of clonazepam and paraldehyde remain unclear,[119,133] but bromides and magnesium sulfate do not have this enzyme-stimulating effect and their safe use in porphyria has been reported.[22,118,161,176,192] In vitro or animal studies of some of the newer antiepileptic agents, including lamotrigine, felbamate, topiramate, and tiagabine, suggest that they may exacerbate hepatic porphyrias[76,99]; one case report supports this idea for lamotrigine, which was implicated in inducing a porphyric attack that led to multiorgan system failure.[71] Other new agents, such as gabapentin, pregabalin, and levetiracetam, do not induce the relevant hepatic enzymes and may offer additional therapeutic options, as discussed later.

Seizures occurring during acute attacks of porphyria are managed by treating the underlying porphyrinogenic metabolic defect. This includes intravenous administration of a 10% dextrose solution, infusions of hematin or heme-arginate,[93] and correction of associated metabolic abnormalities such as hyponatremia. If seizures persist, magnesium sulfate, given as an intravenous infusion to maintain serum magnesium concentrations between 2.5 and 7.5 mEq/L, may be helpful.[170,176] Others prefer paraldehyde or intravenous benzodiazepines,[161] but this remains controversial.[176] More recently, successful treatment of seizures or status epilepticus in patients with hepatic porphyria has been reported with gabapentin[98,194,213] or levetiracetam,[149,212] although the numbers of cases are small.

Choices for long-term antiepileptic drug therapy in the setting of hepatic porphyria are likely to expand, given the availability of newer antiepileptic drugs without hepatic enzyme–inducing properties. In the past, bromides were commonly recommended despite their toxicity and narrow therapeutic index[22,64,118,161,176]; when using bromides, serum concentrations should be maintained <90 mg/dL.[176] Many reports suggest that low-dose clonazepam is safe for the long-term treatment of patients with hepatic porphyria.[22,64,105,176,192] The current agent of choice, however, is probably gabapentin or levetiracetam,[98,149,194,212,213] although clinical experience is limited. Pregabalin is not an enzyme-inducing agent and may eventually be a useful alternative. A single case report described the safe and effective use of oxcarbazepine in a patient with porphyria cutanea tarda,[62] but this safety profile may not extend to hepatic porphyrias because oxcarbazepine has some hepatic enzyme–inducing properties. Regardless of the treatment choice, levels of urinary δ-aminolevulinic acid and porphobilinogen should be followed closely during therapy.

Seizures and Connective Tissue Diseases

When seizures occur in patients with connective tissue diseases, it is generally because of a cerebral vasculitis or vasculopathy (Chapter 266). Both systemic and isolated CNS vasculitides may lead to seizures, sometimes accompanied by focal or diffuse cerebral abnormalities. Patients with Sjögren or Behçet syndrome occasionally have convulsions during a flareup of disease activity. Seizures reflecting cerebral involvement are rare in rheumatoid arthritis, scleroderma, and mixed connective tissue disease.[37,133,135] In many connective tissue diseases, seizures result from the effects of the disease on other organs, such as the kidneys, or from complications of therapy, especially with immunosuppressive agents, which predispose to CNS infections.

The connective tissue disease having the highest incidence of seizures and other neurologic manifestations is systemic lupus erythematosus (SLE). Seizures and behavioral abnormalities are probably the most common neurologic symptoms of lupus.[61,178] The incidence of seizures in SLE has ranged in different series from 10% to 54%.[27,61,178,208] Generalized convulsions are especially common, but simple partial, complex partial, absence, and akinetic seizures also occur, as may status epilepticus.[27] Seizures may be the initial feature of SLE, sometimes preceding systemic manifestations by several years.[198]

Pathologic examination in patients with SLE and seizures typically reveals cerebral microinfarcts and, less frequently, subarachnoid and intracerebral hemorrhages that have been attributed to an immunologically mediated vasculopathy.[77] Convulsions may also result from infections related to immunosuppressive therapy, uremia from lupus nephritis, or hypertensive encephalopathy and sometimes occur as a terminal event.[61,208] Evaluation must therefore include brain imaging, CSF examination, and investigation for metabolic abnormalities and systemic disease activity.

The treatment of seizures in patients with SLE depends on their etiology. Convulsions resulting from an exacerbation of cerebral lupus are frequently isolated, self-limited events for which anticonvulsant therapy is unnecessary; if several seizures occur over a period exceeding 48 hours, anticonvulsant medication is prescribed for a limited interval (e.g., 3 months) depending on the response to treatment of the underlying SLE. In cases of severe cerebral lupus associated with recurrent seizures, immunosuppression with corticosteroids, cyclophosphamide, or azathioprine may be required.[27] The occurrence of seizures or psychosis without other neurologic features or significant renal disease does not affect the prognosis for survival adversely.[27]

Many anticonvulsants, especially hydantoins, trimethadione, and ethosuximide, are known to cause drug-induced SLE.[78,206] There are also reports of an SLE-like syndrome associated with primidone,[206] carbamazepine, valproic acid,[3,19,48] and lamotrigine.[172] Symptoms typically occur many months after commencement of anticonvulsant therapy and clear days to weeks after its discontinuation, although they sometimes persist for months. Unlike idiopathic SLE, complement levels are usually normal, and antibodies to native DNA are rarely present.[206] There is no evidence that the implicated antiepileptics exacerbate idiopathic SLE,[85] and appropriate therapy should not be withheld from patients with seizures caused by SLE or with coexistent epilepsy and lupus.

Epilepsy and Cardiac Disease

Seizures caused by focal or global cerebral ischemia may occur in patients with cardiac disease (see also Chapter 275). Focal ischemia usually results from cardiogenic embolism, and global cerebral ischemia from cardiac arrest. Convulsive or myoclonic seizures are common after cardiac arrest, and clinical or electrographic status epilepticus is also well described.

Heart disease and epilepsy often coexist in the elderly, and this may pose therapeutic dilemmas. Thus, although intravenous phenytoin and benzodiazepines are important in the acute management of convulsions and status epilepticus, this approach must be used especially carefully in patients with cardiac disease because of the risk of inducing hypotension and cardiac arrhythmias. This risk depends on the rate of drug delivery, advanced age, and severity of underlying cardiovascular disease[44] and has been related to toxicity of the diluent, propylene glycol, a direct cardiotoxic effect of phenytoin, or both.[36,46] In patients at high risk, intravenous phenytoin should be infused at a rate of 25 mg/min rather than 50 mg/min, with continuous electrocardiographic monitoring and frequent blood pressure measurements.[36,46] Hypotension or an arrhythmia generally resolves with temporary discontinuation of the infusion; when restarted, the infusion rate may require reduction to 10 mg/min or less. Intravenous fosphenytoin appears to have the same therapeutic profile as intravenous phenytoin but with fewer cardiovascular effects.[155]

P.2010

Table 1 Incidence of seizures after transplantation procedure

	Incidence of seizures (%)	Ref.
Bone marrow	3–11.5	65, 148
Kidney	1.5–5	141, 146
Liver	6–25	2, 26, 51, 114
Heart	2–15	72, 150

Long-term anticonvulsant therapy is rarely associated with significant cardiovascular complications. Symptomatic arrhythmias have developed, however, in association with plasma levels of carbamazepine in the optimal therapeutic range, usually in patients with underlying cardiac disturbances.[15,94] It seems appropriate, therefore, to obtain routine electrocardiograms in patients with known cardiac disease who are receiving either carbamazepine or phenytoin on a long-term basis. Any disturbance of consciousness in such patients may relate to a cardiac arrhythmia as well as to seizures, and investigations should be undertaken with this in mind.

The interaction of anticonvulsant and cardiac medications may complicate the management of epilepsy in patients with heart disease. Concurrent use of phenytoin and quinidine sometimes increases ectopy in patients with a history of ventricular arrhythmias.[201] Phenytoin and phenobarbital may increase the metabolism of quinidine, digoxin, lidocaine, and mexiletine through induction of hepatic microsomal enzymes.[46,201] Amiodarone may increase serum phenytoin levels,[126] and calcium channel blockers may increase serum carbamazepine concentrations.[46] It is therefore necessary to measure serum levels of anticonvulsant drugs frequently and to monitor cardiovascular function when introducing or adjusting antiepileptic or cardiac medications.

Seizures in The Transplant Patient

Seizures are frequent in transplant recipients, who may be put at risk by the nature of their underlying illness, prior treatments, perioperative metabolic abnormalities, and postoperative complications such as cerebral ischemia. Following the transplantation procedure, seizures may relate to immunosuppression, drugs, and rejection. The incidence of seizures after transplant procedures depends on the type and method of transplantation and the patient population under study (Table 1). Children are generally at greater risk than adults for posttransplant seizures.[2,66,91,125,129]

The etiology of seizures in transplant recipients is frequently multifactorial. Immunosuppressive agents, especially cyclosporine, may themselves cause seizures. Neurologic complications occur in up to 25% of patients receiving cyclosporine; in addition to seizures, tremor, ataxia, leukoencephalopathy, cortical blindness, neuropathy, quadriparesis, and dysesthesias are well described.[204] O'Sullivan[146] reported cyclosporine-induced seizures in 1.5% of kidney recipients and 5.5% of bone marrow recipients. Others have suggested higher rates, particularly in liver recipients[40,69] and in children.[66,91]

Cyclosporine-induced seizures occur regardless of whether serum levels are within or exceed the therapeutic range and have been attributed to a cyclosporine metabolite.[34] Metabolic and systemic abnormalities and other therapeutic agents may potentiate cyclosporine-related seizures. These various factors include concomitant methylprednisolone therapy,[23,49] hypertension,[89] hypomagnesemia,[2,69,196] hypocholesterolemia,[40] microangiopathic hemolytic anemia,[65,159] and, after renal transplantation, aluminum overload.[141] In many patients with suspected cyclosporine-induced seizures, however, none of these additional abnormalities is present.

Other immunosuppressive agents have also been implicated in the occurrence of seizures after transplantation procedures. Tacrolimus (FK506) has neurologic complications similar to those of cyclosporine, including seizures and encephalopathy.[51,60,174] It is interesting that sirolimus (rapamycin), a newer immunosuppressive agent, does not appear to cause seizures or other neurotoxicity so far as can be determined from an early report that included kidney and liver transplant recipients.[122] Seizures may occur with the antirejection agent OKT3 as one manifestation of a cytokine encephalopathy.[177] Busulfan alone or in combination with cytoxan may be a cause of seizures in bone marrow recipients.[41,197]

Seizures also may occur as an indirect complication of immunosuppressive treatment, for example, as a consequence of CNS infections. They may result from a wide variety of noninfectious structural lesions and metabolic disorders, such as cerebral ischemia or hemorrhage, hyponatremia with central pontine myelinolysis, hyperosmolar states, hypoglycemia, delayed malignancy related to prior treatment, and multiorgan system failure.[66] Finally, transplant rejection may be associated with, or even heralded by, an encephalopathic syndrome that includes seizures.[66,73]

The incidence (Table 1) and etiology of posttransplant seizures depend in part on the type of transplant performed. In bone marrow recipients, seizures may relate to prior irradiation, intrathecal or systemic chemotherapy, systemic complications such as thrombocytopenia, or disease relapse in conditions such as leukemia. Kidney recipients may be predisposed to seizures as a consequence of uremia or other metabolic abnormalities or as a result of cerebral reticuloendothelial tumors.[66] Heart, lung, or liver recipients are especially likely to have early postoperative seizures as a result of cerebral ischemia. New-onset seizures related to cerebrovascular disease or sepsis after orthotopic liver transplantation appear to portend a very poor prognosis.[33]

Seizures always require detailed evaluation to distinguish the many different etiologic factors that may be responsible. Hematologic and biochemical screening tests, determination of blood levels of immunosuppressive agents, cerebrospinal fluid (CSF) examination, EEG, and cerebral imaging studies (preferably magnetic resonance imaging [MRI]) may all be important.

Antiepileptic medication is not necessarily required for transplant recipients with seizures, especially if seizures are self-limited and relate to reversible abnormalities that are unlikely to recur. When seizures are prolonged or carry a risk of other complications, benzodiazepines may be given to control them acutely. Recurrent seizures require long-term anticonvulsant therapy. The choice of anticonvulsant agents is influenced by the type of transplant procedure and immunosuppressive drugs involved. For example, valproic acid should be avoided in liver recipients because of its potentially irreversible hepatotoxicity, and carbamazepine is best avoided in bone marrow recipients because of its myelosuppressive effects. During the 2 to 6 weeks required for bone marrow engraftment after transplantation, it is also appropriate to use phenobarbital rather than phenytoin or valproic acid.[66] Keppra appears efficacious in controlling seizures in liver transplant patients, typically at a dose of 500 mg twice daily, although the number of reported subjects is small.[32,67]

Anticonvulsants that induce hepatic enzymes will affect immunosuppressive agents that are metabolized by the liver.

Phenobarbital, phenytoin, and carbamazepine increase the clearance of cyclosporine and corticosteroids,[6,66,82,204] and this may decrease graft survival in kidney recipients.[205] When these anticonvulsant drugs are used, the dose of corticosteroids should be augmented by 25% to 30%, and cyclosporine should also be increased, depending on serum cyclosporine levels.[66] Some authors prefer to use valproic acid in such circumstances to avoid pharmacokinetic interactions.[82,179] A single case report describes decreased serum cyclosporine levels and sodium concentration after oxcarbazepine add-on treatment was initiated in a patient with epilepsy that predated a renal transplant, but these changes normalized after reduction of the oxcarbazepine dose.[164] Keppra is unlikely to affect immunosuppressive drug levels, has been used successfully in liver transplant recipients, and therefore may be a good initial choice for antiepileptic drug therapy in the overall transplant population. Gabapentin and pregabalin are potential alternatives, given their lack of hepatic enzyme–inducing properties.

Human Immunodeficiency Virus and Seizures

Seizures are a nonspecific but relatively common consequence of infection with human immunodeficiency virus (HIV) (Chapter 265). Convulsions occur at any stage of HIV disease[209] and are occasionally the presenting symptom of HIV infection.[83] However, seizures are an infrequent manifestation of CNS disease in children with HIV infection.[169]

Generalized convulsions are the most common seizure type in patients with HIV infection or AIDS,[83,209] but simple and complex partial seizures are also frequent. Generalized convulsive status epilepticus occurred at presentation in 8% and 10% of HIV-infected patients with seizures in two retrospective series,[83,209] and nonconvulsive status epilepticus has also been observed.[209] Seizure type does not correlate well with the etiology of HIV-related seizures, and the occurrence of partial seizures does not necessarily predict the presence of an opportunistic CNS infection or intracerebral mass lesion unless there are persistent lateralizing clinical signs.

In >40% of patients with AIDS or HIV infection who present with seizures, no cause other than the HIV infection is found. Many of these patients have evidence of HIV encephalopathy on neurologic examination or at autopsy.[209] Other CNS disorders associated with AIDS frequently result in seizures, however, such as cerebral toxoplasmosis, primary CNS lymphoma, cryptococcal meningitis, and cerebrovascular events. Therefore, a thorough diagnostic evaluation must be undertaken in HIV-infected patients who present with new-onset seizures, including biochemical screening tests, MRI of the brain, CSF analysis (including CSF cytology), and determination of serum and CSF cryptococcal antibody titers.

Because seizures frequently recur and status epilepticus may develop in this patient population, anticonvulsant treatment after an initial seizure is recommended.[83,209] However, antiretroviral therapy with protease inhibitors complicates antiseizure management. Protease inhibitors are extensively metabolized by the liver and also influence hepatic enzyme function; thus, antiepileptic drug toxicity or decreased serum levels of protease inhibitors were reported when HIV-infected patients were treated with anticonvulsants that induce or are metabolized by the same enzymes.[17,28,84,115] Therefore, monotherapy with one of the group of newer antiepileptic agents that do not undergo substantial hepatic metabolism or induce hepatic enzymes, such as levetiracetam, pregabalin, or gabapentin, is appropriate initially. In terms of older antiepileptic agents, in addition to the interactions with protease inhibitors, phenytoin is associated with a high incidence of hypersensitivity and other adverse reactions.[83,209] Phenytoin intoxication also has been observed with the concurrent administration of fluconazole,[29] an antifungal agent often used in AIDS patients. Phenobarbital poses a higher risk of adverse cognitive effects than many of the newer agents. Carbamazepine is suboptimal because of the potential for bone marrow suppression in patients who are often at risk for this complication as a result of concurrent medications. HIV patients with status epilepticus usually respond to typical urgent therapy with benzodiazepines and phenytoin.[109]

Seizures Related to Alcohol and Drugs of Abuse

Seizures are a frequent complication of alcohol and recreational drug abuse[50] (Chapter 268). Most alcohol-related seizures are self-limited generalized convulsions that occur in the first 72 hours after cessation of alcohol use, often in association with signs and symptoms of alcohol withdrawal. Seizures are isolated or occur in flurries typically lasting for no more than 12 hours.[50] Alcohol-related convulsions are generally attributed to brief abstinence or acutely declining ethanol levels in long-standing heavy drinkers. One study of alcohol-related first seizures found no association between the interval from last drink to seizure onset,[139] but this is not the general experience.

Seizures with focal features occurring in alcoholics are often the result of prior cerebral trauma. However, because alcoholics are at high risk for occult head injury, CNS infection, cerebrovascular disease, and metabolic derangements, a thorough clinical and laboratory evaluation is generally necessary whenever seizures occur. Hematologic, biochemical, and toxicologic testing is usually indicated, and brain CT or MRI studies should be obtained if a focal cerebral lesion is suspected or for a first convulsion.[50] Cerebrospinal fluid examination and EEG may also be necessary in certain clinical settings.

Because alcohol-related seizures are self-limited and medication compliance is poor in binge drinkers, acute or chronic anticonvulsant therapy is rarely indicated. Phenytoin is not effective for treating seizures in the setting of acute alcohol withdrawal,[5] but benzodiazepines are effective in treating ethanol withdrawal symptoms and may control seizures as well.[199] Convulsive status epilepticus may also result from alcohol withdrawal. In one urban medical center over the last two decades, alcohol was the major etiologic factor in 15% to 25% of cases of status epilepticus.[117] Alcohol-related status epilepticus should be treated with intravenous benzodiazepines and phenytoin according to standard protocols.

Patients whose seizures occur solely in the setting of alcohol or drug abuse do not, by definition, have epilepsy. However, approximately 2% to 4% of patients with alcohol-related seizures have preexisting epilepsy.[50] Although heavy alcohol intake may exacerbate seizures in epileptics for a variety of reasons,[127] light use of alcohol does not increase seizure frequency. Epileptic patients should be advised against chronic or heavy alcohol intake and instructed to avoid isolated drinking binges that are often associated with sleep deprivation.

Seizures may be induced by illicit drug use as a result of acute intoxication or, less frequently, as a withdrawal phenomenon similar to that occurring with alcohol. Seizures related to drugs of abuse are typically isolated, generalized convulsions that are self-limited and do not require acute or chronic treatment with antiepileptic medications; therapy should be directed at the problem of substance abuse itself. However, prolonged seizures and status epilepticus may rarely result from the administration of certain illicit drugs and necessitate urgent treatment. The occasional patient with preexisting epilepsy who abuses recreational drugs can be identified by a history of seizures occurring in the absence of alcohol or recreational drug use or by the presence of interictal EEG abnormalities.[50]

P.2012

Cocaine is the drug of abuse most commonly implicated in recreational drug–related convulsions.[4,97] Seizures resulting from cocaine abuse have increased in recent years in association with the epidemic use of cocaine.[50] Proposed mechanisms for cocaine-induced convulsions include direct CNS stimulant effects via blockage of neurotransmitter reuptake at dopaminergic and noradrenergic nerve terminals, a possible kindling effect with chronic administration, acute cerebrovascular events or systemic effects, and as a terminal event in massive cocaine overdose.[50,63] Seizures manifest in 2.3% to 8.4% of patients presenting to the emergency room with cocaine toxicity.[97,147] They occur independent of the route of administration and are usually single, generalized tonic–clonic convulsions.[97,147] Most are self-limited, and anticonvulsant therapy is not required except for prolonged seizures or status epilepticus. In addition, seizures having a focal onset or associated with abnormal neurologic findings in cocaine users should raise suspicions of an acute intracranial process that requires evaluation by CT imaging and possibly MRI or cerebral angiography.[147] Neuroimaging should also be performed in patients with new-onset seizures.[50]

Seizures represent an infrequent manifestation of intoxication with other recreational drugs of abuse. Amphetamine intoxication is an uncommon cause of convulsions, which are typically generalized and occur more commonly after intravenous use and administration of high doses.[4] Focal features or abnormal findings on examination should raise concerns for the presence of a cerebral infarct, hemorrhage, or vasculitis.[50] Seizures are also uncommon after phencyclidine (PCP) administration. Generalized convulsions occurred in only 3.1% of 1,000 patients in the largest series of patients presenting to an emergency room with PCP intoxication, although 16% of seizure patients had status epilepticus.[128]

Heroin use has been associated with convulsions.[4,138] Although heroin may act directly as a convulsant agent, it is probably more often associated with seizures related to the concurrent administration of alcohol and other recreational drugs or to the systemic effects of heroin overdose.[4,50] Other complications of intravenous drug abuse that may result in seizures, including infectious endocarditis and HIV infection, should be sought in any patient presenting with convulsions associated with the use of heroin or other intravenous drugs. Marijuana is often used concurrently with heroin and other recreational drugs, but this agent appears independently to lower the risk of a first seizure.[138] Finally, an abstinence syndrome and withdrawal seizures similar to those observed in alcoholics may be induced after chronic administration of sedative agents.[63] Seizures caused by barbiturate and benozodiazepine withdrawal have become less common in recent years, although they are more likely to occur with short-acting agents and should be treated with parenteral benzodiazepines.[63]

Epilepsy and Pulmonary Disease

Pulmonary disease is associated only uncommonly with seizures. Because the prevalence of asthma and epilepsy are both relatively high, the two disorders occasionally coexist in the same patient. In rare instances, epilepsy may result from chronic cerebral injury after recurrent severe hypoxic episodes during asthmatic attacks, and hypoxia-induced seizures occur infrequently during acute asthma exacerbations.[137]

Seizures may result from certain medications used to treat pulmonary illnesses. They occur as a complication of theophylline toxicity in the setting of both chronic use and acute overdose,[13,63] probably from inhibition of phosphodiesterase, which may result in a reduction of adenosine-mediated CNS inhibition.[63] The elderly and patients with coexisting CNS dysfunction appear to be at increased risk for this complication, and seizures may occur with serum levels that are in the therapeutic range or mildly elevated.[13] Partial seizures, generalized convulsions, or status epilepticus occurs with massive acute overdose; when status occurs, it may be refractory to standard anticonvulsants and require hemodialysis or hemoperfusion therapy.[145] Theophylline should be used with caution in epileptics because of a possible risk of seizure exacerbation as well as pharmacokinetic interactions with anticonvulsant drugs.[166,173]

Isoniazid (INH) is another medication that may cause seizures during therapeutic use, although convulsions more frequently occur with overdose.[63] Multiple generalized seizures and status epilepticus are common after INH overdose.[132] Isoniazid probably induces convulsions by lowering brain GABA levels via antagonism of a pyridoxine-dependent cofactor used in its synthesis, and prolonged seizures should be treated with intravenous pyridoxine and benzodiazepines.[63]

Metabolic Causes of Seizures

Disorders of Glucose Metabolism

Seizures may occur in the setting of abnormal serum glucose concentrations (see also Chapter 267). Symptomatic hypoglycemia most often arises as a complication of insulin or oral hypoglycemic therapy, but it may also result from severe he-patic disease, sepsis, alcoholism, insulinoma, terminal cancer, hypothyroidism, fasting, and reactive hypoglycemia.[120,133] In a prospective study of 125 patient visits to the emergency room of an urban hospital for symptomatic hypoglycemia, Malouf and Brust[120] documented seizures in 7%. Seizures typically consisted of focal motor or generalized fits, but multiple seizures or convulsive status epilepticus also occurred. Other neurologic symptoms included depressed sensorium or coma, behavioral changes, tremor, and acute hemiparesis. Symptoms and signs did not correlate well with the degree of hypoglycemia, although most symptomatic patients have blood glucose levels <40 mg/dL.[133] Hypoglycemia should be considered in any patient presenting with seizures. Treatment consists of intravenous dextrose administration and correction of any associated metabolic abnormalities. Death or neurologic sequelae are rare with prompt therapy, but patients are best admitted to hospital for observation because significant hypoglycemia may recur hours after adequate initial treatment.[133]

Nonketotic hyperglycemia manifests with seizures in approximately 25% of patients,[183] and partial motor seizures or epilepsia partialis continua is often the first recognized feature of the disorder,[80,182,203] occurring in 19% of cases.[183] In addition to simple partial clonic or tonic motor fits, nonketotic hyperglycemia may cause complex partial, generalized tonic–clonic, and movement- or posture-induced seizures.[9,25,203] Patients are typically >50 years of age, may not have a known history of diabetes, and present with recurrent partial motor seizures involving one limb; confusion or mildly depressed sensorium and associated focal neurologic deficits may be present, but obtundation or coma is unusual early in the course of nonketotic hyperglycemia, when seizures occur. Serum glucose is often between 600 and 800 mg/dL, although the range of glucose elevation is very broad and is commonly associated with only mild elevation of serum osmolarity.[182,203]

Seizures associated with nonketotic hyperglycemia are refractory to conventional anticonvulsant therapy but respond rapidly to correction of hyperglycemia with insulin and intravenous fluid replacement. Associated focal neurologic abnormalities are usually transient,[203] and recovery typically occurs without sequelae if the condition is recognized and treated before coma ensues.[182] Significant underlying cerebral structural

abnormalities are uncommon, even in the setting of epilepsia partialis continua. However, the occasional discovery of such lesions[182] makes it prudent to obtain neuroimaging studies when seizures first occur in association with nonketotic hyperglycemia or in any patient with persistent neurologic deficits. No role exists for acute or chronic anticonvulsant therapy in the setting of seizures related to nonketotic hyperglycemia. Convulsions may recur despite antiepileptic drug treatment if glycemic control in not maintained,[83] and phenytoin should be specifically avoided in these patients because it may exacerbate hyperglycemia through inhibition of insulin release.[119]

Possible mechanisms of seizures from nonketotic hyperglycemia include localized cerebral ischemia with or without a previous underlying structural abnormality, cortical deformation from brain dehydration, and increased metabolism of GABA via the succinic semialdehyde pathway as a result of depression of the Krebs cycle.[25,133] Depressed brain GABA levels presumably lower the seizure threshold by decreasing cortical inhibition. Although the Krebs cycle is also inhibited in diabetic ketoacidosis, seizures rarely occur in this setting, perhaps because of the anticonvulsant properties of ketosis and the resultant intracellular acidosis, which may lead to increased cerebral GABA concentrations.[25]

Hyponatremia

Hyponatremia, which is one of the most common electrolyte abnormalities found in hospitalized patients, is commonly manifest by an alteration of consciousness ranging from mild confusion to coma. Hyponatremic encephalopathy results from cerebral edema caused by an osmotic imbalance between the extracellular fluid and brain cells, and perhaps also from the effects of the compensatory loss of intracellular cations.[101] In general, symptoms correlate more with the rate of development of hyponatremia than with serum sodium levels,[162] and chronic hyponatremia may be well tolerated.[188] Mild manifestations, such as confusion and lethargy, occur when the serum sodium concentration falls acutely to below 125 or 130 mEq/L.[101] Severe symptomatic hyponatremia (resulting from an acute reduction of serum sodium concentration to <115 mEq/L) is associated with seizures, obtundation, and coma and has a mortality rate >50%.[101,162]

Both partial seizures and generalized convulsions may occur with hyponatremia and are sometimes the first sign of symptomatic water intoxication.[58] Hyponatremic convulsions are common in infants and children, and water intoxication is probably the most common cause of afebrile seizures in children <2 years of age.[171] Hyponatremic seizures constitute a medical emergency requiring aggressive treatment. Hypertonic saline should be administered intravenously but at a rate designed to increase the serum sodium concentration by no more than 1 mmol/L per hour until the patient is asymptomatic or the sodium concentration has increased by up to 12 mmol/L over the first day and 25 mmol/L in the initial 48 hours.[101,189] There is a risk of causing a pontine and extrapontine myelinolysis syndrome with more rapid correction of hyponatremia[108,188,189]; hypertonic saline should not be used once the plasma sodium concentration reaches 125 to 135 mEq/L.[101]

Hypernatremia

Neurologic manifestations occur in >50% of patients with significant hypernatremia.[193] Hypernatremia most commonly arises from conditions resulting in excessive dehydration, typically through gastrointestinal fluid losses or an inability to obtain water. Less frequently encountered causes include diabetes insipidus, hypothalamic lesions, and excessive salt intake.[162] Neurologic signs generally develop with serum sodium concentrations >160 mEq/L,[162] and their severity depends on the rapidity of change in serum sodium concentration.[193] Depression of consciousness is the most common neurologic abnormality in hypernatremic patients. Seizures, either generalized or partial, may occur and are commonly observed during rehydration.[133,193] Cautious correction of hypernatremia with half-isotonic saline may reduce the likelihood of convulsions occurring during treatment.[193]

Disorders of Calcium and Magnesium

Significant hypocalcemia is most frequently observed following thyroid or parathyroid surgery. However, it may also occur in other types of hypoparathyroidism (primary, secondary, and pseudohypoparathyroidism), as well as in other conditions such as renal failure or acute pancreatitis, and in neonates.[162] Altered sensorium and seizures are its most common neurologic manifestations.[162] Hypocalcemic seizures are typically generalized, but partial seizures occur in 20% of patients and may include either motor or sensory phenomenology.[39] Among patients with hypoparathyroidism, 30% to 70% experience seizures, typically in association with an altered sensorium and tetany,[133] although tetany is occasionally absent.[39] Movement disorders such as chorea or tremor may also be produced by hypocalcemia and must be distinguished from epileptic phenomena. Treatment of hypocalcemic seizures involves restoration of serum calcium levels and correction of the underlying disorder.

Deficiency of magnesium typically results from a combination of inadequate dietary intake and excessive gastrointestinal fluid and electrolyte loss. It may also relate to excessive renal excretion of magnesium because of diuretics and other medications, hyperaldosteronism, diabetic ketoacidosis, chronic alcoholism, and renal tubular acidosis.[162] Hypomagnesemia is associated with tetany similar to that occurring with hypocalcemia, and it is not uncommon for hypocalcemia to accompany hypomagnesemia. Multifocal and generalized seizures may be provoked by hypomagnesemia.[57] Seizures and other neurologic symptoms typically occur when the serum magnesium concentration decreases to <0.8 mEq/L.[162] Convulsions produced by hypomagnesemia require treatment with parenteral magnesium salt solutions,[57,162] which should be administered by slow intravenous bolus after the adequacy of renal function has been evaluated, and with calcium gluconate available to counteract transient hypermagnesemia.[162]

Seizures Caused by Anoxic–Ischemic Encephalopathy

Comatose survivors of cardiopulmonary arrest are frequently encountered in hospital intensive care units. Seizures resulting from global anoxic–ischemic cerebral damage occur in the acute setting after resuscitation in 15% to 44% of these patients.[24,100,113,207] Epileptic manifestations of anoxic–ischemic encephalopathy typically commence within 24 hours of cardiopulmonary arrest and include generalized tonic–clonic, tonic, myoclonic, and partial seizures.[100,186] Patients often have several types of seizure,[90,100,186] and status epilepticus and generalized tonic–clonic and myoclonic seizures are frequent.[31,90,100,207,211] In addition, electrographic status epilepticus, with clinical manifestations limited solely to extraocular or facial muscles, may occur in patients after cardiopulmonary arrest.[181]

Several reports suggest that the occurrence of seizures after cardiopulmonary arrest does not influence the eventual clinical outcome in comatose patients with anoxic–ischemic

encephalopathy.[113,186] Even generalized tonic–clonic status epilepticus may not be predictive of a poorer outcome in this patient population, although the data are limited by the small number of cases reported.[100] However, myoclonic status epilepticus, generally defined as at least 30 minutes of continuous myoclonus with or without other seizure types,[31,90,100] appears to correlate with a poor prognosis after global cerebral anoxic–ischemic insult.[31,100,207,211] Myoclonic status epilepticus begins between 30 minutes and 5 days after cardiopulmonary arrest, but most often within 24 hours.[90,186,211] The myoclonus may be generalized and synchronous or asynchronous, with predominant involvement of axial muscles and extremities[90] or facial muscles.[90,211] The EEGs typically reveal either bursts of generalized spike- or polyspike-and-slow-wave discharges superimposed on an abnormal background or a burst-suppression pattern; a diffuse alpha-frequency pattern is found on occasion.[90,207,211] Neuropathologic examination shows diffuse anoxic–ischemic damage involving cerebral cortex, hippocampus, cerebellar Purkinje cells, thalamus, basal ganglia, and, to a lesser extent, the brainstem and spinal cord.[90,207,211]

Myoclonic status epilepticus is generally resistant to anticonvulsant therapy (Chapter 62).[90,207,211] Although aggressive treatment of this condition has been recommended to prevent additional cerebral damage from seizures,[100] it is likely that myoclonic status epilepticus represents a marker of severe cerebral anoxic injury that is incompatible with recovery except in rare patients. Treatment decisions in this setting should be individualized using data from the clinical examination and neurophysiologic studies.

Thyroid Disease and Epilepsy

The incidence of seizures in hypothyroidism is relatively high, approaching 20% in patients progressing to myxedema coma.[54] Seizures are usually generalized and resolve with correction to a euthyroid state.[1,134] The EEG in hypothyroidism typically reveals mild slowing of the background or voltage attenuation; abnormalities are reversible with correction of the hypothyroid state.[1,92] Anticonvulsants may decrease the values obtained in certain thyroid function tests, but patients usually remain clinically euthyroid.[1,102]

Seizures occur uncommonly in thyrotoxicosis,[1,70,96] although several lines of evidence suggest that hyperthyroidism or excess thyroxine may cause seizures or exacerbate preexisting epilepsy. Administration of thyroxine in several animal models of epilepsy reduces seizure threshold, whereas thyroidectomy protects against pharmacologically induced seizures.[175,184] Both partial and generalized seizures have been reported in patients with hyperthyroidism,[88,92,96] and generalized tonic–clonic seizures or absences may occur in individuals receiving thyroxine for hypothyroidism.[88,191] Smith and Looney[184] described a patient with thyrotoxicosis who developed generalized seizures only after treatment with high-dose propranolol. In addition, exacerbations of both partial and generalized epilepsies have been associated with increased thyroxine levels.[190,195] In two patients with juvenile myoclonic epilepsy and Graves disease, seizures could not be controlled by anticonvulsants until the hyperthyroidism was adequately treated.[190] Therapy for seizures that occur in the setting of thyrotoxicosis consists of correction of the hyperthyroid state; anticonvulsants are generally not required except sometimes in the acute setting.

Seizures Associated with Systemic Cancer

Table 2 Causes of seizures in the setting of systemaic cancer

Neoplasia
Direct effects: focal metastasis; carcinomatous meningitis
Remote effects: paraneoplastic encephalitis
Cerebrovascular events
Thrombosis (venous or arterial); embolism; hemorrhage
Central nervous system infection Bacterial; viral; fungal; parasitic
Metabolic disorders Hypoglycemia; hyponatremia; hypocalcemia; hypomagnesemia

Complications of therapy

Radiation therapy

Chemotherapy: alkylating agents; antimetabolites; cytokines

Symptomatic therapeutic agents: antibiotics; analgesics; antiemetics

Seizures are one of the neurologic complications of systemic cancer or its treatment (Chapter 264). Seizure prompted initial neurologic consultation in 5.4% of 851 (mainly adult) patients with systemic cancer in one prospective study.[35] Etiologies included intracranial metastasis in one half of cases and metabolic abnormalities in one third; the remainder was made up of intracerebral hemorrhage, longstanding epilepsy, or undetermined cause. Seizures appear more commonly in association with childhood systemic cancers. In one series of 158 children with systemic cancer, for example, seizures were the second-most-common reason for neurologic referral.[8] One third of the 29 cases with seizures were found to have a structural brain abnormality. Seizure types in patients with systemic cancer vary by etiology and may include simple or complex partial, secondarily generalized tonic–clonic, or primarily generalized tonic–clonic seizures. In addition, the diagnosis of nonconvulsive status epilepticus should be considered in cancer patients with an altered mental status.[47]

The differential diagnosis of seizure etiology in cancer patients is fairly long (Table 2). Direct effects of cancer, such as brain metastasis, must be excluded. Although brain metastases less commonly produce convulsions than primary brain tumors, those from melanoma, lung, breast, renal cell, gastrointestinal, or germ-cell tumors tend to be involved.[187] Leptomeningeal or dural metastatic disease also may induce seizures. Seizures caused by metastatic disease of brain or meninges are partial or secondarily generalized tonic–clonic in type. Epileptic seizures also may arise after cerebrovascular events in the setting of cancer-related hypercoagulable states or nonbacterial thrombotic endocarditis. Convulsions are often the first symptom of central nervous system infections, including fungal or parasitic abscesses, due to chemotherapy-induced immunosuppression. Seizures occasionally result from complications of chemotherapy, and may be seen with etoposide, L-asparaginase, alkylating agents such as chlorambucil or busulphan, immunotherapies, methotrexate, or cytosine arabinoside.[187] Other causes include delayed effects of cranial irradiation, cancer-induced metabolic disturbances, paraneoplastic encephalitis, and drugs used to treat cancer complications, such as pain medications or antibiotics.

The evaluation of new-onset seizures in patients with systemic cancer is relatively straightforward. Brain MRI with contrast should be obtained to exclude a cerebral structural abnormality. Lumbar puncture should be performed in the absence of a brain lesion, and CSF evaluated cytologically to exclude meningeal tumor involvement and for infectious causes. Coagulation studies and biochemical screening also are warranted,

P.2015

and the cerebral venous system should be imaged if clinical suspicion exists for venous sinus thrombosis. EEG evaluation is helpful for determining the type of seizure and excluding nonconvulsive events. Finally, the medication list should be scrutinized carefully for any potential proconvulsant medications.

Antiepileptic drug treatment should be instituted unless a reversible cause of symptomatic seizures is present. Certain situations may, however, complicate the selection of the appropriate anticonvulsant agent. Phenytoin should not be used in patients receiving whole-brain cranial irradiation, because there may be an increased risk of Stevens-Johnson syndrome.[42] Carbamazepine, which often causes a mild leukopenia, is best avoided in those at risk for bone marrow suppression. The choice of antiepileptic drug is further complicated by potential interactions with chemotherapeutic agents for cancer. Many medications of both classes undergo hepatic metabolism and influence the hepatic cytochrome P450 metabolic enzyme system, leading to lowered effectiveness of cancer chemotherapy, inadequate seizure control, or anticonvulsant toxicity from drug interactions.[202] Thus, the use of newer antiepileptic agents that undergo limited hepatic metabolism and do not influence the hepatic P450 system, such as levetiracetam or pregabalin, may be preferable in individuals undergoing cancer chemotherapy.

Seizures and Central Nervous System Disease

Cerebrovascular Disease

Cerebral infarctions, both ischemic and hemorrhagic, are a common cause of seizures (Chapter 275). Stroke is the most frequent cause of epilepsy in the elderly.[52,111] Although the incidence depends on stroke type and duration of follow-up, seizures occur after cerebral infarction in approximately 6% to 25% of cases,[55,103,144] with some studies suggesting a higher incidence after embolic infarcts and primary intracerebral hemorrhage.[52,55,103,111] Seizures typically present immediately or in the first 48 hours after intracerebral hemorrhage[18,55]; at least one third of seizures occur within a few weeks in patients with ischemic infarcts.[74] Most fits caused by stroke occur in the first 2 years after the initial cerebrovascular event.[55,74,103]

Seizures occurring after stroke are typically of the secondarily generalized tonic–clonic or partial varieties; simple partial seizures, particularly with motor phenomenology, occur more frequently than complex partial spells.[52,74,111] Multiple seizures, as well as convulsive and nonconvulsive status epilepticus and epilepsia partialis continua, may also occur.[74,111] Risk factors for developing late epilepsy after stroke probably include the involvement of cerebral cortex by ischemic infarcts or lobar hemorrhages,[18,55,103,144] persistent hemiparesis,[144] and the occurrence of early (within the first 2–4 weeks) seizures.[52,95] Seizures recur in 32% to 40% of patients experiencing an early fit after cerebral infarction,[74,95] although this has not been a significant risk factor in some studies.[52] In addition, the presence of periodic lateralized epileptiform discharges in the EEG is associated with a high risk for the development of seizures.[74]

There is no justification for prescribing prophylactic anticonvulsant treatment routinely after a stroke.[18,95] When seizures do occur after stroke, however, these are typically well controlled with antiepileptic medications.

Infectious Diseases

Seizures are a relatively common symptom and consequence of CNS infections (see Chapter 265). In a population-based cohort study of 714 survivors of meningitis and encephalitis, Annegers and et al.[7] found a nearly sevenfold increase in the risk of developing late, unprovoked seizures. Viral encephalitis conferred a higher risk than bacterial meningitis, whereas the incidence of late convulsions after aseptic meningitis was not significantly increased compared to the rate in the general population. Most late seizures occurred within 5 years of the infection, although the seizure risk remained elevated for >10 years; 19% of patients experienced symptomatic fits during the acute illness, and this increased the likelihood of late seizures for all categories of CNS infection.

In a prospective study of 185 children with bacterial meningitis, late seizures (not associated with fever) occurred in 7%.[153] Most patients had their first late seizure within 2 years of the acute infection; seizures were either partial or secondarily generalized and were often difficult to control with anticonvulsant therapy. The occurrence of seizures during the acute illness and the presence of residual neurologic deficits significantly increased the risk of developing late seizures.

Seizures related to a preceding meningitic or encephalitic illness may be refractory to anticonvulsant medications and are sometimes amenable to surgical therapy for partial epilepsy. In a report of 38 patients undergoing presurgical evaluation for medically refractory seizures after bacterial meningitis or viral encephalitis, Marks et al.[124] found an association between the occurrence of infection before 4 years of age and mesial temporal sclerosis, a pathologic finding that is highly correlated with a good surgical outcome.

Other types of intracranial infections that frequently result in seizures include supratentorial brain abscess, subdural empyema, and parasitic CNS diseases. Convulsions occur in >25% of patients with bacterial cerebral abscesses[121,140] and in >50% of those with subdural empyema.[180] Late convulsions occur in >30% of patients with subdural empyema who survive the initial infection and usually commence within 18 months.[38]

Neurocysticercosis is the most common parasitic infection of the CNS and is the leading cause of late-onset epilepsy in developing countries.[131] Seizures are the most frequent manifestation of neurocysticercosis and are typically partial or secondarily generalized fits.[43,131] Both anticonvulsants and anticysticercal agents (praziquantel or albendazole) are required to control seizures in patients with active neurocysticercosis.[43,131] In patients with inactive disease (manifest solely by cerebral calcifications), convulsions typically respond well to antiepileptic drug therapy alone, although the relapse rate is high after medication withdrawal even in patients who have remained seizure free for several years.[43]

Degenerative Diseases

Neurodegenerative diseases are an important cause of seizures in the elderly. Alzheimer disease is associated with seizures, typically generalized tonic–clonic, in 10% to 16% of cases,[79,165] although even higher prevalences have also been reported.[163] Convulsions have been reported in both early and late stages of the disease,[79] although most reports suggest that seizures are more likely to occur late in the course of Alzheimer disease.[163,165] Convulsions arise much less frequently in the setting of neurodegenerative disease affecting mainly subcortical structures. Huntington disease is rarely associated with seizures in adults, although epilepsy is common in patients with juvenile Huntington disease and occasionally is the presenting symptom.

Summary and Conclusions

Seizures may result from a variety of medical conditions. Furthermore, the treatment of epilepsy may cause or complicate the course of other medical disorders. In general, acute seizures

produced by endogenous or exogenous systemic disturbances require treatment directed at the underlying cause and do not necessitate antiepileptic drug therapy. Prolonged seizure activity or status epilepticus, however, requires immediate intervention. Certain medical illnesses influence the choice and manner of antiepileptic drug therapy, and comorbidity must be taken into account during the initiation of treatment and the chronic management of epileptic disorders. Seizures and epilepsy also frequently arise as a symptom of acute or chronic neurologic diseases. Recognition of the specific epileptic manifestations of various CNS disturbances serves to aid diagnostic and prognostic considerations and allows for the institution of appropriate therapy.

Chapter 192

Comorbidity and Immunizations in Children

Trevor J. Resnick

Michael S. Duchowny

Introduction

Comorbidity refers to the effect of other diseases and conditions on the management of epilepsy and to the special problems posed by the underlying condition of epilepsy and its association/causation with other disorders. This chapter is concerned with comorbidity in children; Chapter 191 addresses comorbidity in adults. Potential overlap between the two chapters is considerable with respect to drug interactions and the effect of systemic diseases on seizure control, especially those disorders that compromise hepatic and renal function. To avoid repetition, this chapter concentrates on child development and leaves much of the material on drug interactions and the effects of systemic disease to Chapter 191.

Multiple factors contribute to "comorbidity" in childhood epilepsy, and the relative contributions of these factors are a matter of continuing debate. The core issues that relate to comorbidity include the underlying substrate of the seizures, the effect of the seizures themselves, adverse effects of antiepileptic medications, and the psychosocial burden of coping with a stigmatizing paroxysmal disorder that limits employment, driving, and other "lifestyle" activities. This chapter reviews the extent to which these variables, both individually and together, affect developmental, cognitive, and psychosocial outcomes of childhood epilepsy.

Developmental Disabilities

Although epilepsy is widely known to be multifactorial in origin, a high proportion of seizures in childhood are developmentally based. Approximately two thirds of new-onset seizures in children have no apparent etiology.[23] This close relationship of childhood epilepsy with disordered brain maturation allows for significant and complex relationships with other developmental disorders, including behavioral problems, learning disabilities, attention-deficit hyperactivity disorder, autism, depression, and psychiatric disturbances. The frequent occurrence of one or more comorbid disability significantly complicates the management of the epilepsy and seriously impairs overall quality of life. It is therefore critical that clinicians caring for children with epilepsy understand comorbid conditions and be knowledgeable about their treatment.

Incidence

There are no studies that comprehensively define the incidence of all comorbid conditions in children with epilepsy. Methodologic difficulties arise because childhood epilepsy often occurs in developmentally disabled populations, making it difficult comprehensively to assess the entire spectrum of disability and epilepsy. General cohort studies report that a high proportion of children experience at least some degree of socially unacceptable behavior. In a study of 127 preadolescent children with chronic epilepsy, Austin et al.[3] noted that approximately half experienced some form of behavioral problem. A more recent population-based retrospective survey conducted over a 15-year period identified a similar prevalence rate in 134 children and adolescents.[24] This cohort was surveyed for a mean follow-up period of 117 months and found to have a psychiatric comorbidity of 51%, as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV).

It is also difficult precisely to time the onset of comorbid disorders, but several studies suggest that comorbidity can begin early in children with seizure disorders and occasionally pre-dates seizure onset. Both Austin et al.[2] and Oostrom et al.[42] found the incidence of behavior disorder to be significantly higher than in the general population. Although the incidence in newly diagnosed patients (32%) was slightly lower than the incidence in children with chronic epilepsy, the high incidence underscores the selective vulnerability of children as well as their potential to deteriorate further. Problems with attention and socializing were particularly prevalent.

Children with structural brain damage are at even greater risk of comorbid disability and, in general, experience risk proportional to the severity of the brain damage. Children with cerebral palsy who have four-limb spasticity have the highest incidence of seizures, whereas children with milder forms of cerebral palsy such as spastic diplegia affecting predominantly the lower limbs have the lowest incidence.[51] Factors responsible for the occurrence of cerebral palsy in most children are acquired prior to birth, confirming that in childhood, even seizures clearly attributable to brain damage are developmentally based.

Cognitive Impairment

Children with chronic epilepsy are at considerable risk for cognitive disability.[4,8] Learning problems and school failure are common and are due to heterogeneous causes. Impairment of attention plays a significant role and is affected by medication in conjunction with seizures. There is evidence, however, that cognitive deterioration in childhood epilepsy is a progressive process that is independent of medication and begins soon after seizure onset.[40]

Studies using standardized measures to assess attention suggest that as many as one third of children with epilepsy suffer some form of attentional impairment.[46] In a study of 175 children with epilepsy of at least 6 month's duration who were administered subscales for attention from the Child Behavior Checklist,[19] 58% were found to have some degree of attentional impairment and 37% had overt symptoms of attention-deficit hyperactivity disorder. The Analysis of the Child Symptom Inventory indicated that 24% were experiencing predominantly the inattentive type, 11% had the combined type, and 2% had the hyperactive-impulsive type. Of note, this

P.2022

population had a gender ratio of 1:1 and a significant overrepresentation of the inattentive type compared to the general population.

Children with frontal lobe epilepsy are at even greater risk of developing cognitive dysfunction. In a comparison of 16 children with frontal lobe epilepsy to 8 children with temporal lobe epilepsy and 8 children with generalized absence seizures, Hernandez et al.[27] found that the frontal lobe group scored more poorly on tasks assessing attention, impulse control, and working memory. Poorer perceptual organization and a range of maladaptive behaviors were also observed. These observations suggest that school performance and social patterns of children with frontal lobe seizures may need to be monitored even more closely than those of children with other seizure types or other anatomic localizations.

The ways in which recurrent seizures contribute to cognitive and attentional impairment remain to be elucidated. There is experimental evidence that recurrent seizures affect the developing brain, leading to consequences in later life. Although seizures in early development may not produce discernible cellular loss, synaptic reorganization is known to follow neonatal seizures. Both pentylenetetrazol- and flurothyl-induced seizures alter mossy fiber distribution in the hippocampus of rats after neonatal convulsions.[30,37] Alterations in neuronal circuits render the brain more susceptible to further seizures and cognitive dysfunction. Lipp et al.[36] showed that conditioned learning in the rat is directly influenced by the extent of mossy fiber projections to the pyramidal layers of the CA3 region, with a larger number of fibers associated with poorer performance.

Even less is known about the direct effects of antiepileptic drugs (AEDs) on cognition and learning. Many studies are either poorly controlled for seizure type or use methodologies that do not lead to definitive conclusions. In clinical experience, higher rates of depression, learning problems, and negative behavior are associated with the long-term administration of barbiturates and benzodiazepines in children. Psychiatric and behavioral side effects are seen more commonly in AEDs with mechanisms that are associated with a γ-aminobutyric acid (GABA)-ergic component.

Genetic contributions to learning disabilities have recently been described in children with inherited forms of epilepsy. Chang et al.[13] reported a deficit in reading skill despite normal cognition in 10 patients with periventricular nodular heterotopia. All had a diagnosis of epilepsy, and most manifested partial seizures with or without secondary generalization. Patients with autosomal-dominant lateral temporal lobe epilepsy have been shown to have abnormal phonologic processing.[43] Genetic molecular analysis revealed a new LG11 missense mutation causing a Leu154Pro substitution in six affected and one unaffected individual.

Depression

Depression is a well-known accompaniment of adult epilepsy but has received relatively less scrutiny in children. The rate of depression in children and adolescents with chronic epilepsy as described by self-reporting instruments has been estimated at one fourth of patients.[18] Children and adolescents remain vulnerable to the same risk factors that exist in adults, whereas epilepsy may lead to further stress on their families. Using DSM-IV-R criteria, it has recently become possible to diagnose depression in children as young as age 6 years.[55] A detailed family history is an important part of the evaluation because rates of depression are higher in children with a family history of mood disorder.[54] Recognizing depression is an important element in the overall care of the child with epilepsy because treatment is available in the form of counseling and, in certain circumstances, pharmacotherapy.

Appropriate treatment is based on the proper evaluation of the biologic, family, social, and iatrogenic factors, including choice of AED. Unlike the situation in adults, the role of seizure type and lateralization of the epileptic focus has not been shown to influence the incidence of depression. Age of seizure onset and electroencephalogram (EEG) findings also do not appear to exert an influence. However, depression in children with epilepsy has been linked to seizure recurrence, high seizure frequency, and longer duration of epilepsy.[44]

The role of anxiety in children with epilepsy and depression is more controversial. Williams et al.[59] noted mild to moderate symptoms of anxiety in 23% of 101 children between the ages of 6 and 16 years who were administered the Revised Children's Manifest Anxiety Scale. The investigators noted, however, that a high proportion of their patients had other comorbid conditions. In contrast, Baki et al.[5] studied 35 children and adolescents with seizures and found higher rates of depression compared to normal controls but no differences in rates of anxiety. They also noted no differences in rates of depression or anxiety in mothers of children with epilepsy and controls.

In a structured psychiatric interview administered to 100 children with complex partial seizures (CPS), 71 children with childhood absence epilepsy (CAE), and 93 normal children ages 5 to 16 years and a behavioral checklist given to parents, Caplan et al.[10] found that significantly more patients had affective and anxiety disorder diagnoses and suicidal ideation compared to the normal group. Children with both CPS and CAE were five times more likely to have an affective or anxiety disorder. Despite this, very few patients were receiving mental health services, but there were no suicide attempts. These observations emphasize the importance of early detection and treatment of symptomatic children.

Psychosis

The diagnosis of psychotic thinking and behavior can be difficult in childhood, especially in the developmentally disabled population. Impaired thinking, delusions, and hallucinations may go unrecognized if there is significant language impairment. Despite these methodologic limitations, interictal psychosis in the children with epilepsy appears to be rare. The prevalence rate of interictal psychosis was reported to be 0.7% in Japanese children, but even this prevalence may have been biased in favor of patients with long-standing epilepsy.[38] One study of children with complex partial seizures found possible early symptoms of psychotic thinking including hallucinations.[10] Similar symptoms were not observed in children with generalized seizures.

The occurrence of interictal psychosis is generally regarded to be an adult-onset disorder. Several investigations have shown that seizures, especially of temporal lobe origin, must be present for at least 10 years before the onset of psychotic symptoms.[45] Thus, it is unlikely that frank interictal psychotic symptomatology will present in the preadolescent child. The onset of frank psychosis in a child with epilepsy should trigger a suspicion of another underlying neurologic disorder or adverse medication effect.

Autism

Almost one third of children with autistic spectrum disorder will experience at least one seizure in childhood.[57] Epileptiform discharges are noted in almost half during overnight video/EEG studies.[56] In a population of children at a tertiary care epilepsy clinic, Clarke et al.[14] noted that 32% fit criteria for autism spectrum disorder. Children with the higher risk had a younger age of seizure onset, approximately age 2 years. This interval correlates with the known timing of the onset of autistic regression.

Psychosocial Consequences

A comprehensive understanding of the consequences of unremitting seizures that have their onset in childhood is in its early stages. Apart from the social stigma attached to epilepsy and the potential consequences of long-term AED administration, the effects of recurrent seizures on the developing brain represent a major cause for concern. There is considerable evidence that when epilepsy is acquired in early life, multiple functional domains are affected to a degree that is often more severe than for other chronic childhood illnesses.[17,29] Even children who are intellectually normal are prone to emotional and social problems that may compromise their development and school performance.[44]

Social Consequences

A number of factors, both biologic and social, appear to increase the risk of poor psychosocial outcome. It has been shown, for example, that parental beliefs and attitudes concerning epilepsy may significantly affect adjustment and quality of life for both the child with epilepsy and the family.[60] Fastenau et al.[20] administered a comprehensive neuropsychological battery to 173 children ages 8 to 15 years. They noted a wide range of neuropsychological deficits and identified a subgroup of patients with a disorganized or unsupportive home environment who were at especially high risk for adverse academic outcomes.

Children with complex partial seizures have a greater risk for adverse long-term brain function. In a study comparing neurodevelopmental outcome in early versus late-onset childhood temporal lobe epilepsy compared to healthy controls, Hermann et al.[26] showed that the early-onset group exhibited widespread compromise in neuropsychological performance and substantial reductions in brain tissue volumes extending to the extratemporal regions compared to other groups. Reduction in total white matter volume was highly correlated with long-term cognitive deficiency. Further cross-sectional analyses indicated that longer duration of epilepsy in childhood-onset patients resulted in declining performance across both intellectual and memory measures, consistent with a progressive disorder.[25]

Outcome of Adults With Childhood-Onset Seizures

Many investigations have confirmed the poor social adjustment of many adults with epilepsy. However, there are few studies investigating the social outcomes of adults whose epilepsy began in childhood. The role of underlying neurologic dysfunction and comorbid disorders has also not been studied extensively. In one of the few well-controlled studies, Jalava et al.[34] prospectively studied a population-based cohort of childhood-onset epilepsy to ascertain the effect of early seizure onset on adult social adjustment and competence. They hypothesized that patients who had “only epilepsy” would not be at risk for impaired social adjustment and competence. They found the opposite—that many patients with seizures beginning in childhood who have no associated neurologic deficits exhibited poor social adjustment that was directly or indirectly related to individual seizures or chronic epilepsy. They also had lower rates of educational achievement despite the lack of evidence of learning impairment. Additional analysis of this cohort also revealed that patients with childhood-onset epilepsy have an unexpectedly high incidence of psychiatric and psychosomatic illness whether or not they were receiving concurrent AEDs.[33]

These early observations were confirmed in an independent investigation of a cohort of 243 consecutive newly diagnosed patients with epilepsy followed for average of 34 years.[48] A high proportion of the patients were diagnosed with epilepsy before age 15 years, and many experienced frequent seizures. Patients had a positive health evaluation, but although 55% had been seizure free for the previous 5 years, fewer patients married or had children and more lived at home or in foster homes or institutions. Acquiring epilepsy during school age had a particularly negative impact on school achievement. Sillanpaa et al.[49] also found that adults with childhood-onset epilepsy had significantly compromised quality of life despite being in remission and off medication.

These findings collectively lend strong support to the long-term impact of childhood-onset epilepsy on social functioning in later life. Problematically, social dysfunction occurs often in patients who do not have active epilepsy and are not taking medication. The reasons for this phenomenon are not well understood but attest to the negative effect of seizures that begin early in life.

Immunizations

Vaccines have had a profound effect in the eradication and control of many childhood infectious diseases; however, the risks have not been accurately defined. Over the last 10 to 15 years, concerns relating to the risks of immunization grew as case reports of neurologic and other complications associated with immunizations were published. As a result, some parents refused to have their children vaccinated, the incidence of lawsuits against vaccine manufacturers increased, and some companies threatened to stop vaccine production.

The National Childhood Vaccine Injury Act was passed in 1986; it established a federal compensation program for those judged to have incurred damage from a vaccine. In early reports, the major presumed offender in the causation of “immunization-induced encephalopathy” was pertussis. In published clinical descriptions, the terms encephalopathy and encephalitis are used interchangeably and include several symptoms and signs such as alteration in behavior or level of consciousness, seizures, headache, and focal neurologic deficits. When fever or cerebrospinal fluid pleocytosis is present, the term encephalitis is used.

Although no specific or consistent clinical presentation is evident in case studies of alleged vaccine-induced encephalopathy, the reported clinical patterns included (a) convulsions and coma occurring within 12 hours of immunization; (b) a “pertussis reaction syndrome” characterized by persistent screaming, irritability, refusal of feeds, seizures (usually associated with fever), and altered responsivity; and (c) a generalized seizure occurring within 2 days of the immunization and followed within days and or weeks by increasingly frequent seizures and developmental regression.

In 1948, Byers and Moll[9] reported on 15 cases of “pertussis-induced encephalopathy” characterized by fever, irritability, seizures, and coma occurring within 12 hours of pertussis immunization. All but one of the children suffered permanent neurologic deficits with seizures and/or mental retardation. Kulenkampff et al.,[35] in 1974, reported on 36 children with encephalopathic symptoms, mostly seizures, beginning within 24 hours of pertussis immunization. Two children died within 6 months, 30 had seizures and/or mental retardation, and 4 recovered completely. Subsequent case reports documented similar findings following measles, mumps, and rubella (MMR) vaccine, oral poliovirus vaccine (OPV), and diphtheria, tetanus, and pertussis (DTP) immunization.

The causal relationship of adverse events to immunization was questioned because no consistent encephalopathic pattern

P.2024

was evident in the various case reports, and the possibility of a noncausal temporal relationship could not be excluded. Furthermore, the clinical manifestations of whooping cough encephalopathy differed from many of the case reports of immunization-induced encephalopathy.[52] Postmortem examination of brains from children dying with an encephalopathy during natural pertussis infection showed nonspecific changes usually associated with anoxia (brain edema, petechiae, small subarachnoid hemorrhages, and lymphatic plugs in veins and capillaries) and no evidence of inflammation. Corsellis and colleagues[16] reported the neuropathology of 27 postmortem examinations on individuals who were alleged to have suffered a pertussis-vaccine encephalopathy. No consistent pattern of brain damage was identified as a specific consequence of pertussis immunization. Similarly, animal studies have not supported a relationship between pertussis immunization and encephalopathy.

It was not until the 1980s that population-based epidemiologic studies were designed to objectively evaluate the relationship of immunizations to temporally-associated adverse events.

Population Studies

The National Childhood Encephalopathy Study (NCES) in Great Britain[1] is the most widely quoted epidemiologic study of the adverse effects of DTP vaccine. In a case–control design, 1,182 cases of acute encephalopathy in infants 2 to 35 months of age admitted to hospitals in England, Scotland, and Wales were registered in the study. Each index case was matched with two control children by gender, age, and geographic location. The study sought to address the relationship of DTP immunization to (a) acute serious neurologic events and (b) permanent brain damage. Immunization data were available for 1,167 of the 1,182 cases. Among these, 263 children had infantile spasms and are discussed separately. Of the remaining 904 children, 30 (3.3%) developed encephalopathy within 7 days of DTP immunization as compared to 23 (1.3%) of controls whose index date was within 7 days of immunization. The relative attributable risk of an acute encephalopathy associated with immunization was approximately 1 in 140,000 vaccinations, and the attributable risk of permanent brain damage was 1 in 310,000 vaccinations; the confidence limits for both risks were considerable. In three other controlled studies, only 2 cases of encephalopathy occurred within 7 days of immunization, and no statistically significant risk for encephalopathy was identified.[21,22,58]

The Institute of Medicine has critically reviewed and analyzed the studies concerned with a possible association of whole-cell pertussis vaccine and neurologic illness with particular reference to chronic encephalopathy. Notwithstanding criticism of the NCES methodology, they concluded that "the balance of evidence is consistent with a causal relationship between DTP and the forms of chronic nervous system dysfunction described in the NCES in those children who experience a serious acute neurologic illness within 7 days after receiving DTP vaccine."[32]

Immunizations and the Risk of Epilepsy

Seizures are frequently reported as a solitary feature and as part of an encephalopathy following immunizations. Among 54,000 children followed in a prospective study by the National Collaborative Perinatal Project (NCPP), 2,766 experienced a seizure before age 7 years.[29] In 39 children (1.4%), the seizure occurred within 14 days of immunization. In 10, the seizure followed DTP, usually within 2 days. In 10 others, the seizure followed measles or smallpox vaccination, usually within 7 to 10 days. The seizures were mostly brief and generalized, and all but 1 was associated with fever. Twenty-three percent had a family history of febrile or afebrile seizures. The children were reevaluated at age 7 years; 2 had had a subsequent single seizure, but none developed epilepsy. All children who had experienced single generalized seizures were intellectually normal.

Cody et al.[15] compared the adverse effects following DPT in 15,752 children and DT in 784 children. Nine children had seizures following DTP and none following DT; 7 of the 9 seizures were associated with fever. Follow-up evaluations in 8 children showed that all were neurologically normal, and none had recurrent seizures.

Stetler et al.[52] evaluated data on 2,062 reports of adverse events following DTP immunization from the Monitoring System for Adverse Events Following Immunization (MSAEFI) at the Centers for Disease Control and Prevention (CDC). Children with a neurologic event (mostly seizures) after DTP had a 7.2-times higher risk for a personal history of seizures and a 4.5-times higher risk for a family history of seizures than children who did not have a seizure.

Griffin et al.[22] evaluated the risk of seizures and other neurologic events following DTP immunization in 38,171 children aged 0 to 3 years. Six children had febrile seizures within 6 days of immunization. The study did not show that immunization was associated with either a significant risk for febrile seizures or for later epilepsy.

Shields et al.,[48] in a retrospective epidemiologic study, reviewed the association of adverse neurologic events following DTP immunization in Denmark, where the immunization schedule was changed in 1970. The first group (pre-1970) received DTP at 5, 6, and 15 months and the second group at 5 weeks, 9 weeks, and 10 months. Epilepsy developed in 286 children from the first group and 268 from the second, but the age distribution at onset was the same in both groups. Febrile seizures occurred in 2,199 children, and in contrast to epilepsy, the association between age of febrile seizures and age at immunization was significant. Febrile seizures were more common in the second group and clustered around 10 months of age, suggesting that febrile seizures following immunization have their highest incidence at the age when children are most susceptible to seizures from febrile illnesses of any cause.

Adverse events occurring within 48 hours of DTP immunization were studied prospectively by Baraff et al.[6] in 15,752 children. Nine children had seizures and 9 had hypotonic–hyporesponsive episodes, which are generally regarded as syncopal rather than epileptic. Sixteen of the 18 children were contacted 6 to 7 years later, and all were considered normal by their parents and were doing well in school. Psychometric testing in 13 of the 16 children revealed normal performance IQ scores (104.3±15.8) but low verbal IQ scores (91.8 ± 18.4). The lower verbal scores were felt to be related to the high proportion of Hispanic and bilingual children.

As a group, these studies indicate a small but statistically significant risk of febrile seizures following immunization, especially in children with a personal or family history of seizures. As with other normal children who experience seizures with fever, the risk of subsequent nonfebrile seizures or neurologic disturbances is not increased.

Immunization and the Risk of Infantile Spasms

An association between routine immunization, especially DTP, and infantile spasms has been postulated repeatedly by single case reports and case series. The association is confounded, however, because the onset of infantile spasms is difficult to

date and the usual age at onset of infantile spasms coincides with the recommended age of several routine childhood immunizations.

