psychogenic polydipsia.[95] Acute non-oral water intoxication has been reported following tap water enemas or excessive parenteral administration of water in hospitalized patients receiving intravenous fluid.[114] It is also seen in postoperative patients with extrarenal loss of electrolyte-containing fluids undergoing parenteral replacement with hypotonic fluid, which normally leads to an increased plasma ADH concentration and a decrease in urinary output.[74] In postoperative patients, excessive ADH secretion may be caused by pain or emotional stress. Most of these patients have a superimposed condition that impairs excretion of free water.[37] Acute hyponatremia followed by seizures may also occur after desmopressin treatment. Desmopressin is an ADH analogue used to improve hemostasis in patients with bleeding disorders and in patients suffering from nocturnal enuresis. Therefore, fluid restriction, avoidance of hypo-osmolar fluid, and close monitoring of fluid and electrolytes are recommended in patients who undergo desmopressin therapy.[59,143] The risk of imipramine administration also has to be taken into account in patients who are given desmopressin.[92]

In *chronic hyponatremia*, the osmotic gradient occurs gradually, so that diffusion of sodium chloride is sufficient and the respective volumes are kept constant. As a result cerebral edema and convulsions do not occur. On the other hand, during these adaptive changes, sodium and potassium are lost from the brain, rendering it susceptible to dehydration during correction of hypersalinity if this occurs more rapidly than the brain can recover solute.[195] The suddenly higher plasma osmolality may cause dehydration and injury of the brain, leading to *osmotic demyelination syndrome* with central pontine myelinolysis and extrapontine demyelination.[195]

In addition, acute or chronic hyponatremia may occur as a side effect of antiepileptic drugs. Oxcarbazepine and carbamazepine are able to lower serum levels of sodium in 29.9% and 13.5% of patients, respectively.[65] Symptomatic hyponatremia may also be induced by levetiracetam.[149]

Clinical Description

Typical neurologic manifestations of acute symptomatic hyponatremia consist of generalized tonic–clonic seizures,

P.2663

hypothermia, and respiratory failure. Nausea, vomiting, muscular twitching, and, in later phases, coma may also occur.

In diuretic-induced acute hyponatremia, hyponatremic seizures are usually generalized tonic–clonic, with frequent progression to status epilepticus.[110] In SIADH acute hyponatremia, neurologic manifestations are headache, incoordination, disturbances of consciousness, and especially generalized tonic–clonic seizures.[47,178] Persistent simple partial motor seizures and multifocal seizures have been reported in a patient with SIADH, acute intermittent porphyria, hyponatremia, and hypomagnesemia; seizures were controlled by magnesium therapy.[180]

Infants affected by acute oral water intoxication exhibit persistent, severe generalized tonic–clonic seizures, usually with progression to status epilepticus. The seizures are intermixed with periods of reduced responsiveness, which have been considered to represent a postictal state or persistent, clinically unapparent seizures.[114] Seizures may be preceded by twitching of the eyes. Brief seizures lasting <10 minutes are rare (9% in the series of Farrar et al.[74]). Clinical features may also include opisthotonic posturing, restlessness, weakness, nausea, vomiting, diarrhea, polyuria or olyguria, and muscle fasciculations. Seizures are rare in older children and adults. However, in 84 of 121 cases in the literature with psychogenic self-induced acute water intoxication, generalized tonic–clonic seizures were the presenting symptom.[52] Partial jacksonian seizures were reported in only one case.[108] In contrast to oral water intoxication, acute nonoral water intoxication is not characterized by seizures as the presenting symptom, and generalized tonic–clonic seizures lasting several minutes have been reported only anecdotally as the presenting symptom.[39] Seizures are similar to those of oral acute intoxication.

A relationship has been demonstrated between lower serum sodium levels and an increased risk of developing recurrent seizures within the same febrile illness. In fact, sodium levels were significantly lower in children with recurrent "simple" febrile seizures as compared with single febrile seizures.[117] Because this finding has not been confirmed by other authors, the American Academy of Pediatrics Practice Parameter does not recommend routinely obtaining electrolytes in patients with febrile convulsions.[200]

The outcome is usually favorable, and in series of both infants and adults, almost all patients recovered completely after prompt correction of the electrolyte imbalance; severe brain damage is usually prevented.[52] Coma and death resulting from respiratory failure, brainstem herniation, and permanent brain damage occurred only in patients who underwent treatment after respiratory failure and coma had already occurred. Permanent brain damage may take the form of diabetes mellitus, central diabetes insipidus, mental retardation, or vegetative status.[18,19] Mortality has been reported in 50% of adult patients, especially women,[18] and 8.4% of children.[19] Vulnerability to water intoxication seems to be greater in postoperative patients, especially children[19] and adult women,[18] in whom the incidence of death or permanent brain damage is higher. These figures appear to be an overestimate, however, because a more recent review found a much lower mortality rate and only few cases of permanent neurologic sequelae.[74]

Chronic hyponatremia is less symptomatic, brain edema is not severe, and neurologically these patients may experience only minor symptoms. Nonetheless, osmotic demyelination syndrome may occur during the correction phase, producing convulsions, fluctuating levels of consciousness, and behavioral disturbances that progress to pseudobulbar palsy.[195] Thus, patients with chronic hyponatremia may be more likely to become permanently impaired than those with acute hyponatremia.

Diagnostic Evaluation

Because acute hyponatremia was the cause of seizures in 56% of infants <2 years of age who experienced seizures without any obvious cause,[74] a diagnosis of hyponatremia should be strongly considered in infants with long-lasting seizures or status epilepticus that is poorly responsive to antiepileptic drugs in whom evidence of another cause is lacking. Similarly, generalized seizures in psychogenic patients should be suggestive of acute hyponatremia. An accurate history is useful in investigating the vast number of possible causes of acute hyponatremia but not in emergent cases, for which only laboratory evaluations are of diagnostic value. Clinically, hypothermia associated with drug-resistant seizures or status epilepticus (in contrast to the more common situation of a rising temperature in such cases) may be a predictor of hyponatremia.[74]

Moreover, because hyponatremic seizures are usually occasional seizures that occur only once either as an isolated attack or in the form of repeated convulsions, a correct diagnostic evaluation first must consider all the main causes of occasional seizures, such as bacterial and viral infections, intoxication, trauma, cerebrovascular diseases and accidents, burn encephalopathy, and metabolic disturbances, including electrolyte imbalance. Laboratory determinations of serum electrolytes, urea nitrogen, creatinine, glucose, and osmolality and of urinary electrolytes, urea, creatinine, and osmolality are more important and may provide sufficient data for a correct diagnosis. In general, a condition characterized by hypovolemia and low plasma osmolality (<280 mosm/kg) together with excessive levels of total body water and sodium and an abnormally high urinary sodium concentration (>20 mEq/L) is suggestive of a primary renal disorder or of drug- or hormone-induced renal dysfunction, which is associated with renal salt wasting. Low serum sodium associated with low urinary sodium concentration (<20 mEq/L) is caused by extrarenal losses, such as vomiting, diarrhea, sweat, pancreatitis, peritonitis, ascites, burns, and muscle trauma. Water intoxication is confirmed by euvolemia associated with low plasma osmolality (<280 mosm/kg), dilute urine, and low serum sodium levels despite normal or near-normal total body sodium, whereas low serum sodium levels with high urinary sodium concentration (>20 mEq/L) suggest SIADH. A full clinical and laboratory examination is needed to investigate all the possible causes of SIADH, and the diagnosis is confirmed by normal adrenal, pituitary, thyroid, and renal excretory function. Finally, excessive levels of total body water and sodium with low plasma osmolality and low urinary sodium concentration (<20 mEq/L) may suggest nephrotic syndromes, congestive heart failure, or cirrhosis.

Electroencephalographic (EEG) examinations have not been commonly performed in acute water intoxication. Nevertheless, lack of alpha activity and presence of high-voltage slow waves requiring long periods to disappear[155] and diffuse and bilateral periodic lateralizing epileptiform discharges (PLEDs) occurring in relation to hemispheric ischemic disturbance have been reported.[108]

Treatment

Acute hyponatremia must be promptly corrected, even when the cause is unknown, because rapid correction of sodium levels is usually well tolerated before brain adaptation against osmotic swelling is complete.[199] The empiric use of hypertonic saline solution (2–6 mL of 3% sodium solution per kilogram of body weight),[52] producing a rapid increase of 3 to 5 mmol/L in the serum sodium concentration, corrects hyponatremia within 4 hours, may prevent death and brain damage,[183] and should be strongly considered. Further correction toward a normal serum sodium concentration should be continued during the

next 20 to 48 hours. Similar successful correction of acute hyponatremia has been demonstrated in psychogenic water drinkers, either by saline infusion alone or by a combination of saline infusion and fluid restriction,[52] although cases of presumed pontine myelinolysis following fast correction of self-induced water intoxication have been reported in alcoholic, malnourished psychogenic water drinkers.[199] Patients who are potentially more vulnerable to osmotic demyelination are similar to patients with polydipsia-hyponatremia syndrome, which is a chronic hyponatremic condition. Even though they experience episodes of acute water intoxication, these patients may be at risk for osmotic demyelination syndrome if an aggressive therapeutic approach with hypertonic saline solution is administered.[195] Therefore, a more conservative approach, with slow correction of hyponatremia, must be taken. In addition to hypertonic correction, treatment may include intubation and assisted mechanical ventilation in cases of respiratory failure.[19] Finally, special care must be taken if carbamazepine or barbiturates have been administered as treatment of recurrent seizures before hyponatremia was diagnosed. These drugs may cause SIADH, which induces water retention and complicates the clinical outcome. On the other hand, phenytoin has been reported to be the therapy of choice for SIADH, reducing seizures in neonates with SIADH developing refractory hyponatremic seizures.[154]

Magnesium Electrolyte Disorders: Hypomagnesemia

General Findings

The location of magnesium in the body is chiefly intracellular, and about half of the body content is located in bone, with high concentrations also in liver, muscle, and brain. Magnesium is the second-most-abundant intracellular cation in the body and plays an important role in neuromuscular excitability. Magnesium produces a curare-like action on neuromuscular function and has a depressant effect on the central nervous system. A direct correlation between low plasma magnesium concentrations, seizure frequency, and status epilepticus has been demonstrated in generalized idiopathic epilepsies.[33] However, the reason that hypomagnesemia causes seizures is unknown. It has been suggested that hypomagnesemia may remove an inhibitory influence from the *N*-methyl-D-aspartate (NMDA) glutamate receptors. Then, this process may trigger neuronal depolarization. Magnesium specifically inhibits sodium flux through NMDA-type glutamate receptors.[64] Chronic hypomagnesemia, as an isolated abnormality, may be caused by a reduced intestinal absorption due to transport defect or a reduced tubular filtration rate. It may be asymptomatic or symptomatic, depending on the patient's age.[77] Normal serum concentration is between 1.6 and 2.1 mEq/L. In cerebrospinal fluid the normal concentration is 2.4 mEq/L because of active transport of the ion. Symptomatic magnesium deficiency is an electrolyte disturbance defined as a serum magnesium concentration of <1.4 mEq/L (usually between 0.7 and 1.4 mEq/L). A secondary hypocalcemia caused by the inhibitory effects of magnesium deficiency on the parathyroid gland[12] is frequently present, and it is associated with inappropriately low parathyroid hormone levels for the degree of hypocalcemia, as has been found in both primary and secondary hypomagnesemia.[26,175]

Primary hypomagnesemia (*congenital hypomagnesemia*, *familial hypomagnesemia or primary hypomagnesemia with secondary hypocalcemia*, *isolated intestinal magnesium malabsorption*) is a rare condition in infants. Phenotypic characterization of clinically affected patients and experimental studies of appropriate animal models have contributed to a growing knowledge of renal magnesium transport mechanisms. In that context, both autosomal-dominant and recessive models of inheritance have been reported. The autosomal-dominant variant has been found to be associated with hypocalciuria and linked to the gene *FXYD2* on chromosome 11q23, which codes for a subunit of the basolateral Na-K-ATPase on the distal collecting tubule.[120] In the recessive variant, defects and mechanisms for hypomagnesemia are unknown.

Hypomagnesemia may also be associated with other abnormalities in the context of specific syndromes. For example, hypomagnesemia in association with hypokalemia is suggestive of Gitelman syndrome, which also manifests with metabolic alkalosis and high renin and aldosterone levels. Gitelman syndrome is caused by an inactivating mutation in the electroneutral cation-chloride–coupled cotransporter gene *SLC12A3*, which is located on human chromosome 16q13 and functions as a sodium/chloride thiazide-sensitive cotransporter.[138]

Familial hypomagnesemia with secondary hypocalcemia is an autosomal-recessive inherited disorder related to mutations in the *TRPM6* gene located on chromosome 9q21, which encodes for a transient receptor potential ion channel and leads to defects in both intestinal and renal handling of magnesium.