Table 1 Adverse events related to immunizations

Vaccine	Adverse event
DTP	Anaphylaxis[a]
Pertussis	Anaphylaxis[a] Persistent inconsolable crying[a] Acute encephalopathy[b] Hypotonic–hyporesponsive episodes[b]
Diphtheria	Anaphylaxis[a] Guillain-Barré syndrome[b] Brachial neuritis[b]
Tetanus	Anaphylaxis[a] Guillain-Barré syndrome[b]

	Brachial neuritis[b]
Rubella	Acute arthritis (adult women)[a] Chronic arthritis (adult women)[b]
MMR	Anaphylaxis[a] Thrombocytopenia[a]
Measles	Measles vaccine strain viral infection[a] Anaphylaxis[a]
Hepatitis B	Anaphylaxis[a]
OPV	OPV strain viral infection[a] Guillain-Barré syndrome[b]
Hib	Anaphylaxis[a]

DTP, diphtheria, tetanus, pertussis; Hib, *Haemophilus influenzae* type B; MMR, measles, mumps, rubella; OPV, oral polio vaccine.

[a]Evidence establishes causal relationship.

[b]Evidence suggests possible causal relationship.

The first epidemiologic study to address these issues was from Denmark,[39] where immunization schedules changed after 1967. Infantile spasms developed in 86 children immunized between 1957 and 1967, when DTP was given at 5, 6, and 10 months of age, and in 113 children immunized between 1970 and 1975, when whole-cell pertussis alone was given at 5 weeks, 9 weeks, and 10 months of age. The age at onset of infantile spasms was not influenced by the change in immunization practices.

The occurrence of infantile spasms was one of the index conditions studied by the NCES. Among 263 cases reported, no association with pertussis immunization was noted in the 28 days following immunization.[7] Some clustering of infantile spasms did occur in the first 7 days following immunization, but this was compensated for by fewer cases in the remaining 21 days, suggesting that DTP immunization is not a cause of infantile spasms but may bring it to attention.

Adverse Events Following Childhood Immunization

The National Childhood Vaccine Injury Act (Public Law 99-660) was passed by the U.S. Congress in 1986 and became effective in October 1988. Section 312 of Public Law 99-660 required a review and analysis of the available information pertaining to the possible adverse effects of routine childhood immunizations mandated for school entry. This review was conducted by the Institute of Medicine and published in two reports.[31,53] Their conclusions are summarized in Table 1.

Precautions and Contraindications of Immunizations

Immunization is mainly intended for use in healthy children, but children with chronic neurologic problems are especially vulnerable to infectious diseases and need protection. The standards of immunization practices are provided by the Advisory Committee on Vaccine Practices[12] and the American Academy of Pediatrics.[50]

In general, a vaccine that produces a serious adverse reaction should not be readministered. Epilepsy per se is not a contraindication to routine childhood immunizations. Parents of children who are at risk for febrile seizures should be warned that some immunizations cause fever and may trigger seizures. It is reasonable to suggest the use of acetaminophen on the day of DTP immunization.

Summary and Conclusions

Other diseases and conditions commonly affect the management of epilepsy in children; similarly, epilepsy and its treatment may confound treatment of systemic disorders. The effect of immunizations, especially DPT, on seizure susceptibility remains controversial. A large epidemiologic study from Great Britain demonstrated only minimal risk of persistent neurologic abnormalities following vaccination. The Institute of Medicine in the United States, however, concluded that DPT vaccination increased the risk of chronic encephalopathy. Febrile reactions following immunization increase slightly the risk of febrile seizures. Routine immunization, including DPT, does not increase the risk of infantile spasms. Acute encephalopathy, brachial neuritis, and Guillain-Barré syndrome have all been reported as adverse events following various immunizations.

Chapter 193

Procedures and Anesthesia in Patients with Epilepsy

Orrin Devinsky

Douglas R. Nordli Jr.

Introduction

Patients with epilepsy are often considered to be at high risk for routine medical and dental procedures. This designation is based primarily on the risk of seizures occurring during or shortly after the procedure and, to a lesser degree, on the potential interaction between drugs for the procedure and those for seizure control. Although few procedures have been documented to have increased risks among patients with epilepsy, an increased level of concern is often present. Procedures in children and adults with epilepsy raise the following issues: (a) steps that can be taken before the procedure to reduce the risk of seizures associated with it, (b) education of health care workers involved in a procedure about a patient's seizures and medications and first aid for seizures, (c) defining the risks of the procedure for patients with epilepsy, (d) defining the effects of anesthetics or analgesics used for the procedure on seizure threshold and potential for interaction with antiepileptic drugs, which is the focus of this chapter, and (e) differential diagnosis of paroxysmal behavioral events occurring around the time of procedures.

Epileptic seizures during medical and dental procedures can be more dangerous (e.g., onset of uncontrolled clonic movements in an extremity in which a microsurgical procedure is being performed under local anesthesia) or less dangerous (e.g., onset of status epilepticus in a physician's office) than seizures occurring at other times (e.g., while sleeping alone in bed).

Some simple precautions should be employed before a person with epilepsy undergoes a procedure. First, factors that can precipitate seizures should be avoided. Because missed medications are a common cause of breakthrough seizures, the physician should emphasize compliance and ensure that patients continue taking medication up until shortly before the procedure (see later discussion). Although patients are instructed not to eat or drink for at least 8 hours before surgery, medications are often administered with sips of water within a few hours of surgery. Antiepileptic drugs should be given at this time as well. Sleep deprivation, common before many procedures, should be avoided. When needed, low doses of chloral hydrate or benzodiazepines can be safely used for insomnia the night before a procedure. Patients with epilepsy, who should always avoid excessive alcohol intake (i.e., more than two beverages per day), should avoid alcohol for 3 to 4 days before surgery to reduce the potential for withdrawal effects.

Much of the concern regarding patients with epilepsy results from perceived as well as real risks associated with seizures. Health care workers often receive little education concerning seizure classification and phenomenology, duration, and first aid. This lack of understanding fosters fear and conservatism that can lead to excessive precautions and restrictions and to management errors. Induced labor and cesarean section are examples in which interventions and procedures may be undertaken more often in women with epilepsy—two to four times more often than in other pregnancies—than medical reasons alone would justify.[115] Epilepsy alone is not an indication for either of these interventions. However, in selected cases, labor should be induced and cesarean section should be done on an elective (e.g., weekly tonic–clonic seizures during the last trimester) or emergency (e.g., tonic–clonic seizure during labor or lack of active maternal contribution) basis.[44]

Physicians, nurses, dentists, technicians, and other health care workers involved with procedures in patients with epilepsy should have a basic understanding of the patient's seizure types, medications, and first aid for the seizures. A complex partial seizure during a routine dental procedure can frighten both the dentist and technologist. If these professionals are informed of the possibility ahead of time and educated about the need for calm observation as opposed to intervention, fears and chances of inappropriate responses will be reduced. For example, restraint during a complex partial seizure or after a tonic–clonic seizure can provoke an aggressive reaction leading to a dangerous cycle requiring greater restraint. In such cases, restraint should be removed and the patient reassured in a comforting manner.

Paroxysmal behavioral events occurring during or after procedures have a differential diagnosis extending well beyond epileptic seizures.[75] An occasional patient with psychogenic seizures has events mainly around the time of medical procedures. More commonly, patients with convulsive syncope develop symptoms during painful or emotional procedures. In such cases, which can include such procedures as venipuncture, excision of moles under local anesthesia, and electromyography, the patient suffers a tonic–clonic seizure secondary to a fall in heart rate or blood pressure.[64] These seizures are typically brief, lasting <2 minutes, but may be followed by prominent postictal confusion. No specific therapy is required, and antiepileptic drugs should not be prescribed. In selected cases of recurrent convulsive syncope associated with medical procedures, anticholinergic agents may be beneficial.

Premedication and Assessment

During the preoperative interview, the anesthesiologist determines and prescribes premedication for the patient. Choice of premedication can have major implications for the patient with epilepsy. Considerations include the following:

1. Continuing the patient's prescribed daily medications. Administering medications either orally with a sip of water or via an acceptable alternate route (intravenous, intramuscular, or rectally) can avoid decreasing serum levels into the subtherapeutic range. Antiepileptic drugs (AEDs) are included in this category as well as antihypertensives and cardiac, diabetic, and asthma

medications. When oral or parenteral administration of AEDs cannot be done (e.g., because of hyperemesis, gastrointestinal procedures, AEDs without parenteral forms), some may be given rectally (Table 1). Although clonazepam has an intermediate absorption rate,[53] the injectable forms of diazepam and lorazepam are rapidly absorbed rectally.[39,75] Carbamazepine can be given rectally with 80% absorption.[38] Ninety percent of rectal phenobarbital (liquid parenteral form) is absorbed in 4.4 hours.[39] Phenytoin (liquid parenteral form) given rectally is slowly absorbed in dogs.[35] Rectal absorption of oral forms of sodium valproate is complete, with peak concentrations occurring approximately 2 hours after administration.[47]

Table 1 Antiepileptic drugs available for rectal adminisration

Drug	Treatment usefulness	Dose (mg/kg per dose)	Preparation	Pharmacokinetics	Comments
Carbamazepine (CBZ)	Maintenance	Same as oral	Oral suspension (dilute with equal volume of water) Suppository gel (CBZ powder dissolved in 20% alcohol and methylhydroxy cellulose)[a]	Peak concentration 4–8 hr; 80% absorbed	Cathartic effect

Clonazepam	?Acute	0.02–0.1 mg	Suspension	Peak concentration 0.1–2 hr	Onset may be too slow for acute use
Diazepam	Acute	0.2–0.5 mg	Parenteral solution	Effect in 2–10 min; peak concentration 2–30 min	Well tolerated nordiazepam accumulates with repeated doses
Lorazepam	Acute	0.05–0.1 mg	Parenteral solution	Peak concentration 0.5–2 hr	Well tolerated
Paraldehyde	Acute	0.3 mL	Oral solution (dilute with equal volume of mineral oil)	Effect in 20 min; peak concentration 2.5 hr	Moderate cathartic effect; use glass syringe
Phenobarbital	?Acute	10–20 mg	Parenteral solution	Peak concentration 4–5 hr; 90% absorbed	Onset may be too slow for acute use
Secobarbital	Acute	5 mg	Parenteral solution	Peak concentration 0.5–1.5 hr	
	Maintenance	Same as oral	Same as acute	Same as acute	
Valproic acid	Acute	5–25 mg	Oral solution (dilute with equal volume of water)	Peak concentration 1–3 hr	Cathartic effect
	Maintenance	Same as oral	VPA liquid from capsules mixed into Supocire C lipid base	Peak concentration 2–4 hr; 80% absorbed	Well tolerated

(VPA)

These data are based largely on pediatric studies.
[a]Extemporaneously prepared using commercial products; all other preparations are commercial products given rectally.

2. Premedication for sedative or analgesic purposes. To calm the patient for transport to the operating room and smooth induction, benzodiazepines (diazepam, midazolam, lorazepam), antihistamines (hydroxyzine), barbiturates, and narcotics (meperidine, morphine) may be administered. Pro- and anticonvulsant considerations of these medications are addressed later.
3. Diminishing risks of perioperative problems or complications such as aspiration, hemorrhage, or postoperative nausea and vomiting. Complications associated with aspiration are related to both the volume (>25–30 mL) and the acidity (pH <2.5) of the aspirated gastric fluid. Medications are administered based on their ability to increase gastric pH or decrease gastric volume. H2 antagonists (cimetidine, ranitidine, and nizatidine) increase gastric pH and are often administered to patients at high risk for aspiration (e.g., obesity, hiatal hernia). Although H2 antagonists do not have proconvulsant activity, cimetidine can increase phenytoin plasma levels, and these should be monitored. Metoclopromide is also prescribed for patients at risk of aspiration because it increases lower esophageal sphincter tone, facilitates gastric emptying, and has an antiemetic effect. This medication works both centrally and peripherally as a dopaminergic antagonist. Metoclopromide should be used cautiously in epilepsy patients because it may increase the frequency and severity of seizures.[11]

Sodium valproate can cause thrombocytopenia and platelet dysfunction. The mechanism underlying these effects is unknown. Bleeding time and platelet count are essential in the presurgical evaluation of patients on sodium valproate.

P.2029

Specific platelet function tests such as platelet adhesiveness or aggregation may also be helpful. The role of valproate-induced hemorrhage or exacerbation of surgically induced blood loss is not clearly defined. However, valproate has been suspected in the pathogenesis of hemorrhagic complications of surgery. In one study of 29 children with cerebral palsy who underwent bilateral femoral osteomy, platelet counts were lower and the need for transfusion was higher (50% of cases) in those who were on antiepileptic drug regimens including valproic acid.[17] For major surgical procedures, another AED should be substituted if possible. When valproate is used, doses of >40 mg/kg per day should be avoided because the hematologic effects of sodium valproate may be dose related.[65]

Anesthesia

Anesthetics may possess proconvulsant or anticonvulsant properties or both. The effects of local and general anesthetics on seizure threshold have been examined to determine intrinsic pharmacologic properties and mechanisms of action, interictal and ictal effects on surface, depth, and cortical electroencephalogram (EEG) recordings, and behavioral effects in animals and humans.

General Anesthetics

Inhalation and intravenous anesthetics possess proconvulsant and anticonvulsant properties. The mechanisms of these contrasting neural effects are not fully understood. Biologic differences in how patients respond may result from variations in bioavailability, relative effects on excitatory and inhibitory neurons, and the speed of delivery and changes in serum concentrations. With deepening levels of anesthesia, there are characteristic EEG changes, beginning with increased beta activity and followed by progressive slowing of the background until a flat line or burst suppression record is obtained (Table 2). Postoperatively, slowing often persists for several days, and occasionally for several weeks. As general anesthetics, all halogenated inhalational agents have anticonvulsant properties and can terminate status epilepticus.[82]

Table 2 Anesthetic drugs and the electroencephalogram (EEG)

Drug	Effect on EEG frequency[a]	Effect on EEG amplitude	Burst suppression?
Isoflurance			Yes, >1.5 MAC
Subanesthetic	Loss of alpha, ↑ frontal beta	↓	
Anesthetic	Frontal 4–8 Hz activity	↑	
Increasing dose >1.5 MAC	Diffuse theta and delta → burst suppression → silence	↑→0	
Enflurane			Yes, >1.5 MAC
Subanesthetic	Loss of alpha, ↑ frontal beta	↓	
Anesthetic	Frontal 7–12 Hz activity	↑	
Increasing dose >1.5 MAC	Spikes/spike-and-slow-wave → burst suppression; hypocapnia → seizures	↑↑	
Halothane			
Low dose	↑ Frontal 10–20 Hz activity	↓	Not seen in clinically useful dose range
Moderate dose	Frontal 10–15 Hz activity	↑	
Increasing dose >1.5 MAC	Diffuse theta, slowing with increasing dose	↑	
Desflurane	Similar to equi-MAC dose of isoflurane	Similar to equi-MAC dose of isoflurane	Yes, >1.2 MAC

Nitrous oxide (alone)	Frontal fast oscillatory activity (>30 HZ)	↑, especially with inspired concentration >50%	No
Barbiturates			Yes, with high doses
Low dose	Fast frontal beta activity	Slight ↑	
Moderate dose	Frontal alpha frequency spindles	↑	
Increasing high dose	Diffuse delta → burst suppression → silence	↑↑↑→0	
Etomidate			Yes, with high doses
Low dose	Fast frontal beta activity	↓	
Moderate dose	Frontal alpha frequency	↑	
Increasing high dose	Diffuse delta → burst suppression → silence	↑↑→0	
Propofol			Yes, with high doses
Low dose	Loss of alpha, ↑ frontal beta	↓	
Moderate dose	Frontal alpha waxing/waning alpha	↑	
Increasing high dose	Diffuse delta → burst suppression → silence	↑↑→0	
Ketamine			No
Low dose	Loss of alpha, ↑ variabillity	↑↓	
Moderate dose	Frontal rhythmic theta	↑	

High dose	Polymorphic delta, some beta	↑↑(beta is low amplitude)	
Benzodiazepines			No
Low dose	Loss of alpha, increased frontal beta activity	↓	
High dose	Frontally dominant delta and theta	↑	
Opiates			No
Low dose	Loss of beta, alpha slows	↔↑	
Moderate dose	Diffuse theta, some delta	↑	
High dose	Delta, often synchronized	↑↑	

MAC, minimum alveolar concentration.
[a]Delta, <4 hz; theta, 4–7 Hz; alpha, 8–13 Hz; beta, >13 Hz.
Source: Adapted from Black S, Mahla ME, Cucchiara RF. Neurologic monitoring. In: Miller RD, ed. *Anesthesia*. New York: Churchill Livingstone; 1994:1323.

Among the volatile anesthetics, methoxyflurane and halothane produce the least central nervous system (CNS) irritability and enflurane the most; isoflurane and desflurane are intermediate.[21,22] Changes in basicity of these compounds, which depends on the degree of fluorination of the carbon atoms adjacent to the ether oxygen, may parallel effects on cortical excitability. Isoflurane, the least fluorinated and most basic of these ethers, produces the least cortical reactivity.[21] The mechanism of enflurane-induced hyperexcitability in humans is unclear. In animals, enflurane inhibits synapses and stimulates excitatory neuronal transmission in cortical and subcortical areas.[13]

Patients on the ketogenic diet can safely receive general anesthesia.[11] Carbohydrate-free intravenous solutions should be used perioperatively. With more prolonged procedures, serum glucose and pH levels should be closely monitored. Although glucose levels are usually stable, metabolic acidosis can develop and patients may require intravenous bicarbonate.[11]

Enflurane.

Enflurane is the major inhalation agent that anesthesiologists usually avoid when caring for epilepsy patients because it lowers seizure threshold. In children and adults with no history of epilepsy, enflurane can cause epileptiform activity with concomitant facial or appendicular myoclonus or generalized tonic–clonic movements.[15,51,63] In epilepsy patients, the extent but not the frequency of spike activity on the electrocorticogram is increased.[51] Epileptogenic foci may be activated during epilepsy surgery.[33,74] As the depth of anesthesia is increased with enflurane, the EEG demonstrates high-voltage spikes and spike-and-slow-wave complexes—spike with burst suppression. Although low enflurane concentrations (1%–1.5%) administered to a normocarbic patient ($PaCO_2$ = 40 torr) are not frequently associated with seizure activity,[78] increasing enflurane concentrations (2%–3%) or hyperventilating an anesthetized patient enhances seizure activity. Hyperventilation to a $PaCO_2$ of 20 torr from 40 torr is associated with seizure activity at a 1% lower enflurane concentration. Because hyperventilation is frequently employed by neuroanesthesiologists to decrease cerebral blood flow and intracranial pressure, enflurane is avoided when hyperventilation is indicated. An increase in $PaCO_2$ from 40 to 60 torr increases the minimum enflurane concentration at which seizures occur by 1%.[13]

Generalized tonic–clonic and myoclonic seizures can occur within the immediate postoperative period and potentially occur a few days after enflurane anesthesia. The role of other CNS-active drugs is uncertain in these cases.[81] The convulsant effects may result from enflurane's organic and inorganic nonvolatile fluorinated metabolites.[20]

Although anesthesiologists consider diazepam and thiopental anticonvulsant agents and use them extensively to treat seizure activity, there is some evidence that both of these drugs may potentiate enflurane-related epileptiform activity in humans.[25] Nitrous oxide (N_2O) does not alter epileptiform activity induced by enflurane.[78]

Halothane.

Halothane has anticonvulsant properties and can terminate status epilepticus. When used alone, halothane does not cause CNS irritability.[12] In the few reports of halothane-related seizures, N_2O was also administered.[87] Rarely, sharp waves maximal over the vertex can appear during the first postoperative week, usually on the first two postoperative days. Persistence of an epileptogenic halothane metabolite (i.e., trifluoroacetic acid) may contribute to this sharp activity.[14]

Isoflurane.

Isoflurane, a commonly used inhalation agent, is an isomer of enflurane containing little or no epileptogenicity.[21] In the few cases of isoflurane-related seizures, N_2O was also administered.[43] Isoflurane has anticonvulsant properties, suppressing drug-induced convulsions in animals[56] and terminating status epilepticus in patients at inspired concentrations 0.5%–3%.[57,95] Isoflurane reduces both the frequency and field of spikes on the electrocorticogram of epilepsy patients.[51,57]

Desflurane.

Desflurane is an introduced inhalation agent structurally similar to isoflurane. Compared with isoflurane, it has a more rapid onset of action and recovery. The EEG patterns for desflurane are similar to those seen with equipotent doses of isoflurane. Burst suppression is easily achieved. There was some concern that EEG tolerance may develop to desflurane. However, this has not been demonstrated in humans.[90,116]

Sevoflurane.

Sevoflurane is an inhalation agent. Sevoflurane produces dose-dependent epileptiform discharges at surgical levels of anesthesia[52] and is more epileptogenic than isoflurane.[50] Sevoflurane induction can produce epileptiform activity without clinical evidence of seizure activity in children with or without a history of epilepsy.[23,59] In children of age 4 years and under without a history of seizures, sevoflurane induction has been rarely associated with convulsive seizures.[1] Patients with refractory epilepsy administered sevoflurane at a minimal alveolar concentration (MAC) of 0.5 had significantly fewer spikes than those with a MAC of 1.5.[61] In healthy individuals, electrographic and clinical seizures can result from MAC of 2.0.[52] The use of midazolam and thiopental, or nitrous oxide, prevents the appearance of epileptiform activity with sevoflurane induction.[51,79]

Nitrous oxide has very low epileptogenic potential and has been used extensively in both epilepsy and nonepilepsy patients.[74,80] It does not significantly affect neuronal firing in the human limbic areas.[4] Among 11 epilepsy patients

undergoing dental procedures, there were no EEG changes during anesthesia in 9 patients and decreased frequency of paroxysmal discharges in 2 patients.[80]

Barbiturates

Barbiturates are anticonvulsants that can also have proconvulsant actions. Slight structural changes of a barbiturate (e.g., sulfuration or methylation of the 1 position) can convert it from an anticonvulsant into a convulsant.[55] Depending on the dose used, some barbiturates can have both pro- and anticonvulsant properties, with low doses associated with seizure activity in epilepsy patients[58] and higher doses leading to burst suppression.

Thiopental (Pentothal) and Ultrashort-Acting Barbiturates.

Thiopental is used to stop seizures, including those caused

P.2031

by local anesthesia overdose. The proconvulsant action of thiopental is low compared to that of methohexital.[102] This drug is less effective than methohexital in activating existing epileptogenic activity on the electrocorticogram in epilepsy patients. Thiopental may be a safer induction agent than methohexital for patients with epilepsy.[94] Other ultrashort-acting thiobarbiturates such as thiamylal sodium, buthalitone, and thialbarbitone share common pharmacologic properties with thiopental.

Methohexital.

Methohexital is an ultrashort-acting methylbarbiturate that does not cause seizure activity in patients without epilepsy. However, it can be associated with some excitatory phenomena such as hiccoughing, tremors, and abnormal muscle movements.[74] In patients with epilepsy, electrographic and clinical seizures can occur following intravenous (0.5–1.0 mg/kg), intramuscular (10 mg/kg), and rectal (25 mg/kg) administration.[78,82] Low-dose methohexital (<0.5 mg/kg) can activate interictal and ictal discharges among epilepsy patients during electrocorticography.[86] The activating effect of methohexital may be largely restricted to patients with partial epilepsy, occurring in up to 72% of such patients.[77] Methohexital does not appear to cause seizures during anesthetic induction of patients with generalized epilepsy.[77,94] In higher doses, methohexital can suppress epileptogenic foci and cause electrical silence. This suppressive effect is used in the methohexital suppression test, which has been recommended as an adjunctive tool to distinguish the primary focus in patients with secondary bilateral synchrony or multifocal discharges.[102] This is most valuable in the investigation of temporal lobe epilepsy. Methohexital is administered in incremental doses of 0.5 to 1.0 mg/kg until EEG silence is obtained or only a single focus remains. If total EEG silence is obtained, as the EEG returns, it is hoped that a single focus will become evident.

Etomidate

Etomidate is a hypnotic nonbarbiturate ultrashort-acting anesthetic agent associated with involuntary muscle movements in 10% to 70% of patients. These movements can be violent and mimic seizure activity. Etomidate is often administered because of its cardiovascular stabilizing effect. In patients without epilepsy, surface electrode recordings during the myoclonic movements are not associated with epileptiform activity.[28,60] These myoclonic movements are dose related, occurring more often with higher doses.[28] Posttreatment myoclonus can be suppressed by pretreatment with a low dose of etomidate 50 seconds before the main dose.[28]

Etomidate (0.2 mg/kg) can activate seizure foci in epilepsy patients within 30 seconds[29] and has been used intraoperatively for this purpose. Despite lack of evidence that etomidate causes seizures in nonepilepsy patients, epileptiform activity occurred in 6 of 30 nonepilepsy patients who were induced with etomidate for heart valve replacement.[60]

Benzodiazepines

Benzodiazepines are potent anticonvulsants and are commonly used intravenously (and occasionally rectally) to treat status epilepticus.[74] Diazepam, midazolam, clonazepam, and lorazepam are all used as antiepileptic drugs.[58] Intravenous midazolam drip may be more effective for refractory status than other benzodiazepines.[85] Paradoxically, diazepam may induce seizures in patients with Lennox-Gastaut syndrome and lower the seizure threshold in epilepsy patients receiving enflurane.[107]

In patients with epilepsy, benzodiazepines can be used preoperatively to reduce anxiety. Furthermore, depending on the duration of the surgical procedure and the half-life and redistribution of the specific benzodiazepine, these agents may help to prevent seizures during the transition out of anesthesia. This transition is a withdrawal from central nervous system depressants, and in susceptible patients, can lower the seizure threshold sufficiently to cause a clinical seizure. In patients with a history of seizures during the withdrawal of anesthetics or during the postanesthetic state, use of low-dose benzodiazepines before the end of the procedure or an increase in their chronic antiepileptic drugs (before or intravenously during surgery) may help to prevent seizures.

Opioids

Patients without epilepsy are not at risk for seizures when they receive typical anesthetic doses of narcotics. However, high-dose opioids can elicit seizures. What practitioners observe as seizure activity may actually be myoclonic jerks, rigidity, and other nonepileptic drug–induced movements.[74] Simultaneous scalp EEG and electromyographic (EMG) recordings do not reveal epileptiform activity during abnormal movements. In epilepsy patients, high-dose narcotics may elicit seizure activity in isolated cases (see later discussion of fentanyl). However, scalp EEG recordings may not be adequate to determine this, and electrocorticographic recordings may be required to detect narcotic-induced seizure activity in epilepsy patients.[109]

Morphine.

In humans, routine oral or intravenous morphine doses have little or no effect on seizure threshold.[74] Seizures have occurred after epidural administration of morphine in an epilepsy patient[10] and after inadvertent intrathecal administration of a high dose to a cancer patient without prior seizures.[62] In animals, very high doses of intravenous morphine can cause epileptic seizures.[109]

Meperidine.

Myoclonus, seizures, jitteriness, and tremors are neurotoxic effects of meperidine. Myoclonus generally precedes seizures, but both resolve over several days with discontinuation of meperidine adminstration.[54] These neurotoxic effects are directly related to blood levels of normeperidine, the N-demethylated active metabolite of meperidine.[54,105] The half-life of normeperidine (14–21 hours) is longer than that of meperidine (3–4 hours), so continued use can result in high systemic normeperidine levels.[42,88] In patients receiving oral meperidine, normeperidine levels may increase at a faster rate because of hepatic metabolism.[71] Antiepileptic drugs that induce microsomal hydroxylation (e.g., phenytoin, phenobarbital) increase the conversion of meperidine to normeperidine.

If meperidine causes significant neurotoxicity, it should be discontinued. A short course of a benzodiazepine may help to control jitteriness and tremors, although myoclonus can be refractory.[45] Patients with renal disease have decreased normeperidine clearance and increased risk of toxicity.[105] Patients with sickle cell anemia and malignancy are also at increased risk.[54,106] Seizures have been reported in patients receiving long-term or high-dose meperidine via patient-controlled analgesia pumps (PCAPs).[42]

Seizure-like movements have not been reported in epileptic patients during either acute or chronic meperidine administration. It is unknown whether acute or chronic meperidine use activates epileptogenic EEG foci in epilepsy patients. Neither meperidine nor its metabolites have anticonvulsant properties.[74] Electroencephalogram changes in otherwise healthy individuals in whom seizures have occurred after repeated meperidine administration include diffuse slow activity and epileptiform discharges.[3,37]

Fentanyl, Sufentanil, and Alfentanil.

Myoclonic movements and rigidity occurring with fentanyl, sufentanil, and alfentanil prompted reports that high doses of narcotics can cause seizures. However, these reports have not been substantiated with EEG documentation of seizure activity.[91,99] Simultaneous EEG and EMG recordings during fentanyl, sufentanil, and alfentanil induction did not reveal epileptiform activity during intense rigidity and associated movements that might be interpreted as seizures.

Eight of nine patients with complex partial epilepsy had fentanyl-induced epileptiform activity on the electro-corticogram.[109] In four of these patients, epileptiform activity was recorded beyond the seizure focus. Alfentanil increases the mean temporal lobe spike frequency during temporal lobe electrocorticography.[18] Some groups use these agents to activate interictal epileptiform foci arising from the amygdala or hippocampus.[69]

Neuroleptic-Opioid Combination: Innovar (Droperidol plus Fentanyl)

Among 104 patients receiving neuroleptic anesthesia for various neurodiagnostic procedures utilizing metrizamide, there was no clinical or EEG evidence of seizures.[96]

Dissociative Anesthesia: Ketamine Hydrochloride

Ketamine hydrochloride has proconvulsant and anticonvulsant properties. Of eight epilepsy patients undergoing dental work, two had partial motor seizures and another had a generalized tonic–clonic seizure with ketamine.[6] In some patients with epileptiform activity on their baseline EEG, particularly those receiving 2 to 4 mg/kg intravenous doses, the activity progressed to electrical seizure.[32] The EEG recordings in all of these patients returned to their preanesthetic baseline within 1 week.[6] Ketamine should be used with caution in epilepsy patients. If a clinical seizure occurs during ketamine use, further administration of ketamine to deepen anesthesia should be avoided. Instead, a CNS depressant such as a barbiturate or benzodiazepine should be used.[114]

In other studies, ketamine did not increase epileptiform or seizure activity in epilepsy patients.[19,24] Because of the mixed depressant–stimulant effects of ketamine, epilepsy patients should be adequately premedicated with anticonvulsants and sedatives.

Propofol

Spontaneous movements can occur during induction with propofol without associated epileptiform abnormalities. These movements include dystonia, chorea, athetosis, twitches, and opisthotonus. Abnormal movements may mimic tonic and clonic movements during seizures, especially during the postoperative period.[16] In several cases, cortical epilepsy was activated during electrocorticography, with epileptiform activity beginning 20 to 30 seconds after a bolus of intravenous propofol.[46] In patients who receive baclofen, propofol can cause recurrent tonic–clonic seizures.[67] Seizures may recur for 7 to 23 days after propofol anesthesia, suggesting a proconvulsant metabolite.[12,48] Propofol also has anticonvulsant properties in animals[66] and humans.[9] Continuous propofol infusion can terminate status epilepticus refractory to other therapies.[73]

In epilepsy patients undergoing dental procedures, administration of propofol in subanesthetic doses to achieve conscious sedation did not provoke seizures or enhance any interictal epileptiform activity.[63] Propofol can also be used successfully in children undergoing the sodium amobarbital test to produce rapid induction of anesthesia without endotracheal intubation.[70] Neuropsychological testing could be successfully performed after angiographic testing was completed.

Local Anesthesia

Differences in CNS effects of local anesthetics are attributable to differences in potency, systemic rate of absorption from site of injection, speed of passage through the blood–brain barrier, rate of biotransformation, and speed of intravascular injection of the anesthetic.[111] Stimulation of the CNS by some local anesthetics may result from selective depression of inhibitory neurons. Rapid administration or large doses can depress all neuronal activity with only transient or no CNS signs of stimulation.[93]

Lidocaine

Lidocaine has proconvulsant and anticonvulsant effects, with CNS effects related to blood concentrations. Low doses of lidocaine (2–3 mg/kg) can terminate status epilepticus. With increasing blood levels, CNS symptoms and signs of toxicity occur from perioral numbness, lightheadness, dizziness, tinnitus, and fine tremors to generalized seizures and coma. In animals, lidocaine produces epileptiform activity limited to the amygdala and hippocampus.[26]

Lidocaine doses commonly used for local anesthesia can cause CNS toxicity if they are inadvertently administered intravenously. For example, when epidural anesthesia is administered, total doses of 5 to 8 mg/kg are commonly injected into the epidural space.[111] Accidental intravascular injection of this dose can cause epileptic seizures. In addition to direct intravascular injection and immediate toxicity, systemic lidocaine levels can rise to toxic levels by rapid systemic absorption from the area of injection. This can occur 10 to 20 minutes after injection. Anesthesiologists often add epinephrine, 5 g/mL, to the local anesthetic to decrease systemic absorption and decrease peak serum lidocaine levels. When a regional anesthesia block is unsuccessful, early reinjection of local anesthesia can cause toxicity (including seizures) because peak absorption of the first injection is occurring while additional medication is injected.

High doses of lidocaine cause sedation. Increasing $PaCO_2$ decreases the dose of lidocaine needed to produce a generalized electrical seizure.[113] Higher $PaCO_2$ levels increase cerebral blood flow, thus increasing the amount of anesthetic reaching the brain, and may directly excite the amygdala. In contrast to hyperventilation to activate seizure activity, by decreasing cerebral blood flow, hyperventilation may prevent seizures from occurring in patients with lidocaine overdose.

Lidocaine is injected intravenously to provide local anesthesia (intravenous regional anesthesia or Bier blocks). In this technique, after an extremity is exsanguinated and blood supply is arrested by a tourniquet, lidocaine is injected into a vein to provide anesthesia. Doses of lidocaine up to 3 mg/kg of 0.5% solution without preservatives or epinephrine are utilized. Premature tourniquet release (<20 minutes) can result in high systemic lidocaine levels and possible seizure activity. Release after 20 minutes can also be associated with toxicity. Some physicians cycle the deflation of the tourniquet with intermittent inflation–deflation–inflation in an attempt to decrease rapid absorption of lidocaine from the extremity.

Etidocaine HCl, a long-acting derivative of lidocaine, as well as mepivacaine and prilocaine HCl share common pharmacologic properties with lidocaine HCl. Seizures induced by lidocaine can be terminated with barbiturates.

Bupivacaine

Bupivacaine causes CNS toxicity at plasma level >4 g/mL. Seizures can occur with plasma levels of 2.3 and 3.0 g/mL after accidental intravenous injection during obstetric epidural anesthesia.[97] A more dangerous concern with bupivacaine toxicity is intractable ventricular fibrillation.

Cocaine

Cocaine produces electrical and clinical seizure activity in animals. Electrographic discharges arise in the amygdala. Protection against such cocaine-induced seizures is afforded by dibenamine, chlorpromazine, reserpine, pyridoxine, and hydroxylamine but not traditional anticonvulsants. Thus, cocaine

P.2033

may cause seizures by potentiating noradrenergic or dopaminergic activity in the amygdala.[31]

Seizures occurred in an 11-week-old infant receiving intranasal installation of a 4% cocaine solution[101] and in a child receiving topical cocaine solution through a bronchoscope.[100] Edematous and inflamed mucosa may absorb excessive amounts of anesthetic. In these settings, using benzodiazepines or short-acting barbiturates, using local vasoconstrictors, and rinsing the mucosal surface with water or normal saline to prevent further drug absorption have been recommended in managing cocaine-induced seizures in children.[101]

Procaine

At low doses, procaine has anticonvulsant properties.[7] Procaine, given at 18 to 29 mg/kg, causes generalized tonic–clonic seizures. In one study, thiopental pretreatment failed to prevent procaine-induced seizures but increased the dose of procaine necessary to produce seizures. Thiopental given during a procaine-induced seizure stopped the seizure.[111] *p*-Aminobenzoic acid is a procaine metabolite that can prevent seizures induced by local anesthetics.[92] This metabolite might explain the low incidence of generalized convulsions reported during the continuous infusion of intravenous procaine.

Chloroprocaine, a halogenated derivative of procaine, shares the same pharmacologic properties as procaine.

Tetracaine HCl, a derivative of *p*-aminobenzoic acid, is ten times more active and potent than procaine after intravenous injection.

Anesthetic Adjuvants

Muscle Relaxants

None of the Food and Drug Administration (FDA)–approved muscle relaxants used in clinical anesthesia is known to cause epileptiform activity or seizures, nor have there been reports regarding the anticonvulsant properties of these drugs in humans. Accumulation of laudanosine, a metabolite of atracurium, may slightly decrease the seizure threshold.[5] In Italy, three patients treated with thiocolchicoside, a centrally acting muscle relaxant, developed seizures.[27]

Most of the neuromuscular blocking agents are more rapidly metabolized in patients on chronic therapy with antiepileptic drugs that induce the hepatic enzymes. Resistance to metocurine-induced,[84] atracurium-induced, or vecuronium-induced[83] neuromuscular blockade has been demonstrated in patients chronically receiving phenytoin. Similarly, patients receiving chronic carbamazepine therapy have shortened recovery times from the neuromuscular blockage induced by vecuronium. The mechanism is a twofold increase in vecuronium clearance.[2] Children on chronic therapy with hepatic enzyme–inducing antiepileptic drugs have shorter recovery times with the neuromuscular blocker rocuronium.[104]

Anticholinesterases

Anticholinesterases used in clinical anesthetic practice have not been reported to cause or stop seizures.

Anticholinergics

Atropine can reduce abnormal discharges of the EEGs of epileptic patients.[41] It can also block spontaneous and hyperventilation-induced petit mal seizures.[110] These effects are probably related to its central anticholinergic action.

Analgesia: Nonopiate Analgesics

Acetaminophen

Phenytoin facilitates the elimination of acetaminophen by accelerating its biotransformation,[88] and phenobarbital induces acetaminophen metabolism, which can result in an increase in toxic metabolites.[89] This may increase the risk of acetaminophen overdose.

Salicylates

Salicylates compete with phenytoin for plasma protein–binding sites. One study showed an increase from 10% to 16% in the unbound fraction of phenytoin. Changes were proportional to the acetylsalicylic dose, which ranged from 900 to 3,600 mg/d.[34] Although high and repeated doses may cause slight increase in free phenytoin and a decrease in total phenytoin level, there is usually no need to adjust the phenytoin dose.[87] An increase of the free fraction but not of the total valproate concentration can occur in patients

receiving 15 to 30 mg/kg of acetylsalicylic acid. This increase is not clinically significant in most cases.

Ibuprofen

Ibuprofen has not been reported to cause any significant interaction with anticonvulsants or to affect the seizure threshold.

Surgery and Recovery

Neurologists may be asked to provide clearance for an epilepsy patient to have surgery. A good history with particular emphasis on seizure types and frequency is important. History of status epilepticus should be sought because this may place the patient in a higher-risk group. Children with progressive neurologic dysfunction and epilepsy may have inborn errors of metabolism that place them at added risk for anesthesia and procedures. In particular, children with respiratory chain defects such as Leigh disease or other conditions that predispose to metabolic acidosis are at risk for sudden or delayed respiratory decompensation. This appears to be induced by anesthetic agents that interact with mitochondrial function.[30] We recently had experience with a pediatric patient with mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) who died during gastrostomy placement because of extreme fragility of her great vessels. Postmortem analysis revealed a large percentage of mutations in her vessels. Her mother had tragically died after minimal trauma to her vessels during a catheterization procedure.[108] Medication history including reactions, tolerance, side effects, and efficacy should also be obtained. Current medical problems requiring medications should be defined to anticipate possible interactions with habitual medications and anesthetics.

If the patient's epilepsy is in good control and there have been no recent medication changes, serum drug levels are unlikely to be clinically useful. In selected circumstances, it may be beneficial to check serum drug levels, but this need not be obligatory, and serum levels are of secondary importance to good seizure control and the absence of side effects.

Oral doses can be administered the morning of surgery with a small sip of water. Some antiepileptic drugs can be administered intravenously when surgical time exceeds the half-life of the maintenance antiepileptic drug. The decision to use an intravenous antiepileptic drug in patients maintained on antiepileptic drugs that only can be given orally depends on several factors, including degree of preoperative seizure control and the anticipated surgical time. Although intraoperative or postoperative seizures can occur in undiagnosed or undertreated epilepsy patients, it is rare, in our experience, to see substantial alterations in seizure control in well-planned circumstances.[36]

Serum drug levels may be significantly altered by anesthetics and the physiologic changes from surgery. These include antiepileptic drug distribution, enzyme saturation and competition, binding competition at the neuroreceptor level, carrier substances, pharmacokinetics, pharmacodynamics, and blood loss and volume changes. Carbamazepine level can increase up to twofold after surgery and returns back to normal in 7 to 10 days. Phenytoin level can also increase. Serum drug levels should be obtained after surgery to see this pattern. Clinical toxicity from an antiepileptic drug can cause a significant delay in postoperative recovery, and seizures may occur as a result of decrease in drug levels.[58]

Dental Procedures

Before a dental procedure is performed, drug levels should be obtained and adjusted based on the individual patient's history. Precipitating factors such as sleep deprivation or alcohol intake should be avoided before the procedure. The dental team should be informed about the patient's seizure type and first aid. The use of hospital-based dental programs for epilepsy patients can be helpful in patients with moderate to profound mental retardation or serious behavioral problems (31.1%) or if seizures are frequent and occurred during prior outpatient dental procedures.[49]

Methohexital was compared with local anesthetic in conservative dental procedures. Although only 1 seizure occurred among 200 patients, this drug had the additional disadvantages over local anesthetics of side effects that included tongue movements, coughing, hiccoughs, and prolonged lethargy after the procedure.[68] Seizures during or after a dental procedure can occur with nitrous oxide[36] or methohexital.[98] In these studies, seizures most often occur in undiagnosed epilepsy patients or those who missed a dose of their antiepileptic medications on the day of the dental procedure. Other studies demonstrate that nitrous oxide and propofol in subanesthetic doses for conscious sedation are safe for epilepsy patients with mental disabilities undergoing dental procedures.[80] Nitrous oxide and propofol are almost always safe in epilepsy patients who are adequately treated with antiepileptic drugs.

Summary and Conclusions

Proper history taking with attention to the seizure type and frequency as well as medication compliance and response is of basic importance. One priority of prescreening children with severe epilepsy is to exclude inborn errors of metabolism that may be exacerbated by anesthesia with tragic results. Other factors that may precipitate seizures must be identified. The health care provider should be able to identify different seizure types and understand principles of first aid for seizures. Antiepileptic drugs should be administered both before and after a procedure and adjusted individually (if needed) to minimize the risk of seizures or side effects. Drug interactions should be considered in adjusting maintenance doses.

Most general and local anesthetics have both pro- and anticonvulsant properties. Except for enflurane, which has been associated with a higher risk for seizures, all of the anesthetics in use may be administered safely to epilepsy patients if a proper approach to epilepsy patient care is made. The risk of seizures during or after a surgical or dental procedure is minimal when routine precautions and guidelines are followed.

Chapter 194

Hormone Changes in Epilepsy

Cynthia L. Harden

Cheryl A. Frye

Introduction

The relationship between hormones and seizures has long been recognized with the observation of prolactin elevation immediately following generalized seizures. Furthermore, this clinical phenomenon has been diagnostically useful. More recently, however, studies of the effects of seizures on endocrine function have largely focused on reproductive issues. The disruptive effects of seizures on reproductive endocrine functioning are not immediate, however, and appear to develop as a result of chronic dysregulation of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secondary to abnormalities in gonadotropin-releasing hormone (GnRH) from the hypothalamus. This chapter discusses evidence for effects of seizures on hormones and the clinical consequences of this relationship.

Effects of Epilepsy on Hormones in Animal Models

Stress-related Hormones

Stress produces an increase in circulating and brain concentrations of corticosteroids, most importantly cortisol and deoxyocorticosterone. Given that seizures themselves are stressful events, it is expected that stress hormones will increase with seizures. The hormones increased by stress have mixed proconvulsant and anticonvulsant effects. Both pregnenolone sulfate and dehydroepiandrosterone sulfate are increased by stress, and each has a proconvulsant effect in animal models. Deoxyocorticosterone is metabolized to allotetrahydrodeoxycorticosterone, however, which activates γ-aminobutyric acid A ($GABA_A$) receptors. Therefore, seizures may initiate the release of hormones that have mixed effects on brain excitability.[41] The $GABA_A$ receptors of hippocampal neurons in epileptic animals have diminished capacity for modulation by neuroactive steroids,[35] which supports the presence of an interaction between seizures and neurosteroid activity in the brain.

One hypothesis for the etiology of West syndrome and its accompanying infantile spasms is related to the presence of abundant corticotrophin-releasing hormone (CRH) receptors in the brain normally present at the critical infantile time period. Dysfunction of the brain's response to stress-induced CRH elevation triggers the syndrome and further explains the therapeutic response to a hormone that suppresses CRH production, adrenocorticotropic hormone (ACTH).[8]

Reproductive Hormones

Regulation of reproduction involves brain structures as part of a complex, multilocalized system termed the hypothalamic-pituitary-gonadal axis. A critical portion of the hypothalamic-pituitary-gonadal axis is the small and scattered population of GnRH-producing neurons within the diagonal band of Broca, the vasculosum of the lamina terminalis, and the preoptic area of the hypothalamus. When activated, these neurons secrete GnRH into the hypophyseal-portal vasculature, and this hormone then regulates the production and release of the two gonadotropins, LH and FSH. The synchronization and responsiveness of this hormonal system are essential for normal reproductive functioning.[15]

Seizures produce reproductive dysfunction in animal models of epilepsy, and these experiments provide further information about mechanisms of epilepsy-related reproductive dysfunction in humans. Kindling in the basolateral amygdala of intact rats produces reproductive alterations roughly analogous to polycystic ovary syndrome among women. Amygdala kindling disrupts ovarian cyclicity and produces cystic ovarian follicles, high E_2 levels, and increased pituitary weights.[13] The abnormalities in the target organs of the hypothalamic-pituitary-gonadal axis may be due to disruption of normal GnRH release in the hypothalamus due to seizure activity. The evidence for this is that GnRH fibers are reduced following pilocarpine-induced status epilepticus or focal application of kainic acid to the amygdala.[1,16] These findings suggest that temporal limbic structures, such as the hippocampus and the amygdala, that are involved in seizures alter reproductive function via the effects on gonadotropin secretion.

Effects of Epilepsy on Hormones in Humans

Acute Changes in Hormones Following Seizures: Prolactin, Follicle-stimulating Hormone, and Luteinizing Hormone

Further evidence for an effect of seizures on hypothalamic activity is the long-observed elevation in prolactin that occurs after generalized tonic–clonic seizures. Like that of LH and FSH, control of prolactin release from the pituitary is also under hypothalamic control. Acute changes following seizures include increases in prolactin for 20 minutes and serum LH (in women and men) and FSH (in women) for 60 minutes following generalized tonic–clonic seizures.[11,38,43] A recent, evidence-based report on the use of serum prolactin levels in diagnosing epileptic seizures recommended that an elevated prolactin within 10 to 20 minutes after a suspected event is a useful adjunct in differentiating generalized tonic–clonic or complex partial seizures in adults and older children from psychogenic nonepileptic seizures. Syncope may also elevate prolactin levels, however, limiting its diagnostic usefulness.[9] Furthermore, prolactin levels cannot be reliably used for this purpose in infants or in status epilepticus.[9]

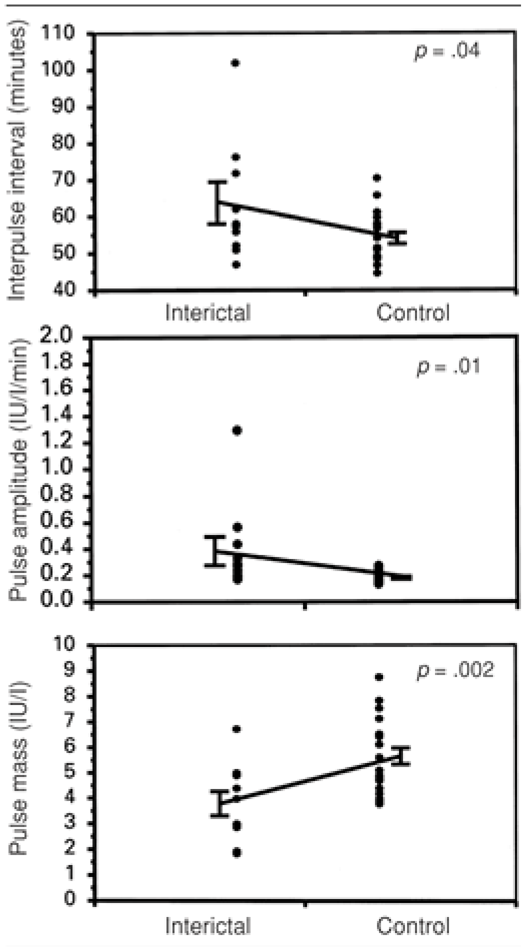

FIGURE 1. Scatterplot of luteinizing hormone interpulse interval, pulse amplitude, and pulse mass calculated from interictal epochs from men with mesial temporal lobe epilepsy compared with those of healthy controls. Error bars are equal to ± standard error of the mean, and *p* values are from Student's paired *t*-tests. (From Quigg M, Kiely JM, Shneker B, et al. Interictal and postictal alterations of pulsatile secretions of luteinizing hormone in temporal lobe epilepsy in men. *Ann Neurol*. 2002;51(5):559–566, with permission.)

Effects of Epilepsy on Luteinizing Hormone Pulsatility; a Possible Cause of Hypogonadotropic Hypogonadism

It is possible that the disruption in gonadotropin secretion produced by seizures, leading to a dysfunctional feedback system between reproductive hormones and LH and FSH secretion, is related to the increased incidence of reproductive endocrine disorders and infertility observed among those with epilepsy.[7] Epilepsy itself, incorporating the subclinical activity of interictal spikes, can also disrupt the finely tuned, pulsatile secretion of LH. It has been shown that LH secretion can be disrupted by interictal spikes in men and women (Fig. 1).[6,12,28,40] Recently, a differential effect of interictal and postictal effects on LH secretion in men with epilepsy was reported. The investigators reported that the circadian peak concentration of LH is delayed interictally compared to controls, and that burst amplitude is generally lower throughout the day. However, postictally, within 24 hours of a seizure, the peak concentrations of LH pulses were dispersed to a more random, rather than rhythmic pattern, with longer interburst interval.[39] These findings offer even more refinement of the evidence for a negative effect of seizures and epilepsy on reproductive functioning and indicate that this sensitive system can be easily disrupted, with clinical consequences.

The absent or decreased ability of the hypothalamus to secrete GnRH or of the pituitary gland to secrete LH and FSH leads to hypogonadotropic hypogonadism, which is a failure of gonadal function due to inadequate stimulation by LH and FSH. This syndrome, or at least partial features of it, has been reported in both men and women with epilepsy.[25,31,36] In one report, hypogonadotropic hypogonadism as defined by reduced gonadotropin release, loss of cyclicity, and/or infertility was present in 12% of women with temporal lobe epilepsy versus 1.5% in the general population.[25]

Polycystic Ovary Syndrome and Epilepsy

As an example of this dysfunctional feedback system, the incidence of polycystic ovary syndrome (PCOS), a form of hyperandrogenic chronic anovulation, which generates abnormal androgen levels and positive feedback at the level of the hypothalamus, ranges from 10% to 25% among women with temporal lobe epilepsy and from 4% to 6% in the general population.[25] One possible cause of this mysterious syndrome is thought to be centrally mediated as a result of abnormalities in LH and FSH stimulation of the ovary. This abnormal hormonal environment results in multiple immature ovarian follicles, which form cysts and secrete testosterone rather than estrogen, which is secreted from a matured follicle. Therefore, PCOS may also be a consequence of a dysregulated hypothalamic-pituitary-gonadal axis.

Although valproate has been associated with PCOS, it is unclear whether it causes, exacerbates, or imitates PCOS because it can elevate androgens in both men and women (see also Chapters 108 and 198). Valproate likely increases androgens, at least in part, by inhibition of aromatase, the enzyme involved in conversion of testosterone to estrogen.[19] In an evaluation of 93 women with focal epilepsy of long duration, PCOS (defined as elevated testosterone levels and oligomenorrhea or amenorrhea) occurred in 10.6%. No difference was found between women taking carbamazepine (n = 20; 10%), valproate (n = 18; 11.1%), or no antiepileptic drugs (AEDs) (n = 19; 10.5%).[4] This study confirms the finding that PCOS is present at a higher-than-expected rate in women with epilepsy, but it does not support a clear association with valproate use.

Epilepsy During Perimenopause and Menopause

During perimenopause, most women with epilepsy report seizure increase.[22] This may be due to an increased estradiol-to-progesterone (E_2/P_4) ratio, particularly at the beginning of perimenopause. At postmenopause, however, when E_2 and P_4 levels become very low and stable, women who had experienced a catamenial seizure pattern during their reproductive years in particular report decreased seizure frequency (Fig. 2).[22] This finding supports the presence of a subset of women with epilepsy who are sensitive to hormonal fluctuations both during reproductive years and after. Furthermore, women have reported increased seizures with hormone replacement therapy (HRT) during postmenopause,[22] and increased seizure frequency has been shown to occur with HRT using conjugated equine estrogens and medroxyprogesterone acetate in a double-blinded, placebo-controlled, randomized study of postmenopausal women with epilepsy.[20] This finding suggest that with this formulation of HRT, the brain milieu that was stable with low levels of reproductive hormones becomes sensitive to the seizure-promoting effects of estrogens.

Seizures and Age at Menopause

Table 1 Age at last menses in seizure frequency groups

Group	Mean ± SD age at last menses (yr)	95% CI
1, n = 15	49.9 ± 4.2	47.6–52.3

2, n = 25	47.7 ± 4.3	45.9–49.4
3, n = 28	46.7 ± 3.5	45.3–48.0

p = .042 (p = .037 between groups 1 and 3 using Bonferroni adjustment). CI, confidence interval; SD, standard deviation.
Groups 1 subjects had <20 seizures in their lifetime, group 2 subjects had >20 seizures in their lifetime but fewer than one seizures per month on average, and group 3 subjects averaged one or more seizures per month for most of their illness.
Source: From Harden CI, Koppel BS, Herzog AG, et al. Seizure frequently is associated with age at menopause in women with epilepsy. *Neurology*. 2003;61(4):451–455, with permission.

Women with epilepsy are at risk for early menopause,[21,23] and the timing of menopause may relate to seizure frequency

(Table 1). Women with frequent seizures report an age at menopause of 3 to 4 years earlier than expected, whereas women with rare seizures become menopausal at the expected age of 50 to 51 years.[21] This finding is another example of an adverse effect on the reproductive system by seizures and epilepsy, and it may be due to chronic abnormal LH pulsatility, although the exact mechanism is unclear.

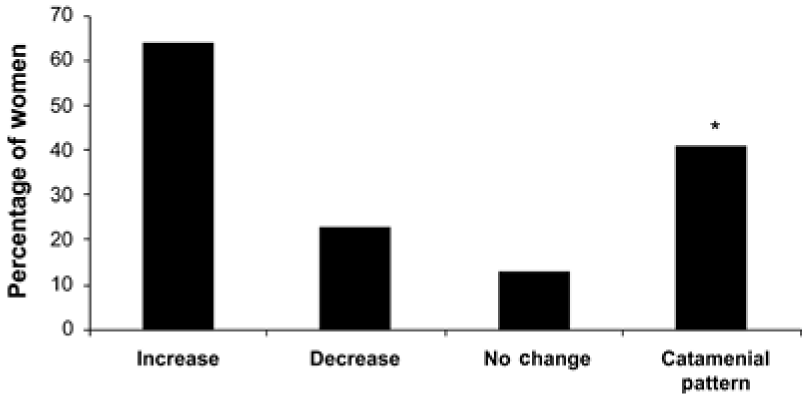

FIGURE 2. Seizure patterns in perimenopausal women with epilepsy. *Significantly associated with an increase in seizures (p = .02).

Effects of Epilepsy on Sexuality in Men and Women

It is noteworthy that men with epilepsy tend to have androgen deficiency more frequently and tend to have early and accelerated reductions in androgen levels compared to men without epilepsy.[26,31] Among men with epilepsy, the incidence of sexual dysfunction, hyposexuality, reduced potency, and/or infertility is reported to be as high as 70% and may be due to hypogonadotropic hypogonadism.[10,29,33] Although sexual dysfunction for persons with epilepsy is often evaluated in terms of an effect of antiseizure medications, it seems clear that an adverse effect of epilepsy itself is present, independent of treatment.[3]

A recent evaluation of the sexual development of a large group of adolescent males with epilepsy (n = 130) reported that sexual development was delayed and free testosterone levels and testosterone-to-LH ratios were lower compared to controls.[14] In this study, polytherapy was associated with greater deviation from expected development and hormonal profiles. This confirms the effects of AEDs and likely epilepsy on sexuality in males and indicates a longitudinal adverse effect of these reproductive alterations.

Women with epilepsy also frequently report decreased sexual desire. In one study, 20% of women with epilepsy reported almost never having sexual desire, whereas this low level of sexual desire was reported only rarely among healthy control women.[5] Sexual dysfunction in women with epilepsy has been associated with right-sided epileptiform discharges and low bioactive testosterone levels.[27] (For additional discussion, see Chapter 197.)

Catamenial Epilepsy

It is recognized that seizures of men and women show clustering patterns[42]; exacerbation or clustering of seizures in relationship to the menstrual cycle is termed catamenial epilepsy. Catamenial epilepsy is best defined as a twofold increase in average daily seizure frequency that typically occurs perimenstrually when estradiol and progestin levels decline, around ovulation when estradiol and progestin levels increase, or during an inadequate luteal phase. The twofold increase in seizure frequency as a cutoff point for catamenial versus noncatamenial seizure exacerbation was derived from evaluating monthly seizure patterns in a large number of women with epilepsy. The authors found that a daily seizure increase of 1.6 to 1.8 times during perimenstrual days, at ovulation, or during the luteal phase compared to other days in the menstrual cycle reliably distinguished between women with seizure exacerbations at those times and those without them.[30] These findings indicate that an approximately twofold increase in seizure frequency during these days of the menstrual cycle is an appropriate amount of seizure increase to constitute a catamenial seizure exacerbation.

In relating these patterns to hormonal changes, seizure exacerbations at ovulation occur when P_4 levels are low relative to E_2 concentrations,[30] as described previously. Indeed, Backström, who was the first systematically to examine the relationship between gonadal steroid levels and seizure frequency, demonstrated a positive correlation between generalized seizures and E_2/P_4 ratio and a negative correlation between seizures and P_4 level (i.e., as P_4 concentration increased, the number of seizures decreased).[2] Seizure exacerbations perimenstrually, which is the most frequently reported pattern of catamenial seizure increase, are thought to be related to P_4 withdrawal.[17,32,42] Ovulation, when the E_2/P_4 ratio is highest, is the second-most-frequent time of seizure exacerbation. The third-most-commonly reported pattern of catamenial seizure exacerbation is during the entire luteal phase, particularly when FSH secretion is inadequate and P_4 levels are low.[30]

Stress Hormones in Epilepsy

Patient's report that day-to-day stress can increase their vulnerability to seizures[24]; whether this is related to alterations

P.2040

in neurosteroids such as corticosteroids has not been ascertained. There are hints, however, that corticosteroids are related to epilepsy in important ways. In one series, women with epilepsy had higher cortisol levels than controls, and within the epilepsy group, women with frequent seizures in particular had high cortisol levels.[18] Furthermore, elevated basal cortisol prior to electroconvulsive shock therapy (ECT) has been associated with a greater decline in performance of executive function, visuospatial processing speed, and verbal memory after a standard course of ECT, suggesting that elevated glucocorticoids may increase the vulnerability of the brain to the adverse effects of repeated seizures.[37]

Summary and Conclusions

Stress-related Hormones

Corticosteroids have effects on brain excitability; however, the association between seizure occurrence or severity in persons with epilepsy and stress hormones requires further investigation.

Prolactin

Prolactin release following generalized tonic–clonic and complex partial seizures is further evidence of the hypothalamic involvement in these seizure types. This effect on hormones by seizure occurrence is so reliable that a prolactin level can be used to distinguish generalized tonic–clonic and complex partial seizures from psychogenic nonepileptic seizures in adolescents and adults. Caveats for the usefulness of a prolactin levels in this clinical situation are that it cannot be used to distinguish a seizure from syncope, reliably used for this purpose in infants, or used in status epilepticus.

Reproductive Endocrine Dysfunction

Seizures and interictal discharges are associated with abnormal FSL and LH secretion in men and women with epilepsy. This chronic effect of epilepsy-related effects on GnRH release and the secondary effect on gonadotropin release likely produces clinically significant but at times subtle effects on reproductive functioning over the long term. These effects include varying degrees of hypogonadotropic hypogonadism, polycystic ovary syndrome, anovulation, early onset of menopause, and a risk of sexual dysfunction in both genders as well as delayed sexual development in boys. The presence and occurrence of these reproductive abnormalities in persons with epilepsy should be monitored for and treated as they are recognized.

Chapter 195

Effects of Hormones on Seizure Expression

Torbjörn Bäckström

Introduction

Epilepsy is a complicated condition that may affect different areas of life. For example, fertility, family planning, and pregnancy are affected by epilepsy in part because of epilepsy-related alterations in hormones. Seizures and epilepsy also have effects on thyroid and adrenal hormones. Thyroid, adrenal, and sex steroid hormones affect the central nervous system (CNS), ultimately altering seizures and epilepsy. This chapter examines how endogenous and exogenous steroid hormones affect the CNS. Metabolites of the gonadal steroid progesterone and the adrenal steroid desoxycorticosterone seem to be of great importance for the hormonal effects on CNS excitability. They have all a similar chemical structure in being 3α-hydroxy-5α-pregnane steroids. The nomenclature of these substances is somewhat confusing because the same steroid can have several names. The progesterone metabolite 3α-hydroxy-5α-pregnane-20-one is also called allopregnanolone; in this chapter we use the abbreviation 3α5α-P. The 3α-hydroxy-5α-desoxycorticosterone is also called tetrahydrodesoxycorticosterone, for which THDOC is often used as an abbreviation.

Adrenocorticotropic Hormone Effect on Seizure Expression

Adrenocorticotropic Hormone

An anticonvulsant effect of adrenocorticotropic hormone (ACTH) in epileptic patients was first described by Klein and Livingston.[87] Subsequently, ACTH was shown to be an effective treatment for patients with infantile spasms,[144,146] cryptogenic epilepsy, and symptomatic seizures following organic brain lesions.[118] Natural ACTH has fewer side effects than glucocorticoid hormones[144] and does not induce seizures.[86] Long-term glucocorticoid treatment, however, inhibits the activity of hypothalamic–pituitary–adrenal axis, which is a serious side effect. ACTH levels may be low in adult patients with epilepsy treated with antiepileptic drugs (AEDs), suggesting dysfunction of the adrenocortical axis.[49,118,122,132,145] In 27 men and women with epilepsy, the mean serum ACTH level was lower than that in a control group, and this reduction was most pronounced in those with more severe epilepsy of longer duration.[122] An ACTH level was evaluated in ten children before and after 6 months of therapy with valproic acid. Before treatment, ACTH values were normal, but they decreased significantly with treatment.[78] Seizures may also alter ACTH release. A significant increase in ACTH occurred in ten patients within 60 minutes of a generalized tonic–clonic seizure.[53] This elevation of ACTH suggests that the hypothalamic–pituitary–adrenal cortex axis may be affected by generalized seizures.

Corticosteroids

Adrenal cortical hormones exert regulatory effects on central nervous system (CNS) excitability.[174] There is a significant increase in serum cortisol level in patients after generalized tonic–clonic seizures. In the rat's brain, concentrations of neuroactive steroids increase with stress.[140] Changes in cortisol levels may respond to physiologic stress associated with seizures.[1] In a group of 45 men with epilepsy not treated with AEDs, cortisol levels were lower than in a control group.[132] After AED treatment, levels decreased further, suggesting that AEDs influence adrenal cortex function.[132] Further studies should evaluate the way in which alterations in the hypothalamic–pituitary–adrenal cortex axis are related to epilepsy or AEDs.

A relationship between adrenocortical steroids and seizures was found in several experimental and some clinical studies.[66,141] Both mineralocorticoids and glucocorticoids alter neural activity,[80] and the adrenal produces both pro- and anticonvulsant steroids[125] (see later discussion). Aird and Gordon[2] as early as 1951 showed that desoxycorticosterone has an anticonvulsant effect in patients with epilepsy. THDOC, a metabolite of desoxycorticosterone, is a potent γ-aminobutyric acid A ($GABA_A$)–receptor agonist with nearly the same inhibitory effects as 3α5α-P (see later discussion).[90,134,160] Although cortisol on its own increases brain excitability and decreases chloride flux through the $GABA_A$ receptor, when it is used together with 3α5α-P and THDOC the effect changes, and cortisol enhances the GABA agonistic effect of 3α5α-P and increases neural inhibition.[160,169] The classic hormonal mineralocortico- and glucocorticoid receptors are present in the brain, and their expression has effects on neural activity in the regions in which they are located, as in the hippocampus.[80] Several mechanisms are therefore likely to operate in parallel, but one can assume that rapid effects within minutes are mediated via the membrane-bound receptors whereas slower effects are via the classical hormonal receptors. More information is also needed regarding the direct role of adrenocortical hormones in seizure expression in patients with epilepsy.

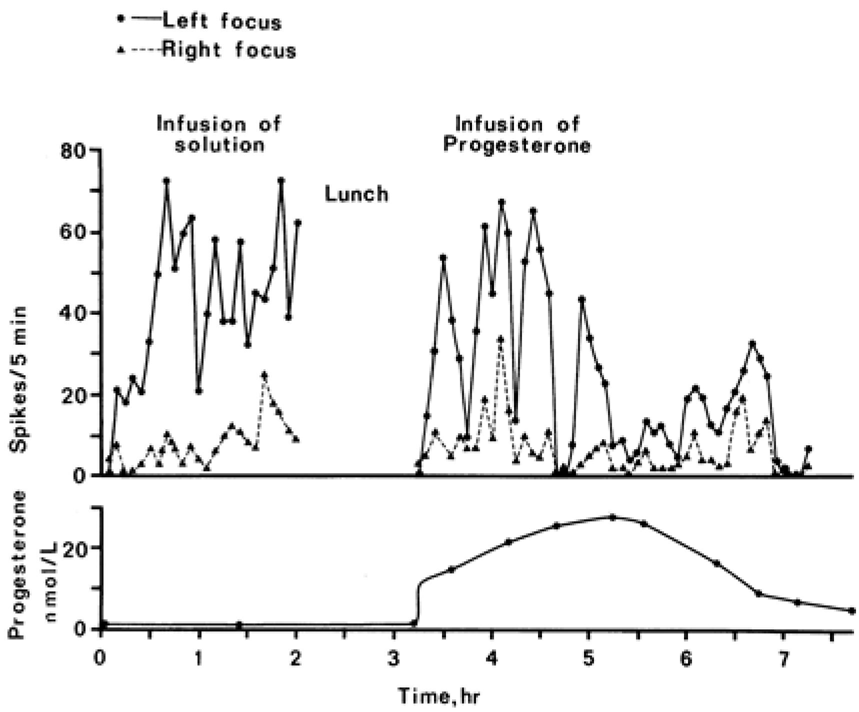

FIGURE 1. The effect of progesterone infusion in a patient with partial epilepsy. A continuous electroencephalogram recording was made to count the epileptic discharges. Effects of continuous progesterone infusion on the epileptic discharge frequency in women with partial epilepsy. *Acta Neurol Scand.* 1984;69:240–248; with permission.)

Sex Hormones

Experimental Data on Excitability

Estradiol decreases the electroshock seizure threshold in rats in a dose-dependent mode.[176] In humans, estrogen activates epileptiform electroencephalogram (EEG) discharges. Increased spike frequency occurred in 11 of 14 women with partial epilepsy given an intravenous (IV) injection of 40 mg of the estrogen Premarin. Generalized tonic–clonic seizures were

P.2044

provoked within 15 minutes in 4 of the patients.[102] An epileptic focus with 3/s spike-and-wave activity can be induced by applying estrogen directly on the cerebral cortex.[111] The convulsive estrogen effect is not consistent, however, and pretreatment with estrogen was neuroprotective against *N*-methyl-D-aspartate (NMDA)–induced seizures in female ovariectomized rats and did not affect any of the seizure parameters measured in the male rats.[82]

In contrast, progesterone in large doses induces anesthesia in humans[116] and animals,[58] increases the electroshock seizure threshold in animals, and protects against metrazol-induced seizures.[158] In oophorectomized cats, progesterone at plasma levels equivalent to those of pregnancy significantly decreased the frequency of interictal spikes from penicillin foci.[95] Progesterone at plasma levels similar to the luteal phase of the menstrual cycle significantly reduced interictal spike frequency in four of seven women with partial epilepsy. The women with low plasma protein binding progesterone showed the best response with the progesterone infusion, whereas women with the highest plasma protein binding did not respond.[15]

Progesterone metabolites that are reduced in the 5 position of the steroid molecule are very potent in their central nervous system (CNS)–depressant action, particularly those steroids with a 3α-hydroxy-5-reduced molecule.[47] The antiepileptic effects of progesterone are mediated by these metabolites.[119,142] In a rat model 3α5α-P is about eight times more potent, on a weight basis, in its anesthetic action than the most potent barbiturate known, methohexital.[129] The 5α derivative of the preceding steroid seems to be somewhat more potent than the 5β derivative.[129] In oophorectomized cats with a penicillin-induced epileptic focus, 3α5α-P is more potent in inhibiting epileptic activity than clonazepam.[94] 5β-Pregnenolone also acts as an anesthetic.[35]

In conclusion, estradiol increases brain excitability, whereas progesterone and some of its 5-reduced metabolites have potent inhibitory effects (Fig. 1). Wooley and Timiras[175,176] showed an estrus cycle–dependent variation in electroshock seizure threshold, and other studies have shown an estrus cycle variation and male versus female difference in pentylenetetrazol seizure threshold.[88] Interestingly, cycle-related changes and gender differences are described only for experimental models of epilepsy that use convulsant drugs specific for the $GABA_A$ receptor complex (GRC).[75] In rats, sensitivity at the GRC also varies over the estrus cycle.[48]

Mechanisms Within the Brain

The classic target organ mechanism of steroid hormone action is via binding to an intracellular cytosol receptor, activating the genome for transcription and protein synthesis. Genome effects take at least 5 to 15 minutes, with some effects requiring hours to days.[137] Steroid hormone effects on sexual behavior are probably medicated via this nuclear mechanism of action.[137] Other possible CNS mechanisms of action of steroid hormones and their metabolites are by direct effects on neural membrane-bound receptors. Membrane effects are very rapid, occurring within a fraction of a second.[7,137]

The rapid antiepileptic effect is demonstrated with injections of 3α5α-P into the carotid artery of oophorectomized cats with an epileptic focus; epileptic spikes were instantaneously inhibited when the steroid solution reached the brain.[94] These steroid effects are too rapid to be mediated via genomic activation and protein synthesis and represent direct effects on neural membrane-bound receptors. In electrophysiologic studies, responses to the excitatory amino acids quisqualate and NMDA were augmented by estradiol.[89,155] Chronic treatment with estradiol may also sensitize the quisqualate system.[155]

3α5α-P acts as a receptor agonist at the $GABA_A$ receptor complex in the brain,[52,109,110] similar to the action of benzodiazepines and barbiturates and some of the effects of alcohol. In mice, 3α5α-P inhibits convulsions induced by a number of convulsive substances acting at that GRC such as metrazol, (+)bicuculline, and picrotoxin but has no effect against maximal electroshock- and strychnine-induced seizures.[21] These rapid actions of 3α5α-P are mediated via actions on the GRC-chloride ionophore complex.[52] Progesterone metabolite effects on the GRC might mediate changes in seizure frequency over the luteal phase of the menstrual cycle. Metabolites of the

P.2045

adrenocortical steroid THDOC have similar effects on the $GABA_A$ receptor.[90]

Accumulating evidence suggests that the neuroactive steroids are very similar to benzodiazepines also in their acute side effects and long-term actions. 3α5α-P induces sedation in humans and inhibition of learning when given IV to rats in the Morris water maze.[81,161] Acute tolerance develops already after 90 minutes of 3α5α-P anesthesia.[179] Increased seizure frequency and decreased seizure threshold occur at 3α5α-P withdrawal.[143] At the molecular level, sustained high levels of neuroactive steroids reduce $GABA_A$ receptor responsiveness.[38,177] 3α5α-P effects in hippocampus vary between CA1 and dentate gyrus and change between different phases of the rat estrus cycle, indicating that a large diversity of effects and mechanisms can be expected.[96]

Another possible CNS mechanism of action of steroid hormones is by direct effects on monoamine turnover, metabolism, and receptors. Monoamines contribute to affective status and sexual behavior.[45] Monoamine oxidase (MAO) and catechol-*o*-methyl transferase (COMT) in the rat brain are decreased by estradiol and increased by progesterone.[32,75] In regularly menstruating women, platelet MAO, serotonin binding, and transport activity change during the cycle.[22,173] Platelet MAO is considered the best peripheral reflection of brain MAO activity. In certain discrete regions of the hypothalamus of the diestrus rat, noradrenaline and dopamine turnover correlate with plasma estradiol and progesterone levels.[100,101] Serotonin receptor expression changes in several brain areas during estrogen and estrogen plus progesterone treatments.[25] Estradiol given to oophorectomized rats increases the turnover rate of dopamine in the hypothalamus,[50] whereas progesterone increases serotonin turnover in limbic structures.[92] Estrogen also alters dopamine turnover in the striatum, increasing dopamine receptor sensitivity there.[76] The consequences of these effects on neurotransmission in relation to epilepsy are difficult to interpret.

Peripheral Neurosteroid Production

Estradiol and progesterone changes during the menstrual cycle and pregnancy are well described. Estradiol concentration increases tenfold from menstruation to ovulation. Progesterone increases 20 times from the follicular to the luteal phase. During menstruation, steroid hormones are at their lowest level. Both in humans and rats, 5α-reduced progesterone metabolites such as 5α-pregnane-3,20-dione (5-DHP) and 3α5α-P are produced peripherally and fluctuate in plasma and ovarian tissue in parallel with progesterone. In humans, 5α-DHP and 3α5α-P increase during the luteal phase of the menstrual cycle.[74,77,167] 3α5α-P and 5α-DHP are produced by the corpus luteum.[8,133,139] During pregnancy, 3α5α-P and 5α-DHP increase about ten times and achieve about one third of the plasma concentration of progesterone.[99,105] The concentration in fetal blood is about ten times that in maternal blood.[99] Enzymes necessary for 5-reduction of progesterone are in the CNS.[84] Brain concentrations of 5α-DHP in progesterone-induced anesthesia are much higher than those in plasma, indicating that progesterone is metabolized to 5α-reduced steroids within the brain.[27] During stress and diurnal variation 3α5α-P and THDOC are produced from adrenal cortex with a short delay after glucocorticoids in both animals and humans.[20,43,140]

In plasma, estradiol is largely bound to transport proteins, sex-hormone–binding globulin (SHBG), and albumin, and only a small fraction (1%-3%) is unbound.[157] Progesterone is bound to transcortin and albumin and about 10% is unbound.[10,171] The 5α-reduced progesterone metabolites bind to albumin with low affinity.[171] The unbound fraction exerts the normal effects in peripheral organs.

Steroid Distribution and Metabolism in the Central Nervous System

Estradiol[114,135,136] and progesterone[5,28] accumulate in specific brain regions in both rats and rhesus monkeys. The classic hormone-specific intracellular receptors have been identified in these regions[104,137] and fulfill all the criteria for classic steroid target organs.[114] The distribution of the estrogen alpha-receptor is different from that of the estrogen beta-receptor.[131] The estradiol concentrations vary with the phase of the menstrual cycle in humans and the estrus phase in female rats.[28,29] In addition, the progesterone CNS concentrations vary with ovarian steroid production. In rats the progesterone concentration in cerebral cortex is about 300 times higher during times of high ovarian progesterone production than during times of low ovarian production, whereas in hypothalamus the increase is 8 times and in plasma it is 12 times.[28] In humans the progesterone and 3α5α-P concentrations are also related to ovarian production and vary among CNS areas.[26] There is a significant correlation between the plasma and cortex, striatum, and cerebellum concentrations of progesterone, but not between the hypothalamus and plasma concentrations.[28,180] This raises the possibility that there are different mechanisms for progesterone accumulation depending on CNS area in the rat. In rhesus monkeys 60% of the luteal ovarian progesterone production is taken up by the brain.[24]

The synthesis and metabolism of progesterone in rat brain have been studied in vivo and in vitro. Progesterone is metabolized to 5α-DHP and further to 3α5α-P. This is the substance active on the $GABA_A$ receptor. The 3α5α-P is further 20α-reduced, and this diminishes the action on the $GABA_A$ receptor (for reviews see refs. 84 and 115). In the primate hypothalamus, progesterone is metabolized to 3α5α-P and 20α-hydroxypregnane-4-one-3-one.[23] The enzyme 5α-reductase is required for the synthesis of the progesterone metabolite 3α5α-P, and it is found in several areas of the mouse brain[152] and in the human fetal brain.[153] Neurosteriodogenesis seems to be important in the developing brain, and disorders of the developing brain are related to disturbed neurosteroid synthesis. This is perhaps not surprising, given that neurosteroid concentrations in fetal blood are very high.[55,72,99] Other steroids with $GABA_A$-receptor antagonist properties, such as pregnenolone sulfate, are also produced in the brain.[109]

Androgens are metabolized to estrogen in the brain of many species, including rats, monkeys, and humans. The aromatization takes place in the hypothalamus and limbic system and is more active in males than in females (for reviews see refs. 108 and 126). Major metabolic routes for estradiol in the brain involve 2- and 4-hydroxylation, forming the catechol estrogen. This metabolism is most active in the pituitary and hypothalamus in female rats (for reviews see refs. 18 and 126).

Central Nervous System Effects of Synthetic Steroids

Synthetic progesterone steroids, such as those contained in contraceptives, may not have the same effects as endogenous progesterone but they are all metabolized in the same way to 3α5α-steroids and are thus potentially active on the $GABA_A$ receptor. 3α5α-P is 20 times more potent than progesterone in reducing epileptic discharges from a cortical focus,[94] but medroxyprogesterone, a synthetic progesterone, is only one half as potent as progesterone in times of CNS inhibition, and levonorgestrel exerts no inhibitory effect.[117] That may be one reason that contraceptives do not significantly alter seizure frequency.

P.2046

Estradiol, ethinylestradiol, and norethisterone have an excitatory effect on the CNS.[117,155]

Clinical Changes Across Reproductive Life

Puberty

At puberty there is a rapid and significant increase in pituitary gonadotropins, and gonadal steroids appear both in boys and girls. The female cyclical pattern of hypothalamic–pituitary–gonadal hormone release is established 2 years after menarche. In boys the hormonal production is steadier, and increases until the end of the teens. This period of hormonal change may coincide with seizure onset and influence existing epilepsy. A tendency for epilepsy to begin with puberty was first reported by Gowers[54] in 1893 and later by Turner in 1907[166] as well as by other authors.[103,181] Lennox and Lennox[98] found a relationship between first seizure and menarche in 25% of 387 women with epilepsy onset between the ages of 8 and 20 years. In a smaller group of 47 patients whose first seizure occurred during puberty (between 11 and 15 years of age), 60% had their first seizure within 6 months of menarche, 23% within 1 year, and 17% within 2 years. In this study age at menarche was not different from that of the general population (12.8 years). Another study found an association between delayed adolescence and late-onset epilepsy.[147] Other studies find that generalized tonic–clonic and partial seizures with and without generalization may occur at puberty.[63,91] Idiopathic generalized epilepsies and juvenile myoclonic epilepsy are common forms with adolescent onset.[172] However, some types of epilepsy, such as benign epilepsy with rolandic spikes, improve at puberty and may even disappear.[31,121] Adult women with catamenial seizures may be more likely to have experienced epilepsy onset during puberty.[102]

Increased seizure frequency, seizure recurrence, a change in seizure type, and even an improvement in seizure control may occur during puberty in girls.[40,51,91,103] Of 113 girls whose epilepsy began at an average age of 5 years, two thirds showed a change in their epilepsy at puberty.[40] In studies by Rosciszewska et al.,[151] two thirds of the girls had increased seizure frequency or a new type occurred; in one third the seizure frequency decreased or seizures remitted. Epilepsy was more likely to worsen in girls with generalized tonic–clonic seizures. In contrast, absence seizures rarely increased and sometimes disappeared, and there was no increase in complex partial seizures. Exacerbation of epilepsy was more likely to occur in girls whose seizure onset was at a younger age, who had a known etiology, neurologic or psychological abnormalities, EEG abnormalities, and a late menarche.[151] One retrospective study showed that changes in seizures during puberty were not related to antiepileptic drug (AED) treatment,[40] although another study found that increased severity of epilepsy was associated with suboptimal AED levels.[128] In many cases, however, a return to peripubertal seizure frequency has been observed later in life.[146]

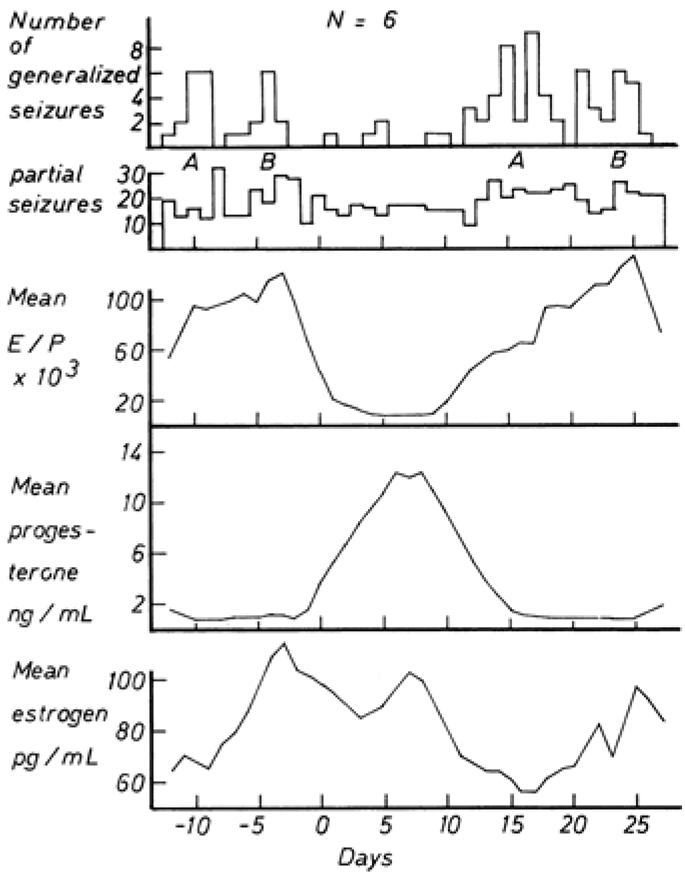

FIGURE 2. Seizure number and hormone concentrations in six women with partial epilepsy. The data are centered around the day of ovulation (day 0). A, peak of seizures during menstruation; B, peak of seizures during the preovulatory estrogen peak; E, estradiol; P, progesterone. Notice the low seizure frequency during the luteal phase. (Reprinted from Backstrom T. Epileptic seizures in women in relation to variations of plasma estrogen and progesterone during the menstrual cycle. *Acta Neurol Scand.* 1976;54:321–347; with permission.)

Menstrual Cycle Linkages

Several clinical studies show that seizure frequency changes at different phases in the menstrual cycle in a subset of women with partial epilepsy.[6,41,64,93,112,149] Discrepancies in the literature regarding the frequency of catamenial seizures may be due to the varied methodologies used to evaluate this relationship, such as using different methods for counting days of the menstrual cycle, lack of hormonal measurements to confirm cycle status, and not defining epilepsy type and severity.[127] The older literature reports large observational studies made at a time when the antiepileptic treatments were not as advanced as they are now, and perhaps it better shows the natural course. Laidlaw[93] found an increase in seizure frequency during menstruation. Almquist[3] found almost no evidence of any such relationship, whereas others describe catamenial seizures in 10% to 72% of women with epilepsy.[41,93] In a prospective study, Rosciszewska observed 69 women for 4 years and found that 63% experienced an increase in seizure frequency 2 days before or during the first day of menstruation. The distribution of 6,900 seizures during 1,237 menstrual cycles is shown in FIGURE 2.[149] In a few women, seizures occurred only during the days immediately preceding menstruation or during menstrual flow. Of 226 female epileptic patients, seizures occurred with menstruation exclusively in only 4 cases.[147]

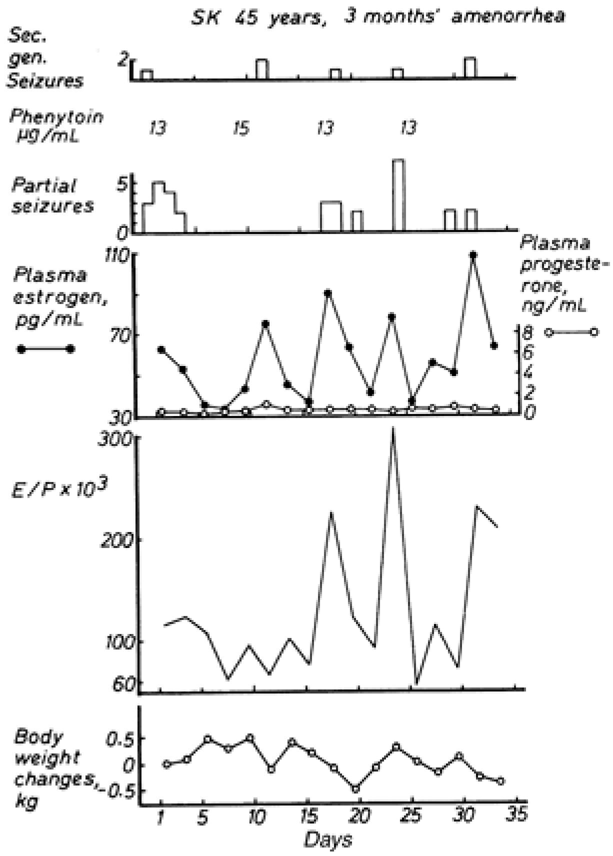

FIGURE 3. Seizure frequency in a patient with estradiol (E) peaks but with a low and constant progesterone (P) concentration. Notice the close connection between estradiol peaks and seizures. Sec. gen., secondary generalized. (Reprinted from Backstrom T. Epileptic seizures in women in relation to variations of plasma estrogen and progesterone during the menstrual cycle. *Acta Neurol Scand.* 1976;54:321–347; with permission.)

Herzog et al. identified three types of menstrual cycle–linked increase in seizure frequency in prospective seizure recordings in 184 women with intractable complex partial seizures.[71] In 87 women who recorded seizures and menses during three cycles, the average daily seizure frequency was significantly greater during the perimenstrual and preovulatory phases. Overall, 39.1% of the women showed catamenial epilepsy.[70] In ovulatory cycles, the most common pattern was an increase during menstruation shortly after the rapid decrease of progesterone and 3α5α-P from the corpus luteum. A second peak in seizure frequency occurred during ovulation when estradiol secretion is high but 3α5α-P is low. These data fit nicely to those from

P.2047

a smaller prospective study of women with partial seizures, in which a relationship between seizure and hormonal variations during the menstrual cycle was noted (Fig. 3). The total number of generalized seizures increased at two time periods. The first occurred shortly after the rapid decrease of progesterone in the first several days of menstrual flow. The second seizure peak occurred during the preovulatory estrogen surge. During high-progesterone phases of the cycle, the number of generalized seizures was very low.[6] In a study by Rosciszewska, repeated EEG recordings during the menstrual cycle were evaluated in 41 women with mainly tonic–clonic seizures. A significant increase in paroxysmal discharges occurred on premenstrual days in 24 patients who had catamenial exacerbation of seizures. In 17 women without catamenial seizure patterns, the highest frequency of paroxysmal discharges was found on days close to ovulation. In both groups the discharges were least frequent on days 6 to 22 of the menstrual cycle.[56] Others have also noted changes in EEG with menstrual cycle.[73]

In patients with anovulatory cycles, estrogen peaks were associated with increased seizure frequency,[6] consistent with estrogen's activating effect. In Herzog et al.'s study, 1,523 seizures were recorded during 86 anovulatory cycles. The cycles were divided into four phases, and results showed a lower seizure frequency during the phase when low estradiol levels are expected compared to phases when higher estradiol levels are expected.[71] In a prospective study with daily recording of seizures in 87 patients, 39.1% of the women had catamenial epilepsy.[70] Results supporting an excitatory effect by estrogen also in humans were found by Logothetis et al.,[102] who provoked seizures with estrogen injections in women with epilepsy.

Decreased frequency of generalized seizures during the luteal phase of the menstrual cycle is most probably due to the CNS effects of progesterone metabolites, such as 3α5α-P, that reduce seizure susceptibility by enhancing $GABA_A$-receptor function and thereby inhibit neuronal excitability.[142] Increased seizures during menstruation could be caused by a rebound effect after a rapid decrease in progesterone or other antiepileptic factors premenstrually, similar to the seizure exacerbations that may occur when antiepileptic drugs are discontinued abruptly.[120] Although one study found that a premenstrual decrease in phenytoin concentrations coincided with an increase in seizure frequency,[150] changes in AED pharmacokinetics cannot explain menstruation-associated seizure cycles.[11] Further indications that the antiepileptic factor is progesterone or its metabolites comes from open studies to be discussed later.

Different types of epilepsy show different cyclical patterns of seizures. In the studies discussed earlier, the patients had partial and secondary generalized seizures. With absence seizures, patients seem to have a different pattern of seizure distribution during the menstrual cycle. Repeated 24-hour EEG recordings and hormonal analysis over one menstrual cycle in patients with absence epilepsy showed that highest seizure frequency occurred during the luteal phase when progesterone and 3α5α-P are high, with a peak during the last five premenstrual days. Seizure frequency decreased rapidly after onset of menstrual bleeding.[9] Similarly, primary generalized tonic–clonic seizures are also more frequent during the premenstrual period than in the rest of the cycle.[149] This seizure pattern is very similar to the menstrual cycle–associated pattern of mood changes in patients with premenstrual dysphoric disorder (PMDD) and premenstrual syndrome (PMS).[12] Progesterone given to women has been shown to exacerbate absence seizures.[57] In animal models of absence seizures both ganaxolone and 3α5α-P exacerbate the seizures.[19,156] Furthermore, in a genetic model of absence epilepsy 3α5α-P increases spike-wave discharges.[34]

Premenstrual syndrome coexisted in 84% of women with catamenial seizures but in only 22% of women with no catamenial exacerbation.[149] Therefore menstruation-associated seizure cycles may be associated with PMS. Progesterone and medroxyprogesterone given to postmenopausal women induces symptoms similar to those in PMDD and PMS. The symptom severity shows an inverted U-shaped relation to the progesterone dose and 3α5α-P concentration in serum.[4,30] All these data indicate that in certain conditions and under certain situations, neuroactive steroids like 3α5α-P acting on the $GABA_A$ receptor are seizure inducing and anxiogenic.[130] Psychological symptoms in patients with PMDD are effectively treated by inhibiting ovulation with a gonadotropin-releasing hormone (GnRH) agonist[60] or with selective serotonin-reuptake inhibitor (SSRI) preparations also in a sequential way only during the luteal phase.[42]

Menopause

Changes in the neuroendocrine system during menopause may influence epilepsy. Early observations suggested that menopause had no influence on epilepsy,[159,166] but other studies report an exacerbation in seizure frequency,[123] seizure recurrence,[51] or first seizures occurring with menopause.[33,147] An improvement after menopause was observed by Zara et al.[178] They reported that 27 of 29 patients experienced a decrease in seizure frequency. In another study of 41 women with epilepsy, 12 improved and 8 experienced an exacerbation.[148] Improvement was more likely if the seizures had started late in life, if they were well controlled, when the age of menopause did not deviate from that in the general population, and when the climacteric symptoms were mild or absent.[61,148]

P.2048

Little is known about the effects of postmenopausal hormone therapy (HT). Logothetis et al.[102] reported seizure recurrence in a postmenopausal woman who was treated with unopposed estrogens. Seizures improved after the introduction of combined estrogen–progestagen treatment. Harden et al. reported that increase in seizure frequency is associated with estrogen-containing hormone therapy in postmenopausal women with epilepsy.[62]

Hormones and Epilepsy in Men

Androgens raise the seizure threshold in some experimental models of epilepsy.[163,170] Some testosterone 3α-hydroxy-5α/β-reduced metabolites are rather potent $GABA_A$-receptor agonists.[83] The production of the precursors and the 3α5α androgens occurs in the testis, but peripheral and CNS metabolism from testosterone is substantial.[115] The secretion of testosterone and thus also that of the metabolites from testis vary with season, age, and physical activity and decrease substantially on stress.[17,36,44] This indicates that also in men, variation in hormone concentrations can change seizure thresholds. Especially rapid withdrawal of the androgen metabolites, such as after acute stress, might provoke seizures, and this can interact with the effects of adrenal hormones (see earlier discussion).

Men with epilepsy may have low levels of free testosterone despite high concentrations of total testosterone[79,163] because of AED-induced increased concentrations of sex hormone–binding globulin (SHBG).[13,157] In men not treated with AEDs, testosterone concentration is similar to that in normal controls.[71] There are only a few studies that describe a relationship between testosterone therapy and course of epilepsy. In most investigations testosterone was given because of decreased libido.[71,163] Badalian et al.[16] reported that testosterone reduced seizure frequency by 50% to 70% in 8 of 15 men and improved the EEG. However, Herzog[66] found no significant effect in 12 male epileptic patients treated with intramuscular injections of testosterone enanthate, 200 to 400 mg every 3 to 4 weeks, although serum-free testosterone levels were normalized. From a clinical point of view there are some differences in epilepsy in female and male patients. Hormones play a more significant role in epilepsy in women. In men there is no obvious cyclical exacerbation in seizure frequency connected with hormone fluctuation. There are also suggestions that gender-related differences in drug responses, including anticonvulsants, may be due to hormones.[69,162]

Future Issues

Neurosteroids in Epilepsy Treatment

Natural and synthetic progesterone have been used to treat seizures, although so far only in open studies.[39,59,65,181] Mattson et al.[113] described a beneficial effect of medroxyprogesterone (Depo-Provera) as adjunctive therapy to AEDs in 7 of 11 women with epilepsy. The treatment was most effective in patients who became amenorrheic. We have also found that Depo-Provera treatment for patients with catamenial partial epilepsy has a beneficial effect on seizure frequency (Bäckström, unpublished data). In our experience, seizure frequency is less likely to be reduced in patients with persistent fluctuations in estrogen levels than in those with amenorrhea. Depo-Provera inhibits ovulation, and in higher doses it inhibits estradiol production. Depo-Provera has an additional benefit of acting as a contraceptive. This treatment may not be effective for patients with absence epilepsy. The usual dose of intramuscular medroxyprogesterone is 150 mg at intervals of 1 to 2 months to induce amenorrhea. The clearance of the medication is long, up to 1/2 to 1 year after last injection. Common side effects are increased appetite, weight gain, and irregular menstrual bleeding. A lifelong treatment can reduce mineralization in bone. Medroxyprogesterone is weaker, however, in its CNS action than progesterone (see earlier discussion). Oral medroxyprogesterone or norethisterone exerted no antiepileptic effects in open studies.[39,68]

Natural progesterone supplied in suppository form also had a beneficial effect in 6 of 8 women with complex partial seizures and an inadequate luteal phase.[65] Average monthly seizure frequency decreased 68%. In 23 of 34 epileptic women treated with synthetic progesterone, a decrease was noted both in tonic–clonic seizure frequency (an average of 62%) and in complex partial seizures (an average of 70%). In 8 women there was no improvement, and in 3 women seizure frequency increased during the time period examined (average 14 months).[46] In an open study with progesterone, 18 of 25 women (72%) experienced a decline in seizure frequency during a 3-month treatment period compared with the 3 months prior to therapy.[67] After a 3-year treatment period with cyclic natural progesterone, 200 mg three times daily, in 15 of 25 patients complex partial seizures decreased by 62% and secondary generalized seizures by an average of 74% compared to baseline.[68] The effect of intravenous progesterone infusion on epileptic discharge spike frequency was studied in 7 women with partial epilepsy. A significant decrease in spike frequency was shown in 4 of them, an effect related to the concentration of plasma progesterone.[15] None of the preceding studies was randomized and placebo controlled, so it is difficult to confirm the clinical value of such treatments.

Because of their enhanced potency, 3α5α-P metabolites of progesterone may be more suitable for use as antiepileptic therapy. One 3α5α-P metabolite (in the form of the anesthetic Althesin) has been used to successfully treat drug-resistant status epilepticus.[124] Eight of 11 patients with status epilepticus resistant to barbiturates and benzodiazepines were successfully treated with 3α5α-P derivative.[124] The 3α5α-P derivative also decreased intracranial pressure[165] and reduced oxygen consumption in the gray matter by 40%.[138]

In addition, one controlled study used the more potent orally active 3α5α-P–like substance ganaxolone and showed that this might be a new way of treating epilepsy.[37] Fifty-two eligible patients were randomized to receive ganaxolone (24 patients) or placebo (28 patients) for up to 8 days in a double-blind presurgical trial design. Ganaxolone monotherapy was well tolerated, and the results provided preliminary evidence that ganaxolone does have antiepileptic activity.[97] Ganaxolone has also been used to treat intractable infantile spasms in a multicenter, open-label, add-on trial with beneficial results.[85]

There are concerns, however, related to long-term use of progesterone/3α5α-P treatments. The neuroactive steroids act as agonists to the $GABA_A$ receptor, and accumulating evidence indicates that they have similar short-term and long-term side effects to all other $GABA_A$-receptor agonists. Patients develop tolerance and withdrawal symptoms.[143,179] The $GABA_A$-agonistic neurosteroids impair memory function and learning,[81] and long-term treatment with medroxyprogesterone in postmenopausal hormone treatment increases the frequency of dementia, mainly of Alzheimer type, compared to placebo.[154] In addition, several women experienced negative mood during treatment with progesterone, and the severity was related to the plasma concentration of 3α5α-P.[4]

This suggests that the neurosteroids might not be as useful in epilepsy treatment as has been hoped. Instead, antagonists to the agonistic neurosteroids may be useful to inhibit the tolerance and withdrawal that occur after cessation of endogenous 3α5α-P production. During the luteal phase or during a longer

P.2049

period of stress, endogenous 3α5α-P is produced in such high amounts that a rebound occurs at withdrawal. If the effect causing the rebound at withdrawal could be blocked with an antagonist, such a substance may be used as a therapeutic agent. Such antagonists exist and are used in animal experiments to block negative effects of 3α5α-P.[14,106,164,168]

Summmary and Conclusions

Many studies using experimental models of epilepsy have shown that steroid hormones have strong effects on CNS excitability. In light of current knowledge, it seems that gonadal steroid hormones play a significant role in seizure expression. Given the endocrine influences on epilepsy in women throughout the lifetime, it is surprising that there are so few randomized, controlled studies concerning the use of agonistic neurosteroids in epilepsy treatment. These are urgently needed, as are controlled studies concerning hormone replacement therapy in postmenopausal women and hormonal treatment of epilepsy.

Acknowledgments

Some of the studies presented here were supported by the Swedish Medical Research Council (Proj 4X-11198) and a European Union objective 1 grant. I acknowledge the importance of Prof. Danuta Rosciszewska to the contribution in the first edition of this book.

Chapter 196

Disorders of Reproduction and Fertility

Andrew G. Herzog

Introduction

Reproductive dysfunction is unusually common among women and men who have epilepsy.[27,47,48] It generally manifests as menstrual disorders, hirsutism, and infertility in women[48] and diminished libido, impotence, and infertility in men.[47] Reproductive dysfunction is often associated with and may be the consequence of abnormal reproductive endocrine function.[28,47,48] Both epilepsy and antiepileptic drug (AED) use have been causally implicated.[28,38,47,48,50] Epilepsy and antiepileptic drugs can target a number of substrates to impact hormone levels. These include the limbic system, hypothalamus, pituitary, peripheral endocrine glands, liver, and adipose tissue.[33,43] Reproductive endocrine disorders, in turn, can lead not only to reproductive dysfunction, but also to exacerbation of epilepsy.[33,43] An understanding of these relationships and mechanisms is important to the comprehensive management of women and men with epilepsy.

Prevalence

Hospital-based[34,48] and community-based[91] studies have shown that menstrual disorders are more common among women with epilepsy than in the general population. Menstrual disorders can be categorized as amenorrhea (no menses for 6 months), oligomenorrhea (cycle intervals >32 days), polymenorrhea (cycle intervals <26 days), abnormal variation in cycle intervals (>4 days), and menometrorrhagia (heavy menses and bleeding between menses[40]). Cycle intervals between 26 and 32 days, rather than the currently popular broader range of 21 to 35 days, should be considered normal in women with epilepsy because ovulatory rates drop substantially and statistically significantly outside of the 26- to 32-day range, specifically from 75% to <50%.[40] Ovulation is considered to be an important criterion in this population because anovulatory cycles are associated with greater seizure frequency.[2,42,61] Menstrual disorders, using the foregoing definition, are estimated to occur in one third of women with epilepsy as compared with 12% to 14% of women in the general population.[34,40,46] More than one third of cycles in women with localization-related epilepsy (LRE) are anovulatory, as compared to 8% to 10% in controls.[12,40,63] There is conflicting evidence as to whether anovulatory cycles are more common with LRE or primary generalized epilepsy (PGE).[12,63] Reproductive dysfunction may be the result of reproductive endocrine disorders, especially those that are overrepresented in women with epilepsy.[12,34,46,48,63] These include polycystic ovarian syndrome, hypothalamic amenorrhea, functional hyperprolactinemia, and premature menopause.[6,27,34,48,56] Women with idiopathic epilepsy are only 37% as likely as unaffected female siblings to become pregnant.[86] This finding is not attributable to marital rate or to seizure type, age at onset, or family history of epilepsy.[86] In comparison to the general female population, fertility is reduced to 69% to 85% of the expected number of offspring among married women with epilepsy, primarily temporal lobe epilepsy (TLE).[14,98] One third of women with epilepsy have sexual dysfunction as determined by standardized questionnaire.[35] They may have sexual anxiety as well as deficits in arousal.[64] Sexual dysfunction is more common with right-sided rather than left-sided TLE[13,35] and is associated with lower serum testosterone levels.[35]

Sexual dysfunction (diminished sexual interest and/or potency) occurs in about 20% of men with epilepsy as determined by standardized questionnaire.[38] Older studies, using mostly structured or unstructured interviews, found higher frequencies ranging from 38% to 71%.[33] Abnormal semen analysis, including decreased sperm count, abnormal morphology, and impaired motility, has been reported in >90% of men with epilepsy.[8,34,53,92] Semen volume is reduced by 25% and sperm count by 67%.[95] Sperm morphologic abnormalities occur in 47%.[92] Although AED use is an important factor and differential AED effects on both sexual function[38] and semen characteristics[54] have been convincingly demonstrated, there is also considerable evidence to suggest that sexual dysfunction, reproductive endocrine disorders, and abnormal semen analysis are also common among untreated men with epilepsy.[38,92] Men with idiopathic epilepsy are only 36% as likely as male unaffected siblings to ever father a pregnancy.[86] This reduction is associated with LRE, onset of seizures before 20 years of age, and absence of a family history of epilepsy.[86] The effect is mitigated by reduced marital rates. Among married men with epilepsy, reproductive disadvantage was confined to those with onset before 10 years of age.[86]

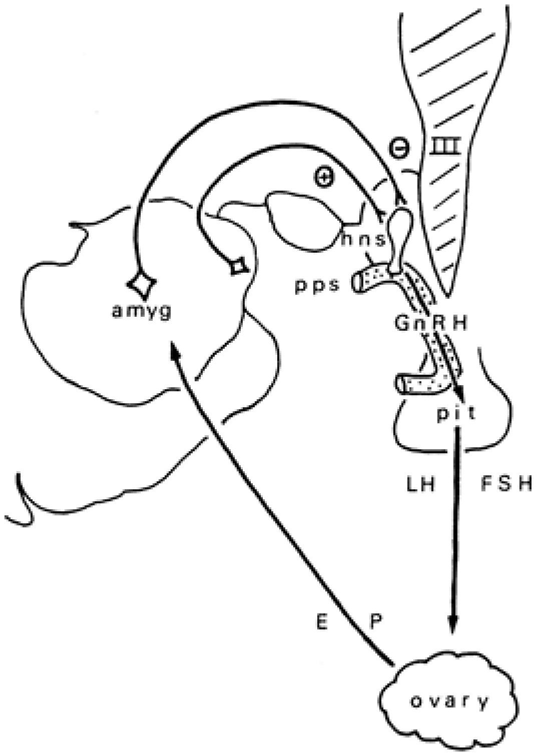

FIGURE 1. A cross section of the anterior temporal lobe and diencephalon. Shown are direct projections from the two anatomically distinct functional divisions of the amygdala (amyg) to the same arcuate hypothalamic neurons. The different influences of these projections on hypothalamic neurosecretory cells (hns) modulate pulsatile gonadotropin-releasing hormone (GnRH) secretion. Releasing hormones enter the pituitary portal system (pps) and regulate the pattern of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion by the pituitary (pit). These gonadotropins induce ovulation and stimulate estradiol (E) and progesterone (P) production. Gonadal steroids, in turn, bind to specific amygdaloid hormone receptors and modulate γ-aminobutyric acid (GABA) and glutamate receptor–mediated conductance at the cell surface to influence neural activity, including epileptiform discharges.

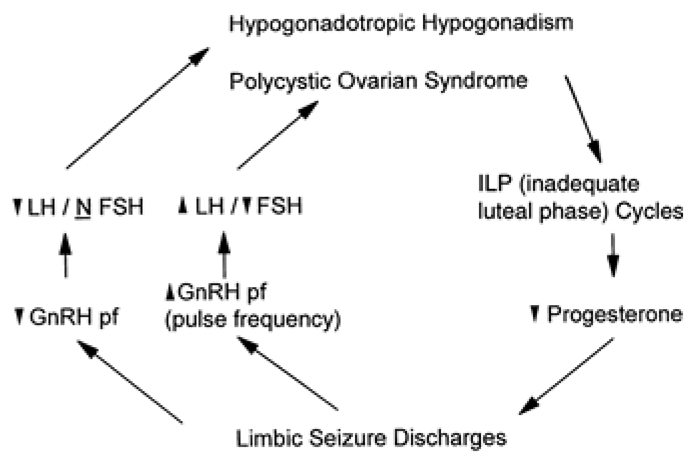

FIGURE 2. Possible mechanisms by which limbic seizure discharges may promote reproductive endocrine disorders and how abnormal reproductive hormone levels may influence epilepsy. This is based on the hypothesis proposed by Herzog et al.[28,34,48] that involvement of limbic structures with epileptiform discharges may disrupt normal limbic modulatory influences on hypothalamic gonadotropin-releasing hormone (GnRH) secretion. Altered frequency or amplitude of GnRH may lead to patterns of pituitary luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion that are found in hypogonadotropic hypogonadism (hypothalamic amenorrhea) and polycystic ovarian syndrome. Reproductive endocrine disorders that are associated with partial seizures of temporal lobe origin are characterized by anovulatory cycles and diminished progesterone secretion. An elevated serum estrogen/progesterone ratio may promote the development of seizure discharges in the brain.

Mechanisms in Women

Reproductive dysfunction is often associated with and may be the consequence of abnormal reproductive endocrine function.[28,34,48] This, in turn, may result from altered neuroendocrine regulation due to epilepsy itself.[7,34,48] Epilepsy may alter the hypothalamopituitary regulation of gonadotropin secretion (Figs. 1 and 2) or may have direct neurally mediated dystrophic effects on the ovaries, mediated by the autonomic nervous system.[25] The neurotrophic effects have been a much-neglected investigational topic but may warrant attention in an era in which vagal nerve stimulators are in common use. AEDs may alter peripheral steroid and binding protein synthesis as well as hormonal metabolism[53,62] and may produce direct gonadal toxicity.[78,94]

The most common reproductive endocrine disorder in women in general and in the epilepsy population in particular is polycystic ovarian syndrome (PCOS).[6,46,48] Its overrepresentation in women with epilepsy[6,27,34,46,48,56] (10%–20% in women with epilepsy vs. 5%–6% in general population studies) may be of considerable significance because in the general population, PCOS is associated with a higher prevalence of

P.2054

migraine, emotional disorders, diabetes, cardiovascular disease, and female cancers.[46] Hypothalamic amenorrhea, functional hyperprolactinemia, and premature menopause have also been found to be overrepresented.[6,27,34,46,48,56] In an investigation of 50 consecutive women with clinical and electroencephalographic features of TLE, 28 (56%) had amenorrhea, oligomenorrhea, or abnormally long or short menstrual cycle intervals.[48] Nineteen of the 28 women with epilepsy and menstrual disorders (68%, 38% overall) had readily identifiable reproductive endocrine disorders: PCOS in 10, hypothalamic amenorrhea in 6 (12%), premature menopause in 2 (4%), and functional hyperprolactinemia in 1 (2%). The numbers of women with clinical and endocrine features of PCOS (20%) and of hypogonadotropic hypogonadism (HH) (12%) were significantly greater than the estimated frequencies (5% for PCOS and 1.5% for HH) in the general female population. The data showed no significant relationship overall between the occurrence of menstrual disorders and the use of AEDs (53% among users vs. 60% among nonusers). Moreover, PCOS was more common among the untreated (30%) than the treated (13%) women with epilepsy, although since then, a notable relationship between the use of valproate, not yet in common use at the time of the investigation, and PCOS[51] has been demonstrated.

PCOS is unlikely to represent a single nosologic entity but rather the failure of the ovarian follicle to complete normal maturation during the menstrual cycle or a series of cycles.[46] PCOS may represent a common endpoint for a number of pathophysiologic conditions, some of which may be attributable to epilepsy itself[6,34,48] or AED use.[50,63] The partially developed follicle is secretory but is deficient in aromatase, the enzyme that converts testosterone to estrogen, and, having failed to release its ovum, is retained in the ovary in the form of a cyst.[46] (The persistent occurrence of such cycles results in hyperandrogenic chronic anovulation, which is currently the simplest and perhaps the most utilitarian definition of PCOS.[46,59])

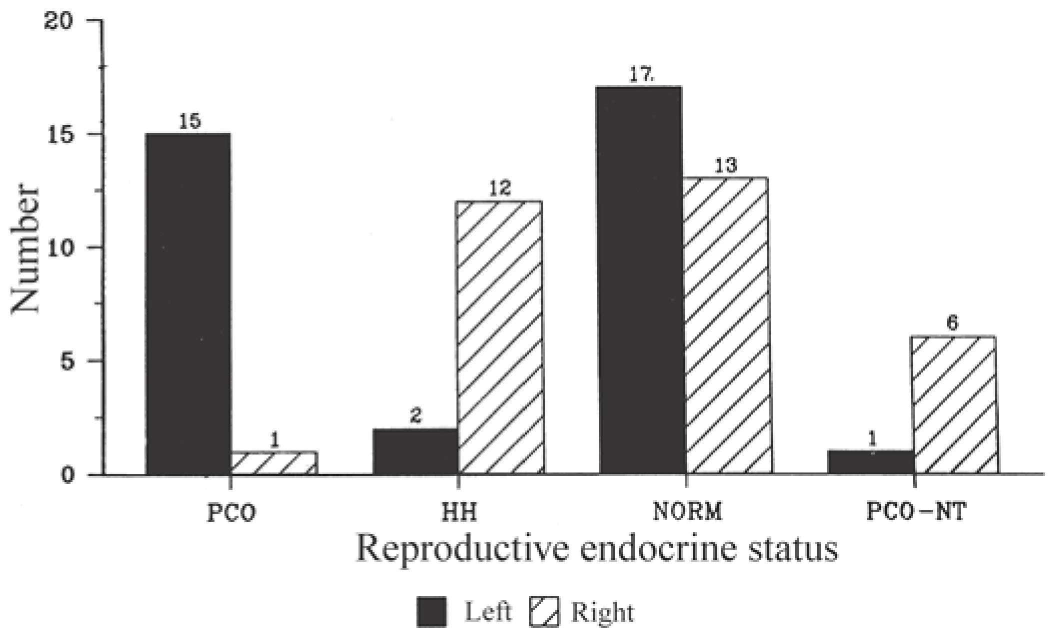

FIGURE 3. Laterality of epileptiform discharges in epileptic women with unilateral temporal lobe electroencephalogram (EEG) foci and polycystic ovarian syndrome (PCO), hypogonadotropic hypogonadism (HH), or normal reproductive endocrine function (NORM) as well as in those with unilateral non–temporal-lobe foci and polycystic ovarian syndrome (PCO-NT). PCO vs. HH: mean = 16.1, $df = 1$; $p < .001$. PCO vs. NORM: mean = 5.1, $df = 1$; $p < .05$. HH vs. NORM: mean = 5.4, $df = 1$; $p < .02$. PCO vs. PCO-NT; $p < .001$, Fisher's exact test.

There are findings that implicate epilepsy itself in the pathogenesis of PCOS. Herzog et al.[29,34,46,48] reported an association between particular reproductive endocrine disorders and the laterality of unilateral temporolimbic epilepsy. Specifically, left laterality has been associated with PCOS, whereas right laterality has been associated with hypothalamic amenorrhea. Nontemporal foci may have different laterality relationships (Fig. 3).[29] Herzog et al.[34] also evaluated reproductive endocrine function in women with unilateral temporolimbic epilepsy and normal controls to assess the effects of epilepsy, epilepsy laterality, and AED use on the cerebral regulation of hormonal secretion. The findings indicate that reproductive endocrine function differs between women with epilepsy and normal controls. Significant differences exist at all levels of the reproductive neuroendocrine axis, that is, hypothalamus, pituitary, and peripheral gland. Differences show significant relationships to epilepsy itself as well as to medication use. Sex hormone changes occur in a stochastic manner such that the laterality of unilateral temporolimbic discharges is associated with predictable directional changes in hormonal secretion at all levels of the reproductive neuroendocrine axis. These directional changes are consistent with the finding that different reproductive disorders may develop in relation to left- and right-sided temporolimbic epilepsy. Some hormonal changes can show close temporal relationship to the occurrence of interictal epileptiform discharges, and these vary in relation to the laterality of the discharges. Antiepileptic drugs differ in their effects on reproductive hormone levels. There are notable

P.2055

differences between enzyme-inducing and noninducing drugs, with the former being associated with lower serum levels of some ovarian and adrenal steroids, such as estradiol, testosterone, and dehydroepiandrosterone sulfate. Menstrual disorders are more common among women with interictal discharges as well as among women with abnormal hormonal findings.

The role of AEDs in the development of reproductive endocrine disorders was first demonstrated in 1993 by Isojarvi et al.,[50] who found a strikingly high occurrence (>60%) of polycystic ovaries and/or hyperandrogenism in women with epilepsy who used valproate (VPA) alone or in combination. The frequency was significantly greater than among women with epilepsy who took carbamazepine (CBZ) alone (33%) or other drugs (14%) and was particularly high among women who started treatment before 20 years of age. Among 23 women who took VPA and had ultrasound and endocrine investigations, 4 (17%) had hyperandrogenism (i.e., elevated serum testosterone levels), with 3 (13%) of these having the combination of hyperandrogenism and menstrual disorder suggestive of PCOS. Murialdo et al.[68] demonstrated combined hyperandrogenism and ovulatory dysfunction in 15, that is, 15%, of 101 consecutive patients with epilepsy, with similar frequencies of menstrual disorders and polycystic ovaries in women with primary generalized epilepsy and LRE. In a comparison of 65 women who had epilepsy, 21 taking VPA monotherapy, and 20 normal controls, Murialdo et al.[67] found that VPA use was associated with substantially and statistically significantly higher body mass index and androgen levels and more anovulatory cycles than with CBZ or phenobarbital use or in normal controls. The role of VPA use was further highlighted in a study by Betts et al.[5] They compared serum hormone levels and ovarian magnetic resonance imaging among 54 women with epilepsy who had only ever taken VPA and for at least 1 year, 51 who had only ever taken either lamotrigine (LTG) or CBZ, and 50 normal controls. Women with epilepsy in general were significantly more likely to exhibit evidence of polycystic ovaries. Women taking VPA were significantly more likely to have hyperandrogenemia than women taking LTG or CBZ or normal controls. Further support for an important role for VPA comes from an investigation by Isojarvi et al.[52]) in which switching AEDs from VPA to LTG in women with epilepsy was associated with statistically significant reductions in weight, androgen levels, and number of ovarian cysts by the end of 2 months.

Although the relative importance of epilepsy versus AEDs, especially VPA, remains a topic of controversy with regard to the relationship between PCOS and epilepsy, the notion that VPA alone may not be entirely responsible draws support from a well-controlled investigation of primates. Ferin et al.[20] treated monkeys for 12 to 15 months with VPA monotherapy that produced serum levels of 88.7 ± 4.0 μg/mL. Monkeys continued to have regular 28-day ovulatory menstrual cycles throughout the time of VPA monotherapy. Follicular and luteal lengths and peak preovulatory estradiol and integrated luteal progesterone levels did not differ between controls and treated monkeys. Ovaries from VPA-treated monkeys showed histologic evidence of ovulation, and none had characteristic features of PCOS. Endocrine PCOS markers, such as increased early follicular ratio of luteinizing hormone to follicle-stimulating hormone (LH/FSH) and androgen levels, were not different in control and VPA treatment cycles. Luteinizing hormone and 17-hydroxyprogesterone responses to gonadotropin-releasing hormone agonist challenges and the insulin response to glucose tolerance tests were similar in control and VPA groups. Lipid profiles were not affected by VPA treatment. The data indicate that a 12- to 15-month therapeutic exposure to VPA does not induce cyclic hormonal or morphologic ovarian abnormalities or characteristics of PCOS when administered to nonepileptic, normally cycling nonhuman primates.

Data from clinical nonepileptic populations, specifically women with bipolar disorder, are conflicting[1,70,73] and complicated by the fact that women with atypical or type II bipolar disorder may have demonstrable brain dysfunction that may confound the conclusion that PCOS is or is not related to VPA use alone.

An alternative and possibly unifying consideration is that PCOS may develop as an interactional effect between AED

P.2056

use and epilepsy.[31,34,46] Specifically, there is the possibility that epilepsy may promote PCOS development and that enzyme-inducing AEDs (EIAEDs) treat not only the epilepsy, but also the PCOS by enzyme induction that increases the synthesis of sex hormone–binding globulin and the metabolism of testosterone, resulting in lower levels of bioavailable testosterone.[31,34,46] There is evidence that testosterone may sensitize the hypothalamopituitary response to estrogen feedback, thereby disrupting normal gonadotropin secretion.[17] In contrast, enzyme-inhibiting drugs, most notably VPA, may retard the aromatization of testosterone estrogen[93] and potentiate the development of epilepsy-related hyperandrogenism and hence PCOS.[31,34,46] Antiseizure medications other than VPA, therefore, may treat hyperandrogenism and thus PCOS, whereas VPA therapy may not. This mechanism, thereby, could contribute to a higher occurrence of PCOS in VPA-treated women with epilepsy. If this were an extant mechanism, then VPA would not be the primary cause of PCOS, yet its selection as treatment may be an important factor.

Mechanisms in Men

Hypogonadism in men refers to diminished gonadal function as determined by low serum testosterone level and/or decreased or abnormal sperm production.[33] It can manifest as diminished sexual interest, potency, fertility, energy, mood, competitive drive, bone and muscle mass, and secondary sexual characteristics. Physical signs include a loss of male escutcheon, gynecomastia, and testicular atrophy. The clinical impression of hypogonadism can be verified by laboratory testing. Testosterone exists in three major forms: (a) tightly bound to sex hormone–binding globulin (SHBG; 45%–50%), (b) loosely bound to albumin (50%–55%), and (c) unbound (1%–2%).[43] The albumin-bound and free portions are available to tissues and, therefore, constitute the clinically important bioavailable portion. Measures of bioavailable testosterone (BAT) suggest that hypogonadism may occur in greater than one third of men with temporolimbic epilepsy.[33,47,57,90] BAT shows a substantially earlier and greater age-related decline in men with epilepsy than in controls.[37,57] In a sample of men with localization-related epilepsy, we found that BAT fell below normal control levels in 11% of men between 20 and 30 years of age, in 27% of those between 30 and 40 years of age, and in 89% of those between 40 and 50 years of age.[37,38] Sexual dysfunction, as determined by standardized questionnaire, affects 20% of men with LRE.[38,90] Several[8,19,38,60,96] but not all[16] investigations have found significant relationship between reduced serum BAT measures and sexual dysfunction. Men with epilepsy may show evidence of sexual dysfunction in the setting of low-normal BAT levels at which men in the general population may not show clinical manifestations.[36,38] This may constitute an argument against the importance of the BAT level. Alternatively, higher BAT levels may be required for normal sexual function in the setting of the altered brain substrate of epilepsy. Semen analysis has consistently revealed a remarkably high frequency, perhaps as high as 90%, of decreased sperm count and/or abnormalities in sperm morphology and motility among men with epilepsy.[8,53,79,92] Men with epilepsy are only 36% as likely as male unaffected siblings to ever father a pregnancy.[86]

The etiology of hypogonadism in men with epilepsy has been attributed to a number of possible causes. These include (a) psychosocial stress, (b) antiepileptic drugs, and (c) epilepsy itself.[33,38,47,65] Each of these is recognized to alter reproductive endocrine secretion.

Psychosocial stress associated with epilepsy may play an important role in hypogonadism.[95] From a neuroendocrine perspective, stress response involves the activation of the hypothalamo–pituitary–adrenal (HPA) axis.[84] Cortisol levels are higher in individuals with epilepsy than in controls, not unlike individuals with depression.[23] Unlike depression, however, diurnal variation is often lost in epilepsy.[23] Factors that increase the activity of the HPA axis interfere with reproductive endocrine secretion as well as reproductive function[84] and may contribute to seizure exacerbation.[55] Stress increases the release of proopiomelanocortin (POMC), the precursor protein that is cleaved to form adrenocorticotropic hormone (ACTH) and endorphin,[9,97] both of which inhibit gonadotropin secretion and reproductive function.[84,85] ACTH increases cortisol secretion; endorphins increase dehydroepiandrosterone production. Both of these steroids have γ-aminobutyric acid (GABA)-negative allostearic modulatory properties that lower seizure thresholds and increase anxiety.[54]

Antiepileptic drugs differ from one another in their effects on reproductive endocrine secretion. Enzyme-inducing AEDs can directly suppress gonadal testosterone synthesis, increase the hepatic synthesis of

SHBG, and increase serum estradiol levels in absolute or relative terms. In vitro investigation suggests that therapeutic range concentrations of EIAEDs, including carbamazepine and phenytoin, act at various specific levels of the biosynthetic cascade to block testosterone production in Leydig cells.[58] EIAEDs increase the hepatic synthesis of SHBG, thereby decreasing the bioactive portion of total testosterone.[33,38,47,49,53,90] Total testosterone levels decrease with age.[37,38,76] SHBG levels increase with age.[53] Consequently, the age-related decline in bioactive testosterone is often significantly greater than the decline of total testosterone levels. EIAEDs can also raise serum estradiol levels, in absolute terms or relative to BAT, thereby producing increased negative feedback on the hypothalamopituitary axis.[44,66] Although it constitutes only 1% of the total reproductive steroid, estradiol exerts one half of the negative feedback on the hypothalamopituitary axis.[33] Therefore, a small increase in estradiol level, presumably as a result of AED-induced increase in aromatase activity, could have a disproportionately large negative feedback effect, thereby contributing to hypogonadism. Elevated estradiol may also lower the ratio of bioactive to immunoreactive luteinizing hormone.[4] Non–enzyme-inducing AEDs have received less attention. In animal investigations, valproate has been associated with testicular atrophy.[77] Although GABA generally suppresses gonadotropin secretion, men with epilepsy who use valproate have been found to have normal testosterone levels and free androgen index.[74] Androstenedione levels and estradiol/testosterone ratios are higher than in controls.[74] Enzyme inhibition by valproate may be a potential factor. The replacement of carbamazepine with oxcarbazepine is associated with a reduction of SHBG.[51] Free androgen index, a measure of bioavailable testosterone, however, does not increase even after 6 months.[51] This is consistent with our recent findings that, despite the more rapid normalization of SHBG, BAT as well as aromatized and reduced testosterone metabolite levels may remain altered as late as 3 years following the discontinuation of EIAEDs.[37,38] (AEDs differ in their effects on sexual function and reproductive hormone levels. In a comparison of sexual function and reproductive hormone levels among 85 men with epilepsy who took various or no antiepileptic drugs (25 on carbamazepine, 25 on phenytoin [PHT], 25 on lamotrigine, and 10 untreated for at least 6 months [no AED]) and 25 controls, Herzog et al.[38] found that sexual function scores (S-scores), hormone levels (bioactive testosterone, estradiol), hormone ratios (bioactive testosterone/bioactive estradiol), and gonadal efficiency (bioactive testosterone/luteinizing hormone) were significantly greater in the control and LTG-treated groups than in the CBZ- and PHT-treated groups. Sex hormone–binding globulin was significantly higher in the CBZ and PHT groups than in all other groups. The S-scores were below the control range in 20% of the men with epilepsy, including 32% on CBZ,

24% on PHT, 20% on no AEDs and 4% on LTG (X^2: p = .08 for all four groups; X^2: p = .02 for the three AED groups). Bioactive testosterone was below the control range in 28.2% of the men, including 48% on CBZ, 28% on PHT, 20% on no AEDs, and 12% on LTG (X^2: p = .02). Among men with epilepsy who had low S-scores, 70.6% had bioactive testosterone levels below the control range as compared to 17.6% among men with normal S-scores (X^2: p <.0001). Among men with epilepsy who had abnormally low bioactive testosterone, 50.0% had low S-scores; among men with normal bioactive testosterone, 8.2% had low S-scores (X^2: p <.0001). Bioactive testosterone decline with age was significantly greater among men with epilepsy than among controls and notably greater in the CBZ and PHT groups than in the LTG and untreated groups. Overall, sexual function, bioavailable testosterone levels, and gonadal efficiency in men with epilepsy who took lamotrigine were comparable to control and untreated values and significantly greater than with carbamazepine or phenytoin treatment.

The temporolimbic system plays an integral part in endocrine regulation and feedback, as well as in epilepsy.[28] It has massive direct anatomic connections to regions of the hypothalamus that are involved in neuroendocrine control, that is, the regulation, production, and secretion of peptides that control pituitary function (Fig. 1). The pulsatile secretion of gonadotropin-releasing hormone (GnRH) is an intrinsic feature of GnRH neurons in the preoptic and ventromedial hypothalamus and depends on the integrity of sodium, potassium, and calcium channel conductance, factors that may potentially be influenced by the direct action of some AEDs.[33,57] Synchronization of neurons may be accomplished by local circuit neuronal connections as well as diffusible chemical factors.[57] The neurons are sensitive to basal forebrain and brainstem modulatory influences mediated by glutamate, GABA, and other neurotransmitters.[57] Epileptiform discharges in medial temporal lobe structures may disrupt hypothalamic regulation of pituitary secretion and hence alter gonadal function.[28] Focal limbic seizures, as well as generalized seizures, disturb normal gonadal structure, physiology, and serum androgen levels in the male rat.[18] Animal studies demonstrate that unilateral amygdaloid seizures have a laterally asymmetric effect on hypothalamic reproductive endocrine nuclei.[21,88] There is significantly greater Fos activation[88] and loss of GnRH fiber immunoreactivity[21] ipsilaterally than contralaterally. These ipsilaterally predominating responses are of potential interest because there are lateralized asymmetries in the temporolimbic system with regard to reproductive effects[82] and in the hypothalamus with regard to GnRH content[26] and sexual function that may suggest potentially different consequences of unilateral left and right temporolimbic seizures. Clinically, there may be a greater occurrence of sexual dysfunction in men with right, rather than left, lateralized temporolimbic epilepsy.[3,13,69] Hormonally, temporolimbic seizures produce an abnormal elevation in prolactin levels, reaching a peak in 20 to 30 minutes and then returning to baseline over 1 hour.[89] Prolactin responses may reach higher levels with right- than left-sided epileptiform discharges.[30] There are clinical studies that also suggest that temporolimbic epilepsy may be associated with altered gonadotropin response to GnRH infusion regardless of AED use[45] and that mean baseline LH and LH pulse frequency are significantly more variable among men with epilepsy than among controls.[36] Quigg et al.[72] found that interictally, pulse frequency and mean concentration are lower and pulse amplitudes are higher than in controls. Postictally, they found no change in mean pulse frequency but did detect a significant change in the orderliness of the pulses. These seizure-related findings, as well as our demonstration of laterality effects and a close temporal relationship between discharges and endocrine events in women[34] and possibly in men,[33] provide clinical evidence to support a temporolimbic modulatory influence on GnRH secretion.

The temporolimbic system projects to dorsomedial and lateral regions of the hypothalamus that are the source of direct fibers to the intermediolateral column of the thoracic spinal cord that provides sympathetic innervation of the testes.[33,83] Similarly, the temporolimbic system projects to the dorsal motor nucleus of the vagus that is the source of the parasympathetic innervation of the testes.[33] Autonomic innervation plays an important trophic as well as endocrine regulatory role.[24] Reciprocally, the vagal afferents from the testis project to the solitary nucleus that provides direct afferents to the amygdala.[28] The amygdala shows sensitive electrophysiologic responses to vagal stimulation.[28] The effect of vagal nerve stimulation therapy for intractable seizures has not been formally evaluated with regard to reproductive endocrine effects.

Changes in reproductive steroid concentrations may affect seizure tendencies as well as reproductive function. Although estrogen is proconvulsant and progesterone is anticonvulsant in most adult animal models of LRE, the effect of testosterone on experimental seizures appears to be mixed.[55] This may be related to its ready metabolism by aromatase to estradiol, which has neuroexcitatory effects, whereas it can also be metabolized by reductase to dihydrotestosterone, which may block *N*-methyl-D-aspartate (NMDA)-mediated conductance,[71] and, by further reduction to androstanediol, a potent GABAergic steroid with antiseizure properties.[22] Although testosterone replacement has proven only moderately effective in restoring sexual function, possibly because of its ready metabolism to estrogen, especially in the setting of antiepileptic drugs, one pilot study has reported superior results using combined treatment with testosterone and an aromatase inhibitor that blocked the transformation of testosterone to estradiol.[41] Combined therapy was associated with seizure reduction as well.[41] The neuromodulatory role of reproductive steroids suggests that a greater understanding of neuroendocrine regulation in men with epilepsy may be important not only for reproductive function, but also for optimal management of seizure disorders.