Finally, hypomagnesemia, hypercalciuria, and nephrocalcinosis also comprise a rare autosomal-recessive disorder in which polyuria and hyperuricemia may occur. Mutations in the paracellin-1 or *CLDN16* gene located on chromosome 3q, which encodes for paracellular transport pathways, have been found.[64]

Secondary hypomagnesemia has been reported after removal of parathyroid neoplasm and in cases of diabetic acidosis, malabsorption syndromes caused by intestinal injury, bowel resection (for carcinoma, enteritis, mesenteric thrombosis), prolonged loss of gastrointestinal fluids, hyperaldosteronism,[10] excessive use of diuretics, prolonged treatment with platinum compounds,[26] and closed heart surgery.[184] Frequently, it is associated with concurrent metabolic disorders, such as electrolyte deficiencies, hypo-osmolality, and septicemia, which may make it difficult to recognize hypomagnesemia. In neonates, transient hypomagnesemia is known to occur in children of toxemic and diabetic mothers, intrauterine growth retardation (IUGR) infants, or infants with transient hypoparathyroidism or maternal hypomagnesemia due to celiac disease.

Generalized or partial seizures have also been described in patients with hypomagnesemia induced by the ketogenic diet for intractable epilepsy,[9] cyclosporin A therapy,[9] and ibuprofen overdose.[7]

Clinical Description

In general, magnesium depletion is characterized by an epileptic syndrome consisting of generalized seizures or partial seizures with single or multiple foci. There is a complicated symptomatology associated with neuromuscular irritability resulting in action-intention tremor, myoclonic jerks, startle response, generalized tendon hyperreflexia, Chvostek's sign without concomitant Trousseau's sign or carpopedal spasm (which may be found in primary hypomagnesemia with secondary hypocalcemia; see later discussion), tachycardia, and rarely athetoid and choreiform movements.

Infant patients are classically seen with partial seizures that have one or multiple foci. They are conscious and hyperactive. Diarrhea and secondary hypocalcemia are present.[3] Seizures occur repeatedly and are resistant to antiepileptic drugs. Stiffness of all four extremities and hypertonia also have been reported.[50] In children and adults, generalized tonic–clonic seizures associated with nonepileptic massive myoclonic jerks and carpopedal spasm, without diarrhea, were the presenting

P.2665

symptoms.[175] Sudden-onset aphasia and no clear initial motor seizure activity have also been reported.[64]

Convulsions and diarrhea are intractable, and children may die if the magnesium disorder is not recognized and corrected early.[3] Otherwise, the prognosis is relatively good with normal psychomotor development as long as magnesium supplements are maintained.

Diagnostic Evaluation

Hypomagnesemia should be strongly suspected in infants with generalized or partial seizures with one or multiple foci of unknown cause that are resistant to treatment and are associated with diarrhea and tetany that do not respond to calcium replacement. Given that older patients are less symptomatic, isolated magnesium malabsorption has to be investigated at any age. Finally, complete investigation of magnesium metabolism should also be considered in cases of idiopathic epilepsy because of reports[91,193] concerning a direct correlation between low levels of serum magnesium and the frequency of seizures and status epilepticus in patients with idiopathic generalized epilepsies.

Intestinal malabsorption of magnesium is confirmed by markedly elevated fecal magnesium levels and low serum magnesium levels, even if serum magnesium concentrations do not reflect total body magnesium stores. A 24-hour urine collection and intravenous magnesium loading test for total body magnesium determination are very sensitive. When facilities for serum magnesium determinations are not available, a trial of parenteral magnesium sulfate may serve as a therapeutic test if renal function is not impaired. Comprehensive intestinal and renal investigations to detect intestinal malabsorption and renal failure or tubulopathy, hormone and electrolyte determinations to detect hypoparathyroidism, hyperaldosteronism, and conditions associated with hypokalemia or hypocalcemia, and X-ray of the carpal bones to detect other metabolic diseases are also required.

In addition, because of the associated movement disorders, specific investigations to detect disease of the basal ganglia (computed tomography, magnetic resonance imaging, neurophysiologic evaluations, and laboratory tests for liver disease, metabolic disorders, and immunologic disease) should be considered.

Treatment

Elective therapy in isolated magnesium malabsorption consists of high-dose oral or parenteral magnesium supplements. Typically, magnesium administration alone controls convulsions and low serum levels of magnesium and calcium in primary hypomagnesemia; administration of calcium and vitamin D is not effective. The major complication of magnesium supplementation appears to be diarrhea caused by the magnesium itself.

Renal Failure

Renal failure leads to disturbances in the function of every organ system in the body. Complications of renal failure become increasingly prevalent as the glomerular filtration rate decreases below 5 mL/min/1.73 m^2, the level of function that defines end-stage renal disease. Neurologic disorders remain an important source of morbidity and mortality in this vulnerable patient population. With the introduction of dialysis and renal transplantation, the spectrum of neurologic complication has changed. On one hand, the incidence and severity of uremic encephalopathy, neuropathy, and myopathy have declined.[40] On the other hand, dialytic regimen or renal transplantation may determine neurologic disorders such as dialysis dementia, dialysis dysequilibrium syndrome, cerebrovascular accident, and hypertensive encephalopathy, which are thought to be the consequence of ultrafiltration-related arterial hypotension directly related to dialysis. Moreover, hemorrhagic stroke, subdural hematoma, osmotic myelinolysis, opportunistic infections, intracranial hypertension, Wernicke encephalopathy and peripheral neuropathy can also occur. In patients who undergo renal transplantation, immunosuppressive drugs may cause encephalopathy, movement disorders, opportunistic infections, neoplasms, myopathy, and atherosclerosis. The neurologic manifestations of renal failure are summarized in Table 2.

Table 2 Neurologic manifestations of renal failure

Neurologic manifestations of uremia
Uremic encephalopathy
Hypertensive encephalopathy
Aluminum encephalopathy in infancy and childhood

Uremic polyneuropathy
Cranial nerve dysfunctions
Autonomic dysfunctions
Neurologic complications of uremia treatment
Dialysis disequilibrium syndrome
Dialysis encephalopathy syndrome
Neurologic complications of transplantation
Rejection encephalopathy

This section discusses epileptic seizures in *uremic encephalopathy*, *aluminum encephalopathy in infancy and childhood*, *dialysis disequilibrium syndrome*, and *dialysis encephalopathy syndrome*.

Neurologic Manifestations of Uremia

Uremic Encephalopathy

General Findings.

Uremia can be defined as "systemic intoxication caused by severe glomerular deficiency associated with disturbances in tubular and endocrine functions of the kidney. It is characterized by retention of toxic metabolites derived mainly from proteins associated with changes in volume and electrolyte composition of the body fluids and excess or deficiency of various hormones."[35] The pathophysiology of uremic encephalopathy is complex and poorly understood. Renal failure results in a gradual accumulation of several substances, but no single metabolite has been identified as the sole cause of uremic encephalopathy.[204] Accumulation of urea, uric and hippuric acids, phenols and conjugates of phenols, phenolic and indolic acids, glucuronic acid, various amino acids, polyamines, polypeptides, carnitine, sulfates, phosphates, and "middle molecules" has been observed.[61] It may also depend on guanidino compounds; acidosis; hyperhydration and dehydration; electrolyte disorders (hyponatremia, hypomagnesemia, hypocalcemia, hyperkalemia); hormonal disturbances (parathyroid hormone, thyrotropin, prolactin, luteinizing hormone, growth hormone, insulin, and glucagon); disturbances of cerebral amino acid metabolism; decreased concentration of γ-aminobutyric acid (GABA); increased concentrations of dopamine and serotonin; diminished cerebral uptake of glutamine, valine, and isoleucine; and increased extraction of glycine and cystine.[38] Seizures may be related to hypertension, electrolyte imbalance, aluminum toxicity, drug toxicity, and infections. Inhibition of cerebral sodium-potassium adenosine triphosphatase (ATPase) has been demonstrated in experimental animals, which might be correlated with elevation of intracellular sodium and seizure activity.[142] A main role is thought to be played by guanidino compounds such as

P.2666

methylguanidine and guanidinosuccinic acid, which were found to be highly increased in cerebrospinal fluid (CSF) and brain of uremic patients.[61] They may also induce a disorder similar to the "twitch-convulsive" syndrome, including epilepsy.[144] Activation of the excitatory NMDA receptors and concomitant inhibition of inhibitory $GABA_A$-ergic neurotransmission have been pointed out as underlying mechanisms.[61] Intrahippocampal guanidinosuccinic acid injection in unanesthetized rats triggered partial clonic seizures leading to generalized tonic–clonic seizures and eventually status epilepticus.[158] Moreover, inhibition of cerebral sodium-potassium-ATPase was shown in experimental uremic animals.[42] This might correlate with the elevation of intracellular sodium and might therefore be associated with the epileptogenicity affecting this population.[40] In this context, the pathophysiologic role of parathyroid hormone should also be considered. Although the mechanisms are unknown, parathyroid hormone is able to facilitate the entry of calcium in brain tissue.[42] Because calcium is an essential mediator of neurotransmitter release and plays a major role in intracellular metabolic and enzymatic processes, alterations in brain calcium may possibly take part in determining cerebral dysfunction and seizures. Focal or multifocal and stimulus-sensitive myoclonus is supposed to originate in the brainstem reticular formation.[49] Uremic encephalopathy is reversible on correction of renal insufficiency, consistent with the failure of histopathologic studies to find a specific anatomic lesion.[156]

Clinical Description.

Uremic encephalopathy almost invariably complicates both chronic and acute uremia, its severity depending on the rate of renal failure. Neurologic manifestations of acute and chronic renal failure do not differ qualitatively, but clinical symptomatology is usually more severe and progresses more rapidly in patients with an acute deterioration of renal function.[42] The clinical course is characterized by variability from day to day. Presenting symptoms may be subtle and represented by apathy, irritability, inattentiveness, clumsiness, and fatigue. Tests show that attention span is impaired at this stage.[42] “Frontal lobe” dysfunction manifests with deficient abstract thinking, behavioral disorders, paratonia, and palmomental reflex.[42] Recent memory deficits indicate a more advanced stage of disease. Later, remote memory fails, and confusion, lethargy, stupor, and ultimately coma develop. Typical features of delirium (toxic psychosis), such as hallucinations, agitation, confusion, and disorientation, are especially frequent in acute renal failure. Mental impairment is greater in children who experience onset of chronic renal failure during the first year of life, especially within the first 2 months.[166] Psychomotor and mental development are delayed, and a small head circumference and progressive decrease in IQ may be encountered, even in the absence of neurologic signs.[4] Even in patients who have been treated with renal replacement therapy, memory deficits and sleep disturbances are not uncommon. Neuropsychological investigations showed significant deviation from normal controls in areas of attention/response speed, learning and memory, and perceptual coding.[42] Movement disorders and epilepsy constitute a very characteristic clinical feature of uremic encephalopathy and define the so-called “*uremic twitch-convulsive*” syndrome,[2] which consists of intense asterixis and multifocal myoclonic jerks that are accompanied by fasciculations, muscle twitches, and seizures.[60] Early manifestations include muscle cramps, tremors, and asterixis. Muscle fasciculations and myoclonus appear in advanced encephalopathy. Asterixis or “flapping tremor” is probably caused by sudden loss of tonus, originating from cortical dysfunction and clinically consists of multifocal action-induced jerks that can even mimic drop attacks in severe cases. In uremia, both spontaneous action myoclonus and stimulus-sensitive myoclonus with good response to benzodiazepines can occur. Uremic myoclonus may be caused by a dysfunction in the lower brainstem reticular formation due to water-electrolyte imbalance leading to microcirculatory and degenerative changes.[40] Thiamine deficiency is thought to determine chorea by interfering with basal ganglia function.[106] “Alternating hemiparesis” can occur in up to 45% of patients.[42]

Epileptic seizures have been reported in about one third of patients with uremic encephalopathy. In cases of chronic renal failure, they are most often a late manifestation and sometimes a preterminal event.[169] In acute renal failure, seizures occur within the first 15 days of disease.[60] Late-onset seizures have been rarely observed in association with hemiparesis and transient blindness as a result of a posterior reversible encephalopathy syndrome.[34] Usually, seizures are generalized tonic–clonic or myoclonic, but focal motor seizures and even epilepsia partialis continua have also been reported.[60] Nonconvulsive status epilepticus characterized by acute confusion or stupor without motor seizures has also been observed in patients with end-stage renal failure.[53]

Neurophysiologic Investigations.

The EEG is abnormal in the setting of acute encephalopathy due to renal failure. EEG background activity becomes progressively disorganized. Decreased alpha activity is associated with the appearance of intermittent paroxysmal bursts of bilaterally synchronous slow waves, with largest amplitudes over the frontal regions (projected rhythm). In chronic renal failure, changes are less dramatic. As the uremic state progresses, the EEG becomes slower, with a recognizable correlation between the percentage of frequencies <7 Hz and the increase in creatinine. Bilateral spike and wave complexes, in the absence of evident clinical seizure activity, have been reported in up to 14% of patients with chronic renal failure.[42] A paradoxical response to eye opening and an abnormal arousal response to afferent stimuli consisting of bursts of slow waves may occur. Photic driving, photomyogenic response, and photosensitivity manifested by paroxysmal epileptiform discharges are more characteristic of uremic encephalopathy. They may be elicited just before the onset of convulsions. Electroencephalographic features correlate with alteration in consciousness to a greater degree than with the degree of uremia, electrolyte imbalance, and acidosis.[185] Asterixis is electromyographically characterized by typical silence, which follows a biphasic wave in the backaveraged EEG activity.

The N75 and P100 components of one visual-evoked potential (VEP) are significantly prolonged in chronic renal failure.[57] Peak V and I–V and III–V interpeak latencies of brainstem auditory-evoked responses (BAERs) were significantly prolonged in one third of chronic renal failure patients.[176] Unfortunately, no significant correlations have been documented between the degree of prolongation of various VEP or BAER component latencies and the severity of chronic renal failure or its associated metabolic complications.

Visually-evoked event-related potentials (ERPs) in neurologically asymptomatic patients affected by chronic renal failure clearly showed an increased P3 latency and decreased P3 amplitude. After hemodialysis, P3 latency showed a significant decrease, and P3 latency habituation during the ERP measurement was also significantly decreased. These data suggested that impaired cognitive processing can be disclosed by ERP even in neurologically asymptomatic chronic renal disease. Removal of uremic toxins by hemodialysis leads to an improvement in cognitive function.[73]

Somatosensory-evoked potentials (SEPs) after median nerve stimulation are enhanced bilaterally. Both the biphasic wave and the giant SEP are believed to have a common origin in the sensorimotor cortex in brain-mapping recordings.[22]

Diagnostic Evaluation.

A combination of clinical signs of depression and signs of cerebral excitation, such as multifocal myoclonus and epilepsy, is strongly suggestive of uremia.

P.2667

When seizures are present, a series of investigations, including determination of bone and plasma aluminum concentrations and plasma and urinary electrolyte concentrations, osmolality, volume, and levels of ADH, has to be performed to exclude other, superimposed causes of seizures, such as hypertensive encephalopathy, electrolyte imbalance (water intoxication, hypocalcemia, hyponatremia, hypomagnesemia), or aluminum encephalopathy. Computed tomography followed by lumbar puncture (unless intracranial pressure is increased), which may show elevated protein concentrations or pleocytosis, can aid in the diagnosis of infection of the central nervous system. Papilledema, focal neurologic signs, and elevated opening pressure at lumbar puncture may suggest hypertensive encephalopathy or intracranial hemorrhage. If no causes are demonstrated, an idiopathic seizure disorder must be differentiated. When a patient with acute or chronic renal failure experiences an unexpected onset of seizures, asterixis, myoclonus, and behavioral disturbances such as agitation and confusion (toxic psychosis), a drug-induced encephalopathy should be suspected. In the case of renal failure, the availability of certain drugs, such as vigabatrin, acyclovir, chlorpromazine, cyproheptadine, salicylates, phenytoin, barbiturates, and benzodiazepines or their metabolites, is increased by the diminished urinary elimination of active metabolites or diminished protein binding, which increases their plasma concentrations. Immunosuppressive-associated encephalopathy has been described with cyclopsorin,[51] tacrolimus,[161] and muromonab-CD3.[159] The clinical picture involves tremor, cerebellar and and/or extrapyramidal signs, and headache. Sometimes a reversible posterior leukoencephalopathy syndrome may complicate the clinical course,[161] with white matter changes. Subcortical and cortical involvement has also been described.[31] Recognition of immunosuppressant-associated encephalopathy is crucial because modulation in immunosuppressive drugs administration may result in resolution of clinical symptoms and neuroimaging abnormalities.

Finally, possible thyroid disorders have to be investigated (see section on endocrine disorders). Video-polymyographic-EEG recordings and electromyographic (EMG) examinations must be performed to differentiate epileptic events from other, nonepileptic movement disorders such as asterixis, tremor, and myoclonus.

Treatment.

Clinical symptoms of uremic encephalopathy may improve following dialysis and renal transplantation. The development of uremic encephalopathy is an indication for prompt initiation of dialysis and consideration of renal transplantation.

Seizures may be treated with standard antiepileptic drugs, taking into account the changes in renal excretion and reductions in plasma protein binding that may occur in renal insufficiency. Therefore, monitoring of blood levels of drugs is advisable; levels of unbound antiepileptic drugs, which increase during renal disease, are most informative. In general, oral doses of all the antiepileptic drugs should be reduced and the intervals of administration modified. Sodium and magnesium valproate and phenytoin free plasma fractions increase, whereas lamotrigine clearance is not significantly modified in renal disease. Carbamazepine (which may exert a significant antidiuretic effect, causing increased danger of fluid retention), vigabatrin, and felbamate (which are excreted almost entirely by the kidneys) should not be given.[129] Benzodiazepines, and especially clonazepam, are effective against myoclonus,[4] whereas piracetam and l-5-hydroxytryptophan cannot be used in renal failure. Sedative hypnotics and antipsychotic tranquilizers, which may cause toxic psychosis,[122] and antibiotics, which may induce myoclonus, asterixis, seizure, and coma, must be administered with extreme care.[172] With respect to the newer antiepileptic drugs, zonisamide and oxcarbazepine are cleared by both the renal and hepatic routes. The clearance of both drugs has been shown to decrease with decreasing creatinine clearance. No specific guidelines for dose adjustment have been provided for zonisamide. Oxcarbazepine should be initiated at one half of the usual starting dose and increased to achieve clinical response.[41,128] More than two thirds of levetiracetam and topiramate is excreted in the urine. A reduction in the dosing rate for both drugs is recommended for patients with moderate or severe renal impairment.[41]

Aluminum Encephalopathy Syndrome in Infancy and Childhood

General Findings.

Aluminum encephalopathy syndrome is a progressive encephalopathy that tends to occur in infants and children with chronic renal failure following prolonged exposure to aluminum-containing solutions and compounds, such as aluminum-containing phosphate binders.[165] It has also been described in adults.[177] Although the mechanisms for the entry of aluminum into the central nervous system (CNS) are poorly understood,[174] the aluminum content of brain gray matter of these patients has been found to be markedly elevated in comparison with controls.[6] It has mainly been found in the nerve cells of the cerebral cortex.[6] Neuropathologically, the brain shows cortical atrophy and stromal spongiosis.[190] The mechanisms associated with the pathogenesis of the neurotoxicity of aluminum are unknown.[174] The increased bioavailability of aluminum in chronic renal failure seems to be related to decreased urinary excretion and enhanced gastrointestinal aluminum uptake induced, in turn, by secondary hyperparathyroidism, which is common in infants and children with chronic renal failure. Aluminum in individuals with chronic renal failure is stored in bone tissue, from which it may be mobilized during intercurrent stress, thereby causing acute aluminum intoxication.

Clinical Description.

Usually, aluminum encephalopathy syndrome develops in children with chronic renal failure who have been exposed to aluminum for several years. Clinically, aluminum encephalopathy syndrome is closely similar to both uremic encephalopathy and dialysis dementia syndrome. Features are a progressive encephalopathy with arrest or regression of psychomotor development, disturbances of motor function (such as dysmetria, tremor, hypotonia, focal or generalized myoclonus), seizures, speech disturbances, and ultimately vegetative status. Seizures are usually generalized, but simple and complex partial seizures with secondary generalization have also been reported.[177] Subacute aluminum encephalopathy with loss of consciousness, myoclonic jerks, and status epilepticus leading to the exitus was related to the direct exposure of CNS to aluminum.[170] Computed tomography shows cortical atrophy. Electroencephalographic features, which evolve simultaneously with clinical features, consist of diffuse slowing of background activity with superimposed bursts of high-amplitude slow waves and multiple paroxysms of triphasic contoured waves, sharp waves, and complexes of spikes and slow waves.[103]

Diagnostic Evaluation.

The presence of typical clinical features in children with chronic renal failure who have been taking aluminum-containing phosphate binding gels or formulas suggests aluminum encephalopathy syndrome. Computed tomography showing cortical atrophy, presence of specific EEG features, and demonstration of high bone and plasma aluminum concentrations confirm the diagnosis. Aluminum encephalopathy syndrome has to be differentiated from uremic encephalopathy, which also causes mental retardation, myoclonus, and seizures. This differential diagnosis is very important because uremic encephalopathy promptly improves with dialysis, whereas aluminum encephalopathy syndrome does not in all cases. Electrolyte determinations may differentiate aluminum encephalopathy syndrome from

P.2668

acute hypercalcemia, severe phosphate depletion, and other electrolyte imbalances that may complicate chronic renal failure. Finally, aluminum encephalopathy syndrome must be differentiated from the rare cases of aluminum intoxication in nonuremic patients.[102,174] Video-polymyographic-EEG recordings and EMG examinations are mandatory in the differential diagnosis of movement disorders, such as asterixis, tremor, and myoclonus, and other epileptic events.

Treatment.

Prompt discontinuation of the use of aluminum gels is indicated. Dramatic improvement in advanced stages has been achieved by aluminum chelation (deferoxamine). The combined use of deferoxamine and appropriately timed hemodialysis has been proposed in the rare patients presenting with severe acute aluminum intoxication.[147] Common antiepileptic drugs and especially benzodiazepines are effective in the treatment of myoclonus and seizures, but the same risks are encountered as in the treatment of uremic encephalopathy (see earlier discussion). Because the main cause of aluminum encephalopathy syndrome is gastrointestinal absorption of aluminum, infant diets should consist of low-phosphate formulas with the addition of calcium carbonate. Calcium citrate– and aluminum-containing antacids should be avoided.

Neurologic Complications of Uremia Treatment

Dialysis Dysequilibrium Syndrome

General Findings.

Dialysis dysequilibrium syndrome is an acute reversible neurologic syndrome caused by exacerbation of the neurologic manifestations of renal failure during a patient's first few dialysis maintenance treatments. Dialysis disequilibrium syndrome has been attributed to the “reverse urea effect” during rapid hemodialysis. Urea is believed to be cleared less rapidly from the brain than from the blood, producing an osmotic gradient and shift of extracellular water into the brain to cause cerebral edema.[115] Experimental data showed a reduced expression of urea transporter (UT-B) and increased expression of aquaporins in brain cells. Urea exit from astrocytes is therefore delayed during rapid removal of extracellular urea through fast dialysis. An osmotic driving force that promotes water entry into the cells is also favored by abundant expression of aquaporins.[203] Moreover, it has been demonstrated that cerebral edema may result from the generation of idiogenic osmoles in association with a decrease in intracellular pH of the cerebral cortex.

Clinical Description.

The symptoms of dialysis dysequilibrium syndrome are irritability, restlessness, headache, nausea, emesis, hypertension, blurred vision, epileptic seizures, muscular twitchings, fasciculations, asterixis, and confusion. Seizures usually are generalized tonic–clonic, and status epilepticus may also occur.[189] When delirium appears, it tends to persist for several days. Death from brainstem herniation has been reported in the past, while in more recent years only milder symptoms have been reported. After a general trend toward normalization, marked EEG changes may develop during dialysis, consisting of increased slow-wave activity, bursts of bilateral symmetric rhythmic slow waves, and increased photosensitivity.[185] Patterns of VEPs are exaggerated, with abnormal prolongation of P100;[57] BAER latencies are abnormal.[176] Computed tomography demonstrates cerebral edema. Brain magnetic resonance imaging (MRI) may show white matter changes in the posterior area mimicking a reversible posterior leukoencephalopathy syndrome (RPLS).[189] Central pontine and extrapontine myelinolysis has also been reported in children.[25]

Diagnostic Evaluation.

Diagnostic evaluation must exclude all other causes of irritability, headache, nausea, hypertension, muscular twitchings, fasciculations, asterixis, confusion, and seizures that can occur in patients on maintenance dialysis. Seizures are a key symptom. When seizures occur with various degrees of impairment of consciousness, headache, nausea and vomiting, hypertensive encephalopathy, intracranial hemorrhage, and subdural hematoma[127] should be investigated. Papilledema, focal neurologic signs, typical findings on computed tomography, and elevated opening pressure at lumbar puncture confirm the diagnosis of these conditions. When seizures are generalized or partial and are associated with irritability, headache, restlessness, or twitchings, special consideration must be given to disorders of electrolyte imbalance, including hyponatremia and hypernatremia (which in renal insufficiency may induce seizures more frequently than hyponatremia), hypocalcemia and hypercalcemia, hypophosphatemia, abrupt increase in blood pH (which can lower the serum concentration of ionized calcium), and nonketotic hyperosmolal coma in nondiabetic patients, which is caused by increasing levels of glucose after repeated peritoneal dialysis. Determination of plasma and urinary electrolyte concentration, glucose concentration, osmolality, volume, ADH levels, and presence of acidemia may aid in the differential diagnosis. Full neurophysiologic monitoring is useful to differentiate epileptic myoclonus and seizures from other, nonepileptic movement disorders and detect any sudden changes of central nervous system electrical activity during dialysis.

Treatment.

If a patient experiences seizures during dialysis, treatment must be discontinued immediately until vital signs have stabilized. Standard therapy of movement disorders and epileptic seizures may improve the patient's course but must be monitored carefully in renal failure (see earlier discussion of treatment of uremic encephalopathy). Hypocalcemic seizures may be controlled with calcium gluconate administration.

Dialysis Encephalopathy Syndrome

General Findings.