Gonadal Steroid use for Family Planning and Treatment of Reproductive Dysfunction

It has long been recognized that the use of the older enzyme-inducing AEDs, such as barbiturates, phenytoin, and carbamazepine, is associated with higher failure rates of oral contraceptive pills (OCPs).[11] The failure rate was estimated to be 3.1 per 100 woman-years for the original 80-μg estrogen plus 1-mg progestin formulation in women on EIAEDs as compared to 0.7 per 100 woman-years in untreated epileptic women and women in the general population.[10] The failure rate is likely to be considerably higher for the currently popular formulations, which have less than half of this estrogen and progestin content. The use of these lower-dose pills is associated with unregulated cycles in about 10% of users. The greater failure rate is likely due to the induction of the catabolism and binding of reproductive steroids as well as the induction of hormone conjugation in the gut.[11] A newer enzyme-inducing AED, topiramate, has also been shown to lower serum OCP steroid levels.[15] Clinically significant interactions between OCPs and enzyme-neutral (e.g., lamotrigine, gabapentin) and inhibitory (e.g., valproate) drugs were not considered to be of concern until some recent reports suggested that the use of OCPs by women who take lamotrigine is associated with statistically significant and substantial (>50%) reductions in the serum levels of lamotrigine.[80,81] In one of these reports,[81] the introduction

of OCPs was associated with increased seizure frequency or recurrence of seizures in most of the cases. The possibility of a similar relationship between valproate and OCP use has been raised by a well-documented case report.[39] The change in lamotrigine levels has been attributed to the estrogen rather than the progestin component of the pill.[75] During the 7-day pill-free period of OCP use, lamotrigine levels have been noted to increase progressively by >100%.[87] By way of mechanism, both valproate and lamotrigine are largely inactivated by hepatic glucuronidation, a process that is induced by OCPs.[39,80,81] Further investigations of the reciprocal interactions between AEDs and OCPs are required to establish the optimal use of OCPs in women with epilepsy. Although interactions between AEDs and OCPs are increasingly recognized by the medical community in the setting of birth control, they must also be considered in women with epilepsy who take hormones for other reasons such as menstrual disorders and endometriosis, in which treatment failures may lead to needless hysterectomy, and in the use of hormone replacement therapy for menopausal women with epilepsy. Higher-dose, rather than minipill-formulation, birth control pills have been recommended for women with epilepsy who take AEDs, especially if they experience irregular cycles and breakthrough bleeding. The potential benefit of increasing OCP dose, however, must be weighed against the potential adverse effects of these higher doses on serum AED levels and seizures.

Summary and Conclusions

Reproductive dysfunction is unusually common among women and men with epilepsy. Reproductive endocrine disorders are a major cause. Both AEDs and epilepsy affect hormones and differences in levels and patterns of reproductive endocrine secretion vary with different AEDs and the characteristics of the epilepsy, including classification, laterality, and nature of paroxysmal discharges. Gonadal steroid use for family planning purposes or for the treatment of reproductive dysfunction is complicated by the concomitant use of both enzyme-inducing and some noninducing AEDs. Because hormones influence epilepsy and neuropsychological well-being[32] as well as reproductive function, the comprehensive management of women and men with epilepsy requires a clear understanding of the reciprocal interactions epilepsy, AEDs, and hormones.

Chapter 197

Sexuality in Epilepsy

Martha J. Morrell

Introduction

Men and women with epilepsy are believed to be at high risk for sexual dysfunction, although the precise frequency with which sexual dysfunction occurs in epilepsy (and other chronic neurologic illnesses) is not known. However, a number of social and biologic variables that could negatively impact sexual behavior in people with epilepsy have been identified. These include low self-esteem, mood and anxiety disorders, a disruption to central nervous system regions mediating sexual behavior, and disturbances of hypothalamic, pituitary, and gonadal hormones. Sexual dysfunction in people with epilepsy can serve as a model to aid in understanding the neurobiology of sexual behavior. Most important, recognition of sexual deficits in this patient population is necessary for effective treatment to be developed and delivered.

The Sexual Response

Sexual behavior can be considered as comprising two main components—desire and arousal.[4] Sexual desire refers to the willingness to engage in sexual behavior when given an appropriate sexual stimulus. In animals, this is evaluated as willingness to engage in sexual activities when given a receptive mate. In humans, sexual desire is equated with libido or sexual drive. Sexual desire reflects the individual's psychological health, cultural expectations, and past sexual experiences and requires salient sexual stimuli. Hormones are also required to support sexual desire, including the gonadal sex steroids—estrogen, progesterone, and especially testosterone—as well as hormones of the pituitary, including the gonadotropins—luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—and prolactin. In nonprimate mammals, the hypothalamic hormone gonadotropin-releasing hormone is required to maintain sexual desire.

The second component of the sexual response is defined as sexual arousal. This is strictly defined as the capacity to respond to an appropriate sexual stimulus with a series of stereotyped vascular, neural, and muscular responses. A normal physiologic sexual response requires an intact, functioning cerebral cortex, brainstem, spinal cord, and autonomic nervous system including the sympathetic and parasympathetic divisions. Genital structures must be anatomically and functionally normal. The physiologic sexual response also requires that the hormone milieu include adequate levels of gonadal steroids.

Sexual arousal is characterized by nonspecific physiologic arousal and by a series of stereotyped events in genital tissue, as first described by Masters and Johnson.[34] The male sexual response cycle begins with the excitement phase. A sexual stimulus elicits increases in heart and respiratory rates, blood pressure, and skin vascularity. Vasocongestion begins in the penis, eventually with attainment of erection and rigidity. This response is mediated by the parasympathetic branch of the autonomic nervous system and depends on sacral nerves 2, 3, and 4. When vasocongestion is maximal, the plateau phase begins and is then maintained for a variable period. The plateau phase terminates with orgasm, mediated by the sympathetic nervous system and by sacral nerves 2, 3, and 4. The resolution phase follows orgasm and is a refractory period during which no amount of sexual stimulation can elicit physiologic arousal. The refractory period is variable and tends to increase with age.

The sexual arousal cycle in women is quite similar to that in men. An excitement phase is characterized by generalized physiologic arousal and by vaginal vasocongestion and myotonia, which depends on the parasympathetic nervous system and sacral nerves 2, 3, and 4. Following the plateau phase, orgasm occurs, mediated by somatic and sympathetic nerves. The physiologic events of orgasm include rhythmic 0.8-second contractions of the pelvic floor, uterus, and fallopian tubes. In women, the refractory period is short, permitting multiple orgasms.

Neuroendocrinology of Sexual Behavior

Regions of the cerebral cortex that mediate sexuality include the medial frontal lobe, structures within the circuit of Papez, limbic tissues, the hypothalamus, and distinct regions of the brainstem. Stimulation of the septum, the circuit of Papez, including the dorsolateral tegmentum of the midbrain, the medial orbital gyrus,[33] and the hippocampus,[32] stimulates erections in primates, whereas ablative lesions in the medial forebrain bundle, the hypothalamus, and the dorsolateral tegmentum of the midbrain markedly depress or even eliminate erections and other sexual behaviors.[13,19] Lesions to the medial temporal lobe bilaterally result in the Kluver-Bucy syndrome, which is characterized by uninhibited sexuality.[30]

The amygdala appears to be critical in mediating sexual and emotional behavior. The amygdala is rich in estrogen and androgen receptors, as well as endocannabinoid, opiate, and catecholamine receptors, all of which affect sexual behavior.[46] Bilateral amygdala ablation causes sexual dysfunction as well as disruption in other social behaviors.[19,55] Amygdala lesions are also associated with reproductive dysfunction in animals, including aspermatogenesis, anovulatory menstrual cycles, and polycystic ovaries.[56]

Cortical representation of sexual behavior is not well understood in humans. One study in patients implanted with intracranial electrodes, however, reported that erections were elicited by stimulation in the circuit of Papez.[21] Sexual orgasm was associated with high-frequency rhythmic discharges in the hippocampus, whereas chemical stimulation of the hippocampus reproduced feelings of pleasurable sexual sensation.[20] The cerebral cortex, particularly limbic structures, also influences sexual behavior by modulating the hypothalamic-pituitary-gonadal axis. The amygdala, a region of limbic cortex, contains two distinct nuclear groups that are reciprocally connected with the hypothalamus. The corticomedial nuclear group relays excitatory impulses to the hypothalamus, increasing the

P.2062

release of hypothalamic trophic hormones. The basolateral nuclear group has an inhibitory effect on the release of these same trophic hormones. The cerebral neocortex also is directly connected with the hypothalamus, modulating the release of trophic hormones. In nonhuman mammals, gonadotropin-releasing hormone (GnRH) from the hypothalamus supports mating behavior.[40] In all mammals, GnRH acts on the pituitary to influence the release of the gonadotropins LH and FSH. The pituitary hormones LH, FSH, and prolactin affect sexual behavior. Elevated pituitary prolactin is associated with reduced libido and with impotence.[8] The pituitary gonadotropins LH and FSH may have direct effects on the cerebral cortex to support normal sexual behavior.

The gonadotropins stimulate the release of gonadal sex steroid hormones. The gonadal steroids—estrogen and progesterone in women and testosterone in men—exert positive and negative feedback at every level of the cortical–hypothalamic–pituitary axis. In addition, high-affinity receptors for all sex steroids are extensively distributed within the amygdala and other limbic tissues, thereby affecting hypothalamic functions.[42,43,47,52] Any disturbance to the cerebral cortex and to limbic structures could theoretically disrupt the dynamic relationship among the hormones of this neuroaxis. Finally, the dynamic equilibrium of the endocrine axis can be disturbed by medications, including many antiepileptic medications, that enhance or reduce the hepatic metabolism of steroid hormones.

Sex steroid hormones are required for normal sexual desire and arousal. Sexual desire appears to be supported by androgens in both men and women. Normal physiologic sexual arousal in males requires the support of androgens, although a relatively profound androgen deficiency is required before sexual arousal fails. In fact, at least 20% of castrates continue to maintain normal sexual potency. Testosterone and another androgen, dehydroepiandrosterone sulfate, contribute and may be essential to sexual desire in women. Estrogens appear to support the vaginal vasocongestive response associated with the first phase of the sexual response cycle.[36]

Sexual Dysfunction in Epilepsy

Sexual dysfunction, most often described as global hyposexuality, has been reported in people with epilepsy since 1956.[18] Disorders of desire and of arousal, typically impotence, have been described in 30% to 60% of men with epilepsy.[7,27,44,53] Interviews with 97 men with chronic epilepsy[16] found that 21% had never experienced sexual intercourse despite having had the opportunity to do so, and at least one third of sexually active patients had difficulty achieving and maintaining an erection or ejaculating. Sexual deviancy appears rarely in this population, and hypersexuality was found in only 1% of patients evaluated in one study.[53]

Deficits in women have not been as well described. By self-report, there is a high incidence of dyspareunia, vaginismus, and arousal insufficiency.[38] One third of women with epilepsy described themselves as dissatisfied with their overall sexual function, in contrast to a community prevalence of 8%. More subtle differences in sexual desire are appreciated in some women with epilepsy. One inventory, inviting subjects to imagine and rate their degree of arousal and of anxiety in response to a number of sexual activities, found that sexual arousal was similar in women with localization-related and primary generalized (presumed genetic) epilepsies, but that women with localization-related epilepsy imagined they would experience significantly more anxiety in sexual situations.

Sexual deficits may vary by culture. In Egypt, a psychosexual history obtained in 700 women patients of an outpatient epilepsy clinic found that 18% had sexual disorders, including inhibited desire and arousal.[12] Only 29% of epileptic women in a Scandinavian outpatient clinic complained of dysfunction, which was no different than the rate for healthy controls.[29]

Two studies have evaluated physiologic sexual function in people with epilepsy. Fenwick et al.[15] assessed nocturnal penile tumescence in men with epilepsy. The patients were divided into two groups—one with relatively low testosterone levels and one with higher testosterone levels. Nocturnal penile tumescence over two nights of monitoring was diminished and disorganized in the low-testosterone group relative to the high-testosterone group. Procedural difficulties of the study included the lack of measurement of rigidity and the relatively arbitrary division into high- and low-testosterone groups. The low-testosterone group did not have a testosterone reduction that would routinely be associated with sexual dysfunction.

Stimulus-induced physiologic sexual arousal was evaluated in men and women with localization-related epilepsy of temporal lobe origin and compared with that in similarly aged controls.[39] In this protocol, genital vasocongestion in response to erotic video stimuli was assessed by noninvasive devices. The genital blood flow response, corresponding to the excitement phase of the sexual arousal cycle, was significantly diminished in the men and women with epilepsy. Moderate subjective sexual arousal was reported by all subjects—both those with and those without epilepsy—suggesting that the men and women with epilepsy experienced a disorder of arousal rather than a disorder of desire.

Cmechanisms of Sexual Dysfunction in Epilepsy

There are a number of potential mechanisms by which sexuality may be disturbed in people with epilepsy. Psychosocial deficits, such as restricted social opportunities and poor self-esteem, limit the opportunity for normal sexual interactions. Poor disease acceptance is associated with sexual dysfunction in other chronic illnesses and may contribute to impaired sexuality in epilepsy.[29] Depression is common in persons with epilepsy and is associated with loss of sexual desire as well as arousal deficiencies. However, physiologic mechanisms may be more relevant than psychological variables. Disruption of cortical regions mediating sexual behavior, either by fixed lesions or by epileptiform discharges, could influence sexual desire and arousal. Changes in hormones supporting sexual behavior occur in epilepsy because of seizures and antiepileptic drugs. Antiepileptic drugs have direct effects on cortical regions mediating sexuality and may also cause sexual dysfunction by secondary effects on reproductive hormones.

Psychosocial disability can adversely impact sexuality in men and women with epilepsy. Individuals with epilepsy are susceptible to poor self-esteem. Recurrent seizures may lead to a sense of vulnerability and helplessness, impairing the capacity to form healthy, nurturing relationships. Having epilepsy may limit social development, particularly for patients with frequent seizures who have restricted access to usual educational and occupational experiences. Finally, sexual behavior may be negatively reinforced if sexual feelings are a component of the seizure. Many patients are also concerned that sexual activity will precipitate a seizure, particularly those whose seizures are sometimes triggered by hyperventilation or physical exertion.

Sexual experience may be limited in some individuals with epilepsy. A study in Philadelphia evaluating sexual experience in men and women with temporal lobe epilepsy found that these men and women had significantly fewer sexual experiences than similarly aged controls.[39] The same study repeated in Palo Alto, California, however, found no difference between the sexual experience of men and women with epilepsy and that of similarly aged men and women with no medical or

neurologic illness,[38] suggesting that experience may be more directly determined by prevailing cultural expectations.

Mood and anxiety disorders have a high prevalence in persons with epilepsy, affecting 49% of 174 patients participating in a multicenter investigation.[30] Major depression was the most common individual diagnosis, affecting 17.2% of patients. Mood and anxiety disorders are highly correlated with sexual dysfunction.

Several clinical observations suggest that dysfunction in limbic structures predisposes to sexual dysfunction. Sexual dysfunction usually arises after the onset of seizures[7,44,47] and may be most common in individuals with localization-related epilepsy, particularly those whose seizures arise from the amygdala and hippocampus.[6,12,23,26,47] Several authors report that sexual dysfunction improves after temporal lobectomy for medically intractable seizures, despite continued treatment with antiepileptic drugs.[6,9,14,49] Patients with extratemporal resections were less likely to experience an improvement in sexual function than were those with temporal lobe resections.[3] Patients treated with temporal lobe resection for medically intractable epilepsy were more likely to have postoperative sexual dysfunction if the volume of the contralateral amygdala was small compared to those patients with a large volume of the contralateral amygdala.[3]

The laterality of the epileptogenic focus may also influence the nature and extent of sexual dysfunction. Sexual dysfunction scores were significantly higher in women with right temporal lobe onset epilepsy than those whose seizures arose in the left temporal lobe.[23] Another study described a reduction in sexual interest in men and women with epilepsy of right temporal lobe origin but not in those with epilepsy of left temporal lobe origin.[11]

Antiepileptic drugs affect sexual behavior by at least two mechanisms: (a) alterations in hormone metabolism and binding and (b) direct cortical effects.[10,45,54] Antiepileptic drugs that induce or inhibit the hepatic microsomal enzyme system alter metabolism of sex steroid hormones. Many antiepileptic drugs also induce production of sex hormone–binding globulin (SHBG), a binding protein for steroid hormones. Increased binding reduces the free, biologically active fraction. These two mechanisms cause a reduction in the free level of steroid hormones.[10,28] Antiepileptic drugs are also associated with elevations in prolactin and gonadotropins. They may act as suppressants of sexual behavior. Diminished libido and arousal were described in 12% of men beginning an antiepileptic drug,[35] an effect that was most pronounced with barbiturates.

Antiepileptic drugs do not cause all sexual deficits observed in people with epilepsy. First, sexual dysfunction generally arises with the onset of epilepsy, before treatment;[27] occurs in men and women not treated with antiepileptic drugs;[25,26] and is not correlated with the number of antiepileptic drugs used or with their serum levels.[44] Sexual deficits may improve when seizures are controlled, even if this requires higher doses of antiepileptic drugs,[27] or after temporal lobectomy.[7]

Alterations in pituitary and gonadal hormones can negatively affect sexual behavior in people with epilepsy (see Chapter 194). Interictal elevations in prolactin are observed in men and women, both those treated and those not treated with antiepileptic drugs (AEDs).[45,51] Seizures can cause marked elevations in prolactin (see Chapter 194) that are maximal at 20 minutes and persist for approximately 1 hour. Whether these pulses of elevated prolactin contribute to sexual behavior and arousal deficits is not known; however, elevated prolactin is one of the most frequent causes of impotence in otherwise healthy males. Reductions in LH may also contribute to sexual deficits. Low LH appeared to be associated with low-desire disorder in one study of women with localization-related epilepsy of temporal lobe origin.[26]

Although total levels of sex steroid hormones are within the normal range in most individuals with epilepsy, the free fraction of sex steroid hormone, which is the biologically active component, may be reduced.[10,28] This is typically the case in individuals taking cytochrome P450 enzyme–inducing AEDs, which increase the level of sex hormone–binding globulin and reduce the concentration of circulating free hormone.

Sexual dysfunction in women with epilepsy appears to be related to levels of sex steroid hormones. Women with epilepsy and low testosterone levels are reported to be more likely to have disorders of sexual desire and arousal.[23,37] Serum estradiol is lower in women with epilepsy treated with phenytoin[37] and carbamazepine (cytochrome P450-inducing antiepileptic drugs)[23] but not with lamotrigine.[23,37] Low estrogen levels were associated with sexual dysfunction in women with epilepsy and may contribute to dyspareunia, vaginismus, and lack of lubrication.[37]

Men with epilepsy are also susceptible to endocrine-associated sexual dysfunction. Low levels of free testosterone have been associated with disorders of sexual desire[16,51] and arousal[5] in epileptic men, although the range of testosterone would still be considered adequate to maintain normal sexual function in most individuals. Men receiving the AED carbamazepine or phenytoin had significantly lower bioavailable testosterone levels and poorer sexual function than did men receiving lamotrigine, men with untreated epilepsy, and nonepileptic controls.[24]

Sexual dysfunction may be a consequence of ictal alterations in neurotransmitters, including γ-aminobutyric acid (GABA), opioids, and serotonin. Brain opioids and GABA are released after kindled seizures and after ejaculation, causing behavioral depression.[41] Elevations in GABA inhibit sexual behavior in rabbits,[1] and postictal elevations in GABA and opioids are associated with prolonged neuronal depression.[41] Serotonin agonists specific to one receptor subtype ($5\text{-}HT_{1B}$) inhibit sexual desire and sexual arousal in rats,[17] an action mimicked by serotonin reuptake inhibitors in humans.

Evaluation and Treatment of Sexual Dysfunction

Patients with epilepsy presenting with sexual complaints must be evaluated for other causes of sexual dysfunction. Psychogenic causes of sexual dysfunction include psychiatric disease, psychosis, and affective disorders, such as depression and bipolar illness. Sexual symptoms may also arise as a result of religious, social, or family taboos or because of negative early life experiences. A dysfunctional relationship involving a sexual partner is a common cause. Concomitant medication, such as psychotropic drugs and antihypertensive agents, can be associated with desire and arousal deficits. Medical conditions causing sexual dysfunction include those associated with small-vessel disease, such as diabetes, hypertension, and hyperlipidemia; endocrine disorders producing hyperprolactinemia, hyper- or hypothyroidism, or significantly low testosterone; and systemic illnesses, including renal, hepatic, cardiac, and pulmonary disease. Infections or injury to genital structures can impair sexual arousal. Neurologic causes of sexual dysfunction include injury or disease involving the spinal cord, peripheral or autonomic neuropathy, and nonepileptogenic cortical lesions, particularly those involving the frontal and temporal lobes.

Table 1 Evaluation strategy by type of sexual complaint

	Disorder of desire	Disorder of arousal
Medical and sexual history	X	X
Duration of symptoms		

Situational anxieties		
Affective symptoms		
Medication, substance abuse		
Review of systems		
Physical and neurologic exam	X	X
Gynecologic exam		X
Urologic exam		
Nocturnal penile tumescence	X	X
Penile hemodynamics		X
Laboratory tests		
Testosterone	X	X
Prolactin	X	X
Luteinzing hormone/follicle-stimulating hormone	X	X
Thyroid hormones	X	X
Complete blood count/chemistries		X
Triglycerides/cholesterol		X
Glucose tolerance test		X

An evaluation for sexual dysfunction can be modified according to the type of dysfunction—a disorder of sexual desire or of sexual arousal (as shown in Table 1)—but always begins with a thorough medical, neurologic, and sexual history. This requires that the physician ask specific questions about sexual well-being. Patients are unlikely to volunteer sexual complaints, particularly in a first or second visit. In one Danish study of 16,000 patients from general practitioner's clinics, the frequency of sexual complaints depended on the physician. Sexual dysfunction was more likely to be detected by female physicians who were <45 years of age and practiced in urban areas.[30] The physician determines whether symptoms are acquired or chronic. Situational anxieties are explored, as are phobias or avoidances. The patient is evaluated for an affective disorder. Medication use and substance abuse are carefully explored. The patient is asked about other physical complaints that might reveal systemic illness.

A complete physical and neurologic examination is always indicated. Screening laboratory tests at initial presentation include testosterone, prolactin, LH and FSH, thyroid hormones, complete blood count and chemistries, triglycerides and cholesterol, and a glucose tolerance test. The patient may also be referred for a gynecologic or urologic examination. The urologic evaluation may include tests of erectile capacity, including nocturnal penile tumescence and penile hemodynamics.

Therapeutic intervention begins with an explanation that sexual dysfunction is an epiphenomenon of epilepsy. This may prove tremendously relieving to the patient, who is likely to attribute sexual dysfunction to personal inadequacy. Educating the epileptic patient and his or her sexual partner about epilepsy in general and about the degree to which seizure control can be expected acutely and over the long term will improve disease acceptance, especially when combined with realistic and frank discussion about the impact of epilepsy on the lives of patient, family members, and friends.

An effort is made to improve seizure control with the patient's current antiepileptic drugs. If this is not successful, an alternative antiepileptic drug is considered, especially if the patient is taking a barbiturate. Individual patients may experience sexual deficits on one antiepileptic drug and be asymptomatic on another. Until further research clarifies the extent to which individual mediations affect sexual function, it is reasonable to switch to an alternative medication if seizure control is equivalent.

If other medical or psychological causes of sexual dysfunction are excluded and adjustment of antiepileptic drugs is not helpful or possible, specific sex therapy techniques may prove useful. Individual and couple psychotherapy may be indicated if there are problems in the relationship. If a woman complains of painful intercourse, relaxation techniques and lubrication products may be of benefit. For men with erectile difficulties, pharmacologic and surgical treatments are available.

Summary and Conclusions

A number of questions must be answered before the relationship between epilepsy and sexual dysfunction is better understood. The prevalence of sexual dysfunction and epilepsy must be contrasted with that in other chronic illnesses. The effects of individual antiepileptic drugs on sexual behavior must be elucidated. A better understanding of endocrine abnormalities associated with epilepsy must be achieved. Finally, and most important, attention must focus on treatments that can be offered to those men and women with epilepsy who experience sexual dysfunction.

Chapter 198

Pregnancy and the Mother with Epilepsy

Mark S. Yerby

Introduction

The management of women with epilepsy is an area that has received increased attention from neurologists. The discrimination and bias of past eras has gradually given way to an atmosphere in which marriage and child rearing is considered acceptable for women with epilepsy (WWE). We therefore tend to forget that in the not too distant past, most states had legislation prohibiting marriage for persons with epilepsy.

The advent of better neurologic training, improved diagnostic techniques, the development of vagal nerve stimulation, and a group of new and effective medications have vastly improved the management of epilepsy. The majority of women with this disorder can have healthy children. The management of women, however, presents unique issues not present for men. To be effective, neurologists need to understand these issues. Fluctuations in sex steroid hormones can have an impact on seizure control. Sexual dysfunction is seen more often in persons with epilepsy. Infertility is more common in women with epilepsy. It is unclear whether this is a function of the treatment or the underlying disorder. Enzyme-inducing antiepileptic drugs (AEDs) may reduce the effectiveness of hormonal contraceptives. Hormonal contraceptives may impact plasma concentrations of specific AEDs. Women with epilepsy are at greater risk for complications of pregnancy and adverse pregnancy outcomes. The following is a practical discussion of the management of these problems.

Infertility and Reproductive Abnormalities

Epidemiologic studies have demonstrated that women with epilepsy have only one fourth to one third as many children as women in the general population.[8,35] A variety of hypotheses have been developed to explain this phenomenon. A direct effect of seizures or epileptiform discharges on the pituitary and hypothalamus could disrupt ovulation. Electroconvulsive therapy increases prolactin concentrations over fivefold within 15 to 20 minutes, and in premenopausal women there is an acute increase in luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Generalized seizures also increase prolactin serum concentrations within 15 to 20 minutes by a factor threefold. This fact has been used to assist physicians in differentiating epileptic from nonepileptic seizures.[20]

Women with epilepsy have higher rates of reproductive and endocrine disorders (REDs) than expected. In a large clinical center, 50% of women with epilepsy were found to have menstrual abnormalities, 20% amenorrheic and 35% anovulatory.[24] Herzog et al. were among the first to demonstrate REDs in women with temporal lobe epilepsy.[25] Women with primary generalized epilepsies also have REDs. Five of 20 women studied by Bilo et al. had REDs, three with polycystic ovarian disease, and two with hypogonadotropic hypogonadism.[8]

Antiepileptic drugs may also interfere with the hypo-thalamic-pituitary axis. Amenorrhea, oligomenorrhea, and prolonged or irregular cycles have been described in WWE by Isojarvi et al.[35] Women with epilepsy taking valproate were overrepresented: 45% of those on valproate monotherapy and 25% on valproate polytherapy had menstrual disturbances. Polycystic ovaries were found in 43% of valproate-treated women and 80% of women treated with valproate before the age of 29 had polycystic ovaries.

Women with epilepsy have more variation in LH pulse frequency and lower LH concentrations than controls.[20] In addition, women with left-sided ictal epileptiform foci had polycystic ovarian disease, and those with right-sided foci hypogonadotropic hypogonadism.

Libido is significantly reduced in one third of men and women with epilepsy.[58] Increasing seizure frequency appears to decrease sexual desire, while there is no difference in libido between treated and untreated women with epilepsy. Hyposexuality and orgasmic dysfunction has been reported in 8% to 68% of women with epilepsy.[48] Persons with localization-related epilepsies appear to have higher rates of sexual dysfunction compared to those with primarily generalized epilepsies. Shukla et al. have demonstrated that 64% of women with partial epilepsies, compared to 8% with generalized epilepsies, report hyposexuality and sexual dysfunction.[79]

The problem of infertility in WWE is therefore complex. There are multiple factors: Seizure type, frequency, site of ictal onset, and use of AEDs, which may affect an individual patient. Infertility in a couple deserves a careful evaluation of both partners. For WWE, ultrasonography to rule out polycystic ovarian disease, serum LH and FSH concentrations, and an evaluation of AED use will help one narrow the focus of treatment. There is evidence that valproate may adversely impact the fertility of some women. If the patient's seizures are controlled, discontinuation of valproate is not warranted unless polycystic ovarian disease or hypogonadotropic hypogonadism is found.

Pregnancy

The majority of WWE can conceive and bear normal, healthy children. The pregnancies of WWE do present a greater risk for complications of pregnancy, they are more likely to have difficulties during labor, and there is a higher risk of adverse pregnancy outcomes.

Increased Seizure Frequency

One quarter to one third of WWE will have an increase in seizure frequency during pregnancy. This increase is unrelated to seizure type, duration of epilepsy, or seizure frequency in a previous pregnancy. While most studies have demonstrated

P.2068

that the increase tends to occur toward the end of pregnancy, recent reports find that a substantial number (31%) have their increase in the first trimester.[11]

Plasma concentrations of anticonvulsant drugs decline as pregnancy progresses, even in the face of constant and in some instances increasing doses.[63,72,92,93] Plasma concentrations tend to rise postpartum.[65,103] Although reduction of plasma drug concentration is not always accompanied by an increase in seizure frequency, virtually all women with increased seizures in pregnancy have subtherapeutic drug levels.[15,36,67,75] The decline of anticonvulsant levels during pregnancy is largely a consequence of decreased plasma protein binding, reduced concentration of albumin, and increased drug clearance.[14,36,63,68,69,93,104] The clearance rates are greatest during the third trimester.

Seizures during pregnancy increase the risk of adverse pregnancy outcomes. Generalized, tonic–clonic seizures increase the risk for hypoxia and acidosis as well as injury from blunt trauma.[85] Canadian researchers have found that maternal seizures during gestation increase the risk of developmental delay.[52] Although rare, stillbirths have occurred following a single generalized convulsion, or series of seizures.[10,27,87]

Generalized (though not partial) convulsions occurring during labor can have a profound effect on fetal heart rate.[90] The increased rate of neonatal hypoxia and low Apgar scores may be related to such events.[104] Partial seizures may also have similar effects, if less often.[74]

Complications in the Offspring

The infants of epileptic mothers are at greater risk for a variety of adverse pregnancy outcomes. These include fetal death, congenital malformations, neonatal hemorrhage, low birth weight, developmental delay, feeding difficulties, and childhood epilepsy.

Infant Mortality

Fetal death (defined as fetal loss after 20 weeks' gestation) appears to be as common and perhaps as great a problem as congenital malformations and anomalies. Studies comparing stillbirth rates found higher rates in infants of mothers with epilepsy (1.3% to 14.0%) compared to infants of mothers without epilepsy (1.2% to 7.8%).

Spontaneous abortions, defined as fetal loss prior to 20 weeks of gestation, do appear to occur more commonly in infants of mothers with epilepsy.[102] Women with localization-related epilepsies appear to be at greater risk for spontaneous abortions than those with other seizure types.[76] Other studies have demonstrated increased rates of neonatal and perinatal death. Perinatal death rates range from 1.3% to 7.8% compared to 1.0% to 3.9% for controls.

Malformations

Fetal malformations have been associated with in utero exposure to AEDs. Congenital malformations are defined as a physical defect requiring medical or surgical intervention and resulting in a major functional disturbance.

Infants of mothers with epilepsy exposed to anticonvulsant drugs in utero are twice as likely to develop birth defects as infants not exposed to these drugs. Malformation rates in the general population range from 2% to 3%. Reports of malformation rates in various populations of exposed infants range from 1.25% to 12.5%.[12,21,37,40,44,59,62,69,84,91,94,99] These combined estimates yield a risk of malformations in a pregnancy of WWE of 4% to 6%. Cleft lip, cleft palate, or both, and congenital heart disease account for many of the reported cases. Orofacial clefts are responsible for 30% of the increased risk of malformations in these infants.[1,22,43]

A wide variety of congenital malformations have been reported, and every anticonvulsant drug has been implicated as a cause. No anticonvulsant drug can be considered absolutely safe in pregnancy, yet most of these drugs do not produce any specific pattern of major malformations.

An exception to this is the association of sodium valproate with neural tube defects (NTDs). Methodologic problems make frequency estimates imprecise since most published data are case reports, case series, or very small cohorts from registries that were not designed to evaluate pregnancy outcomes. The prevalence of spina bifida (SB) with valproate exposure is approximately 1% to 2%, and with carbamazepine 0.5%.[28,53,73] However, a prospective study in the Netherlands found that infants of mothers with epilepsy (IMEs) exposed to valproate had a 5.4% prevalence rate of SB. Average daily valproate doses were higher in the IMEs with SB (1,640 ± 136 mg/day) than in the unaffected IMEs (941 ± 48 mg/day). Another group of investigators has found that valproate doses of 1,000 mg/day or plasma concentrations of 70 µg/mL or less are unlikely to cause malformations.[40,94]

Women with epilepsy should, as should all women of childbearing age, take folate supplementation. The dose recommended by the Centers for Disease Control and Prevention of 400 µg/day may not be high enough for many women who do not metabolize folate effectively. Even with folate supplementation, women taking valproate or carbamazepine should avail themselves of prenatal diagnostic ultrasound to rule out NTDs.

Neonatal Hemorrhage

For many years, it has been believed that infants of mothers with epilepsy are at greater risk of neonatal hemorrhage. This was reported first by Van Creveld, who suggested that vitamin K deficiency might be the cause.[95] Since then, there have been numerous reports that in utero exposure to AEDs is associated with neonatal hemorrhage.[9,19,46,50,81,83,86] Early reports attributed this to phenobarbital or primidone, but a hemorrhagic diathesis has subsequently also been described in children exposed to phenytoin, carbamazepine, diazepam, mephobarbital, amobarbital, and ethosuximide.

This has been differentiated from other hemorrhagic disorders in infancy in that the bleeding occurs internally, during the first 24 hours of life. Accurate prevalence figures are lacking.

The hemorrhage appears to be a result of a deficiency of vitamin K–dependent clotting factors II, VII, IX, and X. Maternal coagulation parameters are invariably normal. The fetus, however, will demonstrate diminished clotting factors and prolonged prothrombin and partial thromboplastin times. A prothrombin precursor, protein induced by vitamin K absence (PIVKA), has been discovered in the serum of mothers taking anticonvulsants.[16] Assays for PIVKA may permit prenatal identification of infants at risk for hemorrhage.[6,97]

The historical demonstration of an increased risk of neonatal hemorrhage coupled with a demonstrated deficiency of vitamin K and PIVKA led clinicians to believe that the relative lack of vitamin K and the presence of PIVKA was the cause of this particular neonatal hemorrhage. Three studies demonstrated that oral maternal supplementation increased neonatal vitamin K and reduced hemorrhage.[4,13,18] However, this practice has been challenged. Kaaja et al. found no difference in the rates of neonatal hemorrhage in 667 infants of mothers with epilepsy (0.7%) and 1,334 control infants (0.4%).[39] No

mothers in either group were supplemented with vitamin K, but all infants received intramuscular vitamin K at delivery. They concluded that on the basis of their experience, no evidence of a difference in clinical bleeding could be found; hence, supplementation was not recommended. Hey measured cord blood from 137 infants of mothers with epilepsy taking phenobarbital, phenytoin, or carbamazepine and found that 14 of 105 had prolonged prothrombin times but none had any clinical bleeding.[26] He believed that the lack of clinical bleeding in his series made supplementation with vitamin K inappropriate.

Some background may help clarify the apparent differences in conclusions made by these observers. Vitamin K deficiency is common in neonates. Maternal vitamin levels are not reflected in cord blood. When Shearer et al. measured vitamin K in mothers, they found values ranging from 0.13 to 0.29 ng/mL, but none in the cord blood.[80] Even after IV supplementation raised levels to 45 to 93 ng/mL, cord values rose only to 0 to 0.14 ng/mL. This discrepancy between maternal and neonatal vitamin K levels has lead researchers to look for PIVKA as a proxy for vitamin K deficiency. PIVKA is formed as a result of incomplete carboxylation of protein precursors of vitamin K and so is present when vitamin K is absent or present in very small concentrations.

The problem is, in part, that there has been confusion between vitamin K deficiency, laboratory evidence of abnormal coagulation parameters, and clinical bleeding. Vitamin K deficiency is common, the presence of PIVKA is less so, but clinical bleeding in neonatal life is rare. Shapiro et al. demonstrated that PIVKA presence is fairly uncommon in the general population of newborns (2.9%) and more common in premature infants.[78] We have no good data on prevalence of neonatal hemorrhage in infants of mothers with epilepsy, but we do have reasonably accurate case reports.

There is also reasonable causation. Anticonvulsants can act like warfarin and inhibit vitamin K transport across the placenta. These effects can be overcome by large concentrations of the vitamin. Despite lower coagulation factor levels, the fetus is generally able to obtain enough maternal vitamin K in utero. After birth the newborn must rely on exogenous sources of vitamin K because the newborn gut is sterile. Routine administration of vitamin K at birth is not adequate to prevent hemorrhage if any two of the coagulation factors fall below 5% of normal values.[83] Successful treatment requires fresh frozen plasma intravenously.

It is not so much that Kaaja and Hey are incorrect, but rather that it is extremely difficult to measure the effects of infrequent clinical outcomes. Neonatal hemorrhage is also unlikely to be identified unless it is severe and the child is clinically ill in those first 24 hours. The marked increase in PIVKA in infants of mothers with epilepsy suggests that they are at increased risk for hemorrhage, and the increase in developmental delay and need for additional educational assistance seen so often in this population suggests that small degrees of hemorrhage may affect the development of these infants.[3,52,55]

To make the matter more interesting, Howe et al. suggest that vitamin K deficiency in a developing embryo results in a failure of vitamin K–dependent carboxylation processes and an accumulation of compounds that affect embryonic cartilaginous development.[32] Such children are at risk for midface hypoplasia. They base this hypothesis on the clinical similarities between the midface abnormalities seen in warfarin- and phenytoin-exposed children. Howe et al. proposed that vitamin K supplementation should start prior to conception because maternal supplementation with vitamin K reverses the deficiency.

It is clear that one should offer maternal supplementation to pregnant women with epilepsy. The risks of neonatal hemorrhage, while low, clearly exist, as demonstrated by elevated PIVKA levels, particularly with enzyme-inducing AEDs. There is a lack of an effective intervention once a neonate bleeds. There is the additional possibility of small bleeds, which, while not clinically detectable at birth, may have long-term effects. There is a hypothesized possibility of an association of decreased carboxylation secondary to decreased vitamin K and the development of some types of malformations. There is a lack of risk with the recommended vitamin K supplementation (10 mg/day). There is also a clear need for better prevalence data on the true risk of clinical bleeding in infants of mothers with epilepsy.

Low Birth Weight

Low birth weight (<2,500 g) and prematurity have been described in infants of mothers with epilepsy. The average rates range from 7% to 10% for low birth weight and 4% to 11% for prematurity.[5,33,62,88,89] These studies do not analyze the effect of specific seizure types, frequency, or AEDs on this aspect of fetal development.

A prospective study that pooled data from three countries (Canada, Japan, and Italy) on 870 infants of mothers with epilepsy found that 7.8% were below the 10th percentile in weight at birth.[7] The risk was greater with polytherapy.

Body dimensions of infants of mothers with epilepsy have been studied by Wide et al.[100] Infants exposed to polytherapy, not surprisingly, were shorter and smaller than those exposed to monotherapy. Exposure to monotherapy with carbamazepine revealed a tendency toward small for gestational age, birth weight, and head circumference, but it was not statistically significant.

Table 1 IQ Scores of Children of Mothers with Epilepsy and Controls

Group	N	Mean VIQ	Mean PIQ	Mean FSIQ
Entire group	182	92.8	100.3	96.0
No AEDs	45	94.3	98.6	95.6
All monotherapy	107	94.4	101.9	98.0
CBZ monotherapy	86	96.2	103.1	99.7
VPA monotherapy	13	83.5	96.3	89.7
Other monotherapy	8	91.1	96.9	93.6
All polytherapy	30	84.9	97.1	89.5

VPA polytherapy	17	81.5	96.1	86.6
Control	141	94.9	102.4	97.6

AEDs, antiepileptic drugs; CBZ, carbamazepine; FSIQ, full-scale IQ; PIQ, performance IQ; VIQ, visual IQ; VPA, valproic acid.

Developmental Delay

With a prevalence of 0.6% to 1%, it is estimated that there are 24,000 deliveries to women with epilepsy in the United States each year. If 75% to 95% of these persons take AEDs, we can expect 18,000 to 22,800 infants exposed to AEDs in utero per year. It is estimated that half of all AED prescriptions are used for conditions other than epilepsy. Though these patient populations may have fewer women of childbearing years, the numbers of exposed children is substantial.

Most investigators have focused on congenital malformations as the primary adverse outcome for children of mothers with epilepsy. The rates are approximately double those in the general population. I would argue that the magnitude of developmental delay is similar.

Infants of mothers with epilepsy have been reported to have higher rates of mental retardation than controls. This risk is increased by a factor of two- to sevenfold, according to various authors.[29,82] None of these early studies controlled for parental intelligence; although differences in IQ scores at age 7 between groups of children exposed (FSIQ = 91.7) or not exposed (FSIQ = 96.8) to phenytoin reached statistical significance, the clinical significance of such difference is unclear.[29] In comparing 76 IMEs with 71 unexposed control children, Wide et al. found no difference in scores on developmental tests, but did find a tendency for phenytoin-exposed children to have a greater reduction in tests of motor coordination.[98]

Leavitt et al. found that IMEs display lower scores in measures of verbal acquisition at both 2 and 3 years of age. Though there was no difference in physical growth parameters between IMEs and controls, IMEs scored significantly lower in the Bailey Scale of Infant Development's mental developmental index (MDI) at 2 and 3 years. They also performed significantly less well on the Bates Bretherton early language inventory ($p \leq 0.02$) and in the Peabody Picture Vocabulary's scales of verbal reasoning ($p \leq 0.001$) and composite IQ ($p \leq 0.01$), and

P.2070

they displayed significantly shorter mean lengths of utterance ($p \leq 0.001$).[51]

Infants exposed to polytherapy performed significantly less well on neuropsychometric testing than those exposed to monotherapy. Socioeconomic status had the strongest association with poor test scores, but maternal seizures during pregnancy was also a significant risk factor.[54]

Leonard et al. have in part addressed the question of whether maternal seizures or in utero exposure to AEDs are responsible for the developmental delay seen.[52] A group of children of mothers with epilepsy followed to school age were found to have a rate of intellectual deficiency of 8.6%. The Wechsler Intelligence Scale for Children revealed significantly lower scores for children exposed to seizures during gestation (100.3) than for children whose mother's seizures were controlled (104.1) or controls (112.9). All AEDs are clearly not created equal, and Koch et al. have demonstrated that primidone, particularly when used in polytherapy, is associated with a lower Wechsler score of intelligence.[45]

Both maternal epilepsy and AED exposure in utero appear to affect development of offspring in a study by Koch et al.[45] The severity of outcomes increased from control to “maternal epilepsy, no AED exposure” to "maternal epilepsy, AED-exposed" children.

A rigorous retrospective analysis of 100 consecutive pregnancies seen at a tertiary epilepsy center found that 3.9% of the children were premature, 1.1% had congenital malformations, and 6.2% developmental delay. This was despite the fact that 59% of the mothers were seizure free and 98% took folic acid during their pregnancy.[41]

Another retrospective study demonstrated that 16% of 594 children of mothers with epilepsy exposed to AED in utero, compared to 11% of 176 of children with no AED exposure, required additional educational assistance in school. This was felt to be a reasonable marker for developmental delay. In addition, differences between AEDs were found: 30% of children exposed to valproate monotherapy, 24% of children exposed to valproate polytherapy, and only 3.2% of carbamazepine monotherapy–exposed children required additional educational assistance.[3] Monotherapy with other AEDs had rates of 6% and polytherapy without valproate 16%. Children with no AED exposure had an 11% use of additional educational services.

The same cohort of children was studied to determine their IQ scores. Of 251 children tested, the mean IQ for valproate-exposed children was 82, compared to 95 for carbamazepine-exposed and 92 for AED-unexposed children.[96]

The authors followed up their initial cohort, eventually studying 249 children of mothers with epilepsy from ages 6 to 16. The numbers in monotherapy were modest: 41 were exposed to valproate, 52 to carbamazepine, 21 to phenytoin, and 49 to polytherapy, compared to 80 unexposed children. They used regression analysis to demonstrate that both exposure to valproate and frequent generalized tonic–clonic seizures in pregnancy increased the risk of low verbal IQ scores.[2]

Three other studies have found increased rates of developmental delay in children exposed to carbamazepine ranging from 8% to 20%.[38,66,77] One of these studies only used a single standard deviation from the mean to qualify developmental delay and thus overstates the risk.[38]

A retrospective study of mothers with epilepsy delivering in Scotland between 1976 and 2000 used the nonexposed siblings as controls. Developmental delay was demonstrated in 19% of 293 AED-exposed children compared to just 3% of their nonexposed siblings. The rate of delay in valproate-exposed children was particularly high at 37%. Congenital malformations were found in 14% of exposed and 5% of nonexposed siblings. The investigators also stated that facial dysmorphism was present in 52% of exposed and 25% of nonexposed siblings, which makes one wonder about the nature of this population.[17]

Reinisch et al. conducted double-blind studies examining intelligence in adult men with in utero exposure to phenobarbital.[71] Their mothers by and large had not had epilepsy but took the drug for other indications. Unexposed members of the same birth cohort, matched on a large number of variables, were used as controls. The first study used the Wechsler Adult Intelligence Scale (Danish version); the second, the Danish Military Draft Board Intelligence Test. The authors concluded that:

- Men exposed prenatally to phenobarbital had significantly lower verbal intelligence scores (approximately 0.5 standard deviation or 7 IQ points) than predicted.
- Lower socioeconomic status and being the offspring of an "unwanted" pregnancy increased the magnitude of the negative effects to a mean of 20 IQ points less than controls.
- Exposure during the last trimester was the most detrimental.

In one of the best designed prospective studies of outcomes of mothers with epilepsy, Gaily et al. measured the intelligence of 182 children of mothers with epilepsy and 141 controls.[23] The investigators performing the testing were blinded as to the child's exposure. Table 1 is from their report.

P.2071

This suggests that children exposed to valproate and polytherapy are at higher risk for developmental delay than children exposed to carbamazepine or unexposed children.

Specific Effects of Antiepileptic Drugs and Other Interventional Therapies

New Antiepileptic Drugs in Pregnancy

Since 1993 a number of effective new AEDs have been introduced in North America. Their diminished side effect profiles have made them increasingly popular. Gabapentin, felbamate, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, and zonisamide are all now available in the United States. There is some tendency to think that since we know the older AEDs have hazards, the new ones might be acceptable substitutes. Unfortunately, there is little information to support their safety. The numbers of reported exposed pregnancies with these drugs is very low, and unfortunately not large enough for one to determine if there is an increased risk of adverse outcome with fetal exposure to these compounds. We know that lamotrigine and levetiracetam concentrations decline during pregnancy and expect that this is also true for the other new AEDs.[92] To follow is what we know to date.

Gabapentin

A study combining retrospective and prospectively collected cases evaluated 44 children born to 39 mothers with epilepsy taking gabapentin. Two of 44 or 4.5% had major malformations. One child had hypospadias and was exposed to gabapentin and valproic acid. The other was exposed to gabapentin monotherapy until the 16th week of gestation (the mother then switched to phenobarbital) and had only one kidney.[56]

Lamotrigine

The International Lamotrigine Pregnancy Registry has now identified 1,412 pregnancies reported in women taking lamotrigine in the first trimester. There is a significant difference in malformation rates when lamotrigine is used in monotherapy (2.8%; 20 of 707 with a 95% confidence interval of 1.8% to 4.9%) and polytherapy with valproic acid (11.8%; 14 of 119 with a 95% confidence interval of 6.8% to 19.3%) and polytherapy without valproic acid (2.7%; 7 of 256 with a 95% confidence interval of 1.2% to 5.8%).[49]

A recent report from the U.K. Pregnancy Registry found a dose-response effect with higher rates of malformations in infants exposed to doses >200 mg/day (5.4%) than those exposed to lower doses (1.9% at doses of 100 to 200 mg, and 1.5% at doses <100 mg).[60] An analysis of dosing from the Lamotrigine Registry did not find such a dose-response effect. Lamotrigine crosses the placenta and at delivery the fetus and mother have similar plasma concentrations. Elimination in infants appears to be rather slow. Seventy-two hours postpartum infant plasma levels are 75% that of the mother. Median milk:plasma ratios are 0.61.[65]

Oxcarbazepine

The only prospective series reported to date evaluated 42 oxcarbazepine-exposed pregnancies in Buenos Aires. There were no malformations in the 25 monotherapy-exposed cases. One child with a ventricular septal defect was exposed to oxcarbazepine and phenobarbital.[70] In a retrospective study from Finland of 133 women with epilepsy, 101 monotherapy exposures had no malformations and in 17 polytherapy exposures there was one malformation—a ventriculoseptal defect.[34] A recent review of the published world literature on oxcarbazepine exposure in pregnancy suggests that the risk of malformation is similar to that of the general population.[57] Oxcarbazepine crosses the placenta with equivalent maternal and fetal cord levels.[61]

Topiramate

There is little information on the number of pregnancies with topiramate exposure. There is one case report of a child exposed to topiramate monotherapy who developed growth deficiency, hirsutism, a third fontanelle, an upturned nasal tip, and distal digital hypoplasia. During the clinical trials, 28 pregnancies were reported in which there was one malformation and two anomalies. The manufacturer has collected 139 pregnancies during postmarketing surveillance. Of these, 87 resulted in live births, 29 were lost to follow-up, 23 had therapeutic abortions, and 5 cases had hypospadias (OthoMcNeil, personal communication). Topiramate crosses the placenta with cord and maternal plasma levels being equivalent at delivery. Milk:plasma concentration ratios average 0.86. Infant elimination appears to be substantial with little measurable drug found in the plasma of breastfed infants 2 to 3 weeks postpartum.[64]

Zonisamide

There have been 26 reported pregnancies with zonisamide exposure. Two of the 26 (7.7%) had congenital malformations. One child was also exposed to phenytoin and the other to both phenytoin and valproic acid.[47]

Zonisamide also freely crosses the placenta with transfer rates of 92%. Though data is available from only two children, milk:plasma ratios are 0.8 and elimination half-life ranges from 61 to 102 hours.[42]

Pregnancy Registries

The paucity of data on newer AEDs has led to the development of pregnancy registries. These prospective data collection centers can serve as an "early warning system" by looking for either clusters of specific abnormalities or rates of malformation in excess of expected. They are hampered by the fact that not all women with epilepsy who deliver will enroll, and there are poor data on the true number of exposed women. Therefore, no denominator exists to permit the estimation of rates. Such a system can only accurately capture major malformations of the type diagnosable at birth. Given these limitations, this remains the only method currently available for surveillance and physicians and patients are encouraged to enroll.

There are now two major regional pregnancy registries for AEDs: European (EURAP), and North American (NAREP). Both are prospective and collect information for all AEDs. They differ in the source of subjects. The NAREP requires patients themselves to report, while the other relies on physicians.

The North American registry has over 2,970 monotherapy prospective subjects and is the only registry with a concurrent control group. It has found an increased risk of malformations for phenobarbital (6.3%; odds ratio [OR] of 4) and for valproate (10.7%; OR of 7). In addition, it has determined that while lamotrigine has an overall malformation rate of 2.7%, it does appear to increase the rate of oral clefts to 8.9 of 1,000 compared to 0.37 of 1,000 in the general population.[30,31,101]

A Swedish birth registry study has reviewed 1,398 AED-exposed infants. The odds ratio for malformations in infants exposed to AED was 1.86 (95% confidence interval, 1.4 to 2.4). Malformation rates for specific AEDs in monotherapy

P.2072

were 4.0% for carbamazepine, 4.4% for lamotrigine, 6.8% for phenytoin, and 9.7% for valproic acid.[99]

An Australian pregnancy registry has combined prospective and retrospective data in an unusual approach. They have reported in oral platform sessions at the American Epilepsy Society meeting in 2004 on 565 completed cases. They reported a 15% malformation rate with valproate monotherapy, with higher rates seen with doses above 1,100 mg/day.[94]

A registry from the United Kingdom reported on 3,607 pregnancies. The malformation rate was 3.7% for those exposed to monotherapy and 6.1% for those exposed to polytherapy. There were higher rates of malformations in polytherapy with valproate than without (OR 2.49). Carbamazepine monotherapy exposures resulted in the lowest malformation rates (2.1%), followed by gabapentin (3.7%), lamotrigine (3.5%), phenytoin (4.1%), and valproate (6.1%).[60]

Summary and Conclusions

Those who care for WWE face a dilemma. Seizures need to be prevented, but fetal exposure to anticonvulsant drugs needs to be minimized. Though it might appear that the ideal situation would be to withdraw the patient from anticonvulsants prior to conception, for most women this is not a realistic option. Women today are more likely to be employed and the potential disruption of their lifestyle by seizures, such as the risk of loss of driver's license, makes elimination of anticonvulsants impractical. More importantly, maternal seizures increase the risk of injury, miscarriage, epilepsy in the offspring, and developmental delay.

The major organ systems have formed by late in the first trimester. The posterior neuropore closes by day 27 and the palate by day 47 of gestation. By the time most women realize they are pregnant, malformations already may have developed. WWE of childbearing age need to be informed of the risks of pregnancy associated with anticonvulsant use prior to conception if possible. They also need to know that seizures can be harmful to the mother and fetus, and that risks can be reduced with proper care.

Many people appear to be unaware that even healthy parents have a 2% to 3% risk of having a child with a malformation. Given the current state of the art, the best we can do is practice risk reduction. In general, risks can be minimized by the preconceptual use of multivitamins with folate, the use AEDs in monotherapy with the lowest effective dose, and the prevention of maternal seizures. Monitoring free drug levels both prior to and during pregnancy will permit accurate assessment of concentrations in a situation where plasma protein binding is in flux. Dose adjustment, however, should be made on a clinical basis. Plasma anticonvulsant drug concentrations will fall in pregnant women, but only a quarter to one third will have an increase in seizures. We tend to keep dosage as low as possible during conception and organogenesis, but will often raise dosage during the third trimester to reduce the risk of seizures during labor.

Supplementation with at least 0.4 mg/day of folate is recommended by the Centers for Disease Control and Prevention for all women of childbearing age, whether or not they have epilepsy.

Vitamin K1, 10 mg/day, should be initiated late in the third trimester to prevent neonatal hemorrhage. We usually prescribe it during the final month of gestation.

Breastfeeding is generally safe in term infants as they have been exposed to the AEDs for 9 months and have induced their hepatic microsomal enzyme systems. However, breastfeeding should be done cautiously by women receiving phenobarbital or primidone due to the risk of infant sedation.

Pregnant women taking valproate should avail themselves of the prenatal diagnostic techniques of ultrasound and *α*-fetoprotein measurement. Ultrasonography has become much more accurate and in experienced hands can identify the vast majority of structural defects. Current prenatal testing recommendations are as follows:

1. Anatomic ultrasound at 11 to 13 weeks. This can identify the most severe defects such as anencephaly.
2. Maternal serum *α*-fetoprotein
3. Repeat anatomic ultrasound at 16 weeks. This can identify abnormalities such as orofacial clefts, heart defects, and caudal neural tube defects.

When WWE initially present to their neurologist pregnant, their gestational age (GA) needs to be established with reasonable accuracy. One cannot rely on last menstrual period (LMP) alone; an early ultrasound should be obtained to date the pregnancy. Once GA is established, a calendar can be planned with dates for monthly AED level checks, prenatal testing, and initiating vitamin K supplementation determined ahead of time.

The management of women with epilepsy presents unique challenges. Confirmation of diagnosis and verification of the most appropriate AEDs for the individual are the starting points. With effective patient education and careful and consistent management, including a coordinated treatment plan with both neurologist and obstetrician, these patients can and do have successful pregnancies and healthy offspring. Neural tube defects are serious malformations lacking effective therapeutic interventions. Their risk can be reduced by careful management and theoretically eliminated by prenatal diagnosis and therapeutic abortion. In our role as advisors, we need to recognize that all patients may not share our value systems or even begin to perceive what it really means to care for a child with an NTD. Physicians must be sensitive to their patients' anxieties and be prepared to manage not simply their seizures, but also their emotional concerns.

Chapter 199

Overview: Psychiatric Issues

Michael R. Trimble

Introduction

The links between epilepsy and psychiatry have a long and respectable history, but for reasons best deliberated on by historians, the growing gap between neurology and psychiatry in the 20th century led to a considerable divergence of opinion as to the relationships between psychiatric disorders and epilepsy. Part of this confusion was due to the eventually almost exclusive psychological approach taken to neuropsychiatric disorders by psychiatrists, and the relative neglect by neurologists of behavior problems that could be associated with neurologic disorders. Further, in the field of epilepsy there was confusion over the distinction between seizures and epilepsy. Many people equated the two, but seizures as signs and causing symptoms are quite distinct from the underlying pathologic process of the epilepsy. The ongoing interictal electrophysiologic disturbances, which presumably reflect on underlying electrochemical aberrations within the brain that are easily identifiable by various imaging techniques, may be expected to lead to continuing disturbances of cerebral function. If these occur in areas of the central nervous system that have an impact on emotion and behavior, then psychiatric disturbances may be the expected outcome of at least some people with epilepsy, depending upon the site and type of the underlying epileptic discharge.

By the midpoint of the 20th century, it was a strongly held view, particularly in the United States, that people with epilepsy, if they had psychiatric difficulties, had them because of secondary factors. These included not only the stigmatization of having a terrible condition such as epilepsy, with such a poor quality of life and considerable social disadvantage (which was known to occur then and still occurs now), but also drug factors (remembering that phenobarbitone was commonly employed in those times) or, for example, cerebral trauma from head injuries following seizures. The concept that the underlying neurologic disturbance that led to the epileptic seizures could also provoke psychiatric problems was hard for many to accept.

There was, however, a slowly growing literature that emphasized not only the possible neurologic underpinnings of psychiatric disorders generally, but also the psychiatric complications of neurologic disorders, including epilepsy. From a purely anatomic point of view, the unraveling of the concept of the limbic system, from the earlier circuitry proposed by Papez to the later, more sophisticated elaborations of people such as MacLean, emphasized that within the brain there were neuronal structures and circuits that had specifically to do with modulation of emotion. This was a new idea, because before the development of the limbic system concept, there was no clear cerebral framework for an understanding of how the brain felt and expressed emotion. It was crucial to elaborating on the link between epilepsy and emotion to realize that two key limbic structures, the hippocampus and the amygdala, were frequently involved in the underlying pathology of epilepsy, particularly in the localization-related epilepsies, and newly developed techniques of recording from sites within the brain revealed that in between seizures, interictal abnormalities were recorded from such structures. More recently, the uncovering and elaboration of the direct associations between medial temporal structures and limbic forebrain structures and the unraveling of the neuroanatomy of the limbic forebrain by authors such as Heimer et al. have given clear neurologic underpinnings for an understanding of the behavioral consequences of neurologic disorders, epilepsy being no exception.[1]

However, understanding the neuroanatomy in more detail is not sufficient. It is clear that people with epilepsy, like anybody else, can have a straightforward psychiatric problem. A number of these are classifiable in terms of standardized diagnostic schedules (for example DSM-VI or ICD-10) and, when present in people with epilepsy, should receive the same amount of attention for management as they would if the patient did not have epilepsy. However, the contention of the last 30 or so years has been that there are some psychiatric problems that are more intimately imbedded within the context of the underlying neurobiologic process of the epilepsy.

This underlying neurobiology of the behavior disorders is discussed at the very outset of this section. The first chapter essentially makes the point that at least some of the psychiatric presentations are potentially directly interwoven with either the ictus or the interictal neurologic changes, this underlying neurology giving a particular stamp to the clinical presentations that lead them to differ somewhat from the psychiatric presentations diagnosed in the absence of the underlying neurologic disorder.

A further complication arises from the fact that the patients with epilepsy who are most liable to psychiatric disorders are those who are treated with antiepileptic medications chronically, often with polytherapy, and the medications themselves can contribute considerably to some of the ongoing symptomatology. This includes not only some of the more florid psychotic presentations, but also one of the most interesting phenomena in neuropsychiatry, namely, the precipitation of a psychiatric disorder when an antiepileptic drug is prescribed and seizures are suddenly turned off (referred to as forced normalization—the Landolt phenomenon). Equally important, however, are the subtle changes of mood and cognition that can be induced by antiepileptic medications. These matters are noted in several of the following chapters, but need specific highlighting for certain populations, such as those with learning disorders. They form a vulnerable group for the development of behavior disorders, but often their management falls short of the optimum. This may be due to some physicians failing to recognize that patients with learning disorders and seizures do have epilepsy! It may be missed or dismissed on the grounds that this population of patients somehow lies outside of the neurologic limit. With language and motor abnormalities, their

psychopathology is sometimes simply not recognized. A second group that requires special consideration is children. The spectrum of clinical psychopathology is different in younger patients with epilepsy, and the management of such patients also requires different treatment strategies and agencies.

Some of the psychiatric disorders seen in people with epilepsy (e.g., the postictal psychoses) are simply not found in standardized diagnostic manuals for psychiatric disorders, and yet their presentation is highly characteristic and will be found only in people with seizure disorders. Other more subtle neuropsychiatric complications of epilepsy, including the schizophrenialike interictal psychoses (of Slater) and the interictal dysphoric disorder (of Kraepelin and Blumer), have been harder to define, but are now recognized as epilepsy-specific presentations, even if still requiring more elaboration and validity testing. To a large extent, these presentations no longer arouse the controversies that they used to in the past. A more vexed problem is the issue of the interictal personality disorder, particularly as it was described by Waxman and Geschwind in the 1970s.[3] At that time neurologists were becoming cognizant of the fact that patients with frontal lobe damage could develop personality changes reflective of the injuries, and the term *frontal lobe personality disorder* began to appear in neurologic texts. Further, with regard to the temporal lobes, the Klüver-Bucy Syndrome was described, initially in animals but then in patients, with central features to this being alterations of personality with taming of the emotions, alteration of spontaneity, and changes of mood and social behaviors. Thus, it does not seem out of keeping with the growing knowledge of clinical behavioral neurology, and the elaborations of the neuroanatomy of the limbic system, that an interictal personality syndrome may be defined and consequent of temporal/limbic/neuroanatomic/neurophysiologic disturbances. In fact, descriptions of an interictal personality syndrome can be found in the European literature from well over a hundred years ago, but it was well codified by Gastaut and Geschwind. The main features of the disorder, such as hypergraphia and hyperreligiosity, are discussed in the relevant chapter, but other, perhaps even more controversial topics such as the links between aggression and epilepsy are given appropriate space.

Geschwind et al. and followers gave to us the term *behavioral neurology*, essentially an offshoot of 19th-century neuropsychiatry. The paper that introduced the interictal personality syndrome pushed the field in new directions, as it touched on behaviors not usually discussed in neurologic circles (e.g., creativity and religiosity). Although the characteristics of the interictal personality disorder are now very well known, there are still many neurologists, even epileptologists, who find it hard to see the specimen when it flutters before them to be pinned down. In part, this still reflects on that confusion between seizures and epilepsy, which still in the minds of many remains conceptually muddled.

It is important that whatever the clinical problem, patients receive appropriate psychiatric care where necessary. At least part of this will involve psychopharmacology, and therefore, chapters on management and treatment of these problems are also included. All the chapters in this section emphasize the importance of recognizing c-morbid psychopathology in people with epilepsy. If the seizure is considered to be the only problem that patients face and the comorbidities are ignored, then an appropriate schedule of management cannot evolve, and the patient's untreated psychopathology may well undermine the ongoing attempts to manage the epileptic seizures.

David Taylor, in his overview on psychiatric issues of the first edition of this textbook,[2] pointed out that there had been an overcorrection of emphasis from the epoch of psychoanalysis, with the rise of biologic psychiatry, and noted the complexity of trying to disentangle brain–behavior relationships in epilepsy. While the lesion within the developing brain, present at a time when the anlage of the developing personality is being laid down, will be influenced and in turn influences interpersonal and familial relationships, he noted how accommodation and compensation within a brain, which has such developmental skews, may appear to lead to effective ways of coping at certain stages of development but not at others. There is, as he said, "a need to consider the complex interaction, over the course of the development of the individual, among impairments of cerebral structure, disorders of cerebral function, psychological deficits, and the sort of family and peer group functioning within which these deficits interact." He drew clear distinctions between diseases, illnesses, and predicaments, which bear not only on common sense, but also on our clinical experience. By disease he meant evidence of dysfunctions that are more often nowadays revealed through, for example, brain imaging than through postmortem analysis. By illness, he referred to the limitations of functioning and suffering that people experience as a consequence of the underlying disease, and he noted that psychiatric problems essentially are illnesses rather than diseases. The importance is to understand the illnesses and the predicaments that they present to the person who is ill and his or her family. Helping people with their predicaments, trying to understand their illnesses, and attending to their underlying discernible disease are all parts of the complexity of the neuropsychiatry of epilepsy.

Summary and Conclusions

In the 21st century we now have a much clearer understanding of the underlying neuroanatomy and neurochemistry of psychiatric disorders in general, but also of why a number of neurologic disorders, in which neuroanatomic changes are identifiable in limbic and forebrain structures, may lead to a susceptibility to the development of psychiatric syndromes. There is an overlap between psychiatry and neurology, and epilepsy has always been central to discussions about this interface. Most neurologists now accept that psychopathology is an integral part of some epilepsy syndromes, whether it be memory disturbances and other cognitive difficulties or more florid psychopathologies as one may see, for example, in the psychoses. A substantial portion of this comprehensive textbook has been devoted to these behavioral problems, and it is hoped that the chapters in this section will be of interest and importance to both neurologists seeking understanding and psychiatrists seeking enlightenment.

Chapter 200

Neurobiology of Behavioral Disorders

Jerome Engel Jr.

David C. Taylor

Michael R. Trimble

Introduction

Many persons with epilepsy suffer from interictal disturbances in behavior* that can contribute significantly to their illness and in some cases constitute the major disability. Although there remains some controversy on this subject, it is generally accepted by most workers in the field that the degree of behavioral problems associated with epilepsy is greater than would be expected on the basis of the existence of a chronic illness alone, both in adults[40] and in children.[64] To a certain extent, the psychiatric consequences of epilepsy can be attributed to external factors, specifically the predicament imposed by epilepsy not only as a traditionally stigmatizing disorder but also because the unpredictable nature of recurrent ictal events allows society to impose rather severe limitations on activities of daily living.[63] In addition, however, there are legitimate neurobiologic explanations for interictal behavioral disturbances in this patient population, including (a) nonepileptic factors, such as effects of the underlying pathologic substrate itself; (b) the unwanted effects of medical and surgical treatment on cerebral function; (c) epileptic mechanisms consisting of unrecognized prolonged ictal events that are witnessed as interictal behavioral disturbances; and (d) the ability of recurrent epileptic activity to cause enduring changes in neuronal function.