Dialysis encephalopathy syndrome has been described in patients receiving maintenance hemodialysis. The syndrome usually occurs in patients dialyzed for periods >3 years. It is considered to be the most dramatic manifestation of aluminum toxicity, and is caused by an increase in brain levels of aluminum secondary to a high content of this metal in the dialysis bath.[6] Its incidence has sharply decreased with the use of aluminum-free water.[4]

Clinical Description.

Presenting symptoms consist of dysarthria, apraxia, and slurred speech with stuttering and hesitation. The speech disorder is intensified during and immediately after dialysis and at first may be seen only during these periods. Cognitive disturbance usually occurs, and the EEG shows bursts of high-amplitude slow waves in the frontal regions. Within months, myoclonus, asterixis, movement dyspraxia, seizures, memory loss, personality changes, and psychosis develop.[78] In most cases, the disease progresses to apneic spells, tonic–clonic seizures, focal neurologic deficits, and death within months from sepsis or suicide.[6]

After a short and transient improvement, usually following dialysis, the EEG shows progressive abnormalities that become indistinguishable from those seen in aluminum encephalopathy syndrome (see earlier discussion).[185]

Diagnostic Evaluation.

Dysarthria, myoclonus, delirium, and seizures are possible symptoms of clinical conditions that may exist concomitantly with hemodialysis, such as acute hypercalcemia[173] and severe hypophosphatemia,[164] and these must be differentiated from dialysis encephalopathy syndrome. Video-polymyographic-EEG recordings and EMG examinations must be performed to differentiate epileptic myoclonus from other, nonepileptic movement disorders.[105] Water-soluble vitamin deficiency, especially pyridoxine deficiency (removed from blood during hemodialysis), should always be considered

in cases of drug-resistant seizures. Clinical and EEG features similar to those of dialysis encephalopathy syndrome have been described in patients not on dialysis who are receiving large quantities of aluminum salts.[187] The CSF is unremarkable. No distinct abnormalities have been found in brain at autopsy. In all these cases, only the history and laboratory investigations may aid in the differential diagnosis.

Treatment.

The presence of clinical and EEG evidence of dialysis encephalopathy syndrome is a clear indication for discontinuation of aluminum-containing phosphate binders (especially in infants with chronic renal failure) and initiation of chelation therapy. Dramatic improvement in advanced stages has been achieved by aluminum chelation (deferoxamine). Associated myoclonus responds well to clonazepam and diazepam, which are also able to improve speech disorders. Common antiepileptic drugs may be effective in the treatment of seizures, but as with other conditions of renal failure, special care must be taken. Phenytoin usually is used for tonic–clonic seizures. Because a relatively little amount is removed by hemodialysis, it can be given intravenously in loading doses to maintain a desired plasma concentration. Pyridoxine supplementation must be administered in cases of pyridoxine deficiency. Before initiating dialysis, avoidance of aluminum-containing formulas should be recommended. It is also mandatory to test for secondary hypoparathyroidism (frequent in children with chronic renal failure) and iron-deficiency anemia to minimize gastrointestinal absorption of aluminum and restrict dietary phosphate to prevent hyperphosphatemia. Finally, in patients undergoing maintenance dialysis, the aluminum concentration of the dialysate should be monitored periodically.

Endocrine Disorders

Epileptic seizures may occur in patients affected by many endocrine disorders and sometimes constitute the presenting symptom. Epileptic seizures may be caused directly by hormones (as in thyrotoxicosis) or indirectly by metabolic disequilibrium associated with hypoglycemia, hyperglycemia, or electrolyte imbalance (hyponatremia, hypomagnesemia, hypocalcemia), which causes an increase in neuronal excitability. Alternatively, as in the case of hypothalamic-pituitary tumors, epilepsy can result from a temporal lobe extension of the tumor or from the tumor itself (i.e., hypothalamic hamartoma). Finally, epilepsy and an endocrine disorder may both result from one genetic immunologic disease. In general, seizure control is obtained with correction of the endocrine disorder or the related metabolic disturbances. If not, administration of antiepileptic drugs may become necessary, with the associated risk for adverse effects on the endocrine system.

Endocrine disorders associated with epileptic seizures or epilepsy are summarized in Table 3.

Hypothalamic-Pituitary Disorders

Pituitary Disorders

Pituitary disorders can occasionally be associated with epileptic seizures, as in conditions of the posterior pituitary affecting water metabolism, such as SIADH, or in panhypopituitarism with hypoglycemia. Generalized epileptic seizures have been anecdotally reported as the presenting or unique symptom in a case of incidental pituitary macroadenomas or incidentalomas,[48] in a case of normotensive primary aldosteronism with hypopituitarism,[122] and in an infant with panhypopituitarism secondary to hypoplasia of the anterior pituitary.[55] Temporal lobe epilepsy resulting from pituitary adenoma with temporal extension has also been described. Temporal extension of an adenoma might disturb the uncinate gyrus and the medial surface of the temporal lobe, resulting in complex partial seizures.[27]

Table 3 Endocrine disorders associated with epileptic seizures or epilepsy

Hypothalamic-pituitary
Pituitary neoplasms/hypoplasia
Hypothalamic hamartoma/precocious puberty
Inappropriate secretion of antidiuretic hormone (ADH) syndrome
Thyroid
Primary hyperthyroidism/thyrotoxicosis
Primary hypothyroidism/myxedema
Hashimoto encephalopathy
Parathyroid
Hypoparathyroidism
Hyperparathyroidism
Pancreas
Diabetes mellitus
Reproductive system
Polycystic ovaries/hypogonadotropic hypogonadism

Hypothalamic Hamartoma

General Findings

Hypothalamic hamartomas (HHs) are nonneoplastic, heterotopic nodules resembling the normal gray matter of the hypothalamus. They mainly consist of mature neurons and rare large dysplastic neurons, intermingled with glial cells. Myelinated and unmyelinated fibers have been identified, and some of these connect to hypothalamic nuclei.[20] Mature and differentiated ectopic neurosecretory cells secreting luteinizing hormone–releasing hormone (LH-RH) have also been observed. Etiology of HHs is unknown. No genetic anomaly has been found, except for patients with Pallister-Hall syndrome (PHS).

The two main manifestations of HHs are central precocious puberty (CPP) and seizures, and the latter may be the predominant clinical symptom (see Chapter 250). Among 277 sporadic patients with HHs, 63% had CPP, 61% presented with seizures (of any type), and 25% had both CPP and seizures.[151] Typical seizures consist of brief stereotyped attacks of laughter, also known as gelastic seizures (GS) (see Chapter 53). Although a neocortical origin has been found in some cases, GS are pathognomonic of HHs.[36,151] The pathogenesis of the epileptic syndrome occurring in HHs is unknown. It has been suggested that it may result from a general dysgenetic process that includes cortical abnormalities. The size of the lesion and the secondary mechanical compression on hypothalamus and the mammillary bodies seem to play roles in generating seizures.[20] However, several pieces of evidence suggest that the source of GS is HHs per se. In fact, when associated with GS, HH tissues contain predominantly small GABAergic inhibitory neurons that exhibit intrinsic “pacemaker-like” behavior.[213] Moreover, the HH can have a pedunculated stalk or a sessile one. The latter is associated with epilepsy, whereas the former is associated only with precocious puberty. It appears that the epileptiform activity generated inside the hamartoma leads to clinical manifestations only when a sessile attachment to the hypothalamus allows its propagation to the diencephalon.

P.2670

Clinical Description.

The characteristic epileptic syndrome occurring with HHs begins in infancy, even in the first days of life. Brief episodes of pleasant laughter or giggling last a few seconds, and at the beginning occur without loss of consciousness, recurring many times a day, with both diurnal and nocturnal attacks.[36] In the clinical course, GS are more frequently associated with alteration of consciousness and associated with autonomic phenomena, automatisms, epigastric auras, déjà vu, déjà vecu, and motor symptoms. Some patients may also show a pattern of symptomatic generalized epilepsy. Absence, tonic, atonic, and tonic–clonic seizures occur mimicking Lennox-Gastaut syndrome with intractable seizures, progressive cognitive impairment, and severe behavioral disturbances.[196] HHs may determine a less severe epileptic disorder. Indeed, only some cases progress to an epileptic encephalopathic picture, and cognitive disturbances may be mild or absent. Therefore, the severity of the epilepsy syndrome related to HHs may range from mild, drug-resistant epilepsy with a simple “pressure to laugh” in otherwise normal patients up to a catastrophic epileptic encephalopathy.[13,196] Pathogenetically, such an evolution has been related to the anatomic and physiologic connections of the hypothalamus to the thalamus and cortex.[182] Interictal EEG shows generalized and focal frontal or temporal spikes.[36] Neurophysiologic and clinical studies have demonstrated that when the hamartoma connects to the mamillary bodies, a secondary involvement of the temporal lobe is present, suggesting that the projection of the paroxysmal activity to the cortex is due to a specific pathway connecting the hypothalamus with the temporal lobe. By contrast, when the hamartoma connects to the medial hypothalamus, a frontal lobe epileptic activity is recorded. The existence of direct projections of several neuronal groups in the middle and posterior supramamillary hypothalamus to the frontal lobes (bilaterally) has been described, which could provide such a selective propagation of spike activity.[182]

Initially there are no significant EEG abnormalities detected during a gelastic seizure. Subsequently, generalized onset with low-voltage rhythmic fast activity, generalized suppression of background rhythms, or both, sometimes preceded by single or multiple generalized spike-and-wave complexes, are recorded.[36]

Diagnostic Evaluation.

Diagnosis of HH can be evoked in patients affected by gelastic epilepsy and/or PP. The presence on MRI of a nonprogressive, noncalcified, nonenhancing hypothalamic mass that appears isointense to gray matter on T1-weighted images, isointense to mildly hyperintense on proton density-weighted images, and often hyperintense on T2-weighted images confirms the diagnosis.[151] As the seizures become more complex with clinical features of secondary generalized epilepsy, background activity can show variable diffuse slowing, and interictal findings can include unilateral or bilateral temporal/frontal independent epileptiform discharges and/or irregular generalized slow spike-and-wave discharges. Ictally, diffuse nonlocalizing electrographic changes such as generalized low-voltage rhythmic fast activity (LVFA) and/or generalized suppression of background activity have been described. Intracranial studies can be misleading if the hypothalamic lesion is not sampled itself. Depth electrodes advanced into the lesion have revealed LVFA discharges well localized in the hamartoma during GS and more widely extended LVFA in atonic seizures.[151]

Treatment.

The therapeutic approach must consider the risk for death after attempted operative removal and the very slow-growing or nonprogressive nature of the hamartoma. The precocious sexual development can be controlled by treatment with LH-RH agonists, but epileptic seizures are usually resistant to antiepileptic drugs and deaths from status epilepticus have been reported.[36] However, focal seizures and tonic and atonic attacks are at best moderately controlled by antiepileptic drugs. Treatment with clonazepam and, more recently, lamotrigine has resulted in significant abatement of seizures. Epilepsy surgery may be considered when drop attacks occur.[36]

Long-lasting control of seizures can be achieved by complete removal, destruction, or disconnection of the hamartoma. The debate has therefore shifted to the best means of treatment with a variety of surgical approaches and the possibility of destruction of the lesion with radiofrequency probes or gamma-knife surgery. A transcallosal approach reaching the lesion from above through the third ventricle has been performed with low morbidity. At 1 year, 90% of cases are free or essentially free of all seizures. Marked behavioral improvement has been reported, and cognitive decline appears to stop. Dissection of the hamartoma from the wall of the third ventricle and infundibulum or mammillary bodies may be achieved in selected patients under direct vision. All forms of surgery can be associated with transient diabetes insipidus, but no other major endocrinologic or hypothalamic complications have emerged as hazards of these procedures. Destruction of the lesion by focused ionizing radiation (gamma knife) is an approach that does not require conventional surgery. Although the follow-up periods are short, early results suggest an excellent seizure response. Gamma knife has the lowest morbidity rate of all treatments with comparable seizure-free rates. Concerns exist about the long-term effects of radiation in the hypothalamic region. Overall, authors agree that the surgical approach must be tailored to the specific surgical anatomy of the hamartoma.[13]

Thyroid Disorders

Primary Hyperthyroidism

General Findings.

Studies of experimental animals and humans have provided evidence that thyroid hormones can lower seizure thresholds.[198] Epileptic EEG discharges have been found in many patients with *thyrotoxicosis*. Epileptic seizures associated with thyrotoxicosis have been considered an infrequent event: 9% of all admitted patients with thyrotoxicosis.[109] Nevertheless, epilepsy associated with thyrotoxicosis remains a possible infrequent event,[167,181] and thyrotoxicosis must be considered among the causes of adult-onset epileptic disorders.[121]

Thyrotoxicosis (or thyrotoxic crisis) is an uncommon but severe complication of hyperthyroidism that occurs in *Graves disease* (an autoimmune disorder associated with the HLA-DQA1*0501 allele and characterized by thyrotoxicosis and ophthalmopathy in the presence of autoantibodies to thyroglobulin, microsome, or thyroid peroxidase[30]) and *toxic multinodular goiter*, which is almost always precipitated by an intercurrent illness.[181] *Iatrogenic thyrotoxicosis* may occur after treatment of hypothyroidism.[109] The association between juvenile myoclonic epilepsy and Graves disease may be not fortuitous but rather an indication of a shared genetic immunologic etiology.[198]

Clinical Description.