The concept that epileptic seizures themselves can effect a persistent disruption of normal neuronal function leading to the appearance of interictal behavioral disorders is not new[10,17,18,20,21,54,59] but is still not completely accepted and is even adamantly rejected by many. One socially sensitive justification for the contrasting point of view is that there are already too many negative associations with epilepsy, so that to add the fear of becoming "insane," without definitive proof, would impose a further unnecessary burden. On the other hand, formal recognition that epileptic mechanisms *might* contribute to transient and enduring changes of both function and structure in the brain is necessary before investigation of this possibility can begin. Appropriately designed clinical and animal research could lead to interventions that would reverse or prevent a major cause of epilepsy-associated disability.

Nonepileptic Organic Causative Factors

Symptomatic epilepsies result from a variety of underlying pathologic processes that might be localized or diffuse, unilateral or bilateral, static or progressive. These can produce epileptic seizures as their only clinically apparent manifestation. However, they might also give rise to chronic neurologic or psychiatric deficits related to (a) the nature of the pathophysiologic substrate, (b) its precise location in the brain, and (c) the time of its occurrence with respect to brain development. In idiopathic epilepsies, there is no obvious structural pathology, but the genetic defect responsible for the spontaneous recurrence of epileptic seizures presumably produces a disturbance in neuronal responsivity, transmission, or wiring that is continuously present between seizures and could have other, nonepileptic functional consequences manifesting as deficits in learning and skills, as well as interictal behavioral disturbances. Although focused research on this subject cannot begin until the specific defective gene or its aberrant products have been identified, this hypothesis offers a plausible explanation for the association of certain mild behavioral disturbances with some of the idiopathic generalized epilepsy syndromes that have been supposed to be only epilepsy and nothing more.[28,52] All current antiepileptic drugs act nonspecifically to alter excitatory or inhibitory influences or reduce neuronal synchronization, processes that are critical to normal cerebral function.[32] It is not surprising, therefore, that pharmacotherapy can be associated with sedation, cognitive impairment, and a range of psychiatric disturbances.

A hitherto unanswered question is whether psychiatric syndromes associated with antiepileptic drugs are a function of prior risk (i.e., faulty organization): Why are some, but not all, persons affected? Among a group of affected persons, a variety of psychiatric disorders might be associated with the use of any particular medication. This suggests that the specific disorder induced in an individual is that to which they are most genetically liable. Monitoring of these responses on a multicenter basis could be helpful in elucidating not only the problem of drug-induced disorders, but also the mechanism of the psychiatric disorders concerned. Surgical treatment, whether resection, ablation, or disconnection, also disrupts normal neuronal integration and new neurologic or psychiatric disturbances can emerge subsequently, either at the point in development when they normally occur (e.g., schizophrenia) or in direct reaction to tissue damage (e.g., specific learning deficits). Effects of pharmacotherapy and surgical therapy on behavior are dealt with in Chapters 208 and 209 and are not considered further here.

Nature of the Lesion

Epilepsy that is attributed to a lesion typically develops after a prolonged latent period, although brain organization could be adversely affected much earlier. Discrete, well-localized structural epileptogenic lesions in so-called silent brain areas may cause no perceptible disturbances other than recurrent ictal events, but more extensive lesions are likely to impinge on critical cortical areas and be associated with some degree of

interictal impairment. Consequently, cognitive deficits and neurologic signs and symptoms commonly accompany epileptogenic substrates that tend to be diffuse or multifocal. Disorders such as tuberous sclerosis or cortical dysplasia can be sufficiently mild that only a single localized lesion is identified on magnetic resonance imaging (MRI), but chronic behavioral impairment could suggest, in these cases, the presence of much more widespread aberrations in neuronal migration and differentiation that are beyond the resolution of current imaging techniques. For other lesions, disturbances in cerebral function could reflect distant cerebral abnormalities of a related disorder; for instance, the high incidence of schizophrenia reported to occur in women with hamartomas and gangliogliomas[61] was postulated to be caused by a karyotype abnormality associated with ectodermal dysplasias and abnormal behavior.[49] Progressive lesions that continue to destroy or disrupt neuronal function are clearly more likely to give rise to interictal behavioral problems than static lesions, the latter of which permit recovery of function through compensatory mechanisms. For the same reason, rapidly progressive disease processes cause more interictal disturbances than slowly progressive ones. It is also conceivable that some neoplastic lesions could secrete neuroactive substances that influence interictal behavior, and some vascular lesions can cause nonepileptic signs or symptoms by bleeding or a steal phenomenon. Lesions that were thought to be static, such as hippocampal sclerosis, are now reported to be common sequelae of stress in its widest sense.[56] Thus, stress would be an important factor in the epilepsies and in psychiatric disorders.

The Location of the Lesion

The neurologic signs and symptoms produced by focal structural lesions depend on the function of the brain area involved. Discrete neocortical lesions in primary areas produce very localized deficits, whereas diffuse bilateral abnormalities cause cognitive impairment and more global dysfunction. Lesions of the limbic system are of particular interest in epileptology because they are the most likely to produce epileptic seizures and because these lesions are associated with much more varied interictal behavioral disturbances than lesions of neocortex.[35]

The most common deficit associated with lesions of the mesial temporal limbic system is impairment of episodic memory, which is usually material specific for the hemisphere involved.[41] This is more noticeable, and therefore more disabling, when the lesion is in the language-dominant temporal lobe, and there is usually an associated verbal learning disturbance. The limbic system, however, also plays a key role in modulating mood and affect, basic drives (including sexual function), and motivation, functions that, when distorted by structural or functional lesions, could conceivably give rise to virtually every behavioral aberration attributed to epilepsy, including specific psychiatric illnesses.

It is important to note that lesions in certain locations that are epileptogenic might be more likely to cause enduring disturbances referable to the normal function of that area than lesions that are purely ablative.[61] Because there is a certain degree of plasticity of brain tissue, even in the adult, destructive lesions can cause transient deficits that eventually recover as other brain areas take over the function. When the neuronal disruption is intermittent, however, as with epileptic seizures, it is possible that natural compensatory mechanisms are not activated, and recovery of function does not occur. Furthermore, epileptic discharges propagate and can disrupt function at a distance from the primary epileptogenic region, including contralateral structures. Consequently, specific temporal lobe or frontal lobe signs and symptoms that require bilateral homotopic dysfunction would not occur with a nonepileptic destructive lesion in one hemisphere but are commonly seen with unilateral epileptogenic lesions. The existence of secondary bilateral involvement and its reversibility are readily demonstrated following successful anterior temporal lobectomy, when material-specific memory referable to the contralateral temporal lobe subsequently improves and patients may experience an overall increase in IQ.[47,62]

Developmental Considerations

Classical neurology has an adult perspective. Its premise is of some fault or accident that disrupts a previously normally functioning central nervous system (CNS). The lesson of epilepsy has been that the faults are often early prenatal or late prenatal or early postnatal, but the problem of interest (the epilepsy or the cognitive capacities or the behavior) becomes “eloquent” at some later stage. Models of this exist in syphilis, encephalitis, rheumatic heart disease, Huntington chorea, and many other conditions. The developmental perspective is to consider the possibility that the lesion or fault could have been “eloquent” in other ways before the condition of interest arose or could become “eloquent” in those ways later in development. This removes a need for thinking that a chronic lesion that arose in embryonal life has somehow acquired new powers at age 14 (or whenever) because “it has started to cause epilepsy.” It allows consideration that the condition of interest (e.g., epilepsy) arises from a constellation of circumstances that have not existed previously, a combination of aging and maturation together with hormonal and psychosocial factors.

Ordinarily, localized destructive cortical lesions that occur early in the course of development are less likely to cause lasting deficits than lesions occurring in later life because of the increased plastic potential of the immature brain. For instance, patients with extensive damage to the left hemisphere incurred within the first few years of life usually have a pathologic compensatory shift of language dominance to the right hemisphere, with little or no disturbance in speech or language.[48] On the other hand, more diffuse bilateral lesions occurring early in life are usually accompanied by a developmental delay that persists into adulthood. Taylor,[62] however, challenged functional shift as the only basis of handedness change, because alien tissue lesions are associated with left handedness whether they are in the left or right hemisphere. He suggested that an alien tissue lesion could act by reducing the effect of the gene for right-handedness bias. If this is confirmed in other studies, it would help our understanding of prenatal organization of cerebral functions.

As mentioned in the previous section, epileptogenic lesions may be more likely to produce a lasting effect on behavior than destructive lesions because intermittent disturbances could confound compensatory recovery processes. This appears to be particularly true during the period of cerebral development. Furthermore, the widespread electrical epileptiform electroencephalogram (EEG) abnormalities that characterize certain epileptic syndromes in infancy and early childhood, such as West syndrome, can reflect propagation of discharges from a localized epileptogenic lesion that also produces the same global behavioral disturbances usually associated with a diffuse bilateral destructive lesion. The evidence for this comes from the observation that some infants and small children with developmental delay who initially appear to have catastrophic secondary generalized epilepsy actually have a single lesion localized to one hemisphere, and surgical removal of this area not only eliminates the ictal events, but also helps to reverse the developmental delay.[53]

Epileptic Causative Factors

Unrecognized simple partial status epilepticus causes behavioral disturbances that can be mistakenly labeled "interictal," and prolonged convulsive status epilepticus can cause brain damage. There is an abundance of evidence for epilepsy-induced enduring functional disturbances from well-described phenomena in experimental animals.[10,14] The confounding effects of the pathologic process responsible for the epileptic condition on behavior and the effects of antiepileptic drugs, which are invariably present, make it extremely difficult to demonstrate, in a clinical setting, that recurrent, transient epileptic events alone can cause interictal behavioral disturbances.[59] If such changes do occur in patients, undoubtedly they are more likely to result from some types of epileptic abnormalities than others, and conceivably there are also ictal and interictal epileptiform events that pose no risk for persistent dysfunction. For this reason, it would be inappropriate to suggest that all epileptiform abnormalities are capable of inducing enduring neuronal dysfunction or that all epilepsies have the potential of being progressive in some way. On the other hand, it is of great practical importance to make every effort to document the occurrence of such epilepsy-induced behavioral disorders in patients in order to determine what types of seizures and epileptic syndromes are likely to give rise to persistent problems and at what point in the course of these conditions the disturbance might become irreversible. Such information would provide essential guidelines for early aggressive intervention in patients who are deemed to be at risk.

Unrecognized Prolonged Ictal Events

One inarguable cause of an inappropriate diagnosis of "interictal" behavioral disturbances, although perhaps rare, is nonconvulsive status epilepticus. Simple partial seizures of limbic origin can cause virtually any psychiatric sign or symptom in clear consciousness, and the scalp EEG in this condition is almost always normal.[71] Sensory symptoms caused by simple partial status epilepticus of neocortical origin can give rise to bizarre experiences that are acted on in strange ways to create a persistent interictal behavioral disturbance. These forms of simple partial status epilepticus (also called aura continua) are easy to recognize when they occur in patients with known epilepsy, and the ongoing signs and symptoms match those of the habitual simple partial seizures (auras) that usually precede more obvious ictal events. In patients who have never had an obvious epileptic seizure and who have a normal EEG, this diagnosis would be exceedingly difficult. Rapid reversal of signs and symptoms with intravenous benzodiazepines suggests, but in no way proves, a diagnosis of epilepsy because many nonepileptic conditions can also transiently respond to this treatment. Complex partial status epilepticus and absence status can also rarely be mistaken for a psychiatric condition when the clouding of consciousness is subtle. EEGs in these conditions, however, reveal the diagnosis, although sometimes only after extreme persistence.[2]

In patients with known epilepsy and well-documented, frequent interictal EEG abnormalities, the only surface EEG correlate of a simple partial seizure is, classically, disappearance of the interictal EEG spike. For instance, in temporal lobe epilepsy, a simple partial seizure is associated with an ictal discharge in mesial temporal lobe structures, which are then no longer able to generate interictal spikes that ordinarily would propagate to temporal neocortex and appear on the scalp EEG. Consequently, disappearance of the typical interictal EEG spike pattern in a patient with persistent behavioral disturbances could be used as supportive evidence for simple partial status epilepticus. Indeed, one postulated explanation for Landolt's so-called "forced normalization"[31] (the occasional observation that the EEGs of some patients with known epilepsy normalize during episodes of psychosis) is that the behavioral disturbance is actually simple partial status epilepticus.[72]

Epileptic Brain Damage

Another incontestable consequence of epileptic seizures is cell death from the excitotoxic effect of excessive release of excitatory amino acids during status epilepticus.[59] It is well known that susceptible cerebral structures, particularly the hippocampus, undergo irreversible damage in patients after prolonged convulsive status epilepticus, and studies in experimental animal models show that this occurs even when cerebral perfusion, ventilation, and normothermia are preserved.[39] Much is now known about the cellular mechanisms of excitotoxic cell death, but it is unclear whether (and if so, to what extent) this occurs in human epilepsy apart from the severe insult associated with convulsive status epilepticus.[59] Excitotoxic effects are associated with massive calcium influx, which may be insufficient to cause cells to die but, rather, turns on genetic mechanisms that could profoundly alter cell structure or function, perhaps inducing transsynaptic changes at a distance from the epileptogenic lesion. Such a mechanism could provide a ready substrate for persistent interictal behavioral disturbances.

Hippocampal sclerosis, believed to result, at least in part, from processes inducing excitotoxic cell death, has been associated with behavioral disturbances described mainly in terms of effects on personality, with evidence of immaturity, irritability, and trivial aggression, at that time recorded as psychopathy.[60,66] Hippocampal sclerosis has been shown to follow from conditions other than prolonged febrile convulsions, such as trauma, that occur early in life.[36] It is intriguing that there is now also considerable literature on the deleterious effect of high levels of cortisol, produced in response to stress, on the developing hippocampus.[56] It is possible that hippocampal sclerosis arising from prolonged febrile convulsions is a unique syndrome. Various other mental states have been associated with hippocampal sclerosis, including schizophrenia[7,42,58,69] and depression.[33,60] The behavioral syndrome associated with mesial temporal lobe epilepsy is subtle and deserves more research.[5,70] The immaturity, irritability, rigidity, stickiness, hypergraphia, and hyperreligiosity that most often are mentioned with this syndrome are, importantly, relieved by successful mesial temporal resection and disappear rapidly over the first 2 or 3 postoperative years.[66] Because the treatment is ablative, the effect must be through relief of seizures and/or obliging the rest of the limbic system to take over the tasks of the ablated tissue. Psychological evidence[47,62] suggests that successful surgery leads to generally improved functioning in other domains, too.

Kindling and Secondary Epileptogenesis

Although kindling[23] and secondary epileptogenesis[43] are extremely well documented in the animal laboratory, their relevance to human epilepsy remains controversial.[24,44] In virtually all vertebrate animals tested, from frogs to subhuman primates, subthreshold stimulation of susceptible limbic and neocortical structures, when repeated at appropriate intervals, gives rise to epileptiform EEG and behavioral abnormalities that become increasingly prolonged and severe, and eventually, spontaneous seizures occur. This phenomenon has been demonstrated with both electrical and chemical stimulation; there is crossover from one stimulation modality to the other, and the effect is persistent, at least to some degree, for as long

as the animal is subsequently tested. The kindling paradigm brings under experimental control the more naturally occurring process of mirror focus development,[43] whereby a region capable of generating spontaneous epileptic seizures gradually develops contralateral and homotopic to an experimental epileptic focus, presumably as a result of continuous bombardment of epileptiform discharges across the corpus callosum. Nevertheless, despite years of research, there remains debate about the existence of significant secondary epileptogenesis in humans.

Some studies of patients undergoing surgical treatment for brain tumors provide evidence for mirror focus development,[44] and similar secondary epileptogenesis may account for the inverse relationship between duration of epilepsy and surgical outcome reported for anterior temporal lobectomies.[15] But the abrupt cessation of seizures and abnormal electrical discharges after successful surgery on patients who have had years of apparent provocation of secondary foci requires us to keep the issue open. There are a few scattered reports of seizures in patients following repeated brain stimulation that might mimic electrical kindling.[55] In a more general sense, the latent period between the occurrence of an epileptogenic insult and the appearance of spontaneous epileptic seizures that commonly occurs in humans,[29] what Penfield and Jasper[45] referred to as "ripening of the scar," has been taken as evidence that some kindling process is necessary for seizures to occur spontaneously.[22] In some cases, however, this could reflect the time required to reach the stage of cerebral and physical development necessary to support the manifestations of seizures.

Whether or not kindling and secondary epileptogenesis occur in the human brain to produce additional independent epileptogenic areas, the fact that such activity-induced changes occur at all in the mammalian brain strongly suggests that they could also exist to some extent in the human epileptic brain. The exact mechanisms underlying these functional or structural transsynaptic changes are unknown; however, they must have some effect on normal neuronal function and certainly could provide a substrate for the development of interictal behavioral disturbances.[16]

One example of how kindlinglike modulatory influences could alter interictal behavior comes from studies of defensive rage in cats.[3] This is a stereotyped behavior that can be induced by electrical stimulation of hypothalamus or periaqueductal gray. The manifestations of stimulation-induced defensive rage can be modified by stimulation of the amygdala and hippocampus, and establishment of an experimental hippocampal epileptic focus not only exacerbated stimulation-induced defensive rage, but also caused this behavior to appear spontaneously in response to rough handling.[25] In the human, such "hard-wired" affective displays come under cortical control and may be more likely to manifest not as rage but as modified responses such as impulsiveness, depression, or other more socially acceptable, albeit disturbing, behaviors.

Another experimental example of kindling-induced interictal behavioral disturbances also derives from studies of cats that showed an enduring enhancement of methamphetamine-induced stereotypy following amygdala kindling.[51] This observation was interpreted to reflect a persistent up-regulation of dopamine receptors that could be another mechanism for the development of psychiatric disorders in patients with epilepsy.

The effect of kindling may depend upon the pre-existing affective state. For instance, amygdala kindling can reduce the manifestations of anxiety in high-anxiety rats, but exacerbates anxiety in low-anxiety rats.[1] The kindling effects of epileptiform discharges in patients with epilepsy, therefore, may depend not only on the location and type of the epileptogenic abnormality, but also on the predisposing behavioral state of the patient.

Some of the personality traits attributed in the literature to patients with temporal lobe epilepsy, such as hyposexuality and emotionality,[5,6,70] have been interpreted as being the opposite of the Klüver-Bucy syndrome[20]; changes in behavior, including taming and loss of affective responses, caused in primates by bilateral amygdalectomies; and seen in humans sometimes following head injuries or with certain dementias. One explanation for this effect could be a kindlinglike enhancement along amygdala projection fields.

Behavioral Effects of Natural Seizure-suppressing Influences

There are numerous inhibitory processes and other seizure-suppressing mechanisms that develop as a homeostatic reaction to the occurrence of epileptic seizures and presumably act to maintain the interictal state. These include the so-called inhibitory surround that limits the spread of localized epileptic activity,[46] the interhemispheric interference that opposes the development of secondary epileptogenesis,[38] and a variety of active mechanisms that terminate epileptic seizures.[8,12] These protective mechanisms persist between seizures and undoubtedly affect normal neuronal activity, conceivably contributing to the development of interictal behavioral disturbances.

Clinically, postictal changes are well documented, ranging from localized Todd paralysis[13] to profound global dysfunction following a generalized convulsion. In some patients, postictal behavior can involve complicated actions, such as the reactive automatisms that follow complex partial seizures, and may result in inappropriate semidirected responses, such as aggression toward someone attempting restraint. Other patients experience postictal psychosis.[6] It is easy to see how these behaviors, if persistent, could explain certain interictal disturbances. Such manifestations were evident in Hughlings Jackson's paradigmatic case of temporal lobe epilepsy, Dr. Z,[67] who diagnosed "pneumonia at the left base" in one of his own patients while totally amnesic after a seizure, a diagnosis that proved correct when he re-examined the child later.

Endogenous opioids are released during some types of epileptic seizures[27] and help to terminate seizures[8] but are also believed to be natural euphorogens, perhaps explaining the therapeutic effect of electroconvulsive shock therapy on clinical depression.[30] Also, there are people who feel much better after they have had a seizure, and parents who, enduring the escalating behavioral problems of their children between seizures, the so-called prodrome, look forward to the positive changes the seizure will bring. Opioid peptides have been shown to mediate several different postictal behaviors in rats, but the mechanisms are complicated. Whereas postictal hypofunction appears to be caused by a direct opioid effect, postictal explosive behavior is more likely the result of opioid withdrawal.[8] Different postictal behaviors appear to be mediated by different cerebral structures because seizures in rats increase opiate release in some brain areas and decrease opioid release in others.[50] Enduring changes in opiate mechanisms clearly occur in some patients with epilepsy, as shown by positron emission tomography (PET) evidence of increased μ-opiate-receptor binding in the neocortex of the epileptogenic temporal lobe.[19] If endogenous opioids are released in some brain structures during seizures and contribute to the appearance of postictal behaviors, it is conceivable that some patients could become dependent on high levels of endogenous opiates when they are having seizures and experience some degree of withdrawal when seizures stop. This might explain the transient depression that is often seen following successful surgical treatment of epilepsy.[14] The fact that depression can also be a side effect of antiepileptic drug treatment suggests that the same withdrawal phenomenon

P.2081

following successful pharmacotherapy could contribute to what has largely been interpreted as a direct effect of medication on mood and affect.

Developmental Factors

Recurrent epileptiform discharges that disrupt function at a distance in the immature brain might interfere with critical phases of development and result in lasting behavioral disturbances.[16] Experimental evidence for epilepsy-induced disruption of normal development derives from a series of elegant experiments that demonstrated that lateral geniculate neurons in rabbits fail to acquire normal visual receptive properties when a chronic epileptic focus is created in the visual cortex to which they project.[4,9] Whether normal neuronal functional integration of the lateral geniculate body is disrupted by antidromic "backfiring" of the epileptiform discharges from visual cortex or orthodromic propagation from cortical neurons that feed back on the geniculate is not known. Conceivably, both mechanisms can influence behavior transiently and presumably effect more persistent functional or even structural changes. The reversibility of the noxious effect of epileptogenic tissue in the immature brain on distant normal structures, at least early in the course of the process, has been demonstrated by the observation that developmental delay is reversed in patients with infantile spasms caused by a unilateral localized lesion when resection of this lesion eliminates the habitual seizures,[53] as discussed earlier in this chapter.

There is a long history to the relationship between epilepsy and psychosis, particularly schizophrenia. Nonpsychiatrists should be aware of major changes in nomenclature, vocabulary, and interpretation that have taken place over the last 50 years when reading older texts.[34,69]

In the 1960s, the dominating influence was a paper by Slater and Beard,[54] some 50 pages long, showing a close association between epilepsy and "schizophrenialike" psychosis. (The label "schizophrenialike" was necessary because everyone important "knew" that schizophrenia was a functional disorder.) Falconer had operated on 16 such patients before deciding that the balance of benefit from surgery was such that it was not appropriate to continue. Taylor[61,62] showed that those patients, with chronic schizophrenic symptoms, were characterized by excesses of (a) females, (b) onsets of epilepsy at ages 5 to 15, (c) left handedness, and (d) alien tissue lesions (e) in the left temporal lobe. This unique material allowed him to suggest that brains that suffered schizophrenia had been biased from embryonal, prenatal life and had required compensations in the organization of speech and language that later proved to be problematic when the normal condensation and shifts in the organization of language occurred. This developmental hypothesis arose from the excess of prenatally acquired lesions, the excess of left handedness, and the relative excess of girls, whose language organization is different from that of boys. The emergence of a neuropathologic basis for schizophrenia in people without epilepsy tends to confirm these findings from patients with epilepsy.

It seems probable, in hindsight, that the benefit of surgery to these patients was underestimated and that their life situations and lack of appropriate modern management contributed to continuing chronicity of their psychoses.

Normally excluded from consideration is the whole issue of autisticlike syndromes and various degrees of language regression associated with Landau-Kleffner syndrome, continuous spikes and waves during slow sleep, and West syndrome. Because about a third of children with autism develop epilepsy, the association deserves urgent research. Taylor et al.[65] reported, in the Great Ormond Street series of patients considered for surgical treatment, a sequence of male children, mostly with dysembryoplastic neuroepithelial tumors of the right temporal lobe, who exhibited marked autistic features. Subsequently, a larger number of children with other lesions have been recruited to that series.[37]

Effects on Sleep and Endocrine Function

There is considerable evidence from both the animal and the clinical literature that certain types of epileptic seizures cause chronic disruption in sleep organization, particularly a reduction in rapid eye movement (REM) sleep.[57] It is well known that REM sleep deprivation can produce behavioral disturbances, including psychosis,[11] so the possibility that this could be an indirect means by which some forms of epilepsy produce lasting interictal disturbances in behavior needs to be further investigated.

Another potential source of epilepsy-induced interictal behavioral problems that has not been adequately pursued relates to the effect chronic epileptic seizures have on endocrine function.[26,68] Seizures are associated with release of prolactin and other hormones, altering diurnal fluctuations and absolute levels in brain and blood, which could have dramatic effects on behavior and might, for instance, account for the sexual dysfunction seen in some patients with epilepsy.

Summary and Conclusions

Suffering from epilepsy is not limited to having seizures. Indeed, it has to be emphasized that seizures are not the same as epilepsy, and are but one manifestation of the underlying neuroanatomic/neurophysiologic changes that represent the latter. The brain has a problem to deal with and is dealing with it all the time. Whether by developmental anomaly, scar, tumor, or the effect of trauma, the process by which persons come to declare their brain abnormality by having noticeable epileptic seizures will have originated at some point in time before that manifestation, and it is clearly present between each noted seizure. There are other ways in which the brain problem can manifest itself, such as gross or minor neurologic signs and, we argue, gross (or minor) behavioral signs and learning problems. The various expressions of the brain problem will not be constant over time. Just as seizures are not constant over time and are often reactive to circumstance, so too the behavioral problems are not constant and are reactive. Even severe psychoses can come and go. Medications will also affect the chemical manifestations of the brain problem, but so will other natural physiologic processes. As the brain changes radically over development, and those changes are often reflected in the scale, type, and frequency of seizures, so too the behavioral manifestations will change during the course of development. Furthermore, seizures can alter brain function in a manner that influences behavior just as behavior influences seizures. Behavioral changes are important because they are clinically relevant, but there is important research to be done not just on the mental states of people with epilepsy, but also in understanding these mental states, behavioral changes, serious psychoses in general, and their causes, using the models provided in the animal laboratory and by people with epilepsy.

Chapter 201

Cognitive Side Effects of Antiepileptic Drugs

Albert P. Aldenkamp

Joanne Taylor

Gus A. Baker

Introduction

Cognitive impairment is the most common comorbid disorder in epilepsy.[13,28] Memory impairments, mental slowing, and attentional deficits are the most frequently reported cognitive disorders.[14,29] Such consequences may be more debilitating for a patient than the seizures; thus, it is worthwhile to explore the factors that lead to cognitive impairment. The exact cause of cognitive impairment in epilepsy has not been explored fully, but three factors clearly are involved: Etiology, the seizures, and the "central" side effects of drug treatment.[3] In this chapter we will concentrate on the unwanted effects of antiepileptic medication on cognitive function. When evaluating this factor separately, it is imperative to realize that in clinical practice most cognitive problems have a multifactorial origin and that, for the most part, the three aforementioned factors, combined, are responsible for the makeup of a cognitive problem in an individual patient. Moreover, the factors are related, which causes therapeutic dilemmas in some patients when seizure control can only be achieved with treatments that are associated with cognitive side effects.

The interest in the cognitive side effects of antiepileptic drug (AED) treatment is of recent origin. The possibility that cognitive impairment may develop as a consequence or aftermath of epilepsy was raised as early as 1885 when Gowers described "epileptic dementia" as an effect of the pathologic sequela of seizures. Nonetheless, the topic was not coupled to AED treatment until the 1970s,[27,38] probably stimulated by the widening range of possibilities for drug treatment during that period (i.e., the introduction of carbamazepine and valproate). Since then, a plethora of studies have been published, the majority on the commonly used AEDs: valproate (VPA), carbamazepine (CBZ), and phenytoin (PHT).

In the last decade, several new AEDs have been introduced. Although it is claimed that these drugs have different efficacy profiles and that some drugs are particularly efficacious in specific syndromes (e.g., vigabatrin [VGB]), head-to-head comparisons between the newer drugs and the commonly used drugs (such as CBZ and VPA) are rare. The types of studies used to investigate the newer AEDs are summarized in Table 1. Nonetheless, meta-analyses such as the influential Cochrane reviews[39,54] do not show significant differences in efficacy between these newer and commonly used drugs. Also, studies analyzing long-term retention do not show differences between the drugs.[78,90] Several studies have shown retention rate to be the best parameter of the long-term clinical usefulness of a particular drug.[47] Retention rate is considered to be a composite of drug efficacy and drug safety and expresses the willingness of patients to continue drug treatment. It is therefore the best standard for evaluating the clinical relevance of side effects. The 1-year retention rate is reported not to be higher than 55% for topiramate (TPM),[41] 60% for lamotrigine (LTG), 58% for VGB, and 45% for gabapentin (GBP).[53] Long-term (mostly 3-year) retention is about 35% for all newer AEDs.[52] Side effects appear to be the major factor affecting long-term retention for most drugs.[4,22] In clinical practice, tolerability is therefore a major issue and the choice of a certain AED is at least partially based on comparison of tolerability profiles of the drugs. Also, the tolerability profiles of the newer drugs have become a more important issue in drug development, stimulated by the interest of regulatory agencies.[4] Cognitive side effects have been demonstrated to be one of the most important tolerability problems in chronic AED treatment.

Method

In evaluating studies of the cognitive effects of AEDs, we will follow an evidence-based approach.[12,87] Randomized clinical trials with monotherapy in patients with newly diagnosed epilepsy represent the most accurate procedure for assessing the cognitive impact of AEDs.[4] These studies are not clouded by the effect of concurrent or previous AED use and permit the accurate collection of nondrug baseline data that is required for determining whether a particular treatment affects cognitive processing (i.e., to isolate drug-induced impairments from those due to other sources such as the seizures). Data from such studies can be supplemented with information from studies using add-on or polytherapy designs. In these studies, the use of two AEDs makes identifying the components of the treatment that are responsible for the observed effects more complex. In many cases, however, patients with epilepsy require dual AED therapy before adequate seizure control is obtained; therefore, data from add-on studies does warrant consideration. Also, data from healthy volunteers should be treated with caution. In general, the power of such studies is limited by small sample sizes, and drug exposure periods are typically brief. It is possible that chronic treatment results in entirely different types of cognitive impairment that cannot be observed during short-term treatment. For example, such differences in side effect profile between acute and long-term administration have been found with PHT. Finally, the differing cerebral substrate in patients with epilepsy and healthy volunteers suggests that cognitive responses to AEDs may be different in these populations. Nonetheless, volunteer studies may provide an early insight into the cognitive effects of an AED and therefore provide a foundation for further studies in patients with epilepsy (see reference 87 for a discussion of methodologic aspects of cognitive drug trials in epilepsy).

Results

Phenobarbital

The main anticonvulsant mechanism of action is the increase of the duration (not the frequency) of the γ-aminobutyric acid

(GABA)-activated chloride ion channel opening,[86] hence potentiating GABA-mediated inhibitory neurotransmission. Phenobarbital (PB) can also activate the $GABA_A$ receptor in the absence of GABA, which is sometimes considered to be a mechanism leading to its sedative properties. PB is used for the treatment of epilepsy since the discovery of its antiepileptic effect by Hauptman in 1912.

For PB one study[49] is available allowing the evaluation of the cognitive effects of PB relative to a nondrug condition. This study show relative serious memory impairment (short-term memory recall) in 19 patients with epilepsy.

Comparisons with other AEDs are available from four studies[21,35,60,88] of patients with epilepsy. One of these shows more impairment for PB than for PHT or CBZ on visuomotor and memory tests[35] and two other studies show convincing and clinically highly relevant impairments of intelligence scores after long-term PB treatment in comparison with VPA.[21,88] A randomized, double-blind, crossover study of healthy volunteers also found more impairment on some measures for PB compared to PHT and VPA.[61] Only the study by Meador et al.[60] does not show differences between PB and PHT or CBZ.

Phenytoin

The main anticonvulsant mechanism of action is use-dependent (voltage- and frequency-dependent) sodium channel blocking.[75] It binds to the fast inactivated state of the channel, reducing high-frequency neuronal firing. PHT has a stronger effect on the sodium channel than CBZ, delaying recovery stronger than CBZ. PHT may also have mild effects on the excitatory glutamate system and on the inhibitory GABA system. PHT has been used as an antiepileptic drug since it was introduced for the treatment of epilepsy in 1938 by Merritt and Putnam. For 20 years PHT was (together with PB) the universal treatment of epilepsy. PHT has excellent anticonvulsant properties and is used as a broad-range AED.

For PHT five studies are available[58,59,77,82,83] comparing PHT with a nondrug condition. These studies all reveal PHT-induced cognitive impairment in the areas of attention, memory, and especially mental speed. The magnitude of the reported effects is moderate to large. A caveat is in order, however, as all these studies were carried out in normal volunteers, which opens the possibility that these effects represent short-term outcomes of the drug.

The results of head-to-head comparisons with other AEDs are somewhat more confusing. Using an ingenious long-term treatment and withdrawal design, Gallassi et al.[35] found more cognitive impairment than CBZ. On the other hand, no difference with CBZ, VPA, oxcarbazepine (OXC), and even PB are reported.[2,33,58,59,60,74]

Ethosuximide

Ethosuximide (ESX) modifies the properties of voltage-dependent calcium channels, reducing the T-type currents and thereby preventing synchronized firing. The reduction is most prominent at negative membrane potentials and less prominent at more positive membrane potentials. Most effect is assumed to take place in thalamocortical relay neurons. ESX was introduced in 1960 and is mainly used for the treatment of generalized absence seizures.

No controlled studies are available to evaluate the cognitive effects of ESX.

P.2087

Carbamazepine

The main anticonvulsant mechanism of action is similar to that of PHT with a less “slowing” effect in the recovery state than obtained for PHT. The mechanism of action is also voltage and frequency dependent. CBZ was first synthesized in the early 1950s[68,69] and introduced as an antiepileptic drug by Bonduelle in 1964 in Europe. CBZ is used for patients with partial complex seizures, with or without secondary generalization. Approval by the Food and Drug Administration (FDA) for use in the United States followed much later (1978) because of concerns about serious hematologic toxicity (e.g., aplastic anemia).

For CBZ two studies, one in normal volunteers[82] and one in patients with epilepsy,[6] report “no cognitive impairment” compared to a nondrug condition. This is challenged by the group by Meador et al.[58,59] that reported impairments of memory, attention, and mental speed, largely the areas that may also be affected by phenytoin.

When evaluating the comparisons of CBZ with other AEDs, there are the conflicting results of the Italian study by Gallassi et al., showing a more favorable profile compared with PHT and PB[35] and the U.S.-based study by Meador et al.[58,59,60] that showed no differences compared with PHT and PB.

Valproate

VPA, a fatty acid, is believed to possess multiple mechanisms of action. A number of studies have demonstrated an effect on sodium channels, however, different from PHT and CBZ. An effect on T-type calcium channels has also been demonstrated. Recent studies have, however, demonstrated that a predominant effect concerns the interaction with the GABAergic neurotransmitter system. More precisely, VPA elevates brain GABA levels and potentiates GABA responses, possibly by enhancing GABA synthesis and inhibiting degradation. Furthermore, VPA may augment GABA release and block the reuptake of GABA into glia cells. VPA is one of the most effective drugs against generalized absence seizures. It was introduced in approximately the same period as CBZ.

For VPA, three studies[24,71,84] allow the interpretation of absolute effects and show mild to moderate impairment of psychomotor and mental speed. The comparison with other drugs shows lower performance of memory and visuomotor function compared to CBZ[35] and a favorable profile compared to PHB on tests for intelligence.[21,88] One study does not show a difference with PHT.[33]

Oxcarbazepine

Oxcarbazepine (OXC) is essentially a prodrug, a keto homolog of CBZ, structurally very similar to CBZ, but with a different metabolic profile. In humans, the keto group is rapidly and quantitatively reduced to form a monohydroxy derivative that is the main active anticonvulsant agent during OXC therapy. Metabolism of OXC does not result in the formation of 10,11-epoxy carbamazepine that is sometimes considered to be the main metabolite causing side effects. The mechanism of action is similar to CBZ. However, OXC is also considered to reduce presynaptic glutamate release, possibly by reduction of high-threshold calcium currents. OXC was approved in the European Union in 1999 and is indicated for use as monotherapy or adjunctive therapy for partial seizures with or without secondarily generalized tonic–clonic seizures in patients 6 years of age or older.

The effects of OXC on cognitive function have been evaluated in one study in healthy volunteers and in four studies in patients with epilepsy. A double-blind, placebo-controlled, crossover study was conducted in 12 healthy volunteers.[25] The effects of two doses of OXC (300 mg/day and 600 mg/day) and placebo on cognitive function and psychomotor performance were assessed. The treatment duration for each condition was 2 weeks. Cognitive function tests were administered before treatment initiation and 4 hours after the morning doses on days 1, 8, and 15. In this study, OXC improved performance on a focused attention task, increased manual writing speed, and had no effect on long-term memory proces-ses.

In patients with epilepsy, four monotherapy comparative studies are available to evaluate the effects of OXC on cognitive functions in adult patients with newly diagnosed epilepsy. The first study[44] was a double-blind, active-control study evaluating the effects of CBZ and OXC on memory and attention in 41 patients with newly diagnosed epilepsy. The treatment duration was 1 year. Cognitive function and intelligence tests were administered before treatment initiation and after 1 year of treatment. The results indicated no deterioration of memory or attention with either CBZ or OXC. The second study was an active-control study that evaluated the effects of CBZ, VPA, and OXC on intelligence, learning and memory, attention, psychomotor speed, verbal span, and visuospatial construction in 32 patients with newly diagnosed epilepsy.[73] The treatment duration was 4 months. Cognitive function and intelligence tests were administered before treatment initiation and after 4 months of treatment. The results indicated no deterioration of cognitive function in any treatment group. Significant improvements in learning and memory tests were found for the CBZ- and OXC-treated patients. Improvements were also found in attention and psychomotor speed tests for the VPA-treated patients and partly for the CBZ-treated patients. The third study was a double-blind, randomized, active-control study that evaluated the effects of PHT and OXC on memory, attention, and psychomotor speed in 29 patients with newly diagnosed epilepsy.[2] The treatment duration was 1 year. Cognitive function tests were administered before treatment initiation and after 6 and 12 months of treatment. The results indicated no significant differential cognitive effects between PHT and OXC during the first year of treatment in patients with newly diagnosed epilepsy who achieved adequate seizure control. In the fourth study,[56] three groups of 12 patients taking either CBZ, VPA, or PHT took a single 600-mg dose of OXC followed 7 days later by 3 weeks of treatment with OXC 300 mg thrice daily and matched placebo in random order. Seven untreated patients, acting as controls, were prescribed the single OXC dose and 3 weeks of active treatment only. There were no important changes in cognitive function test results during administration of OXC compared with placebo. Finally a study in newly diagnosed children, randomized to OXC (n= 55), CBZ (n= 28), and VPA (n= 21$) was performed showing no differences between the three drugs.[29a]

In summary, the results of these studies indicate that OXC does not affect cognitive function in healthy volunteers and adult patients with newly diagnosed epilepsy. The effects of OXC on cognitive function, however, have not been systematically studied in children and adolescents. In accordance with the latest revision of the Committee for Proprietary Medicinal Products (CPMP) Note of Guidance (CPMP EWP/566/98 rev 1, dated November 16, 2000, Sections 2.5 and 5.2), a study has recently been launched (Protocol #: CTRI476E2337) to investigate the effects of OXC on cognitive function (i.e., psychomotor speed and alertness, mental information processing speed and attention, memory, and learning) in children and adolescents aged 6 to 17 years with partial seizures.

Topiramate

TPM is a sulfamate-substituted monosaccharide that has clearly multiple mechanisms of action.[89] TPM blocks neuronal sodium channels in a voltage- and frequency-dependent manner, inhibits CA, promotes the action of GABA at the $GABA_A$ receptor complex, and elevates GABA brain concentrations by about 60% at 3 and 6 hours after a single dose; this increase was maintained with 4 weeks of TPM administration.[70] TPM is a carbonic anhydrase–inhibiting drug. TPM has proved to be effective in patients with refractory chronic partial epilepsies.[32,72] It was recently introduced in the United States and Europe.

During the initial add-on clinical trials, central nervous system (CNS)-related "cognitive" subjective complaints were frequently reported, including mental slowing, attentional deficits, speech problems, and memory difficulties.[72] It should be mentioned, however, that higher target doses and faster titration schedules were used than are now common in clinical practice (see reference 32 for a discussion of dose and titration speed). Recent studies with TPM-treated patients have confirmed high levels of adverse cognitive effects based on subjective complaints.[42,80] A follow-up study[19] showed long-term retention of 30% for a 4-year follow-up. For about half of the 70% of patients who discontinued treatment, side effects were the major reason, with cognitive side effects being most frequently mentioned.

Only a few studies have psychometrically measured cognitive changes using neuropsychological tests. A study by Martin et al.[55] in six normal volunteers used an acute dose of 2.8 mg/kg (~200 mg/day) followed by a titration to 5.7 mg/kg (~400 mg/day) in 4 weeks, resulting in weekly dose escalations of about 100 mg. The rate at which TPM was escalated in this study was very similar to the dose escalation used in the initial TPM adjunctive therapy trials,[72] in which escalating the TPM dose to 200 or 400 mg/day over 2 to 3 weeks was associated with somnolence, psychomotor slowing, speech disorders, and concentration and memory difficulties.[19] Martin et al. showed neuropsychometric changes commensurate with these CNS effects. The cognitive effects of the acute starting dose of 200 mg/day were impairments of verbal function (word finding and verbal fluency) of approximately two standard deviations (which represents very serious impairment) and of sustained attention. Titration to 400 mg/day in 4 weeks resulted in impairments of verbal memory and mental speed of more than two standard deviations.

Six studies involving patients with epilepsy are available. In a study by Meador[57] with 155 patients with epilepsy, the effects of the gradual introduction of TPM as add-on (a 50-mg starting dose, followed by increments of 50 mg per week over 8 weeks) were compared with those of more rapid dose escalation (initial dose of 100 mg, followed by two consecutive weekly increments of 100 and 200 mg). In a test battery of 23 variables representing selective attention, word fluency, and visuomotor speed, the subjects who were on a slow-titration schedule and treated with one background AED displayed TPM-associated score changes of more than one third but less than one standard deviation. A study by Aldenkamp et al.[10] was specifically designed to compare cognitive effects of TPM and VPA added to therapeutic dosages of CBZ in 59 patients with epilepsy. In this study, a slow titration speed was used with a starting dose of 25 mg/day TPM and weekly increments of 25 mg. Moreover, the average achieved dose (approximately 250 mg) was relatively low. Neuropsychometric testing was conducted 8 weeks after the last dosage increase (20 weeks after the start of TPM therapy). The study therefore used optimal conditions (i.e., slow titration, relatively low dose, and a longer treatment period), allowing for patient habituation to the effects of TPM therapy. Nonetheless, cognitive impairment was found for verbal memory function both during titration and at end-point. In a study by Burton and Harden,[20] attention was assessed weekly in ten subjects receiving TPM over a 3-month period. Four of nine subjects showed significant correlations between TPM dosage and forward digit span measured weekly, such that higher dosage was associated with poorer attention. In a retrospective study by Thompson et al.,[81] the neuropsychological test scores of 18 patients obtained before and after the introduction of treatment with TPM (median dose 300 mg) were compared with changes in test performance of 18 patients who had undergone repeat neuropsychological assessments at the same time intervals. In those patients taking TPM, a significant deterioration in many domains was found. The largest changes were for verbal IQ, verbal fluency, and verbal learning.

A retrospective study by Kockelmann et al.[43] investigated the cognitive profile of 42 patients on AED polytherapy containing TPM compared to 42 patients taking LTG. Patients were assessed on an extensive battery of neuropsychological assessments and blood serum levels were obtained. The TPM-treated patients performed significantly worse on executive functioning measures such as working memory and verbal fluency. Significant correlations with blood serum levels were only evident for verbal fluency, verbal memory span, and verbal memory (delayed recall and recognition). A lack of correlation with other variables may be in part due to the small sample size.[43]

In an open, prospective study, 41 patients with intractable epilepsy initially received either TPM or tiagabine (TGB) as add-on treatment. Of these, 21 patients were assessed at baseline, after a 3-month titration phase, and after a 3-month maintenance phase. The patients were assessed on various aspects of cognitive functioning such as attention, memory, language, and self-report of mood and quality of life. The TPM group performed worse on measures of verbal fluency and working memory and reported more depression than the TGB group. They also felt that they were suffering from more adverse effects due to the TPM medication. However, TPM patients did report an increase in mental flexibility between titration and maintenance phase.[34]

In summary, there is clear clinical evidence for TPM-induced cognitive impairment. Not all studies are comparable because of the confusion about dose and titration speed (see reference 5 for a discussion). Moreover, the complete lack of controlled studies is remarkable.

Lamotrigine

LTG is a phenyltriazine with weak antifolate activity. The main anticonvulsant mechanism of action is to block voltage-dependent sodium channels that result in voltage- and frequency-dependent inhibition of the channel. This suggests that the mechanism of action is similar to that of PHT and CBZ. However, much attention is focused recently on the fact that this mechanism in LTG treatment results in preventing presynaptic excitatory neurotransmitter release. It is still in debate to what extent the mechanisms of action are different from CBZ.[46] Clinical evidence indicates that LTG is effective against partial and secondarily generalized tonic–clonic seizures, as well as idiopathic (primary) generalized epilepsy. LTG was introduced in Europe in 1991 and in the United States in 1994.

A large number of cognitive studies are available for LTG (see reference 11 for an overview). Five volunteer studies have been conducted with LTG. Doses of 120 mg and 240 mg did not produce a significant change in cognitive function compared with baseline when administered to 12 normal volunteers in an acute study of 1 day.[23] Similarly, five volunteers received LTG (acute dose 3.5 mg/kg and then titrated to a maximum of

7.1 mg/kg) in a single-blind manner and were assessed for change in cognitive function after 2 and 4 weeks.[55] There was no significant change in any of the neurocognitive measures relative to baseline performance. LTG and CBZ have been compared in 12 healthy male volunteers and associations were made between the observed cognitive effects and plasma concentrations of these drugs.[37] The effects of these drugs were examined by means of adaptive tracking, which assesses eye–hand coordination and effects of attention, and eye movement tests. LTG treatment was not significantly different from placebo, but increased CBZ saliva concentrations were significantly associated with impaired adaptive tracking and smooth and saccadic eye movements. The long-term effects of LTG and CBZ were compared in 23 volunteers in a 10-week crossover study.[63] The neuropsychological battery in this study consisted of 19 instruments yielding 40 variables, including both subjective and objective measures. LTG showed better performance or fewer side effects in 17 (42%) of the variables, while no statistically significant differences were seen in the remaining variables. Finally, a study by Aldenkamp et al.[8] in 30 volunteers (12 days of treatment, using a daily dose of 50 mg of LTG) showed evidence for a selective positive effect of LTG on cognitive activation, relative to both placebo and VPA. Although the results of these volunteer studies provide us with preliminary insight into the impact of LTG on cognition, the generalizability of the results from these studies to patients with epilepsy receiving long-term AED treatment is limited.

The effects of LTG on cognitive function have been compared with those of CBZ in patients with newly diagnosed epilepsy. Patients completed tests of verbal learning and memory, attention, and mental flexibility at baseline and then periodically for up to 48 weeks. Significant differences favoring LTG over CBZ were observed with semantic processing, verbal learning, and attention.[36] The authors concluded that LTG may have a favorable long-term effect on cognitive function when compared with CBZ. Other studies have reported positive cognitive effects of LTG used as adjunctive therapy. Two independent double-blind, randomized, crossover studies have examined the cognitive effects of LTG used as add-on therapy.[17,76] Both studies included patients with a history of partial seizures (at least once weekly during the preceding 3 months) who had received no more than two other AEDs or VPA monotherapy. Both studies also used two treatment periods (12 and 18 weeks), which were separated by a washout period (4 and 6 weeks). Despite the similarity in trial design and patients, there is some inconsistency between the findings of these two studies. One study showed a marginal reduction in general “cerebral efficiency” (an indirect measure of cognitive function) following LTG treatment.[17] Conversely, significant improvements were reported in the second study.[76] In an uncontrolled add-on study[15] using CBZ as baseline drug, no deterioration on any of the cognitive tests was found after introducing LTG (200 mg). LTG therapy in seven patients with epilepsy and mental retardation caused both positive and negative psychotropic effects.[31] These findings were based on the observations of parents and supervising staff. Positive effects included reduced irritability and increased compliance with simple instructions, while negative effects included behavioral deterioration with temper tantrums, restlessness, and hyperactivity. Similarly, a second study in 67 patients with mental retardation showed that following adjunctive treatment with LTG, social functioning was stable or improved in 90% of patients.[30]

In addition to clinical studies that have assessed the impact of LTG on cognitive function, further evidence can be obtained from examining the effect of LTG on electroencephalographic (EEG) parameters. Overt EEG discharges can occur without any visible clinical correlate in many patients with epilepsy. These epileptiform episodes may be associated with transient deterioration in cognitive function.[1,9] Data from several studies indicate that LTG may reduce spontaneous epileptiform discharges, which may partially explain the favorable cognitive profile of LTG. In five patients displaying spontaneous EEG discharges, a single dose of LTG (120 mg or 240 mg in addition to existing medication) resulted in a substantial reduction in spontaneous interictal discharges within a 24-hour period.[18] The long-term effects of LTG on paroxysmal abnormalities have also been monitored with a computer-based analysis system.[50] Twenty-one patients with intractable epilepsy (20 of whom were receiving multiple AED therapy) were evaluated before and after LTG treatment for EEG ictal events and number of spikes in a 10-minute period. Before LTG treatment, patients typically showed discharges characterized by diffuse spike-wave complexes. However, following a 4-month treatment period with LTG, ictal discharges disappeared and diffuse slow-wave activity was seen with no adverse effect on background activity. Nineteen of the 21 patients also showed a reduction in seizure frequency.

The effect of LTG add-on therapy in 11 patients with refractory partial seizures with or without secondary generalization has also been reported.[51] LTG was added to existing therapy consisting of CBZ with at least one additional AED. EEG recordings were made at rest with eyes closed, during an attentive task (blocking reaction induced by several episodes of eyes open lasting 8 to 9 seconds), during cognitive tasks, and while performing mental arithmetic. In addition, a battery of neuropsychological tests was carried out. Before LTG treatment, EEG data revealed a decrease in fast activity at rest and a reduction in α and β bands during attentive and cognitive tasks. LTG treatment resulted in a selective increase in α reactivity and β power during the attentive tasks with no other detectable changes. During cortical activation, subtle changes were observed that were taken as indicative of a slight improvement in attention. Neuropsychological evaluation revealed that following 3 months of LTG therapy, no deterioration in cognitive function had occurred.

LTG also shows a promising cognitive profile in elderly patients suffering from age-associated memory impairment.[64] A neuropsychological test battery in combination with auditory event-related potentials (ERPs) was used to measure the impact of LTG on cognitive function. LTG treatment caused a reduction in amplitude of the P300 component of the ERP and a corresponding improvement in immediate and delayed visual memory and delayed logical memory. LTG may therefore improve simple memory functions in a memory-impaired elderly population.

Levetiracetam

Levetiracetam (LEV) is a new AED, structurally and mechanistically dissimilar to other AEDs. It is believed to bind to a specific, as yet undetermined, site on the synaptic plasma membrane. Moreover, LEV seems to reduce the GABA turnover in the striatum by reducing GABA synthesis and increasing GABA metabolism. It is effective in reducing partial seizures in patients with epilepsy, both as adjunctive treatment and as monotherapy. LEV has many therapeutic advantages for patients with epilepsy. It has favorable pharmacokinetic characteristics (good bioavailability, linear pharmacokinetics, insignificant protein binding, lack of hepatic metabolism, and rapid achievement of steady-state concentrations) and a low potential for drug interactions. It is licensed for use as adjunctive treatment for partial seizures, with or without secondary generalization, in people aged over 16 years.

For its impact on cognitive function, we only have data from a small pilot study that does not allow definite conclusions.[66] An international (UK/The Netherlands) cognitive study is

presently being carried out. In this study a first-line add-on design is used, comparing the cognitive effects of LEV with CBZ and VPA.

Tiagabine

TGB is a GABA uptake inhibitor that is structurally related to the prototypic GABA uptake blocker nipecotic acid, but has an improved ability to cross the blood–brain barrier. TGB temporarily prolongs the presence of GABA in the synaptic cleft by delayed clearance. Clinical trials have shown that TGB is effective as add-on therapy in the management of patients with refractory partial epilepsy. TGB was recently marketed and some aspects of the development program are still not finished.

Three cognitive studies are available. Dodrill et al.[26] included 162 patients who received the following treatments: Placebo (*n* = 57), 16 mg/day TGB (*n* = 34), 32 mg/day TGB (*n* = 45), or 56 mg/day TGB (*n* = 26) at a fixed dose for 12 weeks after a 4-week dose titration period. Eight cognitive tests and three measures of mood and adjustment were administered during the baseline period and again during the double-blind period near the end of treatment (or at the time of dropout). The results showed no cognitive effects of monotherapy with TGB at a low or high dose, but there was some evidence for mood effects of add-on treatment with TGB at higher dosing, possibly related to titration speed. In the add-on polytherapy study by Kälviäinen et al.,[40] 37 patients with partial epilepsy were included. The study protocol consisted of a randomized, double-blind, placebo-controlled, parallel-group add-on study and an open-label extension study. During the 3-month double-blind phase at low doses (30 mg/day), TGB treatment did not cause any cognitive changes as compared with placebo. TGB treatment also did not cause deterioration in cognitive performance during longer follow-up with successful treatment on higher doses after 6 to 12 months (mean 65.7 mg/day, range 30–80 mg/day) and after 18 to 24 months (mean dose 67.6 mg/day, range 24–80 mg/day). Finally, a study by Sveinbjornsdottir et al.[79] was an open trial of 22 adult patients with refractory partial epilepsy followed by a double-blind, placebo-controlled, crossover trial in 12 subjects. Nineteen patients completed the initial open titration and fixed-dose phase of the study and 11 patients completed the double-blind phase. The median daily TGB dose was 32 mg during the open fixed dose and 24 mg during the double-blind period. Neuropsychological evaluation did not show any significant effect on cognitive function in the open or double-blind phase.

Gabapentin

GBP (1-(aminomethyl) cyclohexane-acetic acid) is a novel AED, currently used as add-on therapy in patients with partial and generalized tonic–clonic seizures. GBP is a cyclic GABA analog, originally designed as a GABA agonist.[48] Further research has clearly shown a specific effect of GBP on GABAergic neurotransmitter systems, especially influencing GABA turnover. Investigations using nuclear magnetic resonance imaging spectroscopy have confirmed that GBP elevates GABA concentrations, specifically in the occipital cortex of patients with epilepsy.[70]

Two volunteer studies and one clinical study are available to interpret the cognitive effects.

Martin et al.[55] used an acute dose and rapid titration in six volunteers and did not find cognitive effects of GBP. Meador et al.[62] compared the cognitive effects of GBP and CBZ in 35 healthy subjects by using a double-blind, randomized, crossover design with two 5-week treatment periods. During each treatment condition, subjects received either GBP 2,400 mg/day or CBZ (mean 731 mg/day). Subjects were tested at the end of each AED treatment period and in four drug-free conditions (two pretreatment baselines and two posttreatment washout periods [1 month after each AED]). The neuropsychological test battery included 17 measures yielding 31 total variables. Significantly better performance on eight variables was found for GBP, but on no variables for CBZ. Comparison of CBZ and GBP with the nondrug average revealed significant statistical differences for 15 (48%) of 31 variables. Leach et al.[45] studied GBP in 21 patients in an add-on polytherapy study after 4 weeks of adjunctive therapy and found no change in psychomotor and memory tests. Drowsiness was more often found in higher dosing (2,400 mg). Mortimore et al.[65] did not find a difference between continued polytherapy and an add-on with GBP in measures of quality of life.

Zonisamide

The anticonvulsant properties of zonisamide (ZNS) were discovered through extensive testing of a variety of sulfonamide compounds. Like TPM, it has multiple mechanisms of action: Blocking voltage-gated sodium channels, reducing sustained repetitive firing, blocking T-type calcium channels, and inhibiting ligand binding to the $GABA_A$ receptor. Like TPM, ZNS is a carbonic anhydrase–inhibiting drug. Although there is longer experience with ZNS in Japan (where it was developed), it recently was introduced in the United States and Europe for partial-onset seizures in refractory epilepsy.

Clinical anecdotal information and a pilot study by Ojemann et al.[67] show a cognitive side effect profile very similar to TPM, but no controlled studies are available. Also, no information is available about ongoing studies.

Rufinamide

Rufinamide (RUF 331; 1-(2,6-difluoro-phenyl)methyl-1H-1,2,3-triazole-4-carboxamide) is a structurally novel compound that limits the frequency of sodium-dependent neuronal action potentials. One study is available to assess the cognitive effects.[7] The study used a multicenter, multinational double-blind, randomized, placebo-controlled parallel study design with four different doses of rufinamide (based on prior studies): 200 mg/day, 400 mg/day, 800 mg/day, and 1,600 mg/day as add-on to the existing medication. Cognitive assessments were performed at baseline (before the start with RUF treatment) and at end-point (after 3 months of treatment). The most important finding is that for none of the cognitive tests, a statistically significant worsening occurs for any of the doses of rufinamide when the period after 12 weeks of treatment was compared with the baseline before introducing rufinamide. Also, none of the comparisons between dose and placebo showed a statistically significant difference.

Summary and Conclusions

A general conclusion that may be derived from meta-analyses[87] is that polypharmacy shows a relatively severe impact on cognitive function when compared with monotherapy, irrespective of the type of AEDs included. Two drugs that individually have mild cognitive effects may induce serious cognitive impairment when used together, possibly because of potentiation of tolerability problems.[85]

Possibly the most remarkable finding is that, although the severity of cognitive side effects is generally considered to be

mild to moderate for most AEDs,[87] all commonly used AEDs have some impact on cognitive function. Such mild impact may be amplified in specific conditions and may become substantial in some patients when crucial functions are involved, such as learning in children[14] or driving capacities in adults (often requiring millisecond precision), or when functions are impaired that are already vulnerable, such as memory function in the elderly.[85] Moreover, the cognitive side effects represent the long-term outcome of AED therapy; therefore, the effects may increase with prolonged therapy, which contributes to the impact on daily life functioning in refractory epilepsies.[16]

Definite evidence for drug-induced cognitive impairment has been established for phenobarbitone (memory impairment), phenytoin (mental slowing), and topiramate (mental slowing and dysphasia). Treatment with these drugs should consider these side effects and patients should be monitored on a regular basis. Mild effects (mostly psychomotor slowing) were found for carbamazepine, oxcarbazepine, valproate, and lamotrigine (with mild cognitive-activating effects). The effects for ethosuximide, tiagabine, gabapentin, levetiracetam, and zonisamide are inconclusive. It is clear, however, from the available evidence that there still exists a need to conduct studies that compare the relative effects of the neuropsychological consequences of AED treatment using standardized protocols. Further, the lack of well-designed studies of the neuropsychological effects of AED treatment means that we must remain cautious about our level of understanding about the impact of the newer drugs.

Chapter 202

Learning Disorders

Michael P. Kerr

Mary Lou Smith

Introduction

The potential impact of epilepsy and its treatment on learning provides a considerable challenge for clinicians, patients, and families alike. In addition, the picture is often complicated by the association between the presence of epilepsy and apparently already coexistent disorders of learning and development. This poses important heuristic questions into the relative impact of epilepsy on the development of learning disorders.

It is beyond the scope of this chapter to address in detail this crucial question in the field of epileptology. For further reading please refer to the chapters on neonatal syndromes and syndromes of childhood and adolescence. This chapter will have as its focus the nature, impact, and management of epilepsy in those with an apparently coexistent intellectual disability (mental retardation). Such an approach helps the clarity of the chapter, yet it is important to reflect on how the populations of people who have intellectual disability are placed within the scope of learning disorders associated with epilepsy. This will be covered initially within our discussion on classification and terminology and later in the chapter within the section on the impact of epilepsy on people with an intellectual disability.

Key themes discussed in the chapter will include the association between certain syndromes of intellectual disability and seizure types, the impact of epilepsy, approaches to management, the association between epilepsy and behavioral disorders, and the multidisciplinary approach to care.

Classification and Terminology of Intellectual Disability

Considerable variation occurs in the terminology of intellectual disability. While *intellectual disability* is currently the internationally accepted term, *mental retardation* is favored in the United States and much of Europe, *learning disability* in the United Kingdom, *mental handicap* in much of the world during the 1990s, and *intellectual handicap* in Australia and New Zealand.

Definition of Disability

The American Association for Mental Retardation defines mental retardation as follows:

> "Mental retardation is a disability characterized by significant limitations both in intellectual functioning and in adaptive behavior as expressed in conceptual, social and practical adaptive skills…. The disability originates before the age of 18."

It adds five assumptions, which are essential to the application of the definition:

1. Limitations in present functioning must be considered within the context of community environments typical of the individual's age, peers, and culture.
2. Valid assessment considers cultural and linguistic diversity as well as differences in communication, sensory, motor, and behavioral factors.

3. Within an individual, limitations often coexist with strengths.
4. An important purpose of describing limitations is to develop a profile of needed supports.
5. With appropriate personalized supports over a sustained period, the life functioning of the person with mental retardation generally will improve.

From a clinical viewpoint, particularly in administrative terms, mental retardation is defined using the International Classification of Diseases rubric, currently in its 10th version. All codes for mental retardation are prefixed with F7. Assessment should include clinical findings, adaptive behavior, and the use of psychometric tests.

The range of disability is defined in Table 1.

The Nature and Impact of Epilepsy in People with Intellectual Disability

Epidemiology

Epidemiologic data for this population are particularly influenced by methodologic and sampling issues, raising concerns regarding the interpretation of results that vary significantly depending on the study's design.[41,91] These concerns focus on the usually selective nature of the population samples and difficulties in allowing for comparative levels of intellectual disability. The prevalence of epilepsy is significantly greater in people with intellectual disability than in the general population,[62] with estimates in intellectual disability populations ranging from 18% to over 60%.

The major influences on prevalence estimates are (a) age; (b) residence, institution, or community; and (c) the severity of disability.[18,57,84]

Table 1 Classification of Intellectual Disability (ICD-10)

Code	Definition	Attributes
F70	Mild mental retardation	1) Ability to use speech 2) Full independence in self-care 3) IQ range between 50 and 69
F71	Moderate mental retardation	1) Slow in comprehension 2) Immobility or restricted mobility 3) Retarded motor skills 4) IQ range between 35 and 49
F72	Severe mental retardation	1) Marked impairment of motor skills 2) Clinically significant damage to CNS 3) IQ range between 20 and 34
F73	Profound mental retardation	1) Severely limited understanding 2) Immobility or restricted mobility 3) Incontinence 4) Requiring constant supervision

	5) IQ <20 6) Usually organic etiology

CNS, central nervous system; ICD, International Classification of Diseases.

Table 2 Epidemiologic Surveys of the Prevalence of Epilepsy in People with Intellectual Disability (ID)

Sample	Prevalence
Children under age 14	
Community SMR[19]	20%
Children up to 22 yr Community[85]	Mild ID 24% Severe ID 44%
Institution[67]	All 32%
Children 6–13 yr Community[97]	Mild ID 14% Severe ID 24%
Adults, community based[108]	All ID 22.1%
Community identified pediatric sample[1]	All ID: 19% by age 10 years and 21% by age 22 years Severe ID: Fivefold risk as compared with mild ID
All ages, record-linked health data[71]	All ID 18.3%
Primary care health facilities[68]	Down syndrome 13.6% Cerebral palsy 40%

Cohort effects, due to year of birth, are important in defining prevalence in both intellectual disability[37] and epilepsy.[16]

A comparison between community and institutionally based surveys[67,108] show as much as a 10% discrepancy in the prevalence found. Table 2 describes a range of epidemiologic surveys of the prevalence of epilepsy in people with intellectual disability.

P.2094

The increasing prevalence of epilepsy with increasing severity of intellectual disability is well recognized in both children[1] and adults.[4]

Definition of seizure type in populations of people with intellectual disability has proven difficult.[24,57] An example of this is seen in a community study of children with intellectual disability.[90] In this survey, there was evidence of a lack of investigation in the population, with only 10% having had electrophysiologic tests. Despite this, they showed an increase in generalized tonic–clonic and myoclonic seizures and a decrease in partial seizures with increasing handicap. The authors concluded that this increase in generalized seizure disorder was an artifact of the lack of investigation, though other explanations such as genetic causes may be valid.

A Japanese study focusing on people with severe intellectual disability[4] identified cerebral palsy as the most common etiology (42.3%); multiple seizure types were common (almost half had two or more seizures) and paroxysms were found on the electroencephalogram (EEG) in 90.6% of cases and abnormal computed tomography (CT) scan in 82.7% of cases. In a Finnish study in children,[1] prenatal causation was most frequent (47%), and seizures were most frequently partial (72%). As we shall see later, it is unrealistic when considering seizure type to take the intellectual disability population as a whole; individual etiologic characteristics are crucial in syndromal and seizure classification.

Etiologic Issues

Intellectual disability is caused by a range of pathologic processes, as, of course, is epilepsy. In particular, genetic advances into the individual causes of intellectual disability and of the epilepsies have expanded.[5,21]

It is beyond the scope of this chapter to highlight all the etiologic processes involved in the development of an intellectual disability. Two issues are, however, of particular relevance to this population: (a) are specific etiologies associated with recognizable epilepsy patterns? and (b) what impact do seizures have on development and learning?

Etiology Associated Patterns of Epilepsy

A further approach to investigating the etiology of epilepsy in people with intellectual disability has been to define the nature of the epilepsy in individual disability syndromes. This approach will hopefully lead to the matching of known genetic abnormalities with the individual's epilepsy and thus direct treatment options.

This section includes a brief overview of a select group of syndromes that have intellectual disability as a key feature, and that may also have epilepsy as a concomitant disorder. This section is not intended to provide a detailed analysis of the causes of the syndromes, or the etiology, features, or treatment of the associated epilepsies; these issues are reviewed in depth elsewhere in this textbook. This co-occurrence of epilepsy with these syndromes is important to recognize at a clinical level because the seizures add an additional burden to both the individual with the syndrome and to the caregivers.

Down Syndrome

Down syndrome (DS), or trisomy 21, is the most common genetic cause of intellectual disability.[93] In addition to intellectual disability, of which there is a range in severity, DS is characterized by growth retardation, hypotonia, a number of facial dysmorphologies, hypogonadism, an increased risk of cardiac disease and leukemia, and Alzheimer disease in those over the age of 35 years. A bimodal distribution in age of seizure onset has been described, with peaks in childhood and middle age.[82,98,105] The incidence of epilepsy increases with age, and the increase later in life is thought to be related to the onset and progression of Alzheimer disease.[54,63,105] A variety of seizure types have been reported, including infantile spasms, generalized tonic–clonic seizures, Lennox-Gastaut syndrome, and psychomotor seizures.[44,81,98]

P.2095

Angelman Syndrome

Angelman syndrome (AS) is a genetic disorder that is estimated to account for up to 6% of all children presenting with severe intellectual disability and epilepsy.[42] Clinical findings present in all patients include developmental delay, which becomes apparent by 6 to 12 months of age; severely impaired expressive language; ataxic (“puppetlike”) gait; tremulousness of limbs; and a typical behavioral profile, including a happy demeanor, hypermotor behavior, and low attention span. Although development may appear almost normal or only slightly delayed during the first 6 months of life, all patients eventually develop severe intellectual disability. The typical lack of speech may not be due to the intellectual disability alone; oral motor dyspraxia and deficits in social interaction and attention also contribute to the lack of expressive language.[80] Sleep problems may affect a significant portion of individuals with AS and are persistent; parents report adverse effects of their child's sleep problems on their own well-being.[26,92]

Seizures, abnormal electroencephalography, microcephaly, and scoliosis are observed in >80% of patients, with onset of epilepsy typically occurring in infancy or early childhood.[30,34] A variety of seizure types are seen, including febrile, atypical absence, generalized tonic-clonic, myoclonic, and clonic unilateral seizures.[39,43,106] There are contradictory data on whether the severity of the developmental disturbance in AS is related to the severity of epilepsy,[58,77] and whether there is an improvement in epilepsy with age.[59,92,110]

Fragile X Syndrome

Fragile X syndrome (FXS) is the most common known cause of autism or "autisticlike" behaviors, and the incidence of cognitive impairment is quite high. The clinical phenotype in the male typically also includes tall stature, large testes, relative macrocephaly, characteristic facial features, and delays in speech and language development.[23,100,109] Up to 80% of males with FXS are described as cognitively delayed. In the older studies of males with FXS, almost all were described as having moderate or severe mental retardation. However, many of these studies were based upon institutionalized males, and with better ascertainment studies, it has become clear that 10% to 15% of boys with FXS have a less severe degree of developmental delay, with IQs in the borderline or mild intellectual disability range. A high number of boys with fragile X (80% to 90%) are described as distractible and impulsive, with symptoms of attention deficit hyperactivity disorder, and anxiety is a common personality feature.[38]

Girls with FXS tend to be less severely affected in terms of intellectual disability. Approximately 30% of girls with the full mutation have IQ scores above 85, with the other 70% mostly in the borderline or mild mental intellectual disability range.[23] However, those girls with normal intelligence are at higher risk for specific learning disabilities. The behavioral features in girls include shyness and poor eye contact.[100]

Seizures occur in approximately 15% to 20% of children with FXS.[6,53] Seizure types include absence, partial motor, generalized, and partial complex seizures; benign rolandic epilepsy is found frequently.[6,73,74] Epilepsy in individuals with FXS generally follows a benign course, and in a relatively high number, seizures remit before the age of 20.[86]

Rett Syndrome

In Rett syndrome (RS), there typically is normal development until 6 to 18 months (although as long as 30 months), after which development slows, or even deteriorates. The physical characteristics of RS include scoliosis, gait dyspraxia, and repetitive movements of the hands, often involving hand wringing. Individuals may have autonomic dysfunction, difficulty chewing, and teeth grinding, and eventually show growth failure and deceleration of head growth.[40,45] There is a high prevalence of behavioral and emotional disorders in RS, with anxiety, flat mood, self-injurious behavior, and autism seen frequently.[45,88] Frequently, there is a regression in cognition, behavior, and social and motor skills throughout the lifetime of patients with RS. The degree of developmental delay is usually within the severely to profoundly intellectually disabled range, although there is a spectrum of severity ranging from severe neurologic compromise to only minor neurologic symptoms.[51] There is a preserved speech variant, which shows the same course and stereotypic hand movements, but patients typically recover some hand use and speech; epilepsy is rare in this group.[22]

Epilepsy is common, occurring in between 80% and 95% of cases.[45,96] The severity of epilepsy may decrease with increasing age.[96] A variety of seizure types are found in RS, including generalized tonic–clonic, absence, myoclonic jerk, atonic, and tonic seizures. The incidence of true clinical seizures may be overestimated because the autonomic dysfunction may be incorrectly identified as absence or complex partial seizures.

The Impact of Epilepsy on Development and Learning

It is generally accepted that the causal process of epilepsy follows a path from brain damage through to the development of epilepsy.[57] Cognitive decline, as seen in a few patients with epilepsy, is usually associated with repeated head injury or through anoxic episodes in periods of status epilepticus. Other deterioration may be linked to seizures impacting information processing.[8]

However, increasing knowledge on conditions such as infantile encephalopathy (infantile spasms, myoclonic epilepsy) and the treatments for these devastating conditions seem to imply that epileptic phenomena can be associated with the development of intellectual disability.[27] A recent survey in Atlanta on the epidemiology and outcome of infantile spasms suggests that, at age 10 years, 83% will have intellectual disability.[103] The same survey suggested that 12% of 10-year-old children with profound intellectual disability had a history of infantile spasms.

Impact of Epilepsy

People with an intellectual disability are equally susceptible to the negative impacts of epilepsy on physical and psychological health, cognition, life expectancy, and social factors[10,32] as the general population. This impact should be seen as additional to their other impairments, if present. This is particularly important as underestimating the impact of epilepsy may lead to incomplete attempts at treatment.

Physical Health

The known impact of epilepsy on physical health as seen by an overrepresentation of hospitalization[20] and a range of antiepileptic drug (AED)-related morbidity holds true for people with an intellectual disability. An increase in admissions to accident and emergency rooms and to the hospital in general is seen.[71]

P.2096

Psychological Health

Studies have found rates of behavior disturbance and psychiatric disorder to be significantly higher in people with epilepsy[24,50,64] and in people with intellectual disabi-lity.[11,28,64,66] Furthermore, a study in children[12] was able to identify decreasing IQ as a predictor of increasing mental health problems.

Considering the very strong evidence for an increased prevalence of emotional disturbance in individuals with epilepsy who do not have intellectual disability as compared with nonepilepsy controls,[50,64] it has proved much harder to find a similar link within populations who have epilepsy and intellectual disability. That is, it has been difficult to tease out any additional impact from epilepsy with the already high morbidity present in these populations.

Epidemiologic evidence does not support such a population link in adults or children. Deb and Hunter[25] showed an underlying prevalence of behavior disorder of 52.5% and that in the epilepsy population of 58%. An Australian study[61] showed in an epidemiologic-defined population of children with intellectual disability no difference in “caseness” of behavior and emotional disturbance between those with and without epilepsy. Other work has shown that aggression and self-injury were associated with frequent seizures and polytherapy. This approach is almost certainly missing the potential for epilepsy to impact on individuals' patterns of behavior. In particular, it may be that the particularly high frequency of mental illness, depression, and anxiety seen in general epilepsy populations may be underrecognized in people with an intellectual disability.

A study of a large epilepsy service database of people with intellectual disability[33] explored potential predictors of psychopathology within an epilepsy and intellectual disability group. They concluded that there was a relatively weak input from seizure factors such as frequency on psychopathology and that behavior disorders were more related to general disability factors than to seizure related factors.

The Family

Many factors associated with the burden of caring for someone with intellectual disability have been identified.[34,48] The most robustly replicated factor was behavior disorder. Caregiver burden is an important issue as the well-being of caregivers affects the prognosis of people in their care.[14]

The coexistence of epilepsy also seems to be a factor associated with caregiver burden.[32] Unfortunately, however, we know little about the precise impact of epilepsy on families of individuals who also have intellectual disability. A study of people with epilepsy without intellectual disability[102] found that levels of stress and dissatisfaction with their social situation were high, particularly in primary caregivers (mothers, in most instances). Respite periods away from home were few and the perceived level of support was low. Poor emotional adjustment was associated with severity of tonic and atonic attacks and periods of status epilepticus, and low levels of support were associated with depression.

Mortality

Patients with epilepsy are known to have increased risk of mortality over the population in general.[17,47] A recent Dutch cohort study demonstrated that patients with epilepsy have an increased risk ratio of 3.2 for all causes of mortality, and this rose to over 7 in those aged under 20.[89]

This is broadly similar to a Danish study, which demonstrated a standardized mortality ratio (SMR) of 3.6 for all deaths.[76] This excess risk is partly explained by underlying causes of epilepsy such as cerebrovascular disease, injuries, and poisoning. This probably explains the relatively higher SMRs in the year immediately after diagnosis of epilepsy.[17]

Patients with intellectual disability are also known to have a lower life expectancy than the general population[36] and an estimated SMR of 1.6.[35] Not surprisingly, the probability of survival decreases as the severity of intellectual disability increases.[49] This excess is increased for those patients with coexisting epilepsy[35,36] whose SMR may be as high as 5. It is possible that some of this increased mortality may be explained by an increase in sudden unexplained epilepsy death (SUDEP). An institutional review in North America revealed an increase in unexpected death of 1.3 deaths per 1,000 in the nonepilepsy group compared with 3.6 per 1,000 in those with epilepsy.[69] The impact of epilepsy on mortality in people with an intellectual disability appears to hold across all degrees of intellectual impairment.[79]

Management

Epilepsy management requires special skills and competencies for the epileptologist. These include (a) special communication skills specific to this population, (b) analysis of safety and communication of therapeutic interventions, and (c) knowledge of the care environment to work with multidisciplinary teams.

Communication Skills: Management by Proxy

Witness report from a caregiver or family member is common; a report from the individual is less so in people with intellectual disability. Thus, the history and management will commonly progress through, or at least be influenced by, another “management by proxy.” The degree of this will increase as the individual's communicative skills decrease.

Notwithstanding the need to manage third-party clinical consultations, a central aim should be to empower the individual to communicate his or her needs. Components of successful communication methods are highlighted below:

1. Nonverbal: Gaze, appropriate touch, use of gesture
2. Vocal: Appropriate tone, intelligibility
3. Verbal: Greeting, using individual's name, balance of communication with caregiver
4. Response: Recognizing the individual's responses and following leads, respecting information from the caregiver

5. Empathy: Showing appropriate respect and empathy

Table 3 Differentiating Seizure and Behavior Disorder

Seizure	Behavior disturbance
Identical behavior on each occasion	Variation in behavior with circumstances
No precipitant	Commonly that is a precipitant such as demands, need to avoid situation
Unresponsive to communication, calming	Responsive to calming, support, removal from stressor
Investigations:	*Investigations*:
Analysis of behavior: No relationship to behavior and environment	Analysis of behavior: Relationship found
Video: Shows typical seizure features	Video: Atypical picture seen
EEG: Positive interictal EEG	EEG: Negative interictal EEG of some use

EEG, electroencephalogram.

Specific Issues in Differential Diagnosis: Seizures or Behavior Disturbance?

In the majority of cases seizure disorder presents itself as paroxysmal episodes of abnormal behavior. In many cases, for example, a generalized tonic-clonic convulsion, the nature of these behaviors is well defined and cannot be confused with many other conditions. Other seizure disorders, however, are less well defined or are dependent on the verbal description of the individual and witnesses for a diagnosis. An example of the former is the pattern of behavior seen in complex partial seizures, particularly when they are associated with ictal or postictal automatisms. Differentiating these in the general population from psychiatric disturbance or, in some cases, from nonepileptic attack disorder is complex. Communication issues and the high prevalence of behavior and motor disorders in this population further complicate differentiating these in people with intellectual disability.

P.2097

Repetitive episodes of manneristic or stereotyped behavior would be most unusual in many people without handicaps and the diagnosis of epilepsy would be highly likely. However, in a young man with autistic tendencies, for example, such behaviors may be reflections of the cognitive disturbance of the autism and not, in fact, epilepsy. Similarly, brief apparent losses of consciousness can be equally undiscriminating due to concurrent physical illness; an example of Sandifer syndrome misdiagnosed as complex partial seizure would be highly unlikely in an individual who could communicate his or her symptoms.[95] Clinicians need a structured approach to this differentiation. Table 3 highlights guidelines to this differential diagnosis, though in many cases behavioral analysis will be required to sufficiently differentiate the behavior.

Therapeutic Interventions

With such a strong case for the negative impact of epilepsy on individuals with an intellectual disability and their caregivers, there would appear to be a mandate for interventions to alleviate seizure-related morbidity. Such interventions should be guided by appropriate evidence and sensitive to the key concerns in this population that, in general, relate to the balance between seizure efficacy and concern over apparent side effects. Aspects of pharmacotherapy with antiepileptic drugs have been covered elsewhere in this book. We therefore will focus on those elements of particular relevance to this population: (a) recognition of the need for therapeutic intervention, (b) choosing an intervention, and (c) assessing therapeutic outcome.

Recognition of Need of Intervention

Seizures have a profound effect on this population, and intervention needs will usually be defined through an assessment that this impact exists and that a reduction would both reduce seizure-related risk and improve quality of life. Domains of impact as already described—physical, psychological, cognitive, and social—should be assessed on an individual basis.

Choosing an Intervention

Treatment guidelines[52] exist and can guide clinicians. As many of these patients already have longstanding complicated treatment histories, treatment choice will be influenced by which therapeutic options, either AEDs or surgical, remain available.

This therapeutic choice is mainly influenced by the same evidence base and decision-making process as in the general epilepsy population. FIGURE 1 shows a potential treatment pathway for people with intellectual disability who have epilepsy and can be used as a useful marker for judging the options available to an individual on his or her treatment pathway. This pathway relates to the use of AEDs. Surgical options are as relevant for this population both for potentially curative resective seizures and for procedures that may ameliorate the epilepsy, such as vagal nerve stimulation.

There does exist, however, a body of evidence relating to interventional studies in epilepsy and intellectual disability. Such evidence, while frequently hampered by its quality, can provide markers for treatment effect in terms of efficacy and safety.

Quality Evidence?

In general, therapeutic trials of AEDs use measures based on seizure frequency, seizure severity, quality of life, and side effect data. These measures, while appropriate in those without intellectual disability, may not be sufficient or may not be valid in those with intellectual disability.[31,56] It has been suggested that research in this population should use the following standard components:

1. Define the individual—use the Adaptive Behavior Scale.[75]
2. Define the individual epilepsy—etiology of intellectual disability, seizure type, and syndrome.
3. Use measures sensitive to change in the intellectual disability population.
4. Determine seizure frequency using seizure diaries.
5. Assess behavior using validated measure of behavior such as Aberrant Behavior Checklist,[3] or Developmental Behavior Checklist in children.[29]
6. Determine quality of life using specific mental retardation and epilepsy quality-of-life scales—Glasgow Epilepsy Outcome Scale (GEOS).[32]

Learning from the Evidence

Seizure Impact

Several high-quality randomized placebo-controlled trials have been published in populations of people with intellectual disability. The majority of these have been in people with Lennox-Gastaut syndrome. This syndrome is strongly associated with intellectual disability. However, the reproducibility of data from this specific seizure syndrome population into the total intellectual disability population is not proven.

Table 4[55,72,87,101] summarizes the data from these studies.

The advantage of these studies is that the placebo arm may provide some evidence of the natural course of seizure frequency in a trial setting. The studies show variation in seizure change within the placebo arms and by different seizure types. Atonic seizures ranged from a 9% decrease to a 5% increase. Tonic–clonic (recorded in one study) showed a 10% worsening and all seizure types showed from a 9% decrease to a 4% increase.

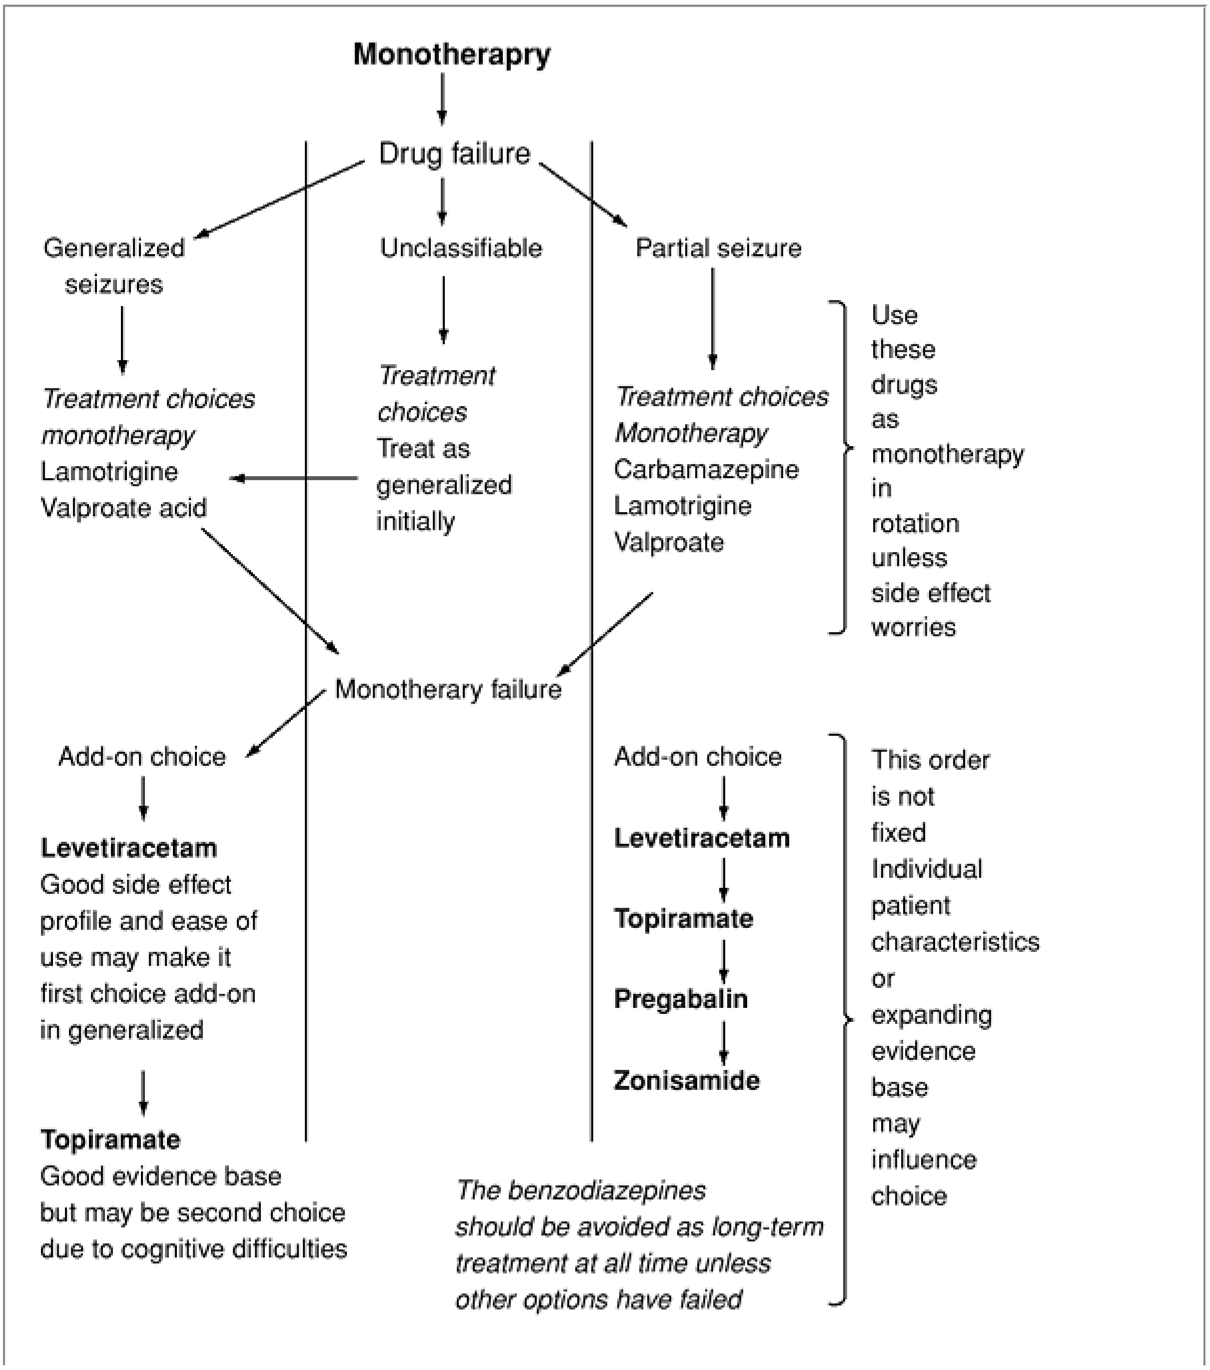

FIGURE 1. A treatment pathway for people with intellectual disability and epilepsy. (Published with permission of Clarion Press.)

A published study[7] used a retrospective case note review to assess the use of vigabatrin, lamotrigine, and gabapentin in adults with mental retardation. The study again showed

P.2098

variation in the percentage of patients reporting an increase in seizure frequency: Two (8%) of the patients on vigabatrin, six (24%) of the patients on lamotrigine, and zero (0%) of those on gabapentin.

It appears that seizure worsening occurs in Randomised Controlled Trials (RCTs) with novel AEDs in patients with intellectual disability, suggesting an association between seizure increase and natural fluctuation in seizure control.

The Impact of Antiepileptic Drugs on Behavior

Randomized placebo-controlled trials that have been published in populations of people with intellectual disability and Lennox-Gastaut syndrome may again offer some insight into safety issues. However, the reproducibility of data from this specific seizure syndrome population into the total intellectual disability population should again be treated with caution.

The studies showed a relatively high level of behavioral symptoms in placebo arms: Nervousness in 10% to 14%, somnolence in 22%, and "behavioral problems" in 10% (Table 4).

Data from the nonrandomized controlled trials are less valuable. However, a UK-based study[7] using a retrospective case note review showed behavior problems in 5 of 23 patients on vigabatrin, 2 of 25 patients on lamotrigine, and 1 of 23 patients on gabapentin.

The data on behavioral side effects in studies of AEDs in people with intellectual disability are particularly poor. The key problem is nonvalidated definitions of behavior. Where blinded control data do exist, they show that behavioral deterioration can occur and may be—in the case of topiramate—a specific drug effect.

Assessing Therapeutic Outcome

A judgment on treatment outcome has particular importance in people with an intellectual disability; there is certainly no "one size fits all" approach to this. In many instances very individualized approaches will be necessary, particularly in those with multiple physical and intellectual disabilities.

In a clinical context the assessment of treatment outcome will involve a more pragmatic approach. This is likely to have several broad aims. The first will be to analyze accurately any seizure change. To do this, accurate seizure charts are necessary. These will need space to identify several seizure types. Acquiring high-quality seizure frequency data can be a long-term and difficult process. Frequently, parents and caregivers will need guidance into differentiating varying seizure types and in accurate recording.

Table 4 Epilepsy and Intellectual Disability: Impact on Seizures and Behavior of AEDs from Controlled Trials

Trial	N	Seizure outcome	Behavioral outcome
Felbamate[101]	73	*Atonic seizures*	*Nervousness*

		Active—34% decrease Placebo—9% *Total seizures* Active—19% decrease Placebo—4% increase	Active—5 (14%) Control—5 (14%) No other behavioral outcome recorded, possibly due to side effects that occurred less than five times not recorded
Lamotrigine[72]	169	*All seizures* Active—32% decrease Placebo—9% decrease *Tonic-clonic seizures* Active—36% decrease Placebo—10% increase *Atonic seizures* Active—34% decrease Placebo—9% decrease	*Somnolence* Active—3 (4%) Control—4 (4%)
Topiramate[87]	98	*All seizures* Active—20.6% Placebo—8.8% *Atonic seizures* Active—14.8% reduction Placebo—5.1% increase	*Somnolence* Active—42% Control—22% *Nervousness* Active—21% Control—10% *Behavioral problems* Active—21% Control—10%
Topiramate[55]	88	*All seizures* Active—30% decrease Placebo—1% decrease	*Somnolence* Active—32.4% Control—10.8% *Nervousness* Active—2.7% Control—13.5% *Behavioral problems* Baseline change in Aberrant Behavior Checklist Active reduction in 7.3 points Control reduction by 9.3

Secondly, clinicians will have to assess any negative impact from the treatment change. This again can be a challenging task, especially in individuals who may have poor communication and a range of concurrent illnesses, all with symptoms not unlike those of potential drug side effects. Of these, the most concerning to clinicians and caregivers alike is the potential for behavior change. A structured approach is necessary to

identify those occasions where behavioral symptoms are likely to be treatment related (Fig. 2).

Surgery

For many years in the history of epilepsy surgery, patients with low IQ were excluded as candidates. One reason was that low IQ has been thought to be indicative of generalized cerebral dysfunction, suggesting that the prognosis for improvement of seizures after focal resection is low.[30,60,99] It has also been suggested that in patients with low IQ, the integrity of brain outside the area of focus may not be adequate to allow for compensation after surgery, thus making these individuals more prone to cognitive deterioration.[9,83] A third reason was the assumption that some patients with low IQ may be unable to cooperate or tolerate the preoperative procedures necessary for identifying good surgical candidates.[107] Despite these assumptions, present guidelines typically do not include intellectual status as an exclusion criterion for surgery.

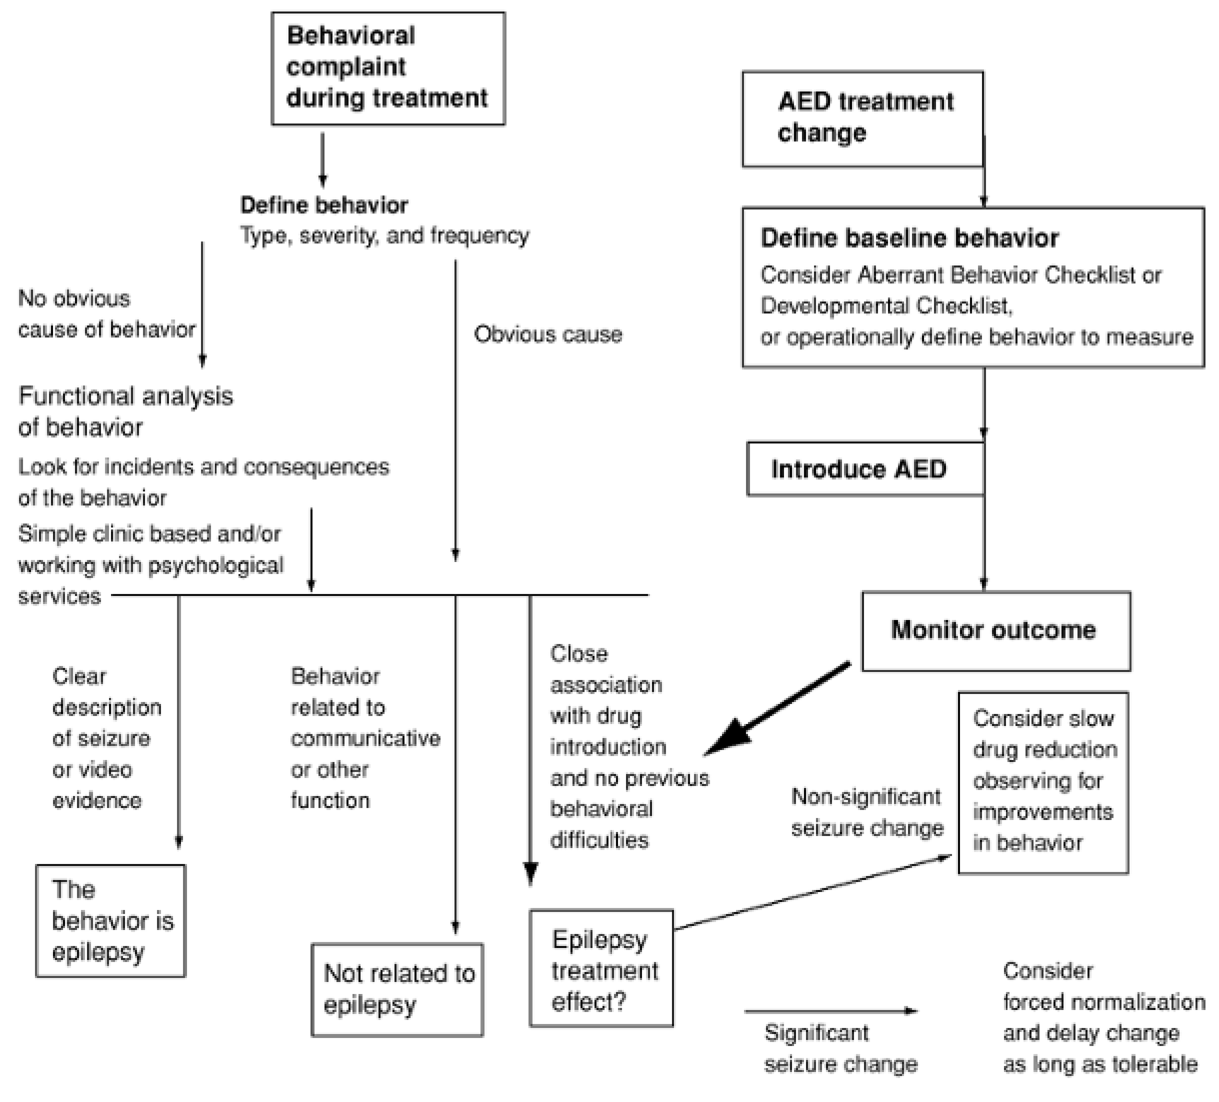

FIGURE 2. Assessing behavioral change during antiepileptic drug treatment. AED, antiepileptic drug. (Published with permission of Clarion Press.)

Vasconcellos et al.[104] examined intellectual function in pediatric candidates for epilepsy surgery. Younger age at onset was associated with lower IQ, and mean IQ was significantly lower in patients with seizure onset at or before 2 years of age. The frequency of patients with intellectual disability varied with age of seizure onset, with 46% of those with seizure onset at or before 2 years of age having IQs lower than 70, compared with only 12% of those with onset after that age. This difference was independent of etiology of the epilepsy[9] reported on surgical outcome in 31 patients with IQ ≤70, approximately 15% of a consecutive surgical series in Norway. Two years after surgery, 52% of those with temporal lobe resections and 38% with extratemporal resections were seizure free. Unfortunately, the authors did not compare outcomes with the other patients in their own series, but comparison with other published series suggested that the seizure outcome was poorer than in patients with higher IQs.[15] An important finding was that the surgical result was related to duration of epilepsy, with greater likelihood of seizure freedom obtained with shorter duration of epilepsy prior to surgery. The authors suggested that when duration was taken into account, the rate of success was comparable to patients with normal intelligence.[60] Cognition did not improve in patients irrespective of IQ, a finding that has been demonstrated in other studies reporting neuropsychological outcomes of surgery in patients of all levels of intellectual

function.[70,94] A review[60] suggested that with careful presurgical evaluations, outcomes are similar between patients with normal IQ scores and those with low scores.

A high proportion of children with infantile spasms have mental retardation and behavior disorders. The UCLA Pediatric Epilepsy Surgery Research Group has compared surgical outcomes in these children with those of children with other forms of intractable symptomatic epilepsy.[13] At 2-year follow-up assessment, both groups continued to show impaired development of language, cognition, and social communication despite improved seizure control.

Vagal Nerve Stimulation

The effects of vagal nerve stimulation (VNS) have been investigated in a number of studies that have included children with intellectual disabilities associated with epileptic syndromes and developmental disorders. Despite reported improvements in seizure frequency and/or severity, mood, and quality of life, changes in cognitive function have not been found.[2,46,65,78] In a series of patients with Lennox-Gastaut syndrome, seizure reduction was highest in patients with highest baseline cognitive function,[2,65] leading these authors to conclude that intellectual disability is a negative prognostic factor for efficacy of VNS.

The Context of Care

Unfortunately, service delivery to individuals with an intellectual disability who have epilepsy has received little attention from the research community. However, five key areas exist around which multiagency care can be structured: Health advocacy, barriers and safety, quality of care, specialist provision, and the needs of the family (Table 5).

Table 5 Multiagency Areas of Need for Individuals with Learning Disability and Epilepsy

Area	Example issues
Health advocacy	Assistance in the communication of an individual's seizures Assistance in communication of an individual's response to treatment and past treatment history

Barriers and safety	Risk assessment of dangers of epilepsy such as bathing Assessment of the impact of epilepsy on an individual's social inclusion
Quality of care	Quality of care environment for individual Ability of environment to supply prescribed treatment Ability to administer rescue medication
Specialist provision	Education, housing Support services such as psychological or behavioral support Investigative services such as EEG and MRI under anesthesia
The family	Respite services Education Training Support

EEG, electroencephalogram; MRI, magnetic resonance imaging.

Health Advocacy

Due to the inherent difficulties in communication associated with intellectual disability, both the individual and the clinician can be disadvantaged. Parents frequently provide communication functions. However, when an individual lives in care, the agency will need to ensure that someone can describe the current seizures, their frequency, and the impact epilepsy is having on the individual. Additionally, services should be able to support the individual to make choices over epilepsy management where appropriate.

Barriers and Safety

Services have a responsibility to the safety of their charges; in particular, risk of bathing accidents must be carefully assessed. Additionally, where epilepsy has become a barrier to social inclusion, this should be identified and appropriate remedies sought.

Quality of Care

Any care setting for an individual with an intellectual disability should be able to meet his or her epilepsy management needs. In particular, medication, where prescribed, should be given, and where rescue medication is prescribed, appropriate management plans should exist.

Specialist Provision

The potential for specialist provision can read something like a wish list of potential services. This, of course, merely reflects the diverse needs of this population. An individual may need appropriate housing or education. Specific support services such as psychology or behavior support agencies may be needed. Completion of investigations will need appropriate disability-aware investigative electrophysiologic and imaging services.

The Family

Families provide much of the health advocacy and housing needs of this population. To deliver this, support is needed with education into epilepsy and its treatment, with the emotional effects on the family members, and with adequate respite services.

Coordinating Multiagency Care Delivery

The delivery of multiagency care does, of itself, need coordination. The availability of resources and trained staff will of course influence the ability to provide and coordinate multiagency care. Some of the key themes can be delivered relatively cheaply such as education on safety and education to caregivers. Where resource exists, other agencies can make a large impact into epilepsy care.

Summary and Conclusions

The interaction between epilepsy and learning disorder is complex and can be subtle and transient. Notwithstanding this for a large proportion of the population with epilepsy major intellectual disability coexists with severe refractory epilepsy. This combination of morbidities impacts on the individuals in their quality of life, and on the professional, demanding specific skills in assessment and treatment. Such skills include the use of communication strategies, recognition of phenotypes, the assessment of behavioural change, application of AEDs and surgical assessment. Our knowledge of this field is advancing as it is in the general epilepsy population. However this advancement is uneven, our chapter shows how the new genetic and aetiological knowledge can be readily applied to this group; yet there are relatively few data from interventional studies and as such the gap in our knowledge on the application and effectiveness of treatments in this group is widening as compared to the general epilepsy population. The challenge for the professional epilepsy community is to close this gap.

Chapter 203

Personality Disorders in Epilepsy

Orrin Devinsky

Bruce P. Hermann

Introduction

At the turn of the 20th century, most of the lay and professional communities believed that people with epilepsy had pathologic personality traits and psychopathologic disorders such as aggression, sociopathy, and psychosis. However, from the medical perspective, this was partly an artifact of the main setting from which epilepsy was viewed: Chronically institutionalized patients, many of whom suffered comorbid disorders (e.g., head trauma, neurosyphilis). The concept of an epileptic personality—a ubiquitous and characteristically negative set of behavioral changes in epilepsy patients—was already established in antiquity, but continued to evolve slowly and relentlessly. Simultaneously, more humanistic and balanced views evolved during the 19th century. Based on extensive experience with a private outpatient population with idiopathic epilepsy, Reynolds[87] concluded that epilepsy does not invariably involve abnormal mental change, and Gowers[42] also recognized that many epilepsy patients had normal personality and intellect, but that many others could develop intraparoxysmal behavioral changes. He suggested that these changes resulted from many factors, but mainly from epilepsy.

The early 20th century brought diverse views concerning people with epilepsy and their behaviors. Wilson[121] offered a progressive psychosocial view: "On epileptic temperament inordinate stress has been laid. Life is difficult for these patients, and much that is attributed to temperament can with greater reason be assigned to chronic invalidism and unlucky circumstance." Sjobring[99] adhered to the negative, pervasive view: "A mental change of a specific nature takes place in individuals suffering from epileptic seizures. They become torpid and circumstantial, sticky and adhesive, effectively tense and suffer from explosive outburst of rage, anxiety, etc." Kraepelin[61] reported aggressiveness in some of his outpatient epilepsy patients: "Almost always an intensification of mental irritability occurs." The adhesive or viscous personality traits in which the patient has difficulty in disengaging from interpersonal exchanges was reviewed by many observers in the European literature under various terminologies such as the "enechetic constitution," "ixoid character," and "glischroid trait."

The Modern Era

Early in the 20th century, the term "epileptic personality" was used by psychoanalytic theorists to describe a set of character traits associated with epilepsy that focused on impulsivity, egocentricity, and affective viscosity.[17] These features were considered to result from hereditary factors, directly from seizures or treatment, or a reaction to painful social situations associated with epilepsy. Others believed that these particular personality features, in individuals with or without seizures, were a direct expression of epilepsy itself. Two coincident developments in the middle of the century helped reintroduce the highly controversial concept of personality changes in epilepsy: Identifying the role of the limbic system in emotion and behavior and localizing the onset of many partial seizures to the temporal lobe.

Papez[81] conceived a circuit of interconnected structures comprising the emotion system: Hippocampus—fornix—hy-pothalamus/mammillary bodies—mammillothalamic tract—anterior thalamic nuclei—thalamocingulate fibers—cingulate cortex—amygdala/hippocampus. This emotion circuit theory was based on anatomic connections, sham rage studies, and lesion studies. Yakovlev[124] conceived a basolateral circuit modulating emotional behavior, including the amygdala, insula, orbitofrontal cortex, and dorsomedial thalamic nucleus. MacLean[67] combined earlier ideas and conceived the limbic system with all the above regions, as well as the septum and nucleus accumbens.

The specific association of temporal lobe epilepsy (TLE) and psychopathology had its major genesis in the 1951 report by Gibbs[40] that up to 33% of patients with "psychomotor seizures" of temporal lobe origin exhibited interictal behavioral changes. Gastaut et al.[36] in 1954 reiterated common observations on the frequency of emotional viscosity, hyposexuality, hypoactivity, and aggressiveness in epilepsy patients, and first suggested that the stereotypic symptom complex was the antithesis of behaviors in the Kluver-Bucy syndrome (KBS). KBS is characterized by oral exploratory behavior, increased sexual appetite, decreased aggressivity, and continuous environmental exploration as a consequence of bilateral anterior temporal destructive lesions.[59]

Waxman and Geschwind[117] proposed a distinct subset of nonpathologic behaviors associated with TLE, which included deepened emotions, circumstantiality, altered religious and sexual concerns, and hypergraphia. They coined the term "interictal behavior syndrome," sometimes referred to as Geschwind syndrome or Gastaut-Geschwind syndrome.[6] Bear and Fedio[4] expanded this syndrome to include the 18 traits based on a literature review. They found an increased frequency of all 18 traits in patients with TLE compared with non-neurologic controls. The interictal behavioral traits described by Bear and Fedio are summarized in Table 1. Some of these traits associated with this syndrome are described below in more detail.

Table 1 Proposed Personality Traits by Bear and Fedio

Hypergraphia
Hypermoralism
Altered sexuality
Religiosity
Aggression
Obsessionalism
Paranoia
Guilt
Humorlessness

Sadness
Emotionality
Circumstantiality
Philosophical interest
Personal destiny
Viscosity
Dependence
Elation
Anger

Viscosity

Viscosity is a tendency for prolonged interpersonal contacts; talking repetitively, circumstantially; and pedantically; and not ending conversations and visits after a socially appropriate interval. Bear and Fedio[4] reported viscosity to be significantly elevated in both right and left TLE compared to normal and neurologic controls. Brandt et al.[10] found increased viscosity among left TLE and generalized epilepsy (GE) patients, with no difference between right TLE and controls. Hoeppner et al.[51] presented the "cookie thief" picture from the Boston

Diagnostic Aphasia Examination, which shows a drawing of a boy stealing a cookie, to TLE, GE, and control subjects. Taped responses were reviewed blindly and all four individuals with verbose responses, characterized by trivial, circumstantial, and subjective details, had left temporal foci. A ten-item viscosity scale revealed significantly higher scores in the self-reports of patients with left TLE compared to right or bilateral TLE, absence seizures, panic disorder, or normal subjects.[86] Proxy raters reported a trend for increased viscosity scores in the left TLE group, endorsing items such as "when I have a phone conversation with him/her, I always find I am the one who wants to get off first." Seizure duration and viscosity score were significantly correlated for patients with left TLE.

Viscosity may result from some combination of linguistic impairment, social cohesion, mental slowness, and psychological dependence. Language dysfunction associated with left temporal lobe seizure foci may contribute to a verbal style characterized by circumstantiality and excessive discourse. However, there may be independent effects of left temporal foci on social behavior. Viscosity, the personality trait, may also result from an increased desire for interpersonal closeness, a need for affiliation with another being. Discrete limbic lesions can profoundly alter how animals maintain contacts with other members of their own or other species.[41,60,73] For example, rats with septal lesions will remain in contact with each other in an open field and, if left alone, will actively approach cats despite expressions of fear.[73] It is possible that some biologic effects of the epileptogenic process or recurrent seizures in a minority of patients with temporolimbic epilepsy, especially in the dominant hemisphere, fosters the development of viscosity.

Hyposexuality

Various changes in interictal sexual behavior occur in patients with TLE. Hyposexuality is frequently reported,[7,31,35,83,93,98,101,108] with anecdotal reports of hypersexuality[38,98] and deviant sexual behavior including exhibitionism,[7,52] transvestism,[27,84] transsexualism,[50] and fetishism.[26,74] Isolated cases of unusual sexual behavior occurring in patients with epilepsy could be chance associations. However, some cases develop profound changes in adulthood, shortly after the onset of epilepsy, raising the possibility of an etiologic relationship. Hyposexuality, including decreased libido and impotence, occurs in approximately half of TLE patients without gender bias. In many cases, especially those with seizure onset before puberty, patients may not marry or regard hyposexuality as a problem. Complaints are more likely to come from the spouse or parent who observes lack of interest in the opposite sex. Much of the original literature on hyposexuality from 1954 to 1985 was based on self-report[76] without detailed interviews to assess the relative roles of libido, arousal, erectile dysfunction, anorgasmia, and sexual satisfaction, as well as physiologic measures of endocrine and sexual function.

Most studies found higher rates of hyposexuality and sexual dysfunction in TLE than other epilepsy groups, although Fenwick et al.[31] did not observe any significant difference in sexual activity related to seizure type, type of epilepsy, or seizure frequency. Among those with TLE, no laterality effects were found for sexual behavior in left- versus right-sided seizure foci.[16] A well-designed study of six men with erectile dysfunction found abnormal nocturnal penile tumescence and rigidity in five.[44] The pattern of abnormality was consistent with neurogenic, not vasogenic, erectile dysfunction. In a self-report survey of 116 women with epilepsy, partial epilepsy patients experienced more dyspareunia, vaginismus, arousal insufficiency, and sexual dissatisfaction, whereas primary generalized epilepsy (PGE) patients experienced more anorgasmia and sexual dissatisfaction.[75] Sexual symptoms were not associated with seizure frequency, antiepileptic drug (AED) exposure, sexual experience, depression, or prepubertal seizure onset.

The pathogenetic role of temporal lobe seizures in hyposexuality is supported by animal models[30] and observations that sexual activity can increase following successful seizure control with AEDs[83] and temporal lobectomy.[7] In some postlobectomy subjects, marked hypersexuality similar to the Kluver-Bucy syndrome can develop occasionally.[9] However, AEDs modulate hypothalamic-pituitary-gonadal axis hormone activity and can directly inhibit sexual behavior.[64] Barbiturates may cause the greatest decrease in libido and sexual dysfunction.[70] Other hepatic enzyme–inducing AEDs are also associated with decreased testosterone levels and diminished libido and function.[49] Valproic acid is associated with menstrual disorders, hyperandrogenism, and polycystic ovaries.[54,78]

Religiosity

The ancient association between epilepsy and mystical/religious phenomena is paradigmatic of the difficulty reconciling dramatic anecdotes and long-standing medical opinion with limited clinical studies. Hippocrates began his monograph *On the Sacred Disease* by refuting the association between epilepsy and the divine. Despite his modern insights, religious and magical treatments of epilepsy predominated throughout the Middle Ages and Renaissance.[109] In the 19th century, psychiatrists stressed the religiosity of epilepsy patients and observed that Siberian medicine men preferred epileptic pupils.[64] Classic monographs on religious mysticism noted that “among the dread diseases that afflict humanity there is only one that interests us quite particularly; that disease is epilepsy.”[64] Intense religious experiences and beliefs are reported frequently by people with epilepsy. Many prominent religious figures allegedly had epilepsy, including prophets and founders of several religions.[116] The evidence supporting epilepsy in these people varies. Intense religious experiences can occur in association with seizures.[13,25,53,66,102]

Dewhurst and Beard[23] reported six TLE patients who underwent sudden religious conversions. There was a clear temporal

P.2107

relationship between conversion and increased seizure activity in five patients; one patient had a marked decrease in seizure frequency prior to conversion (she attributed her improved seizure disorder to the Almighty). Increased religious conviction and practice is not a consistent behavioral feature in patients with epilepsy. There is little evidence that epilepsy or TLE patients as a group are hyperreligious, although a subgroup may have unusually strong religious beliefs. Two studies with questionnaires on religion failed to differentiate patients with right versus left TLE, TLE versus GE, or epilepsy patients and controls.[110,120] However, one study found that patients with smaller right hippocampi had significantly higher ratings on a religiosity scale.[123]

Hypergraphia

Hypergraphia is not characteristic of interictal behavior among TLE or GE patients. However, several studies support that the subgroup manifesting this behavior most intensely are those with temporal lobe foci. Waxman and Geschwind[116] reported seven TLE patients with hypergraphia, which is a tendency toward extensive and sometimes compulsive writing. There was a striking preoccupation with detail—words were defined and redefined and underlined, parentheses were used to make word meaning absolutely clear—and the writers accorded great importance to their material. In four patients, the writings focused on moral and religious concerns. Hypergraphia was viewed as a component of the deepened emotions and especially viscosity of interictal behavioral changes.

Utilizing a mailed standard questionnaire, Sachdev and Waxman[92] demonstrated that TLE patients responded frequently and extensively (mean 1,301 words) as compared to other epilepsy patients (mean 106 words). Hermann et al.[47] replicated the higher response rates and longest letters in the TLE group, but they did not find that the average response was longer in TLE patients compared to other seizure patients. Duration of epilepsy, hypomania, and number of significant life events during the past year positively correlated with hypergraphia.[47,48] Hypergraphia occurs in 7% to 10% of TLE patients.[47,48]

Dostoyevsky was the most famous hypergraphic TLE patient,[39] although his prolific writing also reflected his pay per page and financial troubles. As a person, he was deeply emotional, irritable, angered over minor provocations, guilt ridden, depressed, and tortured over the question of God's existence. He described the relation between his writing and epilepsy in a letter to his brother (August 27, 1849): “Whenever formerly I had such nervous disturbances, I made use of them for writing; in such a state I could write much more and much better than usual.”[24]

Aggression

Interictal violence and aggression is a highly contentious topic, especially the relationship between TLE and aggression. There appears to be a relatively elevated incidence of interictal violence and hostility in patients with epilepsy as compared to healthy controls. The neurosurgical series of Serafetinides[97] and of Taylor[107] demonstrated rates of interictal aggression approaching 30% in TLE patients prior to temporal lobectomy. These studies were criticized for selection bias of refractory patients and those with psychiatric presentations. Rodin[91] identified 5% of patients presenting to an epilepsy center as manifesting aggressive behavior. Seizure type did not distinguish aggressive from nonaggressive patients. Gunn and Fenton[45] documented increased prevalence of epilepsy in British prisons relative to the general population. A study of the Illinois prison system documented a prevalence rate of epilepsy of 2.4%, elevated relative to the U.S. population at the time of the study. However, census of prisoners with epilepsy against matched nonepileptic controls did not reveal more serious violent crimes on the part of the epilepsy group.[118]

Violence and hostility in epilepsy is likely a consequence of an interaction of neurophysiologic as well as social factors. Male sex is a risk factor for violence and epilepsy, and Serafetinides noted that aggressiveness as a personality trait in TLE patients was more likely in those with seizure onset prior to age 10 years. Other risk factors identified in the TLE group include premature interruption of formal schooling, lower intellectual quotient, and lower socioeconomic status. These risk factors are associated with a greater risk of aggression in nonepileptic patients as well. Several studies found that ictal and interictal aggression appear to be more common in children than adults with TLE.[43,80,106] More specific neurobiologic factors were identified in a quantitative magnetic resonance imaging (MRI) analysis of mesial temporal structures in epilepsy patients with and without a history of interictal aggression.[112] Those with interictal aggression had less hippocampal atrophy. Two subgroups of those with aggression were identified: Those with severe amygdala atrophy and a history of encephalitis and those with left temporal lesions affecting the amygdala or periamygdaloid regions.[112]

Problems of Definition and Methodology

Defining specific personality traits and aberrations in patients with epilepsy is difficult and controversial. From a psychiatric standpoint, studies on interictal behavioral changes in epilepsy have not been "discipline neutral."[2] Over the past decades, stereotyped notions of personality attributes in patients with chronic seizures have been dominated by psychoanalysts and those performing trait analyses within the psychometric tradition of self-report methodologies and multivariate statistics. Debates in the literature center on complex personality concepts (e.g., hyperreligiosity) rather than attempt to integrate "first order" biologic variables that underlie the causality of complex behaviors (vide infra).

Considering the variety of epilepsy syndromes and their many etiologies, correlation of interictal behavior with a specific physiologic process or anatomic locus is difficult. Many studies on behavior and epilepsy were done before video-electroencephalographic (V-EEG) confirmation of a specific ictal onset zone and without high-resolution MRI. Many authors simplistically approach "TLE" as a monolithic entity primarily involving mesiotemporal structures. Analyses and speculations thereby focus exclusively on limbic-affective states. However, subdural grid electrode recordings frequently document TLE seizure onsets from neocortical extralimbic regions in isolation or together with mesial structures.[58,68] Even when invasive monitoring documents a temporal lobe "focus," there often is associated extratemporal glucose hypometabolism as defined by positron emission tomography (PET).[57] In patients with TLE, as an illustration, prefrontal metabolic asymmetry is associated with cognitive impairment and depression.[12,57]

Identifying behavioral changes confined to the interictal period is another methodologic challenge. Preictal (premonitory), postictal, and interictal behavioral alterations are less well circumscribed temporally than ictal changes. In the extreme case of partial status epilepticus, cognitive impairments form a continuum despite EEG evolution from discrete seizures to periodic discharges and finally re-emergence of normal EEG background.[88] For isolated seizures, transitions between ictal, preictal, postictal, and interictal behavioral states can be fluid,

and clinical distinctions made may be artificial. These behavioral changes may morph over time and extend from their initial extent during the postictal period to more continuous disorders that fill the interictal periods.[105]

Studies from the pre-MRI/pre–V-EEG era are limited by methodologic issues, including the diagnosis of epilepsy (e.g., nonepileptic events), syndromic diagnosis (e.g., benign rolandic epilepsy vs. TLE in a child), and localization of the seizure focus (e.g., frontal vs. temporal), which may all be more problematic in older than more recent studies. Before high-resolution MRI, structural lesions such as cortical dysplasias, vascular malformations, and low-grade neoplasms were not identified. Studies of TLE patients in the pre-MRI era likely included patients with erroneous localization and lateralization.

Finally, past behavioral analysis of the population with ep-ilepsy focused on personality structure rarely assessed lifetime developmental, antiepileptic drug, or other variables.[14,79,96,104]

Interictal Behavioral Changes in Other Epilepsy Syndromes

Personality Changes in Primary Generalized Epilepsy

Personality changes in epilepsy are not restricted to patients with partial epilepsy; they also occur in patients with PGE syndromes such as juvenile myoclonic epilepsy (JME)[55] and absence epilepsy.[100] In JME, reported traits included irresponsibility and impaired impulse control, neglect of duties, self-interest, emotional instability, exaggeration, inconsiderateness, quick temper, and distractibility. Janz[55] found that many JME patients repeatedly exposed themselves to sleep deprivation and often failed to comply with AEDs, taking their illness lightly. They denied problems and conflicts, or often yielded to temptation against better judgment. There was limited support for Janz's clinical impression,[5] although scientific evidence is sparse and some of these behaviors may reflect adolescence, not JME. Other studies found high rates of psychiatric disorders among patients with JME.[82,113] Gelisse et al.[37] reported 45 (26.5%) of 170 consecutive JME patients with psychiatric disorders. Twenty-four of these 45 patients had personality disorders, including borderline (11 cases), dependent (five cases), histrionic (two cases), obsessive-compulsive (one case), and not otherwise specified (five cases).

Absence epilepsy, long considered one of the most benign forms of epilepsy, recently has been associated with significant behavioral changes in a very well-controlled study. Wirrell et al.[122] compared all children in Nova Scotia with typical absence epilepsy or juvenile rheumatoid arthritis (JRA) diagnosed between 1986 and 1997, who were aged 18 years or older at follow-up (mean age 23 years). Remission occurred in 32 (57%) of the patients with typical absence epilepsy but in only 17 (28%) of the patients with JRA. Five categories of outcome were studied: Academic-personal, behavioral, employment-financial, family relations, and social-personal relations. Patients with typical absence epilepsy had greater difficulties in the academic-personal and in the behavioral categories (p <0.001) than those with JRA. Those with ongoing seizures had the least favorable outcome. Most seizure-related factors showed minimal correlation with psychosocial functioning. Even patients whose epilepsy had remitted had significantly poorer outcomes than the JRA patients in the academic-personal and behavioral domains. Another recent study found that 54% of pediatric patients with PGE had psychiatric disorders.[12] Early age of onset and poor seizure control were significantly associated with the severity of illogical thinking in these children. Thus, the recent literature strongly supports prior research that PGE is a risk factor for cognitive and behavioral problems.

Personality Changes in Patients with Frontal Lobe Epilepsy

The frontal lobes are important in personality, as highlighted by the effects of prefrontal surgeries. Thus, as limbic disorders can alter emotion- and drive-related behavior (e.g., sex and aggression), frontal dysfunction can alter personality, judgment, and executive functions. Further, the posterior orbitofrontal cortex and anterior cingulate gyrus, two critical limbic (paralimbic) areas, are located within the frontal lobe. Patients with anterior cingulate seizure foci can develop interictal psychosis, aggression, sociopathic behavior, sexual deviancy, irritability, obsessive-compulsive disorder, and poor impulse control.[3,19,21,71] Orbitofrontal lesions can cause hyperphagia, failure to use autonomic cues to guide behavior, aberrant emotional responsiveness, increased aggression, dysfunctional social behavior (e.g., case of Phineas Gage[16,97]), behavioral disinhibition, and confabulation.[20] Systematic studies on interictal behavior in patients with orbitofrontal seizure foci are lacking; however, behavioral disorders such as attention deficit hyperactivity disorder can occur.[85] Given the critical role of this limbic cortex in social and emotional behavior, epileptic foci in this site could cause prominent interictal behavioral changes.

In the Vietnam Head Injury Study,[103] patients with tonic–clonic seizures had a higher frequency of psychiatric treatment than those with complex partial seizures, possibly reflecting greater frontal lobe involvement. The role of the frontal lobe in the personality and behavior of epileptic patients deserves greater attention. Functional imaging studies suggest that, even among patients with temporal lobe seizure foci, frontal dysfunction contributes to affective, personality, and cognitive disorders.[11,82,94]

Characterizing the Interictal Behavior Syndrome

The Bear Fedio Inventory

In the original study using this measure, all 18 self-rated traits were significantly higher in the TLE group than in neurologic and healthy controls. The most significant differences (p <0.0001) were humorlessness, circumstantiality, dependence, and sense of personal destiny. Proxy raters (i.e., family or friends) identified TLE patients as significantly different from controls on 14 traits, most strongly (p <0.0001) for circumstantiality, obsessionalism, and dependence. Patients with right temporal foci reported more emotional traits and minimized their behavioral changes (i.e., polished their image), whereas patients with left temporal foci had more ideational traits and often tarnished their image on self-report relative to proxy reports. The previously reported associations of right hemisphere lesions with denial and neglect syndromes and left hemisphere lesions with depression[33,34,89,90] were consistent with the right/left:polish/tarnish correlation.

Replication studies using the Bear Fedio Inventory (BFI) have produced mixed results.[11,22,46,77] Use of the BFI generally reveals increased rates of these behavioral traits in patients with epilepsy (TLE and GE) in comparison to healthy controls or some medical patients, but it does not distinguish epilepsy (TLE or GE) from psychiatric patients. Findings from TLE

versus GE patient comparisons are inconsistent. When differences are present, the TLE group usually has higher scores than the GE group. Left–right differences in TLE are typically minor.

The complicating issue of frontal lobe seizure foci or frontal lobe involvement (e.g., seizure spread or interictal hypometabolism/neuronal dysfunction) should also be considered in patients with TLE. Although personality disorders are highlighted in the literature as elements of TLE, they would be expected to be features of frontal lobe epilepsy (FLE) as well. Indeed, in the literature on the BFI, the study by Wieser[119] was the only one to use invasive electrodes for localization and lateralization, and failed to replicate any laterality effects found by Bear and Fedio.[5] Interestingly, Wieser found a significant increase in humorlessness in the FLE group and a nonsignificant trend for an increase in all BFI behavioral traits in the FLE group.

The studies with the BFI nearly vanished after 1990, just as high-resolution MRI and V-EEG monitoring allowed more confident anatomic and physiologic diagnoses. As the BFI fell out of favor, so did much of the research on personality in epilepsy patients. Consequently, the subject of personality changes in epilepsy warrants further study.

The Neurobehavioral Inventory (NBI) is a more recent tool to specifically assess interictal psychopathology in epilepsy patients.[8] There has been relatively little use of the NBI, but it may prove valuable. In one study, patients with high ratings on the NBI religiosity scale had smaller hippocampi, while in another study, hyposexuality and hypergraphia were associated with bilateral hippocampal atrophy.[111]

Mazzini et al.[72] evaluated 143 patients with traumatic brain injury (TBI), of which 27 developed posttraumatic epilepsy (PTE), using another measure—the Neurobehavioral Rating Scale (NBHRS)—along with the Minnesota Multiphasic Personality Inventory (MMPI), Overt Aggression Scale, Back Depression Inventory (BDI), and *Diagnostic and Statistical Manual of Mental Disorders,* 4th ed. (DSM-IV) definitions for personality disorders. Patients with epilepsy showed a significantly higher incidence of severe personality disorders. Disinhibited behavior, irritability, and agitated and aggressive behavior were significantly more frequent and severe in PTE patients.

Feddersen et al.[29] examined 37 TLE patients, 38 with idiopathic generalized epilepsy with absence and generalized tonic–clonic seizures and 25 healthy controls using the Freiburg Personality Inventory/Form A (FPI-A-H)[28] and the Index of Personality Characteristics (IPC).[62] Patients with left TLE had increased emotional dependency, less externally judged composedness, increased depressive drive and mood, increased nervousness, increased search for information and exchange of disease experience, and greater tendency to persevere ($p < 0.05$). This study supported the differentiation made by Bear and Fedio[4] that patients with left TLE are more rational and tarnish their image, whereas patients with right TLE are more emotional and polish their image.

One study with the Millon Behavioral Health Inventory (MBHI) found that epilepsy patients have deficient coping styles.[115] Patients with epilepsy obtained higher scores on scales assessing inhibition and sensitivity and lower scores on scales evaluating sociability and confidence.

Table 2 Rate of Personality Disorders in Epilepsy

Schwartz and Cummings (1988)[95]	38% (4% controls)
Fiordelli et al. (1993)[32]	21% (0% controls)
Victoroff (1994)[114]	18%
Manchanda et al. (1996)[69]	18%
Arnold and Privitera (1996)[1]	18%
Lopez-Rodriguez et al. (1999)[65]	21%
Krishnamoorthy et al. (2001)[63]	47%
Koch-Stoecker (2002)[59a]	61%
Galimberti et al. (2003)[33a]	38%

DSM Axis II Disorders

Another approach to examining personality disorder in epilepsy is to turn to formal DSM-IV Axis II diagnoses. By definition, personality disorders are characterized by long-lasting patterns of thought and behavior that deviate from cultural expectations, inflexible and pervasive in nature, that result in impairment of function. To receive a diagnosis of personality disorder, the pattern of behavior must result in significant distress or impairment in personal, social, or occupational situations. Several criteria must be met in addition to the specific criteria for individually named personality disorders. These include the following:

1. Experience and behavior that deviates markedly from the expectations of the individual's culture. This pattern is manifested in two (or more) areas including cognition, affectivity, interpersonal functioning, and impulse control.
2. The enduring pattern is inflexible and pervasive across a broad range of personal and social situations.
3. The enduring pattern leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning.
4. The pattern is stable and of long duration and its onset can be traced back at least to adolescence or early adulthood.
5. The enduring pattern is not better accounted for as a manifestation or consequence of another mental disorder.
6. The enduring pattern is not due to the direct physiologic effects of a substance or a general medical condition such as head injury.

There are ten specific personality disorders in DSM-IV, which are grouped into three clusters: *Cluster A* (odd or eccentric disorders) includes paranoid personality disorder, schizoid personality disorder, and schizotypal personality disorder; *cluster B* (dramatic, emotional, or erratic disorders) includes antisocial personality disorder, borderline personality disorder, histrionic personality disorder, and narcissistic personality disorder; and *cluster C* (anxious or fearful disorders) includes avoidant personality disorder, dependent personality disorder, and obsessive-compulsive personality disorder. Finally, *personality disorder NOS* is a category for behavior patterns that do not match these ten disorders but have the characteristics of a personality disorder.

A series of investigations have assessed Axis II disorders (not including mental retardation) in patients with epilepsy using contemporary diagnostic procedures. As can be seen in Table 2, the rate of Axis II disorders range from 18% to 61% across studies, with a mean of 31% (median = 21%). Only two studies incorporated controls. These rates are elevated overall and investigations that examined the distribution of clusters A through C reveal that most individuals with epilepsy with Axis II disorders exhibit cluster C disorders. Even biologically oriented researchers recognize that problems associated with living with epilepsy, particularly early-onset epilepsy, may lead to dependant and avoidant personality traits, although this contention has not been examined empirically.

Table 3 Distribution of Specific Personality Disorders in Epilepsy

Authors	N	A	B	C	Procedure
Lopez-Rodriguez et al. 1999	52	0.0%	5.8%	15.4%	SCID-II
Galimberti et al. 2003	69	1.4%	10.1%	26.0%	SCID-II
Koch-Stoecker et al. 2002	100	6.0%	15.0%	24.0%	DSM-III-R
Krishnamoorthy et al. 2001	35	17.1%	2.9%	22.9%	SAP

SCID-II Structured Clinical Interview for DSM-IV-TR
DSM-III-R Diagnostic and Statistical Manual of Mental Disorders-III-R
PSE Present State Examination
A Cluster A; odd or eccentric disorders
B Cluster B; dramatic, emotional, or erratic disorders
C Cluster C; anxious or fearful disorders

Axis II disorders are probably underrecognized and incompletely addressed in the traditional clinic setting (Table 3). There is little information regarding their consequences, but

P.2110

the evidence available suggests that they are of consequence. Koch-Stoecker examined the predictors of postoperative psychiatric complications in 100 patients who underwent anterior temporal lobectomy (ATL).[59a] Patients were assessed for Axis I and II disorders preoperatively. Fourteen percent of their surgical patients were hospitalized for psychiatric reasons postoperatively and all these patients exhibited Axis II disorders preoperatively, either alone of in combination with Axis I disorders. No patients with just an Axis I disorder underwent postoperative psychiatric hospitalization.

Another indication of the maladaptive consequences associated with adverse personality features is demonstrated by Derry et al., who examined the impact of neuroticism on postoperative course in 45 individual ATL patients.[18] Those who were high in preoperative neuroticism exhibited significantly worse postoperative psychosocial adjustment and quality of life.

Summary and Conclusions

Personality disorders and other, less pathologic personality changes are common and often unrecognized in epilepsy patients. These disorders likely result from biologic factors such as structural and physiologic abnormalities as well as social and emotional factors. The specificity of certain personality traits or clusters and anatomic seizure foci (e.g., TLE or FLE) and epilepsy syndromes (e.g., partial vs. generalized) remains controversial, mired in methodologic issues and limited by a literature that often predated MRI and V-EEG studies. However, traits such as hypergraphia, although present in <10% of TLE patients, appear to be much more common in this form of epilepsy than others. Patients with FLE and idiopathic generalized epilepsy can also develop behavioral changes and personality disorders that can significantly impact their lives. The area remains ripe for additional studies using modern psychiatric and neurologic diagnostic tools.