Both generalized tonic–clonic and partial motor epileptic seizures (including visual-adversive and partial motor seizures with secondary generalization and prolonged postictal coma) associated with or followed by signs of hyperthyroidism (irritability, tachycardia, tremor, anxiety, confusional state) have been reported as presenting symptoms of thyrotoxicosis.[109,167] Juvenile myoclonic epilepsy has recently been reported in two unrelated patients with untreated Graves disease.[198] Typically, in these cases epilepsy begins during adolescence with characteristic clinical, laboratory, and ictal EEG findings; the latter consist of 3- to 3.5-Hz diffuse polyspikes-and-waves and spike-and-wave bursts. Often epilepsy in

hyperthyroidism may be secondary to neurologic disorders such as stroke, Moyamoya disease, and superior sagittal sinus thrombosis induced by thyrotoxicosis rather than to hyperthyroidism per se.[116,168] Recurrent generalized seizures, preceded by an encephalopathy state, coinciding with relapses of the thyrotoxicosis have been reported in a patient. EEG showed bilateral slowing of activity. Characteristically, antithyroid drug treatment was able to control symptoms. Convulsive[126] and nonconvulsive status epilepticus[132] may also represent the first manifestation of thyrotoxicosis. In this context, status epilepticus is often resistant to conventional antiepileptic drugs.[181] The situation is obviously life threatening, requiring vigorous and comprehensive management.

Interictal EEG findings of thyrotoxicosis consist of diffuse slowing, sharp discharges, and occasional bilateral triphasic waves.[167]

Diagnostic Evaluation.

Although seizures are not especially frequent in thyrotoxicosis, thyroid hormone levels should be evaluated during diagnostic investigation at the onset of an epileptic disease.

Differential diagnosis must exclude other metabolic (nonketotic hyperosmolal state) or endocrine (hypoparathyroidism) disorders that may significantly increase focal cerebral excitation.

Treatment.

Treatment of thyrotoxic crisis should begin as soon as the diagnosis is suspected. The aim is to correct both severe thyrotoxicosis and any precipitating intercurrent illness and to provide general supportive therapy. Effective therapy of the endocrine disorder and epileptic seizures comprises administration of antithyroid drugs (propylthiouracil, methimazole, or both), dialysis, plasmapheresis, hemoperfusion (to lower circulating levels of thyroid hormones), administration of glucocorticoids and adrenergic antagonists, supportive therapy (intravenous administration of glucose, saline, vitamin B complex, and sedatives), and correction of hyperpyrexia and heart failure.[181] Common antiepileptic drugs may be useful in controlling seizures, but careful evaluation of other organ systems is required to estimate the risk for adverse effects of antiepileptic therapy.

Primary Hypothyroidism

General Findings.

Primary hypothyroidism is characterized by the combination of low levels of thyroid hormone and high levels of thyroid-stimulating hormone (TSH). Possible causes are Hashimoto thyroiditis (see later discussion), treatment with radioiodine, thyroidectomy, drugs, and thyroid lymphoma; primary hypothyroidism may also be congenital. Decreased TSH resulting from tumor or infiltrative disease of the pituitary causes secondary hypothyroidism.[125] Decreased thyrotropin-releasing hormone (TRH) resulting from hypothalamic tumor causes tertiary hypothyroidism.[125] The most important consequence of *primary congenital hypothyroidism* is impaired brain development, which, if not treated, leads to severe mental retardation. Psychotic manifestations and terminal myxedematous coma are the most common central nervous system manifestations in *primary acquired hypothyroidism*; epileptic seizures only rarely occur. In these cases, convulsions may be the presenting symptom or may occur in untreated cases of myxedema of long duration.[43]

A paroxysmal triad consisting of high fever, seizures, and coma with a flulike prodrome can rarely occur in patients with scleromyxedema and is termed “dermato-neuro” syndrome. It has been found that the incidence of febrile convulsions among patients with congenital hypothyroidism under therapy with L-thyroxine since the age of 1 month was significantly lower than that of normal control children. It seems therefore that patients with congenital hypothyroidism on regular L-thyroxine replacement are less prone to experience febrile convulsions.[23]

Although epileptic seizures do not usually occur in *primary hypothyroidism*, experimental data demonstrated that the number of stimuli necessary to produce lidocaine-kindling seizures (i.e., tonic attacks followed by tonic–clonic movements) in congenital hypothyroid rats was significantly lower than in the control group for both ages.[157] Moreover, it is well known that early-onset hypothyroidism produces audiogenic seizure susceptibility in rodents, in which TR α1 and TR β thyroid hormone receptors seem to play a role.[150]

Clinical Description.

In primary acquired hypothyroidism, generalized tonic–clonic seizures and EEG findings of low-voltage slow waves and dysrhythmic background suggest a nonspecific encephalopathy. Seizures may be characterized by an unexplained prolonged postictal recovery.[43]

Diagnostic Evaluation.

Although hypothyroidism is an uncommon cause of epilepsy, thyroid assessment must be considered in the etiologic diagnosis of cryptogenic generalized seizures, especially when followed by a prolonged postictal recovery. Differential diagnosis should exclude other metabolic or endocrine disorders. However, coarse facies, bradycardia, dry skin, and hair loss (when present) are clearly suggestive of hypothyroidism.

Treatment.

Treatment with L-thyroxine leads to normalization of the endocrine disorder and abatement of epilepsy. Therefore, antiepileptic drug treatment seems to be unnecessary. However, it should be remembered that rapid correction of a hypothyroid state during administration of thyroxine might constitute a risk for thyrotoxicosis, with epileptic seizures as a consequence. In fact, a causal relationship has been presumed between high-dosage thyroxine therapy and a nonconvulsive status epilepticus characterized by absence seizures with eyelid and distal myoclonic twitchings, triggered by spontaneous or passive eye closure and generalized convulsive seizures.[109] These seizures appeared to respond to valproate. Thyroxine-induced epilepsy with hypermotor seizures was also controlled by reducing thyroxine doses.[24]

Hashimoto Encephalopathy

General Findings.

Hashimoto encephalopathy (HE) is a steroid-responsive neurologic disorder associated with antithyroid antibodies. Frequently, epileptic seizures are a presenting symptom.[28,83,98] The term “Hashimoto encephalopathy” is not considered appropriate by some authors because the thyroid condition has not been proved to have a direct relationship with the neurologic process, and the role of thyroid antibodies in the pathogenesis of encephalopathy has not been defined. The term “autoimmune encephalopathy associated with Hashimoto thyroiditis” is considered a more accurate definition. “Nonvasculitic autoimmune encephalopathy” and “corticosteroid-responsive encephalopathy associated with Hashimoto thyroiditis” are also used. In fact, although in some patients thyroiditis is diagnosed before Hashimoto encephalopathy, the disease may affect euthyroid patients with normal levels of thyroid hormones and TSH. At present, HE is suspected whenever symptoms of acute or subacute encephalopathy or myelopathy are associated with high serum levels of antithyroid antibodies.[28]

Several theories have been proposed to explain the pathogenesis of HE. They include autoimmune vasculitis, autoimmune reaction to common antigens between the thyroid gland and the CNS, cerebral hypoperfusion, and toxic effects of thyrotropin-releasing hormone. The presence of antithyroid antibodies in CSF of patients with encephalopathy and myelopathy associated with Hashimoto disease was reported, and indirect evidence was provided to suggest intrathecal synthesis of antithyroid antibodies. Therefore, it has been proposed that the diagnosis of Hashimoto encephalopathy should be based on this CSF finding.[76,83] Specific high

reactivity against human α-enolase has been found to be in patients with Hashimoto encephalopathy. Some authors suggest that the detection of an anti–α-enolase antibody is useful for defining encephalopathy-related pathology.[153]

Postmortem examination in a patient with Hashimoto encephalopathy complicated by fatal status epilepticus demonstrated mild perivascular lymphocytic infiltration throughout the brain and leptomeninges with diffuse gliosis of gray matter in the cortex, basal ganglia, thalamus, and hippocampus.[66]

Clinical Description.

The clinical picture of Hashimoto encephalopathy with epilepsy includes generalized and partial seizures as distinguishing features. Myoclonus, tremor, choreic movements, central nystagmus, gait disturbance and ataxia, and hallucinations may be present, as well as transient aphasia or somnolence, headache, fatigue, confusion, and unilateral sensory loss. Strokelike episodes, palatal tremor, musical hallucination, and cerebellar dysfunction have also been reported in some cases. The symptoms may improve spontaneously or after corticosteroid therapy. Two distinct clinical forms of HE have been suggested: (a) a *vasculitic type* characterized by multiple strokelike episodes and (b) a *diffuse progressive* type characterized by dementia and psychiatric symptoms. Both forms may be associated with tremor, seizures, stupor, and myoclonus. The myoclonic syndrome may be so prominent that Hashimoto encephalopathy has also been defined as *Hashimoto myoclonic encephalopathy*.[28,83]

Recurrent generalized convulsive status epilepticus and recurrent generalized absence status with blinking and/or twitching resistant to antiepileptic medications but successfully treated with corticosteroids have been reported.[139]

The interictal EEG findings are also variable. Most commonly the EEG shows generalized abnormalities including generalized slow wave activity, slow posterior background, and frontal intermittent rhythmic delta activity (FIRDA). Triphasic waves and focal slow waves have been described in some patients. The EEG findings seem to subside with the improvement of the encephalopathy, although the EEG tends to lag behind the clinical improvement.

Ictal recordings showed bitemporal discharges and focal mesial-basal temporal seizure discharges. In the latter patient, the ictal seizure semiology, with gradual onset and slow secondary generalization, was consistent with a temporal onset.[16,83,98,205] Ghika-Schmid et al. considered the clonazepam-induced synchronous paroxysmal monomorphic rhythmic delta activity associated with transient myoclonus recorded in a patient as a peculiar finding and suggested caution in the administration of antiepileptic drugs.[83]

Magnetic resonance imaging findings vary. A review of MRI findings on 82 patients found abnormalities in 49%. Findings are nonspecific and include subcortical white matter abnormality and T2 cortical signal abnormalities and are reversible with recovery or after corticosteroid therapy.

Cerebral angiography has been reported to be normal; in contrast, cerebral blood flow single-photon emission computed tomography (SPECT) scans have shown areas of reduced perfusion in cortical areas and basal ganglia.

Brain biopsy findings were normal in one patient. Patchy myelin pallor, scant perivascular chronic inflammation, mild gliosis, and lymphocytic infiltration of the venous brain system have been reported.[75,152]

Diagnostic Evaluation.

An adult-onset encephalopathy of unknown origin with focal neurologic signs, myoclonus, drug-resistant epileptic seizures, and mental impairment is strongly suggestive of Hashimoto thyroiditis. Therefore, screening for antithyroid antibodies should be performed. Viral and bacterial infections must be excluded. The CSF protein concentrations are high in 78% of patients. Mild lymphocytic pleocytosis may be present occasionally. Differential diagnosis between movement disorders (tremor and myoclonus) and epilepsy requires video-polygraphic-EEG recordings and EMG examination. EEG anomalies are found in 98% of patients. The progressive chronic evolution associated with seizures, myoclonus, and strokelike episodes[98] may cause problems in the differential diagnosis of mitochondrial encephalopathy. Finally, possible kidney disorders must be investigated (see section on renal failure).

Treatment.

Although some patients have been found to be corticosteroid nonresponsive, both high doses of oral prednisone and shorter courses of intravenous methylprednisolone were reported to be very effective in controlling HE symptoms.[83,98] Azathioprine, methotrexate, cyclophosphamide and hydroxychloroquine sulfate, plasmapheresis, and intravenous immunoglobulin have been used with clinical benefit. Spontaneous improvement without corticosteroid therapy occurred in some cases.[75] Because of this rapid seizure control, antiepileptic drugs are not usually given.

Parathyroid Disorders

Hyperparathyroidism

Hyperparathyroidism, characterized by hypercalcemia and elevated levels of parathyroid hormone (PTH), is not usually associated with epileptic seizures. However, a *grand mal* epileptic seizure associated with psychiatric symptoms has been reported anecdotally in patients with hypercalcemia secondary to neoplastic hyperparathyroidism and basal ganglia calcifications.[70]

Hypoparathyroidism

General Findings.