Chapter 204

Schizophrenia and Other Psychoses

Michael R. Trimble

Bettina Schmitz

Introduction

Because the brain is the central organ that regulates behavior, a change of behavior may come about with disturbances of the brain, either through alteration of its structure or via functional change, functional here being used in its original meaning to emphasize disturbance of brain function.[92] Neurologists interested in behavioral disorders have mainly concerned themselves with patients with lesions that cause structural changes, whereas psychiatrists have dealt more with the consequences of disturbed function, where underlying structural lesions have been more difficult to discern. Epilepsy is one of a number of conditions in which there is often an underlying structural abnormality to be found if the appropriate technique is used (e.g., neuropathology, magnetic resonance imaging), but profound functional changes also occur, either as a consequence or independently. These may be reflected in the seizure, one manifestation of the epilepsy process, but may also be associated with some of the less dramatic but nonetheless clinically significant behavioral manifestations of epilepsy.

Definitions and Phenomenology

Psychosis, as used in the International Classification of Diseases (ICD)-10,[25] defines a disorder with the presence of "hallucinations, delusions, or a limited number of severe abnormalities of behavior, such as gross excitement and overactivity, marked psychomotor retardation, and catatonic behavior." In the *Diagnostic and Statistical Manual of Mental Disorders,* 4th ed. (DSM-IV), the term psychotic refers to delusions, any prominent hallucinations, disorganized speech, or disorganized or catatonic behavior.[7]

Hallucinations and delusions, the hallmark of psychosis, suggest some deviant neurologic processing, underlying which are usually structural but sometimes solely functional alterations of activity. Although in epilepsy hallucinations and delusions may be experienced in certain settings for which patients have clear insight, in the majority of cases insight is lacking, and the condition is truly psychotic.

Historical Background

In the middle of the 19th century, European psychiatrists noted the high incidence of psychotic episodes in institutionalized patients with epilepsy. Several authors described the specific psychopathology of psychiatric complications occurring in the context of epilepsy using such terms as "épilepsie lavvée,"[50] "grand mal intellectual,"[9] "epileptoid states,"[18] and "epileptic equivalents."[24] Samt[62] put forward the idea that the pathophysiology of certain psychoses occurring in the context of epilepsy, especially episodic twilight states, was identical to the pathophysiology of motor seizures. He suggested that in the absence of epileptic seizures, such epileptic equivalents could be sufficient for a diagnosis of epilepsy.

Some authors in the 19th century explicitly noted the rarity of chronic paranoia or true madness in patients with epilepsy. These observations resulted in intensive discussions on the nature of the relationship between epilepsy and schizophrenia, a subject frequently chosen in theoretical disputes on definitions of terms such as disease and symptom complex in psychiatry at the beginning of the 20th century.[20,30]

Combined seizures and schizophrenialike symptoms have generally been interpreted either as symptomatic seizures secondary to cerebral sequelae of insanity—for example, brain edema in catatonia—or as symptomatic psychoses caused by seizures or the underlying epileptic process.[32,36] In cases with no obvious temporal relationship between epileptic seizures and psychotic symptoms, it was speculated that both were not directly linked but were caused by the same underlying brain pathology.[54,73] Ganter,[13] Krapf,[32] and Glaus[16] published clinical case series with prevalence rates of combinations lower than expected. These studies, together with observations of alternating periods with seizures and seizure-free periods with psychosis in some patients and the improvement of psychotic symptoms after spontaneous seizures in others, led to the theory of functional dependency and biologic antagonism of schizophrenic and epileptic symptoms, a concept that influenced von Meduna[46] to introduce iatrogenic convulsions into the treatment of schizophrenia.

With progress in diagnosis and treatment in epilepsy, epileptology shifted conceptually to the realm of neurologists in many countries. Psychiatric aspects were neglected until they were “rediscovered” in the 1950s and 1960s.[14,38,82] American and English authors reported an excess of schizophrenialike psychoses in epilepsy patients, especially in those suffering from temporal lobe epilepsy.[15,55,70]

Slater et al. published a detailed analysis of 69 patients from two London hospitals who suffered from epilepsy and interictal psychoses. On the basis of this case series, the authors challenged the antagonism theory and postulated a positive link between epilepsy and schizophrenia. Although Slater was criticized for drawing conclusions on the basis of insufficient statistics,[77] the temporal lobe hypothesis soon became broadly accepted and stimulated extensive research into the role of temporal lobe pathology in schizophrenia. The use of epileptic psychoses as a biologic model or “mockup” of schizophrenia[59] is largely based on Gibbs and Slater's work.

Table 1 Clinical Characteristics of Psychoses in Relation to Seizure Activity

	Ictal	Postictal	Parictal	Alternative	Interictal
Relative frequency	~10%	~50%	~10%	~10%	~20%
Consciousness	Impaired	Impaired or normal	Impaired	Normal	Normal
Typical features	Mild motor symptoms	Lucid interval	Occurs often during presurgical evaluation	Initial symptom insomnia	Schizophrenialike psychopathology
Duration	Hours to days	Days to weeks	Days to weeks	Weeks	Months
EEG	Status epilepticus	Increased slowing, increased epileptic	Increased slowing, increased epileptic	Normalized	Unchanged
Treatment	Antiepileptic drugs IV	Spontaneous recovery, benzodiazepines, seizure control	Seizure control	Sleep regulation, reduction of antiepileptic drugs	Antipsychotics

EEG, electroencephalogram.

The possible impact of research into epileptic psychosis on the understanding of the pathophysiology of endogenous psychoses explains the bias in the literature toward study of interictal schizophrenialike psychoses. The spectrum of psychotic syndromes in epilepsy is, however, much more complex, and psychotic complications are not restricted to patients with temporal lobe epilepsy.

Epidemiology

Some of the earlier studies were reviewed in the first edition of this textbook (Chapter 197). The more recent studies have employed an improved methodology. Bredkjaer[2] in a record linkage study looked for associations between epilepsy from the national patient register of Denmark and the equivalent psychiatric register. The incidence of nonorganic, nonaffective psychoses, which included schizophrenia and schizophrenia spectrum disorders, was significantly increased in epilepsy, even when patients with learning disability or substance misuse were excluded.

Stefansson et al.[76] in a case-control study compared the prevalence of nonorganic psychiatric disorders in patients with epilepsy to those with other somatic diseases, the groups being taken from a disability register in Iceland. Although the difference in psychiatric diagnoses overall was not significant, there was a higher rate of psychoses, particularly schizophrenia and paranoid states, among males with epilepsy.

Qin et al.[56] in another study from Denmark have confirmed the increased risk of schizophrenia and schizophrenialike psychoses in epilepsy, and in this study a family history of psychoses and a family history of epilepsy were significant risk factors for psychosis.

Studies from Japan examining new referrals for epilepsy quote a 6% prevalence of psychoses in those with normal intelligence (in contrast to 24% in those with learning disability).[44]

There are several studies of much more selected populations, such as hospital case series. Thus, Gureje,[19] in patients attending a neurologic clinic, quoted that 37% of patients were psychiatric cases and that 29% of these were psychotic. Mendez et al.[48] in a retrospective investigation reported that interictal psychotic disorders were found in over 9% of a large cohort of patients with epilepsy in contrast to just over 1% in patients with migraine. The epilepsy sample had more complex partial seizures, more auras, and less generalized epilepsy.

None of the above studies has been able to examine issues related to epilepsy classification in any detail, cohorts being derived from case registers lacking detailed information from, for example, brain imaging. Certain risk factors have been defined, but not from these data, and are noted below.

Classification

There is no internationally accepted syndromic classification of psychoses in epilepsy. Most of the previously proposed classification systems for these psychoses[3,10,29,85] are based on a combination of psychopathologic, etiologic, longitudinal, and electroencephalographic (EEG) parameters. Unfortunately, because of a lack of taxonomic studies, our knowledge about regular syndromic associations is still limited.

"Atypical" syndromes are not unusual, and presentations such as those associated with forced normalization (see below) and postictal psychoses make simple divisions between what is ictal and what is interictal difficult to discern. In other words, the above two examples are of psychotic states closely tied to the biology of the ictus but which are interictal in their timing. A new multiaxial approach to the classification of psychoses in epilepsy can be found in the proposal by Krishnamoorthy.[33]

It is suggested that patients with epilepsy and psychoses receive two separate diagnoses according to either ICD-10 or DSM-IV,[7] but in addition, the relationships between onset of psychosis and seizure activity, antiepileptic therapy, and changes of EEG findings should be noted.

For pragmatic reasons, however, it remains convenient to group psychoses in epilepsy according to their temporal relationship to seizures.

Syndromes of Psychoses in Relation to Seizure Activity

The various syndromes are described in Table 1. The ictal psychoses are more likely to be linked to complex partial seizure status but have never been examined in any detail. In clinical practice they are not uncommon in seizures of temporal origin, but some of them are secondary to frontal lobe seizures. Simple focal status or aura continua may cause complex hallucinations, thought disorders, and affective symptoms. The continuous epileptic activity is restricted and may escape scalp EEG recordings. Insight usually is maintained, and true psychoses emerging from such a state have not been described. Nonconvulsive status epilepticus requires immediate treatment with intravenous antiepileptic drugs.

Table 2 Differences between Postictal Psychoses (PIP) and Interictal Psychoses (IIP) (Statistically Significant)

	PIP (n = 45)	IIP (n = 126)
Reduced intelligence (<70 IQ)	4	39
Complex partial seizures	37	84
Déjà vu aura[a]	10 of 43	10 of 103
Temporal MRI lesion	16	25
Temporal lobe epilepsy	39	74
Generalized spike-waves	1	21
Age at epilepsy onset (years)	16	11
Age at psychosis onset (years)	35	25
Interval between onset epilepsy and psychosis (years)	18	13

[a]Calculated for the subgroup of patients with focal epilepsies.
Data from Kanemoto K. Postictal psychosis revisited. In: Trimble MR, Schmitz B, eds. *The Neuropsychiatry of Epilepsy.* Cambridge: Cambridge University Press; 2002:117–134.

Postictal Psychoses

Most postictal psychoses are precipitated by a series or status of generalized tonic–clonic seizures. More rarely, psychoses occur after single grand mal seizures or following a cluster of complex partial seizures.[69] In the elderly, a postictal psychosis may be the first presentation of a new-onset epilepsy disorder.

P.2115

Postictal psychoses account for approximately 25% of psychoses in epilepsy.[17,64]

The relationship to the type of epilepsy is not clear. Dongier[8] described a preponderance of generalized epilepsies, and Logsdail and Toone[41] noted a higher frequency of postictal psychosis in patients with focal epilepsies and complex focal seizures. One of the more comprehensive studies has been that of Kanemoto, and his distinction between postictal and interictal psychoses is shown in Table 2. Essentially, the postictal psychoses occur with later age of onset of epilepsy and at a later age than the interictal psychoses. They are significantly associated with temporal lobe epilepsy, complex partial seizures, and magnetic resonance imaging (MRI) temporal plus extratemporal structural lesions. Patients are less likely to have learning disability and are less likely to have generalized spike-wave abnormalities on the EEG. He also noted an association with déjà vu auras.[27] Others have suggested an association between ictal fear and postictal psychosis.[63]

A characteristic lucid interval is described in most patients during which time the mental state appears to be normal. This interval can last from 1 to 6 days between the epileptic seizures and onset of psychosis.[73] Failure to appreciate the presence of this lucid interval can lead to a misdiagnosis of this condition.

The psychopathology of postictal psychosis is polymorphic, but most patients present with abnormal mood and paranoid delusions.[41] Some patients are confused throughout the episode; others present with fluctuating impairment of consciousness and orientation; and sometimes there is no confusion at all. Kanemoto[27] suggests that up to 50% have a psychosis in clear consciousness. Dominant are delusions of grandiosity and religiosity often associated with an elevated mood when compared with interictal psychoses. Patients may also be anxious and a typical symptom is fear of impending death. Because patients often have a clear sensorium and may receive command hallucinations if the latter relate to violence or suicide, it is during such states that violent attacks on the self or others may occur.

The EEG during postictal psychosis is usually deteriorated, with increased epileptic as well as slow-wave activity, but there are few reliable studies since people with acute psychoses are difficult to examine.

The psychotic symptoms spontaneously remit within days or weeks, often without need for psychotropic drug treatment. However, in some cases, chronic psychoses develop from recurrent and even a single postictal psychosis[41,94]; this is estimated to occur in about 25% of cases.

The pathophysiology is not known. Savard et al.[63] noted the clinical analogy of psychoses following complex partial seizures to other postictal phenomena such as Todd paresis or postictal memory loss. Logsdail and Toone hypothesized that postictal psychosis results from increased postsynaptic dopamine sensitivity. Ring et al.[58] have tested this hypothesis using single-photon emission computed tomography (SPECT) and the D_2 ligand [^{123}I] iodobenzamide (IBZM). They noted that patients with epilepsy and psychoses had decreased binding to the ligand, suggesting that there was increased release of endogenous dopamine in the psychotic state. Kanemoto[27] suggested that we are dealing with a restricted limbic status epilepticus, but limited functional imaging studies produced contradictory results.[39]

Parictal Psychosis

Most authors do not distinguish between parictal and postictal psychoses.[63] In parictal psychosis,[94] psychotic symptoms develop gradually and parallel to increases in seizure frequency. The relationship to seizures is easily overlooked if seizure frequency is not carefully documented over prolonged periods. More rapid development of parictal psychoses can be seen, especially during the presurgical assessment of patients with intractable epilepsy, when series of epileptic seizures may be provoked by withdrawal of antiepileptic drugs. Impairment of consciousness is more frequent than in postictal psychosis.

Interictal Psychoses

Interictal psychoses occur between seizures and cannot directly be linked to the ictus. They are less frequent than peri-ictal psychoses, and account for 10% to 30% of diagnoses in unselected case series.[8,64] Interictal psychoses are, however, clinically more significant in terms of severity and duration than peri-ictal psychoses, which usually are brief and often self-limiting.

Slater and Beard stated that, in the absence of epilepsy, the psychoses in their study group would have been diagnosed as schizophrenia, and noted the frequent presence of the First Rank Symptoms of Schneider.[70] However, there have been persistent arguments as to the exact relationship between the two disorders and the phenomenology of the interictal epileptic psychoses. Slater maintained that there was a distinct difference between schizophrenia and the schizophrenialike psychoses associated with epilepsy, and they highlighted the preservation of affect, a high frequency of delusions and religious mystical experiences, and few motor symptoms.

Other authors have stressed the rarity of negative symptoms and the absence of formal thought disorder and catatonic states.[28] McKenna et al.[45] pointed out that visual hallucinations were more prominent than auditory hallucinations. Tellenbach[82] stated that delusions were less well organized, and Sherwin[67] remarked that neuroleptic treatment was less frequently necessary. There have been other authors, however, who denied any clear psychopathologic differences between epileptic psychosis and schizophrenia.[21,31]

Table 3 Risk Factors Associated with Interictal Psychoses of Epilepsy[a]

Sex	Bias to female patients
Age of onset	Early adolescence
Interval	Onset of seizures to onset of psychosis: Mean 14 years
Epileptic syndrome	Temporal lobe epilepsy
Seizure type	Complex focal
Seizure frequency	Low, diminished
Neurologic findings	Sinistrality
Pathology	Gangliogliomas, hamartomas
EEG	Mediobasal focus, especially left sided

EEG, electroencephalogram.

Using the Present State Examination and the CATEGO computer program, which is a semistandardized and validated method for quantifying psychopathology, it has been possible to compare the presentation of psychosis in epilepsy with process schizophrenia. Very few significant differences emerged from such studies,[53,84] which suggests that, assuming the

P.2116

patients were representative, a significant number will have a schizophrenialike presentation virtually indistinguishable from schizophrenia in the absence of epilepsy.

Phenomenology apart, Slater argued that long-term prognosis of psychosis in epilepsy was better than that in process schizophrenia. In a follow-up study on his patients, he found that chronic psychotic symptoms tended to remit, and personality deterioration was rare.[17] Other authors have also described the outcome to be more favorable and long-term institutionalization to be less frequent than in schizophrenia.[28,67] Unfortunately, there have been no longitudinal studies comparing the long-term outcome of psychosis in epilepsy and process schizophrenia.

Risk Factors

The pathogenesis of psychotic episodes in epilepsy is likely to be heterogeneous. In most patients, a multitude of chronic and acute factors can be identified that are potentially responsible for the development of a psychiatric disorder. These factors are difficult to investigate in retrospect, and the interpretation of them as either causally related or simply intercorrelated is arguable.

The literature on risk factors is highly controversial; studies are difficult to compare because of varying definitions of the epilepsy, the psychiatric disorder, and the investigated risk factors. Most studies are restricted to interictal psychoses. Table 3 summarizes factors that have frequently been described to be associated with the interictal psychosis in epilepsy.[85]

Genetic Predisposition

With few exceptions,[26,56] most authors do not find any evidence for an increased rate of psychiatric disorders in relatives of epilepsy patients with psychoses.[11,53,69] This was one reason why Slater suggested that these psychoses were truly symptomatic, a representative phenotype of the genotype.

Sex Distribution

There has been a bias toward female sex in several case series,[80] but this has not been confirmed in controlled studies.[1,34,35]

Duration of Epilepsy

The interval between age at onset of epilepsy and age at first manifestation of psychosis has been remarkably homogeneous, in the region of 11 to 15 years, in many series.[85] This interval has been used to postulate the etiologic significance of the seizure disorder and a kindlinglike mechanism. However, some authors[5,77] have argued that the supposedly specific interval represents an artifact. They have drawn attention to the wide range, with a significantly shorter interval in patients with later onset of epilepsy. They also have pointed out that patients whose psychoses did not succeed their epilepsy were excluded in most series, and that there is a tendency in the general population for the age of onset of epilepsy to have an earlier peak than that of schizophrenia.

Type of Epilepsy

There is a clear excess of temporal lobe epilepsy in almost all case series of patients with epilepsy and psychosis. Among the pooled data of ten studies, 217 (76%) of 287 patients suffered from temporal lobe epilepsy.[85] The preponderance of this type of epilepsy is, however, not a uniform finding; in Gudmundsson's epidemiologic study, for example, only 7% suffered from "psychomotor" epilepsy. However, in many studies, especially the early ones, the classification of seizures and epilepsy is confused, and not supported by neurologic investigations.

The nature of a possible link of psychoses to temporal lobe epilepsy (TLE) is not entirely clear,[65] partly because of ambiguities in the definition of TLE in the literature, based on either seizure symptomatology (psychomotor epilepsy), involvement of specific functional systems (limbic epilepsy), or anatomic localization as detected by depth EEG or neuroimaging (amygdalohippocampal epilepsy). Unfortunately, most authors have not sufficiently differentiated frontal and temporal lobe epilepsy.

The temporal lobe hypothesis, although widely accepted, has been criticized for being based on uncontrolled case series, such as in the studies by Gibbs[15] and Slater and Beard.[70] It was argued that TLE is the most frequent type of epilepsy in the general population and that there is an overrepresentation of this type of epilepsy in patients attending specialized centers. However, there is a general consensus that psychoses are less common in patients with neocortical extratemporal epilepsies.[5,15,17,51,64,66,77] Adachi[1] suggested that psychoses in patients with frontal lobe epilepsy may be overlooked because of a differing psychopathology, hebephrenic symptoms in particular dominating the presentation.

The findings are less unequivocal regarding TLE and generalized epilepsies. Four studies[19,53,66,68] note significant differences in the frequency of psychoses in temporal lobe epilepsy, but several do not.[4,14,49,64,72,75,77] However, many patients with generalized epilepsy show pathology of temporal structures, making classification difficult, and again many reports lack the sophisticated brain imaging that is now required for such hypotheses to be tested.

There are several studies showing that psychoses in generalized epilepsies differ from psychoses in TLE.[85] The former are more likely to be of short duration and confusional.[4,8,77] Alternative psychoses, which are especially common in generalized epilepsy, are usually relatively mild and often remit before any development of paranoid-hallucinatory symptoms. Schneiderian first-rank symptoms and chronicity are more frequent in patients with TLE.[64,86] This has considerable significance for psychiatrists attempting to unravel the underlying “neurology” of schizophrenia, and the findings from epilepsy were

instrumental in altering the view of schizophrenia away from a psychosocial to a biologic model.

Type of Seizures

There is evidence from several studies that focal seizure symptoms that indicate ictal mesial temporal or limbic involvement are overrepresented in patients with psychosis. Hermann and Chabria[23] noted a relationship between ictal fear and high scores on paranoia and schizophrenia scales of the Minnesota Multiphasic Personality Inventory (MMPI). Kristensen and Sindrup[34,35] found an excess of dysmnesic and epigastric auras in their psychotic group. They also reported a higher rate of ictal amnesia. In another controlled study, ictal impairment of consciousness was related to psychosis, but simple seizure symptoms indicating limbic involvement were not.[64]

No seizure type is specifically related to psychosis in generalized epilepsies. Most patients with psychosis and generalized epilepsies have absence seizures.[64]

Severity of Epilepsy

The strongest risk factors for psychosis in epilepsy are those that indicate severity of epilepsy. These are long duration of active epilepsy,[70] multiple seizure types,[5,22,40,52,60,64,66] history of status epilepticus,[64] and poor response to drug treatment.[40] Seizure frequency, however, is reported by most authors to be lower in psychotic epilepsy patients than in nonpsychotic patients.[11,66,71,74] It has not been clarified whether seizure frequency was low before or during the psychotic episode. This may represent a variant of forced normalization (see below).

Laterality

Left lateralization of temporal lobe dysfunction or temporal lobe pathology as a risk factor for schizophreniform psychosis was originally suggested by Flor-Henry.[11] Studies supporting the laterality hypothesis have been made using surface EEG,[40] depth electrode recordings,[67] computed tomography,[6,83] neuropathology,[79] neuropsychology,[53] and positron emission tomography (PET),[91] and more recently with MRI. The earlier literature has been summarized by Trimble.[85] In a synopsis of 14 studies with 341 patients, 43% had left, 23% right, and 34% bilateral abnormalities. This is a striking bias toward left lateralization. However, lateralization of epileptogenic foci was not confirmed in all controlled studies.[8,34,35,68] Again, it may be that certain symptoms rather than any syndrome are associated with a specific side of focus. Trimble pointed out that a specific group of hallucinations and delusions, defined by Schneider and referred to as first rank symptoms, which usually (but not exclusively) signifies schizophrenia, may be relevant.[89,90] He suggested that these may be signifiers of temporal lobe dysfunction, representing disturbances of language and symbolic representation. In this sense, he then equated to a Babinski sign for a neurologist (i.e., pointing to a location and lateralization of an abnormality in the central nervous system).

These laterality findings have received support from brain imaging studies, especially SPECT and MRI. Mellers,[47] using a verbal fluency activation paradigm and HMPAO SPECT, compared patients with schizophrenialike psychoses of epilepsy (n = 12), with schizophrenia (n = 11), and epilepsy and no psychoses (n = 16). The psychotic epilepsy patients showed lower blood flow in the superior temporal gyrus during activation than the other two groups. Using MR spectroscopy, Maier et al.[42] were able to compare hippocampal-amygdala volumes and hippocampal *N*-acetyl aspartate (NAA) levels in patients with temporal lobe epilepsy and schizophrenialike psychoses of epilepsy (n = 12), temporal lobe epilepsy and no psychoses (n = 12), schizophrenia and no epilepsy (n = 26), and matched normal controls (n = 38). The psychotic patients showed significant left-sided reduction of NAA, and this was greater in the psychotic epilepsy group. Regional volume reductions were noted bilaterally in this group, and in the left hippocampus-amygdala in the schizophrenic group.

Flugel et al.[12] have recently examined 20 psychotic and 20 nonpsychotic cases with temporal lobe epilepsy using magnetization transfer imaging. They reported significant reductions of the magnetization transfer ratio (an index of signal loss) in the left superior and middle temporal gyri in the psychotic patients; this was unrelated to volume changes and best revealed in the subgroup with no focal MRI lesions.

Structural Lesions

The literature on brain damage and epileptic psychosis is very controversial. Some authors have suggested a higher rate of pathologic neurologic examinations, diffuse slowing on the EEG, and mental retardation,[34,35] but others could not find an association with psychosis.[11,26] Neuropathologic studies of resected temporal lobes from patients with TLE have suggested a link between psychosis and the presence of cerebral malformations such as hamartomas and gangliogliomas as compared with mesial temporal sclerosis.[4,59,80] These findings have been seen as consistent with recent findings of structural abnormalities in the brains of schizophrenic patients without epilepsy that arise during fetal development.

Bruton[4] has noted enlarged ventricles, periventricular gliosis, and an excess of acquired focal damage in brains of institutionalized psychotic epileptic patients compared with nonpsychotic controls. Bruton also reported that schizophrenialike psychoses were also distinguished by an excess of perivascular white matter softenings.

In a study specifically looking at hippocampal and amygdala volumes, Tebartz van Elst et al.[81] examined 26 patients with epileptic psychoses, 24 with temporal lobe epilepsy and no psychosis, and 20 healthy controls. The psychotic patients had significantly increased amygdala sizes in comparison with the other two groups, which were bilateral, not related to the laterality of the focus or length of epilepsy history. No hippocampal differences were noted in this study. In a complementary study on the same groups, Rusch et al.[61] were unable to find any neocortical cortical volumetric differences.

Forced Normalization

A full understanding of the relationships between epilepsy and psychosis requires appreciation of this concept.

Earlier this century, reports appeared that suggested that there was some kind of antagonism between epilepsy and psychosis. This was one of the reasons that led von Meduna to introduce convulsive therapy for the treatment of schizophrenia. In the 1950s, Landolt[37,38] published a series of papers on patients who had epilepsy who became psychotic when their seizures were under control. He defined forced normalization as follows: “Forced normalisation is the phenomenon characterised by the fact that, with the recurrence of psychotic states, the EEG becomes more normal, or entirely normal, as compared with previous and subsequent EEG findings.”

Forced normalization was thus essentially an EEG phenomenon. The clinical counterpart of patients becoming psychotic when their seizures became under control and their

psychosis resolving with return of seizures was referred to as alternative psychoses by Tellenbach.[82]

These phenomena have now been well documented clinically. The following are important to note, however. First, the EEG does not need to become “normal,” but the interictal disturbances decrease and in some cases disappear. Second, the clinical presentation need not necessarily be a psychosis but sometimes is. In childhood or in the mentally handicapped, aggression and agitation are common. Other manifestations include pseudoseizures or other conversion symptoms, depression, mania, and anxiety states. Third, the disturbed behavior may last days or weeks. They may be terminated by a seizure, and the EEG abnormalities then return. Fourthly, Landolt originally associated this phenomenon with focal epilepsies, but with the introduction of the succinimide drugs, he noted an association with the generalized epilepsies. Certainly, forced normalization may be provoked by the administration of anticonvulsants and has been reported with barbiturates, benzodiazepines, ethosuximide, tiagabine, topiramate, vigabatrin, levetiracetam, and more recently lamotrigine[5,85] (see Chapter 208).

The literature on antagonism between epilepsy and psychosis has been held to be incompatible with the suggestions outlined above that there is an increased association between epilepsy and psychosis. This has been resolved by more careful understanding of the original literature.[93] Thus, within the association or link between psychosis and epilepsy, there may be an antagonism of symptoms between seizures and the symptoms of psychosis (i.e., the hallucinations and delusions). It is the longitudinal course of the disorders that has to be followed, and forced normalization, as opposed to alternative psychosis, requires serial EEG recordings before the diagnosis can be made.

It is often denied that forced normalization occurs, probably with good reason. Thus, it is certainly rarer than made out by Landolt, and studies are few and far between. It is difficult to document cases precisely, EEG recordings being difficult to obtain at the right times. However, other less enlightened reasons to ignore such findings relate to the fact that the concept brings psychiatry uncomfortably close to neurology, revealing a close biologic link between seizures and psychosis. It also affects treatment. Thus, if in some patients suppression of seizures provokes psychopathology, it reinforces the fact, often ignored or misunderstood, that seizures and epilepsy are not synonymous, and that an understanding of the epileptic process and its treatment goes far beyond the control of seizures. In clinical practice, to ignore the fact that some patients manifest these problems as their seizures come under control can lead to the continuation of severe behavior disturbances, with all of the social disruption that then emerges, and a failure to manage the epilepsy appropriately.

Psychosis Following Surgery

Temporal lobectomy is an ever-increasing treatment for patients with intractable epilepsy. Ever since the early series, the possibility that surgery itself may be associated with the development of psychiatric disturbance, in particular psychosis, has been discussed. Some of the best evidence comes from the Maudsley series, initially described by Taylor[78] and more recently by Bruton.[4] Most centers have stopped operating on floridly psychotic patients, based on the observation that psychoses generally do not improve with the operation. A few centers, however, regularly include psychiatric screening as part of their preoperative assessment, but postoperative psychiatric follow-up is often nonexistent. Assessment of psychosocial adjustment is rarely performed, in contrast to the often scrupulous recording of neuropsychological deficits.

The Maudsley series show that some patients develop new psychosis postoperatively, and there is an increased reporting of depression. Bruton[4] has suggested that the development of postoperative psychoses may be more common with certain pathologies (gangliogliomas). Patients with right-sided temporal lobectomies may be more prone to these psychiatric disturbances.[85] In some cases, the sudden relief of seizures that occurs following surgery may suggest a mechanism similar to forced normalization, although no persistent clear relationship emerges between success of operation and the development of psychotic postoperative states. In recent times, there have been several small series reported of patients with psychoses who have been successfully operated on, without worsening of their seizures but with marked improvement in seizure control. This topic is discussed in much more detail in Chapter 209.[57]

Diagnosis

The principles of diagnosis of psychiatric problems in epilepsy are essentially the same as when a patient does not have epilepsy. However, as noted, it is not possible to apply the strict DSM-IV classifications,[7] and in many patients there are subtle aspects to the clinical picture that may suggest the underlying neurologic flavor of the phenomenology. These include in the schizophrenialike psychoses the retention of affective responses, lack of chronic personality and lifestyle deterioration, and development of some of the personality features noted in the interictal personality syndrome. An inclination to mysticism with developing religiosity is one of the most common.

Close attention to the relationship of the development of the psychoses to the seizure pattern is essential if the peri-ictal disorders are to be distinguished from the interictal, although in many patients this is not always clear, and the pattern may change with time. In particular, there are reports of ictally driven psychoses evolving to a chronic interictal syndrome, subtle at first but then more enduring. In other cases, the acute psychoses may erupt in the absence of an obvious cluster of seizures, even though on previous occasions the relationship has been obvious. The EEG in some cases is very important in clarifying the diagnoses, especially for nonconvulsive status and states of forced normalization.

Because many patients with psychoses of epilepsy display prominent affective symptoms, it is important to identify those patients with an affective disorder, as opposed to a schizophrenialike state or a paranoid illness, that may respond initially to effective antidepressant therapy.

Treatment

Essentially, management of psychiatric problems in patients with epilepsy is similar to that in patients without epilepsy, with a few caveats. Certainly, a number of nonmedical treatments are available. These should always be thought of in individual cases.

Patients with psychoses should be treated with neuroleptic medications, although these, like most antidepressants, can lower the seizure threshold. To date, all known neuroleptics have this potential, although some more than others; this is covered in more detail in Chapter 214.

Postictal psychoses may occasionally need neuroleptic drugs, although they usually settle rapidly. It is more important to prevent patients from damaging themselves or causing harm to others, but a drug such as haloperidol or one of the newer atypical antipsychotics at regular intervals may control behavior satisfactorily. Interictally, the paranoid or schizophrenialike states need to be evaluated in terms of their relationship to seizure frequency. Thus, in patients who stop having seizures in association with the onset of psychosis, a neuroleptic that increases the seizure threshold (e.g., chlorpromazine or even clozapine) may be the most logical prescription.

Where patients with epilepsy have no alteration of the seizure frequency or the psychosis is occurring in the setting of increased seizure frequency, a neuroleptic less likely to precipitate seizures, such as risperidone, an atypical antipsychotic, is logical. It should be recalled that patients taking anticonvulsants that increase hepatic metabolism will show lower serum levels of neuroleptics and may therefore require somewhat higher doses than patients not on these medications to achieve a similar clinical effect. Occasionally, the addition of an antidepressant or a neuroleptic to a patient's prescription may lead to increases in serum anticonvulsant levels.

Postictal psychoses often do not require psychotropic medication, resolving over a few hours. However, it is important to stress how dangerous these cases can be, and it is essential to take note of any command hallucinations or delusions of harm to the self or others and protect accordingly. In the first instance, treatment with a benzodiazepine is helpful, since there is a risk, especially with some of the antipsychotics, of precipitating further seizures and exacerbating the psychosis. Regular benzodiazepines for perhaps 48 hours are often sufficient. In the longer-term management it is important to realize that postictal psychoses have a tendency to recur. It is therefore important to warn about this, and to try with effective antiepileptic drug therapy to try to prevent clusters of seizures. It is sometimes possible to prevent such a cluster and hence the later psychosis by telling patients to take their benzodiazepine at the onset of any cluster and continue then for about 48 hours. Sometimes all these measures fail, and so intermittent or even continuous antipsychotic treatment becomes important.

As with all psychiatric problems, psychopharmacologic management alone is not sufficient. Although the role of psychotherapy in the management of psychotic conditions has not proven of any substantial value, it is important to acknowledge that epileptic patients with psychosis bear the burden of epilepsy in addition to their psychosis. Patients with intermittent psychotic states are often perplexed and embarrassed about what has happened to them while psychotic and fear further continuing bouts with a descent into insanity. Patients with continuous psychosis require the skills of paramedical intervention, and the full resources of community care may be needed to help them rehabilitate and to assist their families in coping with their difficulties. In many patients with chronic psychoses of epilepsy, the preservation of affect and lack of personality disintegration over years sustains them well in their communities and may enable them to live with their families or even marry. Maintaining them and bringing such support to them is important, sustaining them in the community and preventing their recurrent admission to the hospital. Further, in a good family environment with adequate medical facilities and follow-up care, patient compliance will tend to be good. Deterioration of an otherwise delicate situation induced by poor compliance, leading to more seizures and exacerbation of psychopathology with loss of control by the family and the physician, may thereby be avoided.

Summary and Conclusions

There is evidence that psychoses are overrepresented in patients with epilepsy, and few physicians who manage epilepsy have not seen patients with either an ictal, postictal, or interictal psychosis. The link to temporal lobe epilepsy is strong, both clinically and theoretically, because there is an acknowledged link between the limbic system and the modulation of emotional and social behaviors.[88] It has to be of profound interest that epilepsy, which is so often associated with lesions in medial temporal structures that tend to be present from an early phase in life, is linked to psychoses, which often resemble paranoid and schizophreniform states found in the absence of epilepsy. Thus, the latter can also be shown to have pathology in the same areas of the brain,[87] and schizophrenia is now viewed as a developmental disorder associated with anomalous central nervous system development in the fetal or perinatal era of life.

Although the underlying pathology may be different, the absence of gliosis in the hippocampus and related structures characterizing schizophrenia, the site of the pathology, the timing of the lesions, and the consequent functional changes in the brain may all be crucial to the later development of any behavior changes in both epilepsy and schizophrenia. Thus, the behavior changes should be viewed as an integral part of the process of epilepsy that are manifest in some patients. However, the recent evidence, especially from brain imaging studies, suggests that Slater's original hypothesis was part right but part wrong. Thus, the interictal psychoses seem different from schizophrenia, especially with regard to the admixture with affective symptoms and the long-term prognosis. While hippocampal changes may relate to both disorders, the increased amygdala size, bilateral and around 17% to 20%, and the lesser volumetric changes in the hippocampus suggest that the two psychopathologic states are biologically quite different. While the laterality findings with regard to the functioning of the left hemisphere seem to hold up, the data point away from fundamentally cortical abnormalities in these psychoses, and bring the amygdala and related structures as central in pathogenesis. Finally, it has to be repeated that epilepsy is not synonymous with seizures, and the latter are but one manifestation of the disordered cerebral function of patients with epilepsy.

Chapter 205
Affective Disorders

Andres M. Kanner

Dietrich Blumer

Introduction

Mood disorders are the most common comorbid psychiatric disorders associated with epilepsy, but their real incidence and prevalence have yet to be established. Some of the primary reasons for the lack of definitive epidemiologic data include the diversity in methodologies and sample populations across studies, the underreporting of symptoms of depression by patients and families, and the underrecognition by clinicians. Population-based studies, however, have clearly shown that the prevalence of depression in people with epilepsy (PWE) is significantly higher than in healthy controls, as well as in people with chronic medical disorders.[59,62,96,104,144]

There is an ongoing debate as to whether depression in PWE differs from that in people with primary mood disorders.[105] Proponents of both schools of thought are probably correct, as a significant percentage of PWE can experience any of the various forms of primary mood disorders (i.e., major depressive disorder, dysthymic disorder, bipolar disorder, cyclothymic disorder) indistinguishable from those described in the *Diagnostic and Statistical Manual of Mental Disorders,* Fourth Edition (DSM-IV).[57] By the same token, several authors have identified atypical clinical manifestations of mood disorders in a significant proportion of PWE that fail to meet any of the diagnostic criteria suggested in the DSM-III, DSM-III-R, and DSM-IV.[19,105,110,134] Kraepelin and Bleuler were the first to recognize a "unique" clinical presentation of mood disorders in PWE consisting of recurrent episodes of "dysphoric symptoms"[18,115]; Gastaut expanded on Kraepelin's initial observations and Blumer coined the term *interictal dysphoric disorder*.[19,74,75] The purpose of this chapter is to provide a comprehensive review of mood disorders in epilepsy. The aim of this chapter is to provide a general review of the different aspects of affective disorder in PWE with special attention to epidemiologic and clinical data, the underlying pathogenic mechanisms with special attention to the existence of common pathogenic mechanisms that may be operant in depression and epilepsy, and the basic principles in their treatment. The chapter concludes with a brief discussion of interictal dysphoric disorder.

Epidemiologic Data

Lifetime prevalences for major depressive episodes in the general population have been reported to range between 3.7% and 6.7%, for dysthymic and minor depressive disorders between 2.1% and 3.8%, and for manic episodes 0.6% and 1.1%.[111] Recent population-based studies identified significantly higher prevalence rates of depression in PWE. For example, the Canadian Community Health Survey evaluated the existence of mental health problems in a large sample of the population (n = 36,984).[200] A total of 253 subjects were found to have epilepsy (corresponding to a prevalence rate of epilepsy of 0.6%). The investigators used the Composite International Diagnostic Interview (Short Form) to identify a history of depression and found a lifetime prevalence of depression of 22.2% (95% confidence interval [CI], 14.0% to 30.4%) compared with 12.2% in the general population, with higher rates of major depression in younger, but not older (>64 years), age groups. Furthermore, lifetime suicidal ideation was higher in PWE (25.0% [95% CI, 16.6 to 33.3]) than in the general population (13.3% [95% CI, 12.8 to 13.9]). In a separate population-based study, Ettinger et al. investigated the presence of symptoms of depression among 775 PWE, 395 people with asthma, and 362 healthy controls identified from a cohort of 85,358 adults aged 18 years and older using the Centers of Epidemiologic Studies-Depression (CES-D) Instrument.[62] PWE experienced symptoms of depression with a significantly greater frequency (36.5%) and severity than people with asthma (27.8%) and healthy controls (11.8%). Of note, 38.5% of PWE whose score on the CES-D suggested the presence of a depressive disorder and 43.7% of people with asthma and depression were never previously evaluated for depression. The same group of investigators compared the lifetime prevalence rates of bipolar symptoms and past diagnoses of bipolar I and II disorder with the Mood Disorder Questionnaire (MDQ) among subjects who identified themselves as having epilepsy and those with migraine, asthma, or diabetes mellitus or a healthy comparison group.[63] Bipolar symptoms, evident in 12.2% of epilepsy patients, were 1.6 to 2.2 times more common in subjects with epilepsy than with migraine, asthma, or diabetes mellitus, and 6.6 times more likely to occur than in the healthy comparison group. A total of 49.7% of patients with epilepsy who screened positive for bipolar symptoms were diagnosed with bipolar disorder by a physician, nearly twice the rate seen in other disorders. However, 26.3% of MDQ-positive epilepsy subjects carried a diagnosis of unipolar depression, and 25.8% had neither a uni- nor bipolar depression diagnosis.

The impact of seizure control on the prevalence of depression has been investigated in four population-based studies. Using the Hospital Depression and Anxiety Symptoms scale, Jacoby et al.[96] reported that of 168 patients with recurrent seizures, 21% met criteria for clinical depression. Using the same instrument, O'Donoghue et al.[144] showed that among 155 PWE identified through two large primary care practices in the United Kingdom, 33% with recurrent seizures and 6% of those in remission had depression. Edeh and Toone[59] used the Clinical Interview Schedule to demonstrate a depressive disorder in 22% of 88 epilepsy patients identified from general practices in the United Kingdom.

Clearly, the prevalence rates of depression are significantly higher in studies done in tertiary centers. For example, Victoroff et al. assessed the lifetime prevalence of psychiatric disorders meeting DSM-III-R diagnostic criteria by administering the Structured Clinical Interview for DSM-III-R—Patient Version (SCID-P) to 60 patients with medically intractable complex partial seizures.[207] The standard interview was enlarged by explorations of the relationship between psychiatric complaints and course of the epilepsy, of brief periods of depression and elation, and of atypical personality features that had been reported among patients with temporal lobe epilepsy (TLE). Of

P.2124

the 60 patients, 42 (70%) had histories of one or more DSM-III-R axis I diagnoses and 35 (58%) had histories of major depressive episodes or other depressive disorders.

Current diagnoses of depression can also be identified more frequently among patients followed in tertiary centers. In a recently completed study of 199 consecutive outpatients from five epilepsy centers,[103] the presence of an axis I diagnosis was identified according to DSM-IV criteria with the Structured Clinical Interview for DSM-IV diagnosis (SCID) and the Mini International Psychiatric Interview (MINI). Sixty-seven patients (34%) met a DSM-IV criterion of a mood and/or anxiety disorder: 37 (19%) met criteria for major depression, of whom 17 (8.5%) had a mixed major depression and anxiety disorder. Only four patients (2%) met criteria for dysthymic disorder and 27 (13.6%) for an anxiety disorder.

The relation between depression and epilepsy has traditionally been thought to be unidirectional, given the higher incidence and prevalence of depression in PWE and the recognition of several epilepsy-related pathogenic mechanisms, including (a) a reactive process to psychosocial stressors associated with a life with epilepsy, (b) neurophysiologic and neurochemical changes related to the seizure activity, and (c) iatrogenic pharmacologic and surgical factors. Yet, the higher prevalence rates of depression in PWE were based on cross-sectional studies, which do not necessarily establish causality between the two disorders. In fact, three recent population-based studies have questioned this long-held assumption of a unidirectional relation and suggested the existence of a “bidirectional” relation between depression and epilepsy, whereby the presence of a mood disorder can also be associated with an increased risk of developing epilepsy.[20,89,90] Of note, these investigators were not the first ones to suggest the existence of such bidirectional relationship; indeed, 26 centuries ago, Hippocrates wrote: “melancholics ordinarily become epileptics, and epileptics melancholics: what determines the preference is the direction the malady takes; if it bears upon the body, epilepsy, if upon the intelligence, melancholy."[124] Such bidirectional relationship may in fact reflect the existence of common pathogenic mechanisms shared by epilepsy and depression, which facilitate the development of one disorder in the presence of the other (see below).

Clinical Presentations

Symptoms of mood disorders in epilepsy are classified according to their temporal relation to seizure occurrence into peri-ictal and interictal symptoms. Peri-ictal symptoms include symptoms that precede (preictal), follow (postictal), or are the expression of a seizure (ictal), while interictal symptoms occur independently of seizures. Often, patients may experience symptoms of depression during both peri-ictal and interictal periods.

Peri-ictal Symptoms

Peri-ictal depressive symptoms and episodes are the least well studied with respect to their actual prevalence and are usually ignored by clinicians. Their occurrence has never been factored into any study investigating the prevalence of depressive symptoms/disorders in PWE despite the fact that their existence has been known to neurologists and psychiatrists for a long time.

Ictal Symptoms

It has been estimated that psychiatric symptoms occur in 25% of "auras"; 15% of these involve affect or mood changes.[54,209,212] For example, ictal symptoms of depression ranked second after symptoms of anxiety/fear, which are the most common type of ictal affect in one study. Ictal symptoms of depression are of short duration typically, are stereotypical, occur out of context, and are associated with other ictal phenomena. The most frequent symptoms include feelings of anhedonia, guilt, and suicidal ideation.

Preictal Symptoms

Preictal symptoms or episodes typically present as a dysphoric mood preceding a seizure by several hours to days. The best evidence is presented in the study by Blanchet and Frommer, who investigated mood changes in the course of 56 days in 27 PWE who were asked to rate their mood on a daily basis.[17] Mood ratings pointed to a dysphoric state 3 days prior to a seizure in 22 patients. This change in mood was more accentuated during the 24 hours preceding the seizure.

Postictal Symptoms

Postictal symptoms have been recognized for a very long time, but have been poorly studied in a systematic manner. Their detection can often be elusive as they do not occur necessarily on the same day as the seizure. Rather, symptom-free periods of up to 5 days can exist between the seizure occurrence and onset of psychiatric symptoms. The prevalence of postictal psychiatric symptoms was investigated in a study done at the Rush Epilepsy Center in Chicago in 100 consecutive patients with refractory epilepsy.[107] Only symptoms that occurred following more than 50% of seizures in the previous 3 months were included. In this study, the postictal period was defined as the 72 hours that followed a seizure. Symptoms that occurred during both interictal and postictal periods were also identified and compared in their severity during these periods. Since neurovegetative symptoms and fatigue are common postictal symptoms as well as symptoms of depression, they were analyzed separately so as not to inflate falsely the prevalence of postictal symptoms of depression (PSD).

Among the 100 patients, 43 experienced a mean of 4.8 ± 2.4 PSD (range 2 to 9; median = 5). The median duration of two thirds of symptoms was 24 hours. Twenty-five had a history of a mood disorder and 11 of an anxiety disorder. Table 1 shows the PSD and their respective median duration.

There was a significant association between a history of depression and the occurrence of the following PSD: Hopelessness, suicidal ideation, self-deprecation, and guilt. Furthermore, there was a significantly greater number of PSD in the presence of a history of depression and anxiety disorders.

Thirteen of these patients experienced a minimum of seven PSD lasting 24 hours or longer. Postictal suicidal ideation was identified in 13 patients. Eight patients experienced passive and active suicidal thoughts, while five only reported passive suicidal ideation. Ten of these 13 patients (77%) had a past history of either major depression or bipolar disorder, and this association was highly significant. Furthermore, the presence of postictal suicidal ideation was also significantly associated with a history of psychiatric hospitalization.

Among these 43 patients, PSD occurred together with postictal symptoms of anxiety (PSA) in 27 patients (63%) and seven other patients reported as well postictal psychotic symptoms. Table 1 shows the types of PSA and their median duration. Furthermore, 37 patients reported interictal symptoms of depression that worsened in severity during the postictal period in 30 patients.

Table 1 Prevalence and Median Duration of Postictal Symptoms of Depression and Anxiety

Postictal symptom	Prevalence	Median duration in hours (range)
Symptoms of depression, total	*43*	
Irritability	*30*	*24 (0.5-108)*
Poor frustration tolerance	*36*	*24 (0.1-108)*
Anhedonia	*32*	*24 (0.1-148)*
Hopelessness	*25*	*24 (1.0-108)*
Helplessness	*31*	*24 (1.0-108)*
Crying bouts	*26*	*6 (0.1-108)*
Suicidal ideation	*13*	*24 (1.0-240)*
Active suicidal thoughts	*8*	
Passive suicidal thoughts	*13*	
Feelings of self-deprecation	*27*	*24 (1.0-120)*
Feelings of guilt	*23*	*24 (0.1-240)*

Symptoms of anxiety, total	*45*	
Constant worrying	*33*	*24 (0.5–108)*
Panicky feelings	*10*	*6 (0.1–148)*
Agoraphobic symptoms	*29*	*24 (0.5–296)*
Due to fear of seizure recurrence	*20*	
Compulsions	*10*	*15 (0.1–72)*
Self-consciousness	*26*	*6 (0.05–108)*
Hypomanic symptoms, total	*22*	
Excessive energy	*9*	*2 (0.15–48)*
Thought racing	*15*	*2 (0.1–24)*

Postictal hypomanic symptoms (PHM) included excessive energy and racing thoughts, which were identified in 22 patients: 15 patients reported racing thoughts and nine reported increased energy, but only two reported both symptoms (see Table 1). The occurrence of PHM only correlated significantly with that of postictal psychotic symptoms. In contrast to PSD, a psychiatric history was not a risk factor of PHM.

P.2125

Clearly, the occurrence of PSD is relatively high among patients with refractory epilepsy. Yet, in none of the studies on the prevalence of depression in epilepsy published so far has any investigator discriminated between an interictal, preictal, or postictal occurrence. The impact that PSD may have in "shaping" the psychiatric clinical phenomena of depression in PWE has yet to be established. Yet, it is likely that preictal symptoms and PSD may account for the frequent "atypical" characteristic of depressive disorders.

Interictal Depressive Disorders

Interictal depressive disorders have been the most commonly recognized. As stated above, there is an ongoing debate as to whether depressive disorders differ between people with and without epilepsy. In fact, some investigators have found that in up to 50% of PWE suffering from a depressive disorder, the depressive disorder failed to meet a DSM-III or -IV diagnostic criteria for one of the listed mood disorders.[134]

The following categories are included in the DSM-IV: Major Depressive Disorder, Dysthymic Disorder, Minor Depression, Bipolar Disorder, and Depressive Disorder Not Otherwise Specified or secondary to a medical condition or substance.[57] The difference between major depressive disorders and dysthymic disorder is based largely on severity, persistence, and chronicity. According to DSM-IV criteria, symptoms in both disorders may include combinations of depressed mood, anhedonia, worthlessness, guilt, decreased concentration ability, recurrent thoughts of death, and neurovegetative symptoms (i.e., weight loss or gain, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue). In patients with a major depressive episode, at least 2 weeks of either a depressed mood or anhedonia must accompany four of these symptoms. In contrast, dysthymic disorder is a more chronic but less intense process with symptoms persistent for more days than not for at least 2 years. Minor depression is a category that is similar to major depressive episode in duration but encompasses at least two but less than five of the depressive symptoms noted above.

Bipolar disorders are of two types, depending on the occurrence of manic (type I) or hypomanic (type II) episodes in addition to major depressive episodes. The DSM-IV diagnosis for manic episodes includes the requirement of a distinct period of abnormally and persistently elevated mood lasting at least 1 week and of sufficient severity to cause marked impairment in social functioning. The diagnosis for a hypomanic episode includes the requirement of a distinct period of persistently elevated mood lasting throughout at least 4 days and observable as a disturbance by others. The diagnosis of a cyclothymic disorder requires the presence of numerous hypomanic and minor depressive episodes for at least 2 years.

Concurrent Psychiatric Symptoms in Depressive Disorders in Epilepsy

Investigators have reported a frequent co-occurrence of mood and anxiety disorders in patients with and without epilepsy, with comorbid rates ranging between 50% and 80% in patients with primary mood disorders. The existence of comorbid anxiety symptoms or disorders has a significant impact on the quality of life of depressed patients and their recognition is of the essence as they significantly increase the suicidal risk of depressed patients.[29] Thus, any evaluation of mood disorders for clinical or research purposes are incomplete in the absence of an investigation of comorbid symptoms of depression and vice versa.

Similar observations have been made in PWE. In a study of 199 patients with epilepsy from five epilepsy centers, 73% of patients with a history of depression met also DSM-IV criteria for an anxiety disorder.[103] Furthermore, several investigators dating back to Kraepelin, Bleuler, Gastaut, and more recently Blumer and Kanner have made a point of emphasizing the pleomorphic nature of the symptomatology in depressive disorders in PWE, which in addition to symptoms of anxiety include irritability, increased energy, and physical symptoms.[18,19,74,75,110,115] To a significant degree, these authors attributed the atypical manifestations of depression in epilepsy to these symptoms. This point is discussed in greater detail in the section on Interictal Dysphoric Disorder.

Nonetheless, recent studies have shown that these additional symptoms can be identified in PWE suffering from depressive disorders that also meet DSM-IV diagnostic criteria. In the study by Jones et al. cited above,[103] a DSM-IV diagnosis of a mood and/or anxiety disorders was established with the MINI and SCID in 199 consecutive outpatients from five epilepsy centers. These patients completed a 46-item self-rating instrument the Mood and Anxiety Symptoms in Epilepsy (MASE), which includes symptoms from eight domains (depression, anxiety, irritability, self-consciousness, physical symptoms, disturbances in socialization, suicidal ideation, and increased energy) on two occasions, 2 weeks apart. Sixty-seven patients met criteria for a DSM-IV axis I diagnosis: Each one of the 37 patients that met criteria for major depression reported symptoms of irritability and anxiety; 36 experienced physical symptoms, primarily fatigue; and 31 reported periods of increased energy. Clearly, these data show that depression in epilepsy in its “typical” manifestations not only consists of symptoms of depression, but is more often than not accompanied by symptoms of anxiety and irritability and, paradoxically, symptoms of increased energy. Whether this pleomorphic semiology is specific to depression in PWE or may be present in other neurologic disorders has yet to be established.

Atypical Expressions of Depression in Epilepsy

As stated above, depressive disorders in PWE often fail to meet any of the DSM-III, -III-R, or -IV criteria. For example, using DSM-III-R criteria, Mendez et al. had to classify almost 50% of depressive disorders as atypical depression.[134] Wiegartz et al. found that the depressive episodes of 25% of PWE were also classified as atypical depression not otherwise specified.[211] The interictal dysphoric disorder is the classic example of the atypical expression of depression in PWE and is reviewed at the end of this chapter.

In a study of the semiology of depressive episodes severe enough to merit pharmacotherapy in 97 consecutive patients with refractory epilepsy, only 28 (29%) met DSM-IV criteria for major depressive disorder.[110] The remaining 69 patients (71%) failed to meet criteria for any of the DSM-IV categories. These 69 patients presented a clinical picture consisting of anhedonia (with or without hopelessness), fatigue, anxiety, irritability, poor frustration tolerance, and mood lability with bouts of crying. Some patients also reported changes in appetite and sleep patterns and problems with concentration. Most symptoms presented with a waxing and waning course, with repeated interspersed symptom-free periods of 1 to several days' duration. Their semiology resembled the most a dysthymic disorder, but the recurrence of symptom-free periods intermittently precluded DSM criteria for this condition. We therefore referred to this form of depression as *dysthymic-like disorder of epilepsy* (DLDE).

In 33 of these 69 patients, the predominant and most disabling symptom was anhedonia, while in the remaining 36 patients irritability and poor frustration tolerance were the most disabling symptoms. Of note, patients with DLDE in whom anhedonia was the predominant symptom (vs. irritability) were significantly more likely to have experienced a prior history of major depressive episodes (45.5% vs. 19.5%). Whether DLDE is a variant of the interictal dysphoric disorder has yet to be established in systematic studies (see below).

Subclinical or subsyndromic forms of depression are another presentation of atypical depression, both in primary mood disorders and in depressive disorders of PWE. In the study of 199 consecutive PWE cited above,[103,109] 132 patients (64%) failed to meet any DSM-IV axis I diagnosis according to the SCID and MINI; yet, using the self-rating instruments Beck Depression Inventory (BDI) or the CES-D, 32 patients (16% of the entire cohort) were also found to have been experiencing symptoms of depression of mild to moderate severity. Furthermore, symptoms of anxiety were identified in 31 of these 32 patients with the MASE, symptoms of irritability in 32, physical symptoms in 24, and symptoms of increased energy in 18.

Suicidality as an Expression of Depression in Epilepsy

The suicide rate in PWE is five times higher than the expected rate in the general population. However, among patients with TLE the suicide rate can be 25 times higher.[77] For example, Robertson reviewed 17 studies pertaining to mortality in epilepsy and found that suicide was ten times more frequent than in the general population.[166] Rafnsson et al. recently reported the results of a population-based incidence cohort study in PWE from Iceland in which suicide had the highest standard mortality rate (5.8) of all causes of death,[158] and it was 3.5 in a Swedish study carried out among 9,000 previously hospitalized PWE.[142] The topic of suicidality in PWE is reviewed in detail in Chapter 211 in this book.

Impact on Quality of Life

Depression has been found to yield a significant negative impact on the quality of life of PWE. For example, in a study of 56 consecutive patients with TLE, Lehrner et al.[123] found depression to be the most powerful predictor for each domain of health-related quality of life. Even after controlling for seizure frequency and severity and other psychosocial variables, there remained a significant association between depression and ratings indicative of poor quality of life. In another study of 257 patients with epilepsy, Perrine et al.[150] found that the mood factor had the highest correlations with scales of the Quality of Life in Epilepsy (QOLIE-89) and was the strongest predictor of quality of life in regression analyses, as the mood factor was responsible for 46% of the variance in overall quality of life.

Likewise, in a group of 125 patients who had undergone temporal lobe surgery at least 12 months previously, Gilliam et al. showed that mood status was the most significant predictor of the patients' assessment of their own health status.[78] In another investigation, Gilliam examined the variables responsible for poor quality of life identified with the QOLIE-89 in 194 adult patients with refractory partial epilepsy[80] and found that the only independent variables significantly related to poor quality-of-life scores were high levels of depression and neurotoxicity from antiepileptic drugs. Patients had a median 9.7 seizures/month (range 0.3 to 51), but the author saw no relationship between the type and/or the frequency of seizures and quality-of-life scores. Identical findings were replicated by Boylan et al. in a more recent study.[28] Cramer et al. also found

P.2127

that depression was significantly associated with poor quality-of-life scores on the QOLIE-89 independently of the type of seizures; these investigators found, however, that seizure freedom for the last 3 months increased (i.e., improved) the quality-of-life ratings.[47] In the study of 199 patients described above, Kanner et al. found that the scores of the QOLIE-89 were significantly higher (i.e., better quality of life) among patients who had been seizure free for the last 6 months than those with persistent seizures.[109] These patients, however, were significantly less likely to have experienced a depressive disorder. The presence of a comorbid anxiety disorder with depression has also been associated with worse ratings in the QOLIE-89. In the same study cited above, patients with mixed anxiety/major depression had significantly lower scores than patients with major depression alone and these were in turn lower than those with only anxiety disorder.

Depression in PWE can also have a significant impact on health care costs associated with the management of the seizure disorder. For example, Cramer et al. investigated the impact of comorbid depression on health care utilization and health care coverage by PWE in U.S. communities using a postal survey questionnaire.[46] They found that people whose depression was untreated used significantly more health resources of all types, independently of seizure type and time since the last seizure. Furthermore, people with mild to moderate depression had a twofold and people with severe depression a fourfold higher frequency of medical visits than nondepressed people. Also, the presence and severity of depression was found to be a predictor of worse disability scores (Sheehan's Disability Scale), independently of duration of the seizure disorder. These data highlight the impact of comorbid depression on health care utilization by people with epilepsy.

Pathogenic Mechanisms

Is There a Bidirectional Relationship between Depression and Epilepsy?

Three studies published in the last 15 years have raised the possibility of a bidirectional relation between depression and epilepsy.[69,89,90] In the first study, Forsgren and Nystrom conducted a population-based case-control study of patients with newly diagnosed onset epilepsy in Sweden, and discovered that patients were seven times more likely to have reported a history of depression than were controls.[69] Hesdorffer et al. conducted a second population-based case-control investigation of the prevalence of new onset epilepsy among adults aged 55 and older, and showed that compared to controls, patients were 3.7 more likely to have had a history of depression *prior* to their first seizure.[89] The same authors conducted a population-based study in Iceland that included children and adults with newly diagnosed unprovoked seizures and/or epilepsy.[90] They found that patients with a history of major depression (by DSM-IV criteria) were significantly more likely than controls (odds ratio [OR] 1.7) to suffer from unprovoked seizures and epilepsy. Furthermore, a history of suicidal ideation was associated with a significantly greater risk of developing epilepsy (OR 5.5) independent of a history of major depression. These data do not indicate causality between the two disorders, but rather suggest the existence of common pathogenic mechanisms operant in depression and epilepsy.

Common Pathogenic Mechanisms in Epilepsy and Depression

Two classes of pathogenic mechanisms are likely to be operant in both disorders: (a) abnormal secretion patterns of neurotransmitter systems including serotonin (5HT), norepinephrine (NE), dopamine (DA), γ-aminobutyric acid (GABA), and glutamate; and (b) structural and functional abnormalities of common neuroanatomic structures in limbic structures, particularly in temporal and frontal lobes.

Abnormal Secretion of Neurotransmitters

Data from experimental animal studies.

Abnormal serotonergic, noradrenergic, and dopaminergic transmission in the brain has been recognized as a pivotal pathogenic mechanism of mood disorders and has been the basis for the development of antidepressant pharmacologic treatments.[191] By the same token, a decreased serotonergic and noradrenergic activity has been shown to facilitate the kindling of seizures, exacerbate seizure severity, and intensify seizure predisposition in some animal models of epilepsy as shown below.[98] Compelling data are derived from studies with two strains of genetic epilepsy-prone rats (GEPR), GEPR-3 and GEPR-9, which are characterized by genetically determined predisposition to sound-induced generalized tonic–clonic seizures

(GTCSs).[44,50,98,99,100,205] Both strains of rats have innate pre- and postsynaptic noradrenergic and serotonergic transmission deficits, the former resulting from deficient arborization of neurons arising from the locus coeruleus coupled with excessive presynaptic suppression of stimulated NE release in the terminal fields and lack of postsynaptic compensatory up-regulation.[44,50,98,99,100,205] GEPR-9 rats have a more pronounced NE transmission deficit and, in turn, exhibit more severe seizures than GEPR-3 rats.[215] Abnormal serotonergic arborization has also been identified in the GEPR's brain coupled with deficient postsynaptic serotonin$_{1A}$-receptor density in the hippocampus.[49] Of note, GEPRs display similar endocrine abnormalities to those identified in patients with major depressive disorder (MDD), such as increased corticosterone serum levels, deficient secretion of growth hormone, and hypothyroidism.[101]

Increments of either NE and/or 5HT transmission with the selective serotonin reuptake inhibitor (SSRI) sertraline resulted in a dose-dependent seizure frequency reduction in the GEPR, which correlated with the extracellular thalamic serotonergic thalamic concentration.[213,214] In addition, the 5-HT precursor 5-HTP has been shown to have anticonvulsant effects in GEPRs when combined with a monoamine oxidase inhibitor (MAOI),[98] while SSRIs and MAOIs have been found to exert anticonvulsant effects in genetically prone epilepsy mice and baboons as well as in nongenetically prone cats, rabbits, and rhesus monkeys.[133,152,153,213,217] Conversely, drugs that interfere with the release or synthesis of NE or 5HT exacerbate seizures in the GEPRs.[98,138] These include NE storage vesicle inactivators reserpine or tetrabenazine, the NE false transmitter *a*-methyl-m-tryosine, the NE synthesis inhibitor α-methyl-Δ-tyrosine, and the 5-HT synthesis inhibitor Δ-chlorophenylalanine, all of which have also been found to facilitate seizure occurrence in humans.[138,143,197]

An anticonvulsant effect of serotonergic activity has been reported in other animal models of epilepsy. Lopez-Meraz et al. studied the impact of two 5HT$_{1A}$ receptor agonists, 8-OH-DPAT and indorenate, in three animal models of epileptic seizures (clonic–tonic induced by pentylenetetrazol [PTZ], status epilepticus of limbic seizures induced by kainic acid [KA], and tonic–clonic seizures induced by amygdala kindling) in Wistar rats.[127] They found that 8-OH-DPAT lowered the incidence of seizures and the mortality induced by PTZ, increased the latency and reduced the frequency of wet-dog shake and generalized seizures induced by KA and at high doses diminished the occurrence and delayed the establishment of status epilepticus. Indorenate increased the latency to the PTZ-induced seizures and decreased the percentage of rats that showed tonic extension and death, augmented the latency to wet-dog shake and generalized seizures, and diminished the number of generalized seizures.

The antiepileptic effect of 5HT$_{1A}$ receptors has been associated with a membrane hyperpolarizing response associated

P.2128

with increased potassium conductance in hippocampal kindled seizures in cats, and in intrahippocampal kainic acid–induced seizures in freely moving rats.[13,148] Furthermore, antiepileptic drugs (AEDs) with established psychotropic effects (carbamazepine [CBZ], valproic acid [VPA], and lamotrigine [LTG]) have been found to cause an increase in 5HT.[41,42,51,52,53,189,210,216] In fact, the anticonvulsant protection of CBZ can be blocked with 5HT-depleting drugs in GEPRs.[216] Likewise, in a recent study, Clinckers et al. investigated the impact of oxcarbazepine (OXC) infusion on the extracellular hippocampal concentration of 5HT and DA in the focal pilocarpine model for limbic seizures.[41] When OXC was administered together with verapamil or probenecid (so as to ensure its passage through the blood–brain barrier), complete seizure remission was obtained associated with an increase in 5HT and DA extracellular concentrations.[42]

In addition, it has been suggested that the anticonvulsant effect of the vagal nerve stimulator (VNS) in the rat could be mediated by noradrenergic and serotonergic mechanisms, as deletion of noradrenergic and serotonergic neurons in the rat prevents or reduces significantly the anticonvulsant effect of VNS against electroshock- or pentylenetetrazol-induced seizures.[35,139] Furthermore, the effect of VNS on the locus coeruleus and raphe may be responsible for its antidepressant effects identified in humans.[3]

Data from studies in humans.

Depression in PWE has been associated more frequently with seizure disorders of temporal and frontal lobe origin, with prevalence rates ranging from 19% to 65% in various patient series.[6,74,75,95,104,163,207] In contrast to animal studies, the impact of pharmacologic augmentation or reduction in 5HT and NE transmission on seizures in humans has been rather sparse and mostly based on uncontrolled data. For example, depletion of monoamines with reserpine has been associated with an increase in frequency and severity of seizures in PWE,[143,197] while the use of reserpine at doses of 2 to 10 mg/day was found to lower the electroshock seizure threshold and the severity of the resulting seizures in patients with schizophrenia.[138] The tricyclic antidepressant imipramine, with reuptake inhibitory effects of NE and 5HT, was reported to suppress absence and myoclonic seizures in double-blind placebo-controlled studies.[71,72,73] Open trials with the SSRIs fluoxetine and citalopram yielded an improvement in seizure frequency, but no controlled studies with this class of antidepressants have been performed as of yet.[4,65]

Functional Neuroimaging Studies in Epilepsy and Primary Depression.