Hypoparathyroidism is a clinical disorder characterized by hypocalcemia and hyperphosphatemia. It manifests when PTH secreted from the parathyroid glands is insufficient to maintain normal extracellular fluid calcium concentrations or, less commonly, when PTH is unable to function optimally in target tissues, despite adequate circulating levels. Deficiency of PTH may occur following thyroidectomy or other surgical procedures involving the neck. Infections, glandular infiltrations by granulomatous processes, heavy metals, or more commonly autoimmune disorders may cause deficiency of PTH. Congenital parathyroid hypoplasia or agenesis causes congenital hypoparathyroidism. Autosomal-dominant and autosomal-recessive familial idiopathic hypothyroidism have also been identified. Hypocalcemia is the characteristic biologic consequence of hypoparathyroidism. Because low calcium levels result in hyperexcitability of neural membranes, the prominent clinical neurologic manifestations of hypoparathyroidism are those related to hypocalcemia with neuromuscular irritability, perioral paresthesias, tingling of the fingers and toes, and tetany. Generalized tonic–clonic seizures and laryngeal spasm also occur. In a chronic setting, hypocalcemia can be asymptomatic. Alternatively, mild neuromuscular irritability, calcification of the basal ganglia, extrapyramidal disorders, cataracts, alopecia, abnormal dentition, mental retardation, or behavior disorders may be present. From a biochemical point of view, hypoparathyroidism is mainly characterized by hypocalcemia and hyperphosphatemia with normal renal function. Serum levels of PTH are low, except in the setting of PTH resistance, in which case levels are high-normal or elevated. Serum levels of 1,25-dihydroxyvitamin D are usually low or low-normal. The 24-hour urinary excretion of calcium is decreased. Nephrogenous cAMP excretion is low, whereas renal tubular reabsorption of phosphorus is elevated.

DiGeorge syndrome, 10p deletion syndrome, Hallermann-Streiff syndrome, and familial nephrosis with nerve deafness constitute different genetic syndromes with congenital

hypoparathyroidism. In particular, hypoparathyroidism with short stature, mental retardation, and seizures (or Sanjad-Sakati syndrome) is characterized by congenital hypoparathyroidism, growth and mental retardation, and seizures as a prominent finding. Recent studies demonstrated that both Sanjad-Sakati syndrome and the autosomal recessive Kenny-Caffey syndrome are allelic variants caused by mutations in the *TBCE* gene.[160]

Anecdotal reports describe the association between idiopathic hypoparathyroidism and systemic lupus erythematosus[82] or subacute sclerosing panencephalitis,[54] in which the authors suggest a common pathogenetic mechanism. In these reports, epileptic seizures occurred in the period of idiopathic hypoparathyroidism.

Here we present data regarding epileptic seizures in hypoparathyroidism occurring after the neonatal period.

Clinical Description.

Typically, clinical signs of hypoparathyroidism include tetany, epileptic seizures, and, when basal ganglia calcifications are present, hemichorea, choreoathetosis, and parkinsonism.[146] Epileptic seizures may occur at any age and are usually generalized tonic–clonic with loss of consciousness.[54,81,82] Nonconvulsive status epilepticus has also been described in this group of patients.[118]

Seizures may be the presenting symptom, preceding other signs of hypocalcemia such as chorea and tetany. Normally, tetany develops after calcium levels decline further. Generalized convulsive epileptic seizures may also be the presenting symptom in elderly patients with hypoparathyroidism, in association with confusion and then with signs of tetany. In fact, iatrogenic hypoparathyroidism needs to be considered in the differential diagnosis of adult-onset, generalized tonic–clonic seizures even if the thyroidectomy was performed years earlier.[145] Several types of partial motor seizures, including jacksonian seizures, may also be observed. If not treated, the outcome of these conditions may be very severe. Among the members of a familial idiopathic hypoparathyroidism, some untreated members died in infancy because of convulsions. Paroxysmal kinesigenic choreoathetosis and convulsions occurring in clusters at age 2.5 months have been observed in a child with idiopathic hypothyroidism. The clinical picture was indistinguishable from that of infantile convulsions and choreoathetosis syndrome.[96] Reported EEG findings show irregular high-voltage delta activity that is increased on hyperventilation. Paroxysmal abnormalities may also occur during wakefulness and sleep.[111]

Diagnostic Evaluation.

Hypoparathyroidism with hypocalcemia as a cause of epileptic seizures should be considered and investigated in patients of any age. The condition can be treated successfully, whereas if it is untreated, it may be fatal in infants. Tetany, generalized epileptic seizures, and movement disorders may occur at the same time in hypocalcemic states, posing problems of differential diagnosis. Differential diagnosis of partial epileptic seizures and hemitetanic carpopedal spasm may be difficult, as may be the differential diagnosis of reflex epilepsy and paroxysmal kinesigenic choreoathetosis associated with hypoparathyroidism.[29] Finally, the differential diagnosis of primary hypomagnesemia with secondary hypocalcemia must be considered (see section on electrolyte disorders). In all these cases, correct diagnosis requires direct observation of the motor phenomena and ictal EEG investigation during hyperventilation maneuvers. Computed tomography and magnetic resonance imaging of the brain are mandatory to investigate basal ganglia lesions.

Treatment.

The aim of therapy in all hypoparathyroid states is to restore serum calcium to levels sufficient to alleviate symptoms of acute hypocalcemia and prevent the complications of chronic hypocalcemia and hypercalcemia. The main pharmacologic agents available are calcium and vitamin D preparations. Neurologic findings disappear on normalization of calcium levels with calcium supplementation and vitamin D therapy in all cases, including those with extrapyramidal signs and basal ganglia calcifications. Magnesium replacement should also be considered routinely in patients with hypocalcemia because hypomagnesemia induces functional hypoparathyroidism. When antiepileptic drugs are required, it must be emphasized that they may lower circulating calcium concentrations. Regular monitoring of plasma calcium levels is recommended.

Disorders of the Pancreas

Diabetes Mellitus

The most important disease of the pancreas associated with epileptic seizures is diabetes mellitus. Seizures may be induced in diabetes mellitus during nonketotic hyperglycemia or during hypoglycemia resulting from iatrogenic hyperinsulinism; in ketotic hyperglycemia, epileptic seizures are rare.

Nonketotic Hyperglycemia

General Findings.

Seizures associated with nonketotic hyperglycemia were first reported in 1965.[133] Many other subsequent reports confirmed the occurrence of seizures in nonketotic hyperglycemia. Cases in non–insulin-dependent diabetes mellitus may exhibit a spectrum from asymptomatic hyperglycemia without ketosis (which may be clinically asymptomatic for months or years[90]) to hyperosmolal nonketotic diabetic coma (representing the extreme end of a biochemical continuum). Hyperosmolar nonketotic diabetic coma is associated with a high mortality in adults (range, 20%–70%) and children, but it is more common in the elderly and rarer in children.[208] Diabetes is often detected before severe hyperosmolality develops. Neurologic manifestations such as seizures, focal neurologic signs (usually postictal), myoclonic twitches, nystagmus, and meningeal signs often provide the first clinical clues to the presence of nonketotic hyperglycemia.[133] Age at onset of nonketotic hyperglycemia ranges between 48 and 72 years. Epileptic seizures have been rarely reported in juvenile nonketotic hyperglycemia.[179] As a rule, seizures occur when hyperglycemia is not severe and osmolality is normal or only slightly increased, with normal to moderately decreased sodium levels.[191] In this phase, patients are usually alert. If diabetes mellitus is not treated, however, hyperosmolality with progressive impairment of consciousness develops while seizures stop. The pathogenetic mechanism of the association between hyperglycemia and seizures is still debated. Most authors attribute the partial seizures to a preexisting structural lesion activated by hyperosmolality and hyperglycemia.[56,133] An entirely metabolic cause of epilepsy, such as hypertonicity or hyperglycemia, appears unlikely because in diabetic ketoacidosis partial seizures are rare. However, experimental studies demonstrated that susceptibility to clonic and tonic–clonic flurothyl-induced seizures positively correlates with blood glucose concentrations and that the increased glucose concentration is associated with proconvulsant effects.

Similarly, in the in vitro experiments, epileptiform activity was promoted by increased and suppressed by decreased glucose concentrations. Therefore, extracellular glucose itself has proconvulsant activity even without a previous focal lesion.[186] Hyperglycemia may precipitate seizures by lowering γ-aminobutyric acid levels, resulting in a lower seizure threshold. Moreover, the parietal lobe seems to play a role in epilepsia partialis continua, which is often associated with nonketotic hyperglycemia. Ictal SPECT studies in humans[104] and experimental studies, which found that diabetic hyperglycemic animals have more severe neuronal necrosis in the parietal cortex than do normoglycemic animals,[130] corroborate that hypothesis. The apparently protective effect of ketoacidosis may be

P.2674

attributed to an increase in GABA bioavailability secondary to acidosis, which is known to increase glutamic acid decarboxylase activity.[56,94]

Clinical Description.

Seizures occur in about 25% of patients and are the chief initial manifestation in 6%.[94] Seizures are most often partial motor seizures, occurring in 75% to 86% of cases.[94] The seizures are frequent and repetitive and are often followed by transient postictal paralysis.[90] Occipital visual and adversive seizures have been described[92] and have been considered to be a relatively common early manifestation of nonketotic hyperglycemia. Typical jacksonian seizures have also been reported.[97] Epilepsia partialis continua has been described in some cases as the initial symptom of nonketotic hyperglycemia.[56,99,179] Contrary to data in the literature, in some of these cases epilepsia partialis continua could not be attributed to any structural cerebral lesion but seemed to be caused solely by metabolic dysfunction; results of neuroimaging were normal.[56] Nonconvulsive status epilepticus of frontal origin has also been observed.[113,201] Generalized tonic–clonic seizures have been described less frequently.[94] Some patients have reflex or posture-induced epileptic seizures.[99,207] Such seizures are relatively rare and have been defined as kinesigenic seizures[99] or fencing-posture seizures.[207] Characteristically, the seizures are partial, simple, or complex in type, last <5 minutes, and appear within seconds after onset of the triggering maneuver. This maneuver may consist of passive or active elevation of an arm or leg or walking. Seizures are followed by a refractory period during which no further seizures can be elicited.[207] Gaze-evoked sensory visual occipital seizures have been described in an anecdotal case.[67] Ictal stereotypic visual experiences consist of flashing lights followed by formed objects or unfamiliar human faces and may be consistently elicited by having the patient look to one side. Usually, the EEG is normal in uncomplicated diabetes. Focal EEG abnormalities have been found only in nonketotic hyperglycemia, related to an underlying focal cortical lesion, likely vascular in nature, as a consequence of hyperglycemia and hyperosmolarity.[112,133]

Diagnostic Evaluation.

Patients with partial seizures, fencing-posture seizures, and even epilepsia partialis continua without any detectable cause and with normal findings on neuroimaging examinations should be investigated for diabetes mellitus. Consequently, it is very important to check glucose levels in all patients with seizures, especially if they are elderly, to detect the early manifestations of nonketotic hyperglycemia associated with mild or minimal hyperosmolality. In cases of occipital seizures, celiac disease must be excluded (see section on gastrointestinal diseases). Of course, neuroimaging investigations must be performed in patients with partial seizures and epilepsia partialis continua to detect more frequent causes, such as cerebral tumor, infarction, encephalitis, brain malformations, and abscess. CT scans in cases of nonketotic hyperglycemia–related seizures often fail to reveal relevant focal cerebral disease. Hyperintensities in T_2 and fluid attenuated inversion recovery (FLAIR) related to seizure activity have frequently been seen in the cortices. Transient T_2 and FLAIR subcortical hypointensity with or without abnormalities in the overlying cortex in the setting of partial status epilepticus associated with NKH was reported in three patients. The mechanisms of T_2 and FLAIR hypointensities are unclear. These changes may be due to an accumulation of free radicals and iron deposition, as has been described in early cortical ischemia. The decreased N-acetyl-aspartate in the same region observed in some patients suggests reduced vital neuronal tissue.[56,188]

Treatment.

As long as biochemical disturbances remain uncorrected, the seizures are refractory to antiepileptic drug therapy. Patients become seizure free after administration of insulin and rehydration, and they remain seizure free while the diabetes mellitus is controlled. Moreover, patients who receive prompt treatment, before nonketotic hyperglycemic coma develops, have a better prognosis. If antiepileptic drugs are used for seizures, it should be noted that plasma free fractions of valproate are increased in diabetes mellitus, and phenytoin should be avoided because it inhibits insulin secretion and may aggravate hyperglycemia and nonketotic hyperglycemia, precipitating diabetic ketoacidosis.[94]

Diabetic Hypoglycemia

General Findings.

Diabetic hypoglycemia is a common problem in adults and children with diabetes who are treated with insulin and other oral hypoglycemic agents.[123]

Nondiabetic hypoglycemia may have many causes, such as alcoholism, sepsis, fasting, terminal neoplasms, and insulin-secreting neoplasms. There are also anecdotal reports of patients affected by gastroenteritis with diarrhea and dehydration, hypoparathyroidism, and adrenocortical insufficiency.[81,123]

Clinical Description.

Initial clinical symptoms of hypoglycemia are caused by excessive adrenergic activity; patients may be dizzy, tremulous, anxious, and profusely sweating. Hypotonia, motor restlessness, and generalized seizures appear later. Confusion, bizarre behavior, obtundation, stupor, or coma occur in more severe degrees of hypoglycemia. At times, for unknown reasons, the neurologic deficits are of a focal nature, producing partial motor epileptic seizures, focal sensory deficit, and hemiplegia with or without dysphasia.[79,123] Some authors[123,210] have suggested that several mechanisms, including selective sensitivity of neurotransmitters, selective neuronal vulnerability, and loss of autoregulation of cerebral blood flow leading to vasospasm are involved in hypoglycemia associated with focal neurologic deficits.

Hypoglycemic seizures occur in 10% to 20% of adults and more frequently in children.[107] Usually, seizures are generalized, tonic, and tonic–clonic in type. Partial seizures typically occur in adults.[79] There are only two reports of nocturnal partial seizures in children,[123,210] one of them with transient postictal hemiparesis (Todd paralysis).[123] It is well known that unrecognized nocturnal hypoglycemic events are frequent in diabetics, with blood glucose levels returning to normal by morning (Somogyi effect). Therefore, unrecognized nocturnal hypoglycemic seizures may occur in patients with no previous history of fits and hypoglycemic symptoms during waking hours.[123] It appears that severe hypoglycemic events mainly affect the youngest patients and boys (the latter of all ages) rather than adolescents girls, who mainly suffer from ketoacidosis.[171] In this context, Strudwick et al.[197] investigated whether severe hypoglycemic episodes in young children with early-onset type 1 diabetes (T1DM) were associated with subsequent abnormalities in cognitive status. They found that there was no clear evidence that episodes of seizure or coma, even those occurring in very early childhood, resulted in broad cognitive dysfunction, nor was there evidence of specific memory difficulties at the time of testing in children and adolescents with early-onset T1DM.

From a pathogenetic point of view, elegant experimental studies demonstrated that insulin doses of 8 IU/kg were able to induce seizures in 100% of animals and that insulin-induced hypoglycemic convulsions could be mediated by serotoninergic, dopaminergic, and excitatory amino acid pathways.[15]

Interictal EEG findings show different degrees of generalized slowing of background activity, exaggerated response to hyperventilation, increasing of preexisting epileptiform abnormalities, and/or appearance of paroxysmal patterns, such as 3-Hz spike-and-wave discharges or focal abnormalities.[185,192] Blood sugar levels of 50 to 80 mg/dL are associated with slowing of background activity and appearance of diffuse theta activity. At lower glucose levels, EEG shows intermittent bursts of bisynchronous slow waves.[185] Electroencephalographic abnormalities are more frequent in hypoglycemic children,

especially younger ones, and in the case of repeated severe hypoglycemic episodes.[192] Usually, these abnormalities disappear rapidly when blood sugar levels return to normal levels, but they may persist after more severe and prolonged hypoglycemic events.[123] The pathogenesis of these EEG abnormalities is unknown. Repeated hypoglycemic episodes alone do not seem to be the major factor in causing EEG abnormalities, and it has been hypothesized that a diabetic encephalopathy caused by microvascular lesions may be involved.[69]

Diagnostic Evaluation.

Nocturnal generalized or partial seizures in diabetic patients should be strongly considered as evidence of possible unrecognized insulin-induced hypoglycemia. It has been postulated that these seizures are more common than generally thought and that they may be a presenting symptom of diabetes mellitus.[123] Because such seizures are not symptomatic of a brain lesion and because results of computed tomography were normal in all patients,[79,123] seizures could mistakenly be diagnosed as idiopathic epilepsy, leading to unnecessary treatment with antiepileptic drugs, which must be administered with special care to diabetic patients (see section on nonketotic hyperglycemia). Because of its characteristic pattern, the EEG may aid significantly in the diagnosis. Otherwise, laboratory and clinical investigations are strongly recommended to rule out all other causes of hypoglycemia, especially neoplasms secreting insulin.

Treatment.

Reducing the daily dose of insulin and other oral hypoglycemic agents is strongly advised because this is sufficient to prevent hypoglycemia. Antiepileptic drugs should not be considered as elective therapy and must be monitored closely, and it should be remembered that various drugs interact with insulin and other hypoglycemic agents, such as phenothiazine, aspirin, phenylbutazone, sulfa drugs, haloperidol, propranolol, and lithium.

Reproductive Endocrine Disorders

Epileptic seizures as a symptom of reproductive endocrine disorders are problematic. Although there is evidence that reproductive endocrine disorders (especially hypogonadotropic hypogonadism with infertility, hyperprolactinemia, and polycystic ovarian syndrome) and epilepsy (especially temporal lobe epilepsy) frequently occur together, the pathogenesis is controversial.[101,214] Experimental evidence that the temporal lobe modulates sexual, reproductive, and neuroendocrine functions has been obtained in animals, and anatomic-functional pathways connecting the amygdala and hypothalamus have also been defined.[100] Thus, in temporal lobe epilepsy associated with reproductive endocrine disorders, altered impulses arising as epileptiform discharges from the amygdala have been postulated to disrupt normal secretion of gonadotropins and prolactin. In this context, endocrine disorders can be considered as secondary to temporal lobe epilepsy, and so they are beyond the scope of this chapter. However, because experimental animal and human clinical evidence suggests that estrogen and testosterone may precipitate epileptic seizures, and because there are many patients who have temporal lobe epilepsy and reproductive endocrine disorders without taking antiepileptic drugs, it is possible that the presence of a reproductive endocrine disorder may favor the development of temporal lobe epilepsy.[101]

Finally, because of the frequent familial occurrence, a possible contribution of genetic factors to the development of both temporal lobe epilepsy and reproductive endocrine disorders has been hypothesized.[101] A relationship between the type of endocrine disorder and the laterality of temporal epileptiform EEG discharges in women with temporal lobe epilepsy occurs, suggesting the existence of a lateralized asymmetry in cerebral influences on reproductive endocrine function.[100]

Gastrointestinal Diseases

The relationship between epilepsy and gastrointestinal diseases is a very intriguing problem. Apart from vomiting, which may be a common symptom of either gastrointestinal illness or neurologic disturbances such as migraine, epilepsy, increased intracranial pressure, and metabolic disorders, epilepsy and epileptic seizures may be the presenting symptom in some gastrointestinal diseases. Some authors have reported seizures associated with gastroesophageal reflux and suggested that it could be a part of the autonomic dysfunction that accompanies temporal lobe seizures. Afebrile partial or generalized seizures as a presenting symptom have been reported in children with mild gastroenteritis.[119] Generalized tonic–clonic seizures are nearly the most common extraintestinal manifestation of shigellosis.[46] The reported incidence ranges from 12% to 45%.[87]

Epilepsy and epileptic seizures may be a relevant symptom in celiac disease and orthotopic liver transplantation.

Celiac Disease

General Findings

Celiac disease (CD) is characterized by permanent gluten intolerance. Clinically, the "classical or typical" form appears in the first 2 years of life with diarrhea, weight loss, dystrophic appearance, and anorexia. Irritability and vomiting occur in one third of patients. On the other hand, CD may be silent, latent, or potential. These "atypical" forms are more frequent in children older than 2 years and may present with extraintestinal features such as dermatitis herpetiformis and dental enamel defects. Neurologic disorders have been extensively observed in patients with CD. Among them, epilepsy is the most frequent, and its prevalence in CD patients has been estimated to be between 1.2% and 5%. In 7% of newly diagnosed CD patients, neurologic disorders may be the presenting symptoms of the disease, especially in the case of silent and latent CD.[58,67,88,136] Epilepsy as a presenting symptom of celiac disease has also been reported.[88]

In the case of epilepsy and CD, three groups of patients have been identified: (a) patients with celiac disease, epilepsy, and cerebral calcifications (CEC), or "typical form"; (b) patients with celiac disease and epilepsy without cerebral calcifications; and (c) patients with celiac disease and cerebral calcifications without epilepsy. The latter two groups are considered "atypical forms." There is a fourth group of patients with epilepsy and cerebral calcifications without celiac disease, who are believed to be affected by a latent or silent form of celiac disease.[87]

The *CEC syndrome* was first hypothesized in 1988 and then defined in 1992.[86,88] The majority of patients reported in the literature came from Italy, Spain, and Argentina.[87] Fewer patients have been reported in Australia, Canada, Israel, and Sweden. On the other hand, patients from outside Italy do not have an Italian origin. These data demonstrate that this syndrome, although most widespread in Italy, is generally found all over the world. The Italian diet is rich in gluten, but there may be other reasons for the reported high incidence of CEC in the Italian population, such as the particular interest in this condition in Italy. Whether the association between CD and epilepsy and cerebral calcifications is merely a coincidence or a genetic condition, or whether epilepsy and/or cerebral calcifications are a consequence of an untreated CD, still has to be

P.2676

demonstrated. On one hand, clinical and histopathologic findings, which seem to be the expression of vascular calcified malformation instead of the inflammatory lesion, of CEC syndrome are similar to those found in Sturge-Weber syndrome.[202] On the other hand, the high number of cases reported in the literature and the much higher-than-expected frequency of CD (77.5% of cases in the series of the Italian Working Group on Celiac Disease and Epilepsy[88]) in patients with cerebral calcifications and epilepsy, the progressive growth of cerebral calcifications or their late occurrence during evolution before the adoption of a gluten-free diet,[5,44] and the increasing prevalence with age of epilepsy and cerebral calcifications in patients with undiagnosed CD (from 0.79% at mean age of 5.9 years to 3.5% at mean age of 10 years[206]) lead us to consider that the two conditions are related. Epilepsy and cerebral calcifications might be the consequence of an autoimmune disorder affecting the central nervous system triggered by gliadin in predisposed subjects (HLA phenotype) and originating from the jejunal mucosa. In fact, it has been suggested that an altered expression of jejunal mucosa-activated circulating T cells, secreted cytokines, and tissue transglutaminase may initiate an immune response in the CNS tissue and might play a pathogenetic key role in seizures and cerebral calcifications in these patients.[85]

Concerning the genetic predisposition, CD is strongly associated with HLA class II genes. HLA-DQ2 was found in 90% of CD patients and HLA-DQ8 in 10% of cases. Another association with CD is the DR53 heterodimer, which seems to have affinity with gliadin-A peptides. In a minor percentage of patients, DQ2 is not present and CD is associated with DQ8 heterodimer. Those rare CD patients lacking these HLA markers may exhibit the DR4 allele.[85] It has been suggested that different aspects of the syndrome (with or without CD, with or without epilepsy, and with or without cerebral calcifications) might depend on involved genes and their combination.[80]

Epileptogenesis in CD patients does not appear to be directly dependent on the local deposit of calcium. In fact, seizures may occur early in CD patients before the development of cerebral calcifications.[21] Cerebral calcifications might depend also on deposit of calcium due to chronic immune complex–related endothelial inflammation. Chronic folic acid deficiency has also been hypothesized, similar to what occurs in non-CD conditions such as congenital disease, methotrexate therapy, and radiotherapy. Chronic folic acid deficiency could also depend on the effect of antiepileptic drugs, but that seems less probable because antiepileptic drug–induced folate deficiency is rare.[85] Preferential occipital involvement is an unexplained issue, but it could be related to a selective vulnerability of the occipital lobe.[97] According to Martinez-Bermejo et al.,[137] considering that most CEC patients are from the Mediterranean area (Italy and Spain) and Argentina, it could be hypothesized that CEC may represent a genetic, noninherited, ethnically and geographically restricted syndrome associated with environmental factors.

Atypical forms include patients with celiac disease, epilepsy without cerebral calcifications, and patients with CD and cerebral calcifications without epilepsy. Sixty-nine patients of the latter group were reported up to 1996,[87] and one third of them had partial occipital epilepsy. Labate et al.[122a] found that in a cohort of 72 newly diagnosed patients with idiopathic partial epilepsy, 9% of those with occipital epilepsy were affected by silent CD. Of course, it is possible that cerebral calcifications were lacking because of the early age at diagnosis of celiac disease. In fact, it is well known that some CEC patients with an initial normal CT scan may develop bilateral parieto–occipital calcifications later during the evolution.[44,85,86,87,124,135]

Finally, 9 cases in the Italian Working Group (IWG) series and 24 literature patients[87] had *epilepsy and cerebral calcifications without celiac disease*. Some of these patients had strong similarities with the CEC patients. In fact, imaging characteristics of cerebral calcifications overlapped those of CEC patients, appearing to be progressive in one case, and epilepsy was localization related in 24 cases (7 from the IWG and 17 from the literature). Of these, 18 showed partial occipital epilepsy, with evolution toward epileptic encephalopathy in 2. The fact that 7 of 9 cases of the Italian Working Group series had the HLA DQW2 and DR3 phenotype, as in CEC patients, suggested that some of these patients might be affected by a CEC syndrome in which CD is in a latent state, perhaps with mucosal patchiness.[85,87]

Recently, Pengiran Tengah et al.[162] ascertained the prevalence of active epilepsy in a cohort of 801 CD patients by patient interviews and retrospective case note review. All the CD patients had diagnostic confirmation by small bowel biopsy. Twenty-one patients had a history of epileptic seizures, but only 9 (1.1%) had active epilepsy. No specific epileptic syndrome was identified, suggesting that a causal relation between gluten sensitivity and active epilepsy is unlikely.

Clinical Description

In CEC syndrome, epilepsy may start at any age, with a peak between 5 and 6 years. In a more recent Argentinean series, mean age at onset of epilepsy was 6.13 years (range 1–16 years).[21] On the basis of clinical and EEG findings and evolution, the epilepsy was classified as localization related in 109 cases. Among them, 78 patients had occipital epilepsy. The semiology of the seizures may consist of versive and/or visual seizures (simple hallucinations, amaurosis, blurred vision, loss of focus, vision of colored dots, complex visual hallucinations such as seeing unfamiliar faces or scenes).[163] Visual seizures followed by complex seizures or secondary generalization may also occur. Two anecdotal cases had reflex epilepsy, with reading reflex seizures in one[87] and eating-induced seizures in the other.[134] The remaining 31 cases showed other varieties of partial epilepsy, with complex seizures in 15, motor seizures in 9, and partial seizures with secondary generalization in 7.[85] Although clinically heterogeneous, epilepsy in these patients is usually pharmacoresistant, frequently characterized by an early and apparently benign initial phase followed by an epileptic encephalopathy after a seizure-free interval.[89] Nevertheless, in many cases the evolution is benign (20 cases in a review of the literature).[87] In 9 benign cases, the outcome of occipital epilepsy was similar to that of early- and late-onset benign childhood epilepsy with occipital paroxysms. Progressive myoclonic ataxia syndrome with a cortical myoclonus has been reported in 7 cases.[32] Progressive mental impairment has been found in patients having epilepsy with a severe evolution. Typical generalized epilepsies have also been reported.

In patients with CD and epilepsy without cerebral calcifications, one third had partial occipital epilepsy and one half had a benign evolution of the seizures. Some of these patients were believed to have a form of benign occipital epilepsy. In two patients, occipital epilepsy was progressive toward epileptic encephalopathy.

Electroencephalographic recordings mainly showed focal occipital spike-and-wave abnormalities; rarely, focal abnormalities were outside the occipital regions. Bilateral slow spike-and-wave activity occurred in the cases of occipital epilepsy with progression toward epileptic encephalopathy. The EEG normalized in patients in whom the seizures disappeared.[88]

Typical CT features of CEC syndrome consist of bilaterally subcortical, roughly symmetric or asymmetric, occipital calcifications, absence of contrast enhancement, and absence of brain atrophy. Calcifications may also be observed in the frontal region, and scattered cases of unilateral occipital calcifications

have been reported.[21,85,88,134] Calcifications are extremely variable in size, and no correlation between the extension of calcifications and the severity of disease has been demonstrated.[88]

Diagnostic Evaluation

Considering the apparently specific involvement of the occipital lobe in patients with untreated celiac disease, careful investigation of CD in all patients with occipital epilepsy of unknown cause, even if cerebral calcifications are absent, should be performed.[11] Testing for celiac disease is strongly advised also because, as stated earlier, CD is a gluten-dependent syndrome that may be silent, latent, or potential, and clinical signs of malabsorption may be lacking. Pediatric neurologists may be the only specialists who can detect CD early in these patients.[88]

Complete evaluation to identify CD includes xylose load test, determination of serum folic acid, antigliadin immunoglobulin G (IgG) and IgA antibodies, and antiendomysium antibodies (EmA). Transglutaminase antigen (tTG) has recently been identified as the main autoantigen recognized by antiendomysial antibodies in celiac disease. Low CSF folate levels with alteration in the CSF/serum folate ratio associated with increased CSF and serum levels of cystathionine have been described.[45] Peroral biopsy (with a Crosby capsule) of the jejunal mucosa at the ligament of Treitz (crypt hyperplasia and unequivocal flat mucosa were accepted as markers of celiac disease according to the criteria of Dunnill and Whitehead[68]) should be performed before luten-free diet and 1 year later. Determination of HLA phenotype also should be included in the diagnostic evaluation process.

Moreover, all other known causes of cerebral calcifications must be excluded, including encephalitis, purulent meningitis, ossifying meningoencephalitis, leukemia, chemotherapy, neonatal hemorrhage, congenital infections, TORCH group (toxoplasmosis, rubella, cytomegalovirus, herpes simplex) diseases, and disturbances of calcium and phosphate metabolism. The following examinations should be performed: hematology; urinalysis; blood chemistry; serum electrolytes (sodium, potassium, calcium, and phosphate); serum parathyroid hormone; calcitonin; urinary oligosaccharides and mucopolysaccharides; lysosomal enzyme activities; blood antibodies to herpes simplex virus, cytomegalovirus, mumps virus (parotitis), rubella virus, measles virus, Epstein-Barr virus, and *Toxoplasma*; and vitamin B12.

Finally, enhanced CT scan and MRI must be performed to differentiate these cases from the other phacomatoses, such as tuberous sclerosis complex and Sturge-Weber syndrome, especially when port wine facial nevus is absent. In particular, in patients with celiac disease there is no enlargement of the choroid plexus or local or diffuse brain atrophy, which are common imaging findings in Sturge-Weber syndrome.[88]

Treatment

The epilepsy is usually drug resistant, sometimes evolving into epileptic encephalopathy; it is only rarely benign. Reduced efficacy of common antiepileptic drugs because of malabsorption has been supposed but not demonstrated.

The role and the effectiveness of a gluten-free diet as therapy for epilepsy have yet to be established, although there is no doubt that a correct diet may prevent long-term health risks in unrecognized celiac disease.[103] Nevertheless, it has been demonstrated that the chances of seizure control after gluten-free diet (GFD) seem to be significantly inversely related to the duration of epilepsy before GFD, the age at onset of epilepsy, and the age at the beginning of GFD.[88] When GFD is started late during the evolution, epilepsy may be more severe and epileptic encephalopathy may develop.[63,134]

Lesionectomy might be considered in those patients with drug-resistant epilepsy related to unilateral occipital calcifications.[148]

Hepatic Disorders: Orthotopic Liver Transplantation

General Findings

Seizures are not reported in hepatic encephalopathy, which is usually characterized by varying degrees of confusion, tremor, dysarthria, ataxia, and asterixis. In contrast, seizures are a frequent complication of liver transplantation, even though this procedure usually produces a striking improvement in brain function in patients who have preoperatively hepatic encephalopathy. Nevertheless, neurologic complications are frequent and important causes of morbidity and mortality following orthotopic liver transplantation (OLT). The frequency of neurologic complications after a second OLT is significantly greater than after a first or a third transplant.[131] Seizures represent a main complication of OLT. Although seizures may often be related to focal brain injury, metabolic abnormalities may represent a predisposing factor in these patients. Commonly, underlying factors causing seizures in OLT patients include metabolic derangements, drugs such as cyclosporine and muromonab-CD3 (OKT3), hypoxic–ischemic injury, cerebral structural lesions, and infection. The more frequent electrolyte disturbances in these patients are represented by hypomagnesemia, hypocalcemia, and hyponatremia. Hypomagnesemia may also be secondary to cyclosporin A, which can cause magnesium wasting. The latter drug as well as other immunosuppressant medications (OKT3 and tacrolimus [FK 506]) may trigger seizures per se. Dose reduction or discontinuation of the drug usually leads to complete recovery. It has also been hypothesized that the high dose of steroids used in the therapy of graft rejection may play a role in causing seizures. Cerebral structural lesions that may occur in OLT patients, such as cerebral infarction, pontine or extrapontine myelinolysis, hemorrhagic or ischemic infarct, intracerebral hemorrhage, subarachnoid hemorrhage, and brain abscess and viral and mycosis infections of the central nervous system may also contribute to seizures.[1,71,72,131,194,212] In addition, several reports in the transplantation literature link seizures and other neurologic signs such as confusion, blindness or other visual abnormalities, tremor and paresthesias to immunosuppressive therapy, especially with cyclosporine.[1,101a,131,136a,209] Because of MRI findings (see further on), this has been referred to as a "reversible posterior leukoencephalopathy syndrome." Children seem to be more susceptible than adults to cyclosporine-related seizures[1,206] especially in the presence of synergistic factors such as electrolyte disturbances, structural damage, high-dose steroid treatment for rejection,[8] or low serum cholesterol levels.[62]

Clinical Description

Epileptic seizures are a frequent neurologic complication of liver transplantation, affecting 10% to 29% of cases.[131,209] Single or recurrent generalized tonic–clonic seizures are the most common ictal manifestation. Myoclonic seizures, partial motor seizures, partial seizures with secondary generalization, and status epilepticus have been reported.[1,72,131,209] Unlike hepatic encephalopathy, an increased frequency of seizures may occur within the first week after transplantation, especially after the second orthotopic liver transplantation, but not after subsequent transplant procedures.[131] The cause is undetermined. Conversely, alteration in mental status may increase with each successive orthotopic liver transplantation, progressing to coma. Only a few reports describe the postoperative EEG after orthotopic liver transplantation. Usually, the EEG shows nonspecific generalized slowing of cerebral activity consistent with the development of a metabolic encephalopathy. Interictal generalized or focal spikes and sharp waves have been reported.[1,72,209,211] These epileptiform abnormalities have not been found in all patients. They are associated with serious, often irreversible brain damage, and their incidence has been estimated as fivefold higher in patients who died than in those who survived.[211] EEG was performed after seizure onset in the majority of patients, and partial and generalized electroclinical seizures have also been recorded.[211]

Diagnostic Evaluation

Development of seizures after orthotopic liver transplantation should alert the clinician to investigate for one of the cerebral complications listed earlier. Case history and laboratory tests may aid in the differential diagnosis with other associated metabolic disorders. Usually, computed tomographic findings are described as normal in orthotopic liver transplantation patients.[209] In some patients receiving immunosuppressive drugs (e.g. cyclosporine, tacrolimus), MRI scans show extensive bilateral white matter abnormalities consistent with edema involving mainly the parietal-occipital regions that resolve within 2-3 weeks if immunosuppressive therapy can be reduced, changed or withdrawn. This has been termed a *reversible posterior leukoencephalopathy.*[1,62,101a,136a] MRI is difficult to obtain in these critically ill patients, particularly when they are intubated or unable to remain still.[212] Electroencephalographic monitoring is indicated for its prognostic value.[211]

Treatment

Treatment of the underlying cause of the seizures should always be undertaken together with the administration of anticonvulsant medication. Special attention should be given to the correction of electrolyte imbalances, treatment of infection, and intracranial hemorrhage. Neurosurgical management may be necessary in selected cases such as those with cerebral abscess or subdural hematoma.[212]

Usually, seizures can be controlled by antiepileptic drugs such as phenytoin, phenobarbital, carbamazepine, or benzodiazepines.[1,72] However, phenobarbital, diazepam, phenytoin, and lamotrigine, which are highly bound to albumin, and carbamazepine and ethosuximide, which are primarily eliminated by hepatic oxidation, must be administered carefully because their metabolism is impaired in liver insufficiency, and doses need to be reduced. The most useful anticonvulsant in OLT patients remains phenytoin. Higher doses (18–20 mg/kg) than usual may be necessary to achieve high therapeutic levels. Both total and free phenytoin levels should be measured because hypoalbuminemia and decreased protein binding of phenytoin may result in a toxic free phenytoin level even when the total level is in the subtherapeutic range. Phenobarbital can also be considered. However, because of the excessive sedation, hypotension, and respiratory suppression that may occur during intravenous administration, phenytoin remains the drug of choice. The intravenous loading dose of phenobarbital is not well established, but it is generally in the range of 8 to 20 mg/kg. Carbamazepine can be used in patients with a history of epilepsy and on carbamazepine preoperatively. Carbamazepine, phenobarbital, phenytoin, and primidone may decrease cyclosporine blood levels by induction of P450IIIA (cyclosporine oxidase).[212] Sodium and magnesium valproate and felbamate should be avoided because of their hepatotoxic effects. Gabapentin and vigabatrin, which are not metabolized in the liver, are not bound to albumin, and are exclusively excreted by the kidneys, may also be preferable for these patients.[129]

Anecdotal reports showed that levetiracetam might be an attractive treatment because of its efficacy, lack of hepatic enzyme induction, and rapid attainment of serum levels. It is significant that levetiracetam-treated patients require significantly lower doses of immunosuppressant medications to achieve an equivalent antirejection effect.[84]

Summary and Conclusions

Occasional seizures due to metabolic electrolyte and endocrine disorders may occur more frequently in neonates but are also seen in children and adults. Based on the review of the literature presented in this chapter, three different situations must be considered. First, seizures may be an occasional and transient event concomitant with the toxic effect of a metabolic or endocrine disorder; in this case, they usually disappear following correction of the disorder, as in uremic encephalopathy,[156] electrolyte disturbances,[74,195] hypoparathyroidism, hyperthyroidism, and hypothyroidism,[43,167,181] and hypoglycemia and nonketotic hyperglycemia. Second, seizures may be the symptom of a brain lesion produced either by the toxic effect of a metabolic or endocrine disorder on cerebral tissue, as in hyperglycemia and hyperosmolarity,[133] aluminum encephalopathy,[165] and dialysis disequilibrium syndrome,[127] or by an immune-mediated mechanism, as in Hashimoto thyroiditis and probably celiac disease.[88] Third, brain tumors that cause an endocrine or metabolic disorder, as in pituitary incidentalomas and hypothalamic hamartomas, may produce seizures by a mechanical effect on the cortex.

All of these disorders indicate that epilepsy may be a symptom not only of a disease that primarily affects the brain, but also of systemic disorders or diseases that primarily affect other organ systems. Frequently, epileptic seizures may be the presenting symptom in these systemic disorders and also the predominant or sole clinical manifestation.

Consequently, in the presence of new-onset epileptic seizures, clinicians should carefully investigate not only for brain disease, but also for metabolic, endocrine, or gastrointestinal diseases that may be clinically silent. Such investigations may improve the etiologic diagnosis and thereby indicate a more correct therapeutic approach.