The use of positron emission tomography (PET) and single photon emission computed tomography (SPECT) studies has yielded significant data suggestive of abnormal 5HT activity in primary depressive disorders and in epilepsy, with particular involvement of $5HT_{1A}$ receptors. Deficits in 5HT transmission in human depression is thought to be partially related to a paucity of serotonergic innervation of its terminal areas suggested by a scarcity of 5HT levels in brain tissue, plasma, and platelets and with a deficit in serotonin transporter binding sites in postmortem human brain.[8,30,32,33,38,39,120,121,122,129,140,145,146,151,167,192,195] Serotonin stores and transporter protein are important components of serotonin terminals so that a combined deficit is a plausible indicator of reduced axonal branching and synapse formation.

With respect to abnormal serotonergic activity in functional neuroimaging studies of patients with primary major depression, Sargent et al. demonstrated a reduced binding potential of $5HT_{1A}$ receptors in frontal, temporal, and limbic cortex with PET studies using [11 C]WAY-100635 in both unmedicated and medicated depressed patients compared with healthy volunteers.[172] Of note, binding potential values in medicated patients were similar to those in unmedicated patients. Drevets et al., using the same radioligand, reported a decreased binding potential of $5HT_{1A}$ receptors in mesial temporal cortex and in the raphe in 12 patients with familial recurrent major depressive episodes compared to controls.[58] A deficit in the density or affinity of postsynaptic $5HT_{1A}$ receptors has been identified in the hippocampus and amygdala of untreated depressed patients who committed suicide.[147] In addition, impaired serotonergic transmission has been associated with defects in the dorsal raphe nuclei of suicide victims with major depressive disorder consisting of an excessive density of serotonergic somatodendritic impulse-suppressing $5HT_{1A}$ autoreceptors.[122]

Similar abnormalities have been reported in patients with epilepsy. In a PET study of patients with TLE using the $5HT_{1A}$ receptor antagonist [18F]trans-4-fluro-N-2-[4-(2-methoxyphenyl)piperazin-1-yl]ethyl-N-(2-pyridyl) cyclohexanecarboxamide reduced $5HT_{1A}$ binding was found in mesial temporal structures ipsilateral to the seizure focus in patients with and without hippocampal atrophy. Reduced serotonergic activity was independent of the presence or absence of hippocampal atrophy on magnetic resonance imaging (MRI), and reduced volume of distribution and binding remained significant after partial volume correction.[201] In addition, a 20% binding reduction was found in the raphe and a 34% lower binding in the ipsilateral thalamic region to the seizure focus. In a separate PET study aimed at quantifying $5HT_{1A}$ receptor binding in 14 patients with TLE, a decreased binding was identified in the epileptogenic hippocampus, amygdala, anterior cingulate, and lateral temporal neocortex ipsilateral to the seizure focus, as well as in the contralateral hippocampi, but to a lesser degree, and in the raphe nuclei.[174] Other investigators using the $5HT_{1A}$ tracer 4,2-(methoxyphenyl)-1-[2-(*N*-2-pyridinyl)-*p*-fluorobenzamido]ethylpiperazine ([^{203}F]MPPF) found that the decrease in binding of $5HT_{1A}$ was significantly greater in the areas of seizure onset and propagation identified with intracranial electrode recordings. As in the other studies, reduction in $5HT_{1A}$ binding was present even when quantitative and qualitative MRIs were normal.[135]

Reduction in $5HT_{1A}$ receptor binding is not restricted to patients with TLE. PET studies with the $5HT_{1A}$ receptor antagonist carbonyl-carbon 11-WAY-100635 ([11c]WAY-100635) found a decreased binding potential in the dorsolateral prefrontal cortex, raphe nuclei, and hippocampus of 11 patients with juvenile myoclonic epilepsy compared to 11 controls.[136]

With respect to abnormal DA activity as a common pathogenic mechanism, Tremblay et al. recently demonstrated abnormal dopaminergic function in the brain of patients with primary major depressive disorders.[203] Using functional MRI blood oxygen level–dependent activation during a controlled task and measurement of dextroamphetamine subjective effects, patients with major depression had a twofold increase in the response to the rewarding effects of dextroamphetamine, compared to a group of 12 healthy controls. Abnormal brain activation was identified in the ventrolateral prefrontal cortex and orbitofrontal cortex as well as in the caudate and putamen in the patient group.

Likewise, abnormal dopamine activity in the brain of patients with refractory epilepsy has been recently suggested in a PET study using 18F-fluoro-DOPA.[27] Three groups of patients were included: One consisted of 16 patients with a ring chromosome 20 (r20); a second group included 10 patients with absence-like epilepsy; and the third group was integrated by nine patients with intractable TLE. Compared to a group of ten healthy volunteers, patients from all three epilepsy groups displayed a decrease of 18F-fluro-DOPA uptake, but only in patients with TLE was the decreased uptake lateralized to the side of the seizure focus. A bilateral uptake was found in the substantia nigra in all three patient groups.

Involvement of frontal lobes in primary depression has also been demonstrated with functional neuroimaging (PET, SPECT) and neuropsychological studies.[11,114] For example, executive abnormalities are consistently found among studies,

and are more apparent in more severe depressive disorders. These neuropsychological disturbances correlated with reduced blood flow in mesial prefrontal cortex. Furthermore, in tests demanding executive function, cingulate cortex and striatum could not be activated in patients with major depressive disorders.[125] Functional disturbance of frontal lobe structures has been recognized in TLE and particularly among patients with TLE and comorbid depression, as they have been found to have bilateral reduction in inferofrontal metabolism.[31,102] Likewise, neuropsychological testing with the Wisconsin Card Sorting Test (WCST), which is highly sensitive to executive dysfunction, has revealed poor performance in patients with TLE and comorbid depression.[45,82,83,85,86,87,94,178] Of note, inferior frontal cortex is the main target of the mesolimbic dopaminergic neurons and provides input to the serotonergic neurons of the dorsal raphe nucleus.

The abnormal serotonergic secretion in the brain of PWE may account for the prominence of comorbid symptoms of anxiety and panic, irritability, and poor frustration tolerance, as well as the increased incidence rates of suicidality. Neumeister et al., using the selective $5HT_{1A}$ radioligand [18F]-FCWAY, found reduced $5HT_{1A}$ receptor binding in the anterior and posterior cingulate in patients with panic disorder with and without comorbid depression.[1] A relationship between abnormal serotonin activity and suicidal behavior associated with several psychiatric diagnoses has been suggested in multiple studies, including quantitative autoradiography studies of brain tissues obtained from suicidal victims, in studies of serotonin transporter sites, and in studies of $5HT_{1A}$ receptor binding, to name a few.[147] These studies suggest abnormal serotonergic function primarily at the ventral prefrontal cortex.

Common Neuroanatomic Structures Involved in Depression and Epilepsy

Structural changes in temporal lobes.

Structural neuro-imaging studies of patients with major depressive disorders revealed involvement of mesial temporal, orbitofrontal, and mesial frontal structures, as well as subcortical structures including basal ganglia and thalamic nuclei.[185] Sheline et al. reported bilateral smaller hippocampal volumes in two separate studies of patients with a history of primary major depressive disorders in remission when compared to hippocampal volumes of age-, sex-, and height-matched normal controls.[182,183,184] They also identified large hippocampal low-signal foci (≥4.5 mm in diameter) and their number correlated with the total number of days depressed. A significant inverse correlation between the duration of depression and left hippocampal volume was also demonstrated, suggesting that patients with more chronic and active disease were more likely to have hippocampal atrophy. More recently, Sheline et al. demonstrated that hippocampal atrophy was prevented with antidepressant drug therapy in a study of 38 female patients with a history of major depressive disorders.[180] They found a significant correlation between reduction in hippocampal volume and the duration of depression that went untreated, while there was no correlation between hippocampal volume loss and time depressed while taking antidepressant medication or with lifetime exposure to antidepressants. Similar findings have been reported by other investigators.[206]

Atrophy has also been identified in entorhinal cortex and amygdala.[15,154,185] Furthermore, in a neuropathologic study of amygdala and entorhinal cortex, a significant reduction of glial cells and of the glial/neurons ratio was found in left amygdala and to a lesser degree in left entorhinal cortex of patients with major depressive disorder and bipolar disorder (not treated with lithium and valproic acid) compared to those of controls.[181]

By the same token, abnormalities of mesial temporal structures are among the most frequently identified in PWE and comorbid depression. In three studies of patients with TLE, higher scores of depression were associated with the presence of mesial temporal sclerosis (MTS), decreased temporal lobe and frontal lobe perfusion on (99m) Tc-HMPAO SPECT scans, and greater abnormalities identified with magnetic resonance spectroscopy.[79,157,177]

It is important to notice, however, that the magnitude of hippocampal atrophy in TLE is significantly greater than that in major depressive disorder, while the neuropathologic findings are different. In MTS, neuropathologic findings consist of neuronal cell loss and astrocytosis in hippocampal formation (including areas CA1, CA2, CA3, and CA4, dentate gyrus, and subiculum), amygdala entorhinal cortex, and parahippocampal gyrus.[130]

Unfortunately, there have been very few neuropathologic studies of the human hippocampal formation in patients with primary major depressive disorder. Lucassen et al. carried out a neuropathologic study of 15 hippocampi of patients with a history of major depressive disorder and compared them to those of 16 matched controls and nine steroid-treated patients.[128] In 11 of 15 depressed patients, rare but convincing apoptosis was identified in entorhinal cortex, subiculum, dentate gyrus, CA1, and CA4. Apoptosis was also found in three steroid-treated patients and one control. However, no apoptosis of pyramidal cells in CA3 was identified. Other neuropathologic changes in brains from patients with major depression were reported by Stockheimer et al.[194] These investigators compared the density of pyramidal neurons, dentate granule cell neurons, and glia and the size of the neuronal soma from postmortem sections of right hippocampus obtained from 19 patients with major depressive disorders and 21 aged-matched psychiatrically normal controls. They found that in patients with major depressive disorders, the density of granule cells and glia in dentate gyrus and pyramidal neurons and glia in all cornu ammonis was significantly increased by 30% to 35%, while the average soma size of pyramidal neurons was decreased.

Hippocampal atrophy in primary major depressive disorders has been attributed to two potential pathogenic mechanisms: (a) an alteration in neurotrophic factors resulting from the mood disorder[40,141,187] and (b) high glucocorticoid exposure.[92,93,161,170]

Acute and chronic stress decreases levels of brain-derived neurotrophic factor (BDNF) in the dentate gyrus, pyramidal cell layer of hippocampus, amygdala, and neocortex, which may contribute to structural hippocampal changes.[187] These changes are mediated by glucocorticoids and can be overturned with antidepressant therapy, as chronic administration of antidepressant drugs increased BDNF expression and also prevented a stress-induced decrease in BDNF levels.[40,141] There is also evidence that antidepressant drugs can increase hippocampal BDNF levels in humans.[40,141] These data indicate that antidepressant-induced up-regulation of BDNF can hypothetically repair damage to hippocampal neurons and protect vulnerable neurons from additional damage.

The high glucocorticoid exposure mediating hippocampal atrophy is based on the excessive activation of the hypothalamic-pituitary-adrenal axis identified in almost half of individuals with depression resulting in impaired dexamethasone suppression of adrenocorticotropic hormone (ACTH) and cortisol. These changes are reversible to treatment with antidepressants.[93] In experimental studies with rats and monkeys, prolonged increased concentrations of glucocorticoids have been found to damage hippocampal neurons, particularly CA3 pyramidal neurons, possibly by reduction of dendritic branching and loss of dendritic spines that are included in glutamatergic synaptic inputs.[170] Hypercortisolemia has also been found to interfere with the development of new granule cell neurons in the adult hippocampal dentate gyrus. Deleterious effects of chronic glucocorticoid exposure may lead initially to a transient and reversible atrophy of the CA3 dendritic

tree and to an increased vulnerability to a variety of insults and finally result in cell death under extreme and prolonged conditions.[170]

Structural changes in frontal lobes.

Likewise, structural changes have been identified in the orbitofrontal and prefrontal cortex and cingulate gyrus, as well as in their white matter, including a smaller volume of orbitofrontal cortex in young adults and geriatric patients with major depressive disorder.[116,117,198,199] Of note, the magnitude of prefrontal volume changes was related to the severity of the depression, as elderly patients with minor depression had lesser changes than those with major depressive disorder.[116]

Neuropathologic studies have also documented structural cortical changes in frontal lobes of depressed patients. Raj-kowska et al. found a decrease in cortical thickness, neuronal sizes, and neuronal densities in layers II, III, and IV of the rostral orbitofrontal region in the brains of depressed patients.[159] In the caudal orbitofrontal cortex, there were significant reductions in glial densities in cortical layers V and VI that were also associated with decreases in neuronal sizes. Finally, in the dorsolateral prefrontal cortex, there was a decrease in neuronal and glial density and size in all cortical layers.

Other Pathogenic Mechanisms

Psychosocial causes of depression.

For many years, clinicians and patients have, erroneously, attributed and explained their patients' depressed mood solely as a “normal reaction” to the numerous social and personal obstacles resulting from epilepsy. These include (a) the patient's and/or family inability to accept and adjust to a diagnosis of epilepsy; (b) the stigma related to the diagnosis of epilepsy and the well-known discrimination patients face; (c) the lack of control in one's life resulting from the unpredictable occurrence of epileptic seizures; and (d) the patient's lack of social support and the need to make major adjustments in lifestyle, such as giving up driving privileges or changing jobs to maximize seizure precautions.[36,55,56,84,97,175] Any one or combination of these factors could result in an *initial* adjustment reaction with depressive and anxiety features, but they are unlikely *on their own* to result in *chronic* depressive disorder. Also, patients displaying comorbid depression may have less ability to cope with these obstacles. Additionally, even epileptic patients with a normal intelligence have been found to show a lower degree of flexibility of mental processing compared with normal controls in neuropsychological studies.[34,188] Nonetheless, a depressed state that persists after several months can no longer be diagnosed from a clinical standpoint as a “normal” reactive process and warrants a detailed psychiatric evaluation.

Depression as an iatrogenic process.

Every AED, including those with positive psychotropic properties, can trigger depressive symptoms in PWE, some more than others.[132] Phenobarbital (PB) can result in depression that may occasionally be complicated with suicidal ideation; primidone (PRM), tiagabine, vigabatrin, felbamate, topiramate (TPM), levetiracetam (LEV), and zonisamide (ZNS) have also been associated with symptoms of depression.[9,29,66,106,131,137,162,186] On the other hand, the presence of a current or prior depressive disorder may increase the risk of cognitive adverse events associated with topiramate.[106,137]

Depression following epilepsy surgery.

In the last two decades, depressive disorders have been recognized with increased frequency during the first year following an anterotemporal lobectomy.[23,173] It is common for patients to exhibit “mood lability” within the first 6 weeks after surgery, and usually these symptoms subside; however, overt depressive symptoms become clear within the initial 6 months in up to 30% of patients. Typically, symptoms of depression range in caliber from mild to very severe, including suicidal attempts. In general, pharmacologic treatment with antidepressant drugs is effective. Patients with a past history of depression are at increased risk. In a recent study of 90 consecutive patients that underwent an anterotemporal lobectomy at the Rush Epilepsy Center, 23 exhibited an exacerbation or recurrence of a previous depressive disorder and 11 experienced a de novo depressive disorder.[108] Remission of all symptoms was obtained in 22 patients, while in 12 symptoms persisted despite multiple pharmacologic trials with various antidepressants. There was no difference in the risk of developing a persistent depressive disorder among patients with de novo versus those with a prior history of depression. Postsurgical seizure freedom was associated with a lower likelihood of experiencing a postsurgical depressive episode. Thus, all patients preparing for epilepsy surgery should be warned of this possible risk, *prior to surgery*.

A paradoxic “iatrogenic” cause of psychopathology among epileptic patients includes the phenomenon of “forced normalization,” which consists of the development of psychiatric disorders following the cessation of epileptic seizures.[165] An interictal depression, therefore, may exacerbate or present de novo in patients as increased seizure control is attained, although the frequency of this phenomenon remains to be established. This problem is discussed in greater detail in section II.

A genetic predisposition.

A common risk to develop a depressive disorder in patients with and without epilepsy is a family history of depression. In fact, over 50% of PWE suffering from depression have been found to show a family history of psychiatric illness, affective disorders being the most frequent condition.[95,163]

Laterality of the seizure focus.

Despite having been raised as a potential pathogenic parameter, the laterality of the seizure focus remains a topic of debate. Certain authors have suggested, however, that a left hemispheric focus may be a predisposing factor of depression based on PET and SPECT studies.[165]

Treatment

Despite the relatively high comorbidity of mood disorders in epilepsy, they continue to remain unrecognized and untreated in a significant percentage of patients. Indeed, depression in epilepsy remains underrecognized and undertreated. For example, in a study of 97 patients with epilepsy with depressive disorders severe enough to merit pharmacologic treatment, 60% had been symptomatic for more than 1 year before any treatment was suggested.[110] Only one third of the 97 patients had been treated within 6 months of the onset of their symptoms. To our surprise, delay in recognizing the need for therapy was not related to the severity of the depressive disorder, as the proportion of untreated patients for more than 1 year did not differ between patients with major depression and dysthymic disorders. Wiegartz et al.[211] reported similar findings. Thirty percent of 76 patients with partial epilepsy met criteria of a lifetime-to-date diagnosis of major depressive disorder, 9% with a diagnosis of current major depressive episode, and 22% with a lifetime diagnosis of major depressive disorder. Twenty-five percent of these 76 patients reported symptoms of minor depressive disorders (dysthymic disorders, depressive disorder not otherwise specified). None of these patients had received treatment for their dysthymic disorder and commonly had not been trained to understand and treat the psychiatric complications of epilepsy.

Table 2 Efficacy of Selective Serotonin Reuptake Inhibitors and Serotonin Norepinephrine Reuptake Inhibitors in Primary Depression and Anxiety Disorders

Antidepressant drug	Depression	Panic disorder	Generalized anxiety	Starting dose	Maximal dose

Paroxetine	+	+	+	10	60
Sertraline	+	+		25	200
Fluoxetine	+	+		10	80
Citalopram	+			10	60
Escitalopram	+	+	+	5	30
Venlafaxine	+	+	+	37.5	300

Fluvoxamine was not included in this table due to the absence of any data in people with epilepsy.

Even when recognized, clinicians refrain from considering the use of pharmacologic treatment for (a mistaken) fear of worsening the patient's seizures. The hesitancy of using psychotropic medications in PWE has resulted in the absence of controlled studies on the efficacy and safety of antidepressants in these patients. Indeed, to date there has been only one controlled study published in the literature that compared under blind conditions the efficacy of two antidepressant drugs (amitriptyline and mianserin) to placebo in major depression

P.2131

of PWE.[179] Consequently, the data available for the management of mood disorders in PWE have to be derived from open uncontrolled trials, based on the experience obtained in the treatment of primary depression. Given the relatively high frequency of atypical depressive disorders in PWE, one cannot assume that efficacy in mood disorders in patients without epilepsy may apply to PWE. The absence of methodologically sound data has further compounded the clinician's reluctance to treat patients with psychotropic drugs, and in the end the persistence of a mood disorder ends up having a worse impact on the patient's quality of life than the actual seizures and increases their risk of suicide, which has also clearly surpassed the risk of death from a seizure, as documented in a separated chapter.

Some Preliminary Basic Concepts

Before starting any specific treatment strategy, it is important to consider the following questions:

1. Did the symptoms of depression and anxiety appear following the introduction or increase in the dose of an AED known to cause psychiatric adverse events?
2. Did the psychiatric symptoms follow the discontinuation of an AED with positive psychotropic (mood stabilizing, antidepressant, and anxiolytic) properties (i.e., CBZ, VPA, LTG, OXC)? In this case, the psychiatric symptoms may be the expression of recurrence of a latent psychiatric disorder that had been in remission (or masked) by the AED discontinued.[164] By the same token, it is important to investigate the existence of any psychiatric family history that places the patient at an increased risk when exposed to an AED with negative psychotropic properties (i.e., symptoms of depression following exposure to PB, PRM, or ZNS in patients with a family history of mood disorders).
3. Did the psychiatric symptoms occur after the introduction of an enzyme-inducing AED (CBZ, PHT, PB, PRM, high-dose TPM, or OXC) in a patient who was already taking a psychotropic drug for a previously recognized

depression or anxiety disorder? In such case, the symptom recurrence may have resulted from a pharmacokinetic interaction between the AED and the psychotropic drug on board that caused a drop in the psychotropic drug's serum concentration. Accordingly, a readjustment in the dose of the psychotropic drug may be sufficient to induce symptom remission.

4. Are the psychiatric symptoms temporally related to the seizure occurrence? That is, do they precede (preictal), do they follow (postictal), do they precede and follow, are they the expression of an ictal event, or do they occur interictally with a peri-ictal exacerbation in severity? In the case of pre- or postictal without interictal symptoms, pharmacotherapy may fail to yield any benefit. Postictal breakthrough symptoms may occur in patients whose interictal symptoms remitted with pharmacotherapy.
5. Are the psychiatric symptoms related to the remission of seizures following a period of persistent seizures, or are they associated with worsening of the patient's seizure disorder? In the former case, the symptoms may be the expression of the phenomenon known as “forced normalization” or “alternative psychopathology.”
6. Is the patient experiencing other psychiatric symptoms (i.e., symptoms of anxiety) that need to be targeted for treatment?

Pharmacotherapy of Depressive Disorders

Today, SSRIs and serotonin norepinephrine reuptake inhibitors (SNRIs) have become the first line of pharmacotherapy for primary major, dysthymic, and minor depressive disorders as well as for the treatment of generalized anxiety and panic disorders (Table 2).[37,112] These drugs are also being advocated for the treatment of these psychiatric disorders in PWE. Furthermore, the use of SSRIs is particularly relevant in PWE given the relatively high comorbidity of anxiety disorders and the prominence of irritability in which these drugs have shown marked efficacy.

Therapeutic Expectations of Pharmacotherapy of Depressive Disorders

A “primary” major depressive episode left untreated may last between 6 and 24 months in 90% to 95% of cases, while the remaining 5% to 10% could last more than 2 years.[37,60,91,112,202] When pharmacotherapy is started, “responders” to pharmacotherapy experience an improvement in their symptomatology (i.e., at least 50% reduction of severity of symptoms measured with a variety of rating scales) during the first 8 weeks. Two thirds of patients are expected to “respond” to antidepressant medication, and in controlled studies, one third are expected to respond to placebo. “Response to therapy,” however, does not imply a symptom-free state and persistence of symptoms increases significantly the risk of recurrence of future major depressive episodes. When such symptom-free state is achieved,

P.2132

the patient is considered to have entered “remission.” It is estimated that approximately 50% of patients will reach remission within the first 6 months and about two thirds within 2 years of the start of therapy. When remission has lasted for a period of 6 to 12 months, the patient is considered to have reached a state of “recovery.” Approximately 15% to 20% of patients will fail to respond to any antidepressant trial. It has yet to be established whether pharmacotherapy of major depression in PWE yields the same efficacy as that in primary major depressive disorders.

The variables predictive of relapse include (a) multiple prior episodes; (b) severe episodes; (c) long-lasting episodes; (d) episodes with psychotic or bipolar features; and (e) incomplete recovery between two consecutive episodes. Furthermore, premature discontinuation of antidepressant medication can result in relapse. Indeed, only 10% of patients who had an initial response to antidepressant drugs and who were kept for at least 12 months on the drug are likely to experience a relapse, in contrast to 50% of patients in whom the antidepressant medication was discontinued within 6 to 12 months of the start of therapy. If psychotherapy is considered, patients can be referred to a psychologist or to a local mental health clinic for this type of treatment (see below). Many patients will require a combination of pharmacotherapy and psychotherapy.

Pharmacotherapy of Dysthymic-like Disorders

There are no controlled data available on the treatment of DLDE. In an open trial with the SSRI sertraline carried out at the Rush Epilepsy Center in 67 patients with DLDE, complete symptom remission was reached in 57% of patients. While these results are similar to those reported in primary dysthymia, they need to be replicated in randomized placebo-controlled studies in PWE.[110]

Role of the Neurologist in the Management of Mood Disorders in People with Epilepsy

Given their relatively high prevalence in PWE, neurologists should be able to identify the depressive and bipolar disorders described above. They should know how to *initiate* pharmacotherapy for major, dysthymic, and minor depressive episodes. However, the following are the mood disorders that deserve immediate referral to a psychiatrist: (a) any depressive episode associated with suicidal ideation. (b) Any major depressive disorder with psychotic features. Approximately 25% of major depressive disorders can present with psychotic features. In such cases, pharmacotherapy has to include antipsychotic and antidepressant drugs, and at times, the use of electroshock therapy (ECT) has to be considered. Furthermore, the presence of psychotic symptomatology increases significantly the suicidal risk of these patients. (c) Any major depressive or dysthymic episode that has failed to respond to a prior trial with SSRIs or SNRIs at optimal doses. These patients may require a combination of antidepressant drugs or the addition of lithium, thyroid drugs, or central nervous system stimulants to one or two antidepressants and occasionally ECT to reach a euthymic state. (d) Any bipolar disorder. The management of bipolar disorders is fret with a significantly lower therapeutic success and potential serious complications from an inappropriate use of psychotropic drugs such as the conversion of a bipolar disorder into a rapid cycling disorder.[60] Indeed, clinicians must keep in mind that the use of antidepressant medication in a bipolar disorder can facilitate the development of manic and hypomanic episodes and of a rapid cycling bipolar disorder (defined as the presence of four or more depressive, manic, or hypomanic episodes in a 12-month period). The American Psychiatric Association guidelines for the treatment of acute depression in bipolar disease advise against an initial use of antidepressant drugs.[60,202] Thus, in patients with "apparent" stable bipolar disorders, neurologists should at the least refer the patient for *one* psychiatric consultation to confirm that optimal treatment options are being prescribed.

Table 3 Incidence of Seizures in People without Epilepsy

Antidepressants	Incidence of seizures
Selective serotonin reuptake inhibitors	
Sertraline	0.08%
Paroxetine	0.1%
Fluoxetine	0.2%
Fluvoxamine	0.2%

Citalopram/escitalopram	<0.1%
Serotonin norepinephrine reuptake inhibitor	
Venlafaxine	0.3%

Choice of Antidepressant Drug

As stated above, there is a general consensus among psychiatrists that SSRIs and/or SNRIs are the drugs of choice to treat the various types of primary depression. However, when choosing an antidepressant drug in PWE, clinicians must also consider the following issues:

1. The potential of the antidepressant drug to worsen seizures
2. The pharmacokinetic and pharmacodynamic interactions of the AEDs with the antidepressant drug
3. The potential of the antidepressant drug to worsen underlying comorbid disorders specific to PWE

Do Selective Serotonin Reuptake Inhibitors and Serotonin Norepinephrine Reuptake Inhibitors Worsen Seizures?

The incidence of seizures in nonepilepsy patients exposed to SSRIs is presented in Table 3.

Clearly, the incidence of seizures is lower than that expected in the general population. Furthermore, in a recent critical review of the literature, Jobe and Browning concluded that not only is the use of SSRIs safe, but also that the proconvulsant effects of antidepressants cannot be accounted by their serotonergic or noradrenergic effects.[156] A recent study supports these conclusions. Khan et al. compared the incidence of seizures among patients randomized to SSRIs (citalopram, fluoxetine, fluvoxamine), the SNRI venlafaxine, and the α2-adrenergic antagonist antidepressant mirtazapine in regulatory trials. They found that patients randomized to the antidepressants were significantly less likely to have had an epileptic seizure than controls[2] (and Alper et al., submitted). These findings support the conclusions of Jobe and Browning as well as the data presented by Forsgren and Nystrom[103] and Hesdorffer et al.[89,90] in the sense that a history of depression increases the

risk of seizures. These data raise the question of whether the seizures that occur after the start of SSRIs are in fact related to an increased risk associated with the depressive disorder. Yet, this question needs to be examined in prospective and controlled studies, as the occurrence of seizures has been occasionally reported to the introduction of an SSRI (see also Chapter 214).

The use of SSRIs in PWE has been investigated in the case of sertraline, citalopram, and fluoxetine.[4,65,110] In a study from our center, sertraline was found to *definitely* worsen seizures in only 1 of 100 patients.[110] In another five patients, a transient increase in seizure frequency was attributed to this antidepressant drug with a probable, but not definite, causality. Four of these five patients were maintained on sertraline therapy. Following adjustment of the dose of their AED, none of these patients experienced further seizure exacerbation. In the study that investigated the safety of citalopram in 45 PWE, none of the patients experienced a worsening of seizures[4]; in fact the authors noted a reduction in seizure frequency. Similar findings were reported in the study of fluoxetine in PWE.[65]

Blumer has also reported using tricyclic antidepressants (TCAs) alone and TCAs in combination with SSRIs in epileptic patients without seizure exacerbation.[19] No data have been published on the safety of SNRIs in PWE. We have used the SNRI venlafaxine in more than 100 PWE, a significant proportion of whom suffered from intractable epilepsy without observing any worsening in seizure frequency or severity (Kanner, unpublished data).

MAOIs are not known to cause seizures in nonepileptic patients; bupropion, maprotiline, and amoxapine are the antidepressant drugs with the strongest proconvulsant properties and should be avoided in epileptic patients.[48,113]

A review of the literature shows that the variables associated with an increased risk of seizure occurrence following exposure to TCAs in general *in nonepileptic* patients include (a) high plasma serum concentrations; (b) rapid dose increments; and (c) the presence of other drugs with proconvulsant properties.[48,113,196] There are four antidepressant drugs that should be avoided in PWE; these include maprotiline, bupropion, amoxapine, and chlorimipramine. Thus, to minimize the risk of seizures in PWE, antidepressant drugs should be started at low doses with small increments until the desired clinical response is reached; this will minimize the risk of causing and/or exacerbating seizures.

Pharmacokinetic Interactions between Antidepressants and Antiepileptic Drugs

All of the SSRIs and SNRIs are metabolized in the liver via the CP450 system and their metabolism is accelerated in the presence of AEDs with enzyme-inducing properties, which include phenytoin, carbamazepine, phenobarbital, and primidone at regular doses and oxcarbazepine and topiramate at higher doses. This pharmacokinetic effect is not observed with the new AEDs gabapentin, lamotrigine, tiagabine, levetira-cetam, and zonisamide. Thus, upon introduction of an enzyme-inducing AED, clinicians need to advise patients to be on the lookout for symptom recurrence, in which case the dose of the SSRI or SNRI may need to be increased.

Conversely, some of the SSRIs are inhibitors of one or more isoenzymes of the CP450 system. These include fluoxetine, paroxetine, and fluvoxamine and, to a lesser degree, sertraline.[81,149,204] Adjustment of some of the AED (primarily carbamazepine and phenytoin) doses may be necessary. Citalopram, escitalopram, venlafaxine, and mirtazapine are the antidepressant drugs with the least impact on CP450 isoenzymes.

Pharmacodynamic Effects of Antidepressant Drugs to Watch for in People with Epilepsy

The acute stimulation of four serotonin receptor subtypes (5HT-2 A, 5HT-2 C, 5HT-3, and 5HT-4) may account for the adverse events associated with SSRIs and SNRIs.[70,80] In addition, adverse events may result from a direct action of serotonin outside the brain, such as the spinal cord and gastrointestinal tract. The adverse events associated with these drugs include anxiety and agitation during the acute phase of treatment; gastrointestinal symptoms including nausea, abdominal cramping, and diarrhea; changes in appetite and weight; sexual disturbances; and, rarely, involuntary movements.[112] Among the SNRIs, hypertension is a potential adverse event identified in patients taking venlafaxine.[112]

A variety of sexual disturbances including decreased libido, anorgasmia, impotence, and disturbances in ejaculation as well as dyspareunia are more frequent among PWE than the general population, either as an expression of an iatrogenic effect of AEDs and/or as a direct impact of the seizure disorder. Adverse effects of SSRIs and SNRIs have been reported in about 20% to 30% of patients.[37,112] Citalopram and its s-enantiomer escitalopram and mirtazapine have the lowest incidence of sexual adverse events. Whether the adverse effects mediated by these drugs worsen already existing sexual disturbances in PWE has yet to be investigated. Patients, nonetheless, should be advised to report any of these adverse events, either whether occurring de novo or as a worsening of pre-existing disturbances. Tolerance may develop over time, and at times lowering of the dose or switching to another SSRI may improve these side effects.

By the same token, some SSRIs can cause changes in weight in the form of weight gain, as in the case of paroxetine, aggravating a weight gain problem triggered by AEDs like valproic acid, gabapentin, and carbamazepine. On the other hand, fluoxetine can cause weight loss in the first 3 months of therapy, but patients regain the weight lost thereafter.[37]

Finally, discontinuation of antidepressant drugs including TCAs, SSRIs, and SNRIs cannot be abrupt as it can result in withdrawal symptoms[70,112] including nausea, vomiting, tremors, and anxiety.

Other Treatments

Mood-stabilizing Agents

In the treatment of bipolar patients, mood-stabilizing agents have become the first line of drugs to prevent recurrence of major depressive and manic/hypomanic episodes. Fortunately for PWE, several of the AEDs, mainly CBZ, VPA, LTG, and OXC, have been found to show efficacy in this respect.[7,64,68,176,190] Often, however, administration of these AEDs may not be sufficient to cause remission of a major depressive disorder. In such cases a short-term use of an antidepressant may have to be considered, but always in the presence of a mood-stabilizing agent to minimize the risk of conversion to a manic or hypomanic episode. Occasionally, the use of lithium may be necessary to render the patient euthymic; this drug can be fraught with several problems including changes in electroencephalographic (EEG) recordings and proconvulsant properties at therapeutic serum concentrations in nonepileptic patients.[10,190] Its neurotoxicity and related increase in seizure risk increases with the concurrent use of neuroleptic drugs, in the presence of EEG abnormalities, and with a history of central nervous system (CNS) disorder, and thus should be used with caution in PWE. Furthermore, lithium can be associated with neurotoxicity (i.e., dizziness, diplopia, blurred vision, ataxia) when given in combination with CBZ, even when the serum concentrations of

P.2134

both drugs are in the therapeutic range, requiring the reduction in the dose of carbamazepine or a switch to another AED.

Electroshock Therapy

Electroshock therapy may need to be considered in very severe and treatment-resistant major depressive episodes.[14] ECT is not contraindicated in patients with epilepsy.[155] It is a well-tolerated treatment and is worth considering in patients with epilepsy with very severe depression or manic episodes that fail to respond to AD. Blackwood et al. found that the incidence of seizures in patients following treatment with ECT was no higher than in the general population.[155] In fact, several studies have shown that ECT increases seizure threshold by 50% to 100%.[5,16,43,168,169,208] Finally, there are case reports of ECT used successfully for the treatment of seizures in patients with epilepsy not responsive to multiple anticonvulsant medications.[160] Hence, it seems clear that ECT is not contraindicated as a treatment for depression in patients with epilepsy.

When Should Patients Be Referred for Psychotherapy?

Often, mood (and anxiety) disorders may benefit from a combination of pharmacotherapy and psychotherapy, above all when patients have been symptomatic for a protracted period of time and when the psychiatric symptoms have interfered with the patients' ability to maintain employment, a social life, etc. In fact, there are several studies that have established the efficacy of cognitive behavior therapy (CBT) for the management of depressive and anxiety disorders, either by themselves or in combination with pharmacotherapy. In general, CBT consists of short-term treatments of 16 to 20 sessions given during 12 weeks on average.[67] They should only be administered by health care professionals that have been trained specifically in this technique.

Concept of the Interictal Dysphoric Disorder

Modern studies of the interictal psychiatric disorders have usually attempted to identify their similarity to the psychiatric disorders that meet the current DSM-III/IV criteria. Our careful review has shown this to be a difficult task, particularly in view of the pleomorphic and intermittent presentation of the interictal psychiatric changes.

Modern psychiatry excluded epilepsy from its considerations when establishing the DSM classification; it has also omitted genetic considerations and based its classification on the descriptive symptomatology of psychiatric disorders. Admittedly, the current DSM is a work in progress.

Premodern psychiatry deemed epilepsy one of the major spheres of its interests, distinct by etiology and symptomatology from the spheres of manic depressive, schizophrenic, and sexual disorders. Kraepelin[115] precisely described the psychiatric changes among patients with epilepsy as they presented before the modern era of anticonvulsant therapy: Intermittent dysphoric episodes were characterized by irritability, depressive moods, and anxiety, as well as headaches, insomnia, and at times euphoric moods. These pleomorphic dysphoric episodes would occur every few days to every few months and would last from a few hours up to 2 days. Dysphoric symptoms were also observed in the prodromal and postictal phases of a seizure. Kraepelin identified the dysphoric disorder of epilepsy not by cross-sectional inquiries, but based on the daily observations of long-term inpatients with epilepsy at a university hospital. With an appropriate instrument, longitudinal assessment of the dysphoric symptoms in patients with chronic epilepsy has confirmed the pleomorphic and intermittent pattern of the interictal dysphoric disorder.[22,26]

Compared with the premodern psychiatric description of the dysphoric disorder, presumably as an undesirable result of modern antiepileptic drugs, the dysphoric symptoms now appear to be more protracted; for the same reason, chronic interictal psychoses are now more frequent, and suicidality has become a significant problem. This finding needs an explanation.

In 1951, Gibbs observed that the epileptic and psychiatric components of psychomotor epilepsy appeared to be physiologically antithetical.[207] A few years later, Landolt observed a patient whose epileptiform EEG had normalized each time he was dysphoric, ascribed the finding to a "supernormal braking action," and developed the concept of "forced normalization."[118,119] Related studies focused particularly on the alternating pattern of interictal psychoses and seizures, and the term "forced normalization" came into current use. Trimble, in particular, has emphasized the importance of forced normalization in several studies and a recent monograph.[205] Engel[61] and Stevens[193] postulated that the psychiatric disorders of epilepsy may result from the inhibitory activity that develops in reaction to the excessive excitatory activity of the chronic seizure disorder. The following findings are in accordance with this postulate[25]:

> (1) The development of the interictal dysphoric and psychotic disorders is delayed (by about 2 years and 12 years, respectively) following onset of epilepsy as inhibitory mechanisms become increasingly established. This finding accords with the particular linkage of the psychiatric disorders of epilepsy with its common relatively refractory form, mesial temporal lobe epilepsy. (2) Upon decrease, and particularly upon full control, of seizures, dysphoric or psychotic symptoms tend to be exacerbated or to emerge de novo (forced normalization or alternating psychosis). (3) Psychiatric changes emerge at times when severe exacerbation of the seizure activity engages an enhanced inhibitory response; thus, the prodromal phase of seizures may be associated with dysphoric symptoms (such as elated mood or heightened irritability), and the postictal phase is commonly associated with dysphoric symptoms (such as anergia, pain, depression, and, in rare cases, even suicidality) and at times (usually after a flurry of seizures) with a psychotic episode.

According to the above hypothesis of the pathogenesis of the psychiatric disorders of epilepsy, their pharmacologic treatment has to be directed primarily against the inhibitory mechanisms. Safety and effectiveness of prescribing the SSRI-type antidepressants for the mood disorders of epilepsy have been previously discussed. The more proconvulsant tricyclic antidepressant drugs, at modest doses, appear to serve as effective antagonists to excessive inhibition and, in fact, may be indispensable for successfully treating the interictal dysphoric disorders.[21,24] Gastaut et al.[74] pointed out that, as measured by their response to Metrazol, patients with temporal lobe epilepsy (in contrast to those with primary generalized epilepsy) show, surprisingly, a higher interictal seizure threshold than do persons without epilepsy. The bias against the use of antidepressants for the psychiatric disorders of epilepsy, on the grounds that they may cause seizures, is erroneous on both empirical and theoretical grounds. Modest amounts of tricyclic antidepressant medication do not increase the seizure frequency in patients with chronic epilepsy whose dysphoric disorder indicates the presence of marked inhibition, and the SSRIs, which we commonly use as adjuncts to the tricyclic antidepressants, are not known to lower the seizure threshold significantly. The combination appears more effective than the use of a tricyclic or of an SSRI alone.[24] Variations that may be necessary in the pharmacotherapy of the interictal dysphoric disorder have been described elsewhere.[21]

The mechanism of action of the antidepressant drugs in the interictal dysphoric disorder clearly is different than in traditional depressive disorders. The drugs are effective rapidly at lower doses and have a broad-spectrum effect for the entire range of symptoms of the limbic disorder, not just for depressive moods, anergia, and insomnia, but also for anxiety, fears, irritability, atypical pains, and euphoric moods.

It is of interest that DSM-IV recognizes the common premenstrual dysphoric disorder as an entity presenting with pleomorphic and labile symptomatology identical to that of the interictal dysphoric disorder.[20] More than two thirds of women with epilepsy experience their seizures predominantly or exclusively in a catamenial pattern, and many experience severe premenstrual dysphoria. This finding has been related to a shift in the estradiol/progesterone ratio in favor of the proconvulsant estradiol over the anticonvulsant progesterone.[88] It has been suggested that the premenstrual dysphoric disorder—as a subictal disorder—may be best treated, like the interictal dysphoric disorder, with the combination of an antidepressant and an anticonvulsant.[20]

Summary and Conclusions

In conclusion, mood disorders in PWE continue to be underrecognized and undertreated. It is of the essence that double-blind placebo-controlled studies be done in PWE with mood disorders to establish their safety and efficacy as well as ideal doses, more so because of the atypical manifestations exhibited by a significant percentage of patients. After all, as suggested by the data reviewed in this article, depression and epilepsy have a very close relationship, which most likely is bidirectional and not unidirectional, which is the expression of common pathogenic mechanisms shared by the two disorders.

Chapter 206

Anxiety Disorders

Andres M. Kanner

Alan B. Ettinger

Introduction

Anxiety disorders are common in people with chronic medical disorders, including people with epilepsy (PWE). While population-based studies have suggested prevalence rates of 25%, equivalent to almost twice that of the general population, the actual incidence and prevalence rates of anxiety disorders in PWE is yet to be established.[54,96] The lack of such data stems from several methodologic problems including a paucity of population-based studies, the use of *screening* instruments that identify "anxiety symptoms" and not "anxiety disorders" (see section on epidemiology), and, to a large degree, an underrecognition of anxiety disorders by patients and families alike. Indeed, patients often misinterpret symptoms of anxiety as "a normal reaction to a life with epilepsy" or an "expected" response to the stresses associated with the multiple obstacles that PWE have to face, above all when their seizures fail to remit.

Deciding when anxiety symptoms are an appropriate response to stressful experiences or an expression of a pathologic disorder has been the source of debate, with some investigators suggesting a "continuum" between these two extremes. According to Hans Selye, stress is "a nonspecific response of the body to any demand."[156] He added that stressful situations in daily life are not harmful and, in fact, may help individuals to adapt to new life circumstances. In support of these observations, Levine[106] found that young mice exposed to mild stress from time to time consisting of handling or weak electric shocks were better able to handle stressful events and became stronger and larger as adults than the mice that were not subjected to such stressors.

At what point does a "normal" response to stress become pathologic and symptomatic of an anxiety disorder? Selye postulated the existence of a "general adaptation syndrome" that includes three phases:[156] (a) alarm, (b) resistance, and (c) exhaustion. The alarm phase triggers a response of the sympathetic nervous system with activation of corticotrophin-releasing hormone (CRH), which in turn causes secretion of adrenocorticotropic hormone (ACTH), leading to a release of cortisol and norepinephrine (NE) from the adrenal glands. The resistance stage is considered to be aimed at overcoming the stress-producing event, by preparing the animal for fight or flight; during this phase, there is a significant increment of vesicles containing corticosteroids in adrenal glands available for release. According to Selye's theory, if resistance is not successful, the body reaches a state of "exhaustion," during which no further corticosteroid vesicles can be identified, resulting in the animals' death. The corollary of these changes in humans is expressed in the development of mental illness in the form of depression, anxiety, and psychosomatic disorders. Some of these observations may be applicable to the development of anxiety in PWE. For example, Hermann et al. found that psychopathology was associated with poor adjustment to epilepsy, elevated number of stressful life events during the past year, financial stress, vocational problems, external locus of control with increased perceived stigma, and an earlier onset of epilepsy.[71] Multiple regression analyses identified three independent predictors of psychopathology: An increased number of stressful life events in the past year, poor adjustment to epilepsy, and financial stress.

The unpredictability of seizure occurrence can very well play an important role in the generation of anxiety symptoms or full-blown anxiety disorders facilitated by a perception of "loss" of the locus of control. Experimentally, this phenomenon can be studied in the animal model of fear conditioning.[74] This model is based on a classical conditioning paradigm consisting of 20-second conditioning stimulus trials in the animal (using a sound as a conditioning stimulus) that are terminated by onset of an aversive unconditioned stimulus consisting of a footshock of 0.5 second's duration. The resulting conditioned response is expressed by behavioral immobility (freezing) during the 20-second sound-conditioning stimulus. On the first trial, when the sound comes on the animal moves around freely. Within a few trials the animal freezes when the sound comes on, and remains still for most of its duration. The conditioned response—freezing—is used as a measure of fear. The manifestations of the inferred fear state in this animal model closely parallel the clinical criteria of generalized anxiety, as evidenced by increased heart rate and stroke volume, dry mouth/decreased salivation, stomach ulcers/upset stomach, altered respiration, scanning and vigilance, increased urination and defecation, grooming/fidgeting, and freezing/apprehension. Fear conditioning is a strikingly dramatic and reproducible phenomenon and can be elicited among many different animal species.

In addition to the above, it is important to consider the potential pathogenic role of neurophysiologic and neurochemical changes associated with the seizure disorder per se, particularly in temporal lobe epilepsy (TLE). Indeed, mesial temporal structures play a primordial role in the generation of symptoms of anxiety, as exemplified in the animal models of fear sensitization and kindling. Kindling refers to the gradual development and intensification of elicited motor seizures resulting from the repetitive administration of initially subconvulsive stimulations to particular brain regions.[61,87] Kindling of limbic structures has also been shown to effect lasting changes in affect in rodents and cats. For example, kindling of rodents' amygdala facilitates the development of behaviors suggestive of “symptoms of anxiety,” and partial kindling of amygdala and ventral hippocampus in cats leads to less predatory behavior. The question is then raised whether fear sensitization may result from hyperexcitation of fear circuits perhaps via long-term potentiation of excitatory amygdala efferents and whether kindling could be comparable to repetitive seizures, thereby inducing interictal anxiety.[1,2] In this chapter we review the available epidemiologic data, clinical manifestations, and treatment of the four most frequent anxiety disorders in PWE: Generalized anxiety disorder (GAD), panic disorder (PD), phobias, and obsessive-compulsive disorder (OCD). We devote a section to the discussion of the most relevant pathogenic mechanisms operant in the development of anxiety disorders in PWE, with special attention to the pathogenic mechanisms that may be shared by anxiety disorders and epilepsy.

Epidemiology

Together with mood disorders, anxiety disorders are the more frequent psychiatric comorbidity in PWE. The *Diagnostic and Statistical Manual of Mental Disorders,* 4th ed., text revision (DSM-IV-TR) lists 11 different types of anxiety disorders: GAD, PD (with and without agoraphobia), OCD, posttraumatic stress disorder (PTSD), acute stress disorder, specific phobias (i.e., to animals, injections, etc.), social phobia, anxiety disorders due to medical conditions, substance-induced anxiety disorder, and anxiety disorders not otherwise specified,[6] which include all those clusters of anxiety symptoms that fail to meet any of the above-cited categories (i.e., subsyndromic types).

As stated in our introduction, the real prevalence of each one of these anxiety disorders in PWE is yet to be established for the following reasons: (a) underrecognition by clinicians and underreporting by patients; (b) paucity of population-based studies; (c) use of diverse methodologies to identify psychiatric semiology, with some of the studies having relied essentially on the use of screening instruments that identify “symptoms,” while only a few studies having used structured interviews designed to establish current and past psychiatric syndromes (Axis I diagnoses) according to the DSM criteria; and (d) the use of relatively small case series, often derived from tertiary epilepsy centers, which attract patients with more severe forms of epilepsy and comorbid disorders. To make sense of published prevalence and incidence rates data, it is necessary to review separately those studies that screened for *symptoms* of anxiety from those that identified anxiety *disorders* with structured psychiatric interviews.

Prevalence of Anxiety Symptoms

In a review of the literature, Torta and Keller found anxiety symptoms in up to 66% of patients with epilepsy.[174] Using the Hospital Anxiety and Depression Scale in a study of 201 PWE, Cramer et al. found that 48% reported symptoms of anxiety; in 25% of these patients they were rated as mild, moderate in 16%, and severe in 7%.[36] In this study, anxiety symptoms were more prevalent than depressive symptoms, which were reported in 38% of subjects. Similar findings were reported in studies done in other cultures. For example, Nubukpo et al. investigated the presence of symptoms of depression and anxiety in 281 adults with epilepsy in West Africa using Goldberg's Anxiety and Depression Scale.[120] Compared to a control group, PWE had significantly higher depression and anxiety scores, which correlated with higher seizure frequency and lack of treatment.

Symptoms of OCD have been found to be more frequent among PWE than healthy controls in small case series. For example, Monaco et al.[114] investigated the presence of OCD symptoms among 62 patients with TLE, 20 patients with idiopathic generalized epilepsy, and 82 matched healthy controls. Symptoms of OCD were reported by nine of the TLE patients, none of the idiopathic generalized patients, and one control. In another small study, Isaacs et al. investigated the presence of OCD symptoms in 30 patients with TLE using the Obsessive-Compulsive Inventory (OCI).[75] As a group, patients with TLE had a higher prevalence of obsessive and compulsive symptoms than the nonpatient normative sample. In addition, TLE patients exhibited elevated scores on all but 3 of the 16 OCI scales and subscales.

Symptoms of anxiety disorders have also been found to be relatively frequent in children with epilepsy. For example, in a study of children whose age ranged from 7 to 18 years old, Ettinger et al. found elevated scores on the Revised Child Manifest Anxiety Scale in 16%,[50] while Williams et al. found this to be the case in 23%.[183] Alwash et al. found anxiety symptoms in almost 50% of Jordanian children or adolescents with epilepsy.[5]

Anxiety Disorders

Various studies have estimated the prevalence of anxiety disorders to range from 10% and 25%, with the higher prevalence rates found among patients with intractable epilepsy. In one of the few population-based studies, Gaitatzis et al. found a prevalence of anxiety disorders of 11% among 5,834 PWE compared with 5.6% among 831,163 people without epilepsy.[53] The psychiatric diagnoses were obtained from primary care records. In a study of 174 consecutive PWE from five epilepsy centers, current anxiety disorders were identified in 53 patients and comprised 52.3% of all Axis I diagnoses established with the Mini International Neuropsychiatric Interview (MINI).[83] Agoraphobia (15.5%), GAD (13.2%), and social phobia (10.9%) were the most common diagnoses among the anxiety disorders. Among these 53 patients, 27 (50.9%) exhibited symptomatology that met criteria for two or more anxiety disorders.

Several studies have been carried out in refractory patients being evaluated for epilepsy surgery. For example, Wrench et al. found a prevalence of 23% among 43 patients being evaluated for an anterotemporal lobectomy and 18% among 17 patients with an extratemporal seizure focus (mostly frontal).[184] In the largest case series of patients who underwent an anterotemporal lobectomy (N = 322), Devinsky et al. found an anxiety disorder diagnosed before surgery with a structured interview in 18%.[48] In a study of 300 patients with refractory epilepsy (231 patients with a temporal lobe focus, 43 with a nontemporal lobe focus, and 26 with a generalized and multifocal seizure onset), Manchanda et al. found that 88 (29.3%) met criteria for a psychiatric syndrome and 54 (18.0%) for a personality disorder, with anxiety disorders being the most common psychiatric diagnosis (10.7%).[109]

Panic disorder is significantly more frequent among PWE than the general population. In a review of the literature, Beyenburg et al. estimated that PWE were six times more likely to suffer from PD than the general population, with point prevalence rates ranging between 5% and 30%,[15] compared with 3.5% in the general population.[96]

Karno et al. have analyzed the prevalence data of obsessive-compulsive disorder measured in five U. S. communities among more than 18,500 persons in residential settings as part of the National Institute of Mental Health–sponsored Epidemiologic Catchment Area program. Lifetime prevalence rates ranged from 1.9% to 3.3% across the five Epidemiologic Catchment Area sites for obsessive-compulsive disorder diagnosed without DSM-III exclusions and 1.2% to 2.4% with such exclusions.[95] On the other hand, the actual prevalence of OCD in PWE is yet to be established as there are no population-based studies in this group of patients and most of the available data are based on small studies carried out in tertiary care centers.

Several studies have evaluated anxiety in children with epilepsy. In one study of 100 children aged 5 to 16 years with complex partial seizures and similarly sized groups of both children with childhood absence epilepsy and normal children, those with complex partial seizures and childhood absence epilepsy were five times as likely to have an affective or anxiety disorder as normal controls; these disorders were identified in 33% of the epilepsy group.[26,27] Of note, anxiety disorder was the most frequent diagnosis among children with suicidal ideation. Within the epilepsy group, children with absence epilepsy were more likely to have an anxiety disorder alone than the children with complex partial seizures, who were more likely to have comorbid depression with anxiety and depression alone. One additional study confirmed the increased rate

P.2141

of anxiety disorders in children, as an anxiety disorder was present in 31% of 102 adolescents with epilepsy.[4]

Clinical Manifestations

People with epilepsy can present the same clinical manifestations of the anxiety disorders included in the DSM-IV-TR classification,[6] though anxiety episodes/disorders with atypical semiology is not unusual. Such is the case when anxiety episodes are restricted to peri-ictal periods (see below). Thus, it is essential to establish the temporal relationship between the occurrence of psychiatric symptomatology and the seizures, as the duration, course, and response to treatment varies depending on whether an anxiety episode is ictal, postictal, or interictal.[90]

Comorbid mood disorders can be identified in a significant percentage of patients with primary anxiety disorders, and this is also the case in PWE. Thus, any investigation of anxiety symptoms/disorders must always be coupled with a search for mood disorders. This important point is discussed in greater detail below. For example, in a study of 199 PWE from five epilepsy centers, Kanner et al. found that 73% of patients with a history of depression met also DSM-IV criteria for an anxiety disorder.[91]

Interictal Anxiety Disorders

Generalized Anxiety Disorder

To meet diagnostic criteria of GAD, patients have to have experienced the following symptoms for a period of at least 6 months, occurring more days than not: (a) excessive worry and anxiety about a number of events or activities; (b) difficulty in controlling the worry; (c) the focus of the anxiety is not related to another psychiatric disorder (i.e., panic disorder, social phobia, etc.); (d) three or more of the following symptoms: restlessness or feeling on edge, being easily fatigued, difficulty concentrating, irritability, muscle tension, sleep disturbance manifested by either difficulty falling asleep and/or staying asleep and/or restless unsatisfying sleep; (e) symptoms cause clinically significant distress or impairment in the patients' social, occupational, or other areas of functioning; and (f) symptoms do not result from the use of medication or substances of abuse (including alcohol) or a general medical condition (i.e., hyperthyroidism) and do not occur exclusively during a mood or psychotic disorder.

Panic Disorder

PD consists of recurrent panic attacks with a frequency of at least one attack per week for a period of at least 1 month.[6] These attacks are characterized by a subjective sense of dread (feeling of impending doom), associated with a variety of autonomic symptoms including palpitations, sweating, subjective dyspnea, paresthesias, dizziness, nausea, feeling faint, and a sense of abdominal or central chest discomfort. Each attack may last between 5 and 30 minutes and may not have a clear precipitant. Anticipatory anxiety is the second feature of PD, so that the patients fear a recurrence of attacks and may enter a state of chronic lower-grade anxiety. Finally, the patients may show phobic avoidance of situations that they feel may provoke an attack, which may reach total avoidance of leaving the home or fear of being left alone (in which case patients are diagnosed with PD with agoraphobia). Comorbid depression is found in up to 70%, as is the development of secondary psychosocial problems, agoraphobia, and social phobias.[112] It is important to keep in mind that ictal fear can be often confused and misdiagnosed as panic attacks (see below).

Phobias

According to the DSM-IV-TR criteria, specific phobias are described as "marked and persistent fear that is excessive or unreasonable, cued by the presence or anticipation of a specific object or situation (i.e., flying, heights, animals, etc.)." Exposure to the phobic stimulus can trigger an anxiety reaction that may reach proportions of a panic attack.[6] In PWE, agoraphobia or social phobias are among the more frequent types, resulting from fear of injury or social embarrassment should a seizure occur in public. For example, in a study of postictal psychiatric symptoms carried out in 100 consecutive patients with pharmacoresistant partial epilepsy, Kanner et al. found postictal symptoms of agoraphobia in 29 patients; 18 of these patients (62%) attributed these symptoms to the fear of seizure recurrence, but none of these patients experienced seizures in clusters to explain the agoraphobic symptoms.[90] Nonetheless, none of these patients developed full-blown interictal agoraphobia.

Obsessive Compulsive Disorder

OCD consists of the presence of obsessions and/or compulsions causing marked distress, being time-consuming (occurring for at least 1 hour per day) and significantly interfering with the individual's normal routine, occupational functions, or social activities or relationships.[6] The DSM-IV-TR classification defines obsessions as recurrent and persistent thoughts, impulses, or images that are experienced at some time during the disturbance as intrusive and inappropriate and cause marked anxiety or distress. It defines compulsions as repetitive behaviors or mental acts that the person feels driven to perform in response to an obsession or according to rules that must be applied rigidly. These criteria call for the individual to recognize that the obsessions and compulsions are excessive or unreasonable.[6]

There have been several case reports of complete remission of OCD or marked improvement following epilepsy surgery that have spurned hypotheses suggesting common pathogenic mechanisms between OCD and epilepsy. For example, Barbieri et al. reported a patient who had developed obsessive-compulsive symptoms shortly after the onset of temporal lobe epilepsy and who exhibited almost complete symptom remission after being rendered seizure free after a temporal lobectomy.[11] Kanner et al. reported the case of a woman with OCD consisting primarily of obsessions that had been intractable to various pharmacologic and psychotherapeutic interventions prior to surgery and that remitted in toto after a right temporal lobectomy.[88] Remission of OCD has been restricted to TLE surgery. Guarnieri et al. reported two male patients with medically intractable frontal lobe epilepsy and OCD symptoms who experienced remission of obsessive-compulsive symptoms after anterior cingulate cortex ablation.[66]

Peri-ictal Symptoms of Anxiety

Few studies have investigated in a systematic manner the prevalence of peri-ictal anxiety symptoms or episodes, and those available have been limited to selected populations in tertiary centers. The lack of these data is not accidental as clinicians in general fail to inquire about such symptoms in their evaluations of PWE.

Pre-ictal Symptoms

Pre-ictal symptoms of anxiety can precede a seizure by several hours to several days. For example, Blanchet and Frommer identified symptoms of anxiety intermixed with symptoms of depression and irritability in a study of 27 patients who were asked to rate their mood on a daily bases for 1 month.[19] Thirteen patients experienced a variety of dysphoric symptoms,

P.2142

including symptoms of anxiety 3 days prior to the seizure occurrence that increased in severity as the time of the seizure got closer.

Ictal Symptoms of Anxiety

Ictal fear or ictal panic is the most frequent psychiatric symptom presenting as an expression of a simple partial seizure (or aura). It was identified in 60% of patients with auras consisting of psychiatric symptoms.[44,180] As stated above, ictal panic has been confused and misdiagnosed as a panic disorder. For example, in a series of 112 consecutive PWE, Sazgar et al. identified five patients with ictal fear as part of a partial seizure disorder of right mesial temporal origin who had been misdiagnosed with PD.[150] The difficulty in distinguishing the two disorders stems from the following: (a) an inaccurate and/or incomplete clinical history. (b) The absence of epileptiform activity in scalp interictal recordings in patients whose seizures originate from amygdala, a structure that generates epileptiform discharges with very narrow electric fields. In such patients, the use of video-electroencephalographic (V-EEG) monitoring studies may be necessary to record the actual seizure. Often, sphenoidal electrodes inserted under fluoroscopic guidance may be necessary to identify the electrographic ictal pattern of the aura.[89] (c) Ictal fear occurs often in the setting of a partial seizure disorder originating in the nondominant hemisphere. In such cases, patients may continue to respond during the ictus (including during a complex partial seizure) and neither witnesses to the seizure nor the patients may be able to identify a period of confusion or loss of awareness of their surroundings, lest a careful testing of the patient is conducted.

A detailed history can help distinguish a panic attack from ictal panic.[163] Indeed, ictal panic is typically brief (<30 seconds in duration), is stereotypical, occurs out of context to concurrent events, and may be followed by other ictal phenomena such as periods of confusion of variable duration and subtle or overt automatisms when and if the seizure evolves to a complex partial seizure. The intensity of the sensation of fear is mild to moderate and rarely reaches the intensity of a panic attack. On the other hand, panic attacks consist of episodes of 5 to 20 minutes' duration, which at times may persist for several hours, during which the feeling of fear or panic is very intense, often described as a feeling of impending doom and associated with a variety of autonomic symptoms, including tachycardia, diffuse diaphoresis, and shortness of breath. During a panic attack, patients may become completely absorbed by the panic experience to the point where they may not be able to report what is going on around them; nonetheless, there is no real confusion or loss of consciousness as in complex partial seizures. Finally, patients with panic attacks are more likely to develop agoraphobia, while this is rare among patients with ictal panic unless they suffer from interictal panic disorder as well.

Given the relatively high comorbidity of interictal panic disorder in PWE, the concurrent occurrence of ictal fear and interictal PD has to be investigated in all patients. For example, in a small study of 12 patients with temporal lobe epilepsy, Mintzer and Lopez found ictal fear and interictal panic disorder in four of these patients.[113] Two other patients had other forms of interictal anxiety disorder and eight patients had depressive disorder.

Finally, the presence of ictal fear can herald the development of postsurgical mood disorders. Thus, Kohler et al. studied the association of ictal fear with mood and anxiety disorders before and 1 year after temporal lobectomy.[99] They compared 22 patients with ictal fear with matched groups of patients with other types of auras and no auras at all. Mood and anxiety disorders declined in the control groups, but not in the ictal fear group after surgery.

Postictal Symptoms of Anxiety

Postictal symptoms of anxiety are relatively frequent among patients with refractory partial epilepsy. In a study of 100 consecutive patients with pharmacoresistant partial epilepsy cited above, Kanner et al. investigated in a systematic manner the occurrence of postictal psychiatric symptoms during a 3-month period.[90] The postictal period was defined as the 72 hours that followed a seizure. Only symptoms that occurred after more than 50% of seizures were recorded. A median of two postictal symptoms of anxiety (range: 1 to 5) were identified in 45 patients with a median duration of 24 hours (range: 0.5 to 148 hours). In 30 patients, at least 1 postictal symptom lasted 24 hours or longer (15 patients [33%] reported a cluster of 4 symptoms of at least 24 hours); 10 patients reported at least 1 symptom of 1 to 23 hours' duration; and 5 patients had anxiety symptoms lasting <1 hour. Thirty-two patients reported symptoms of generalized anxiety and/or panic; an additional ten patients also reported symptoms of compulsions and 29 patients experienced postictal symptoms of agoraphobia. In 37 of these 45 patients, postictal symptoms of depression were also identified. A prior history of anxiety disorder was identified in 15 patients (33%). There was an association between a history of anxiety disorder and the occurrence of two postictal symptoms of anxiety: Constant worrying and panicky feelings. In addition, there was a significant association between a history of anxiety and depressive disorders and a greater number of postictal anxiety symptoms.

Comorbid Occurrence of Anxiety and Depression Disorders

In patients with anxiety disorders with or without epilepsy, investigation of symptoms of anxiety is not complete without also screening for symptoms of depression or carrying out structured interviews looking for mood disorders (and vice versa). Thus, in a meta-analysis of studies that investigated comorbidity between *primary* depression and anxiety disorders, Dobson and Cheung concluded that among patients with a depressive disorder, a mean of 67% (range: 42% to 100%) also experienced anxiety disorders concurrently or in their lifetime.[49] Conversely, in patients with anxiety disorders, a mean of 40% (range: 17% to 65%) also suffered from depression. By the same token, comorbid occurrence of primary social phobia and both major depression and dysthymia of up to 70% have been reported,[112] while higher comorbidity is also identified in first-degree relatives.[135] Furthermore, improvement in one condition can be expected to have a positive impact on the other. For example, in a study carried out in a general medical clinic setting, 880 patients were screened for depression by using the Diagnostic Interview Schedule version of the DSM-III and the Zung Self-Rating Depression Scale, as well as the Zung Self-Rating Anxiety Scale[192]; 112 patients (13%) were found to have a depressive disorder. Comorbid symptoms of anxiety of moderate severity were identified in 67% of depressed patients. After a follow-up period of 1 year, during which symptoms of depression and anxiety were monitored at five time points, depressed patients who improved showed a significant decrease in severity of comorbid symptoms of anxiety, while depressed patients who worsened showed a significant increase in their anxiety index; the decrease in the anxiety index of patients in the no-change group was not statistically significant.

In PWE, the occurrence of comorbid anxiety and depressive disorders is also common. In a study of 199 patients with epilepsy from five epilepsy centers cited above, 73% of patients with a history of depression met also DSM-IV criteria for an anxiety disorder.[91] In that study the DSM-IV-TR diagnosis of a mood and/or anxiety disorder was established with

the MINI and Structured Clinical Interview for Axis I Diagnosis (SCID). These patients completed a 46-item self-rating instrument, "The Mood and Anxiety Symptoms in Epilepsy" (MASE), that includes symptoms from eight domains (depression, anxiety, irritability, self-consciousness, physical symptoms, disturbances in socialization, suicidal ideation, and increased energy) on two occasions, 2 weeks apart. Sixty-seven patients met criteria for a DSM-IV Axis I diagnosis: Each of the 37 patients that met criteria for major depression reported symptoms of anxiety. Furthermore, several investigators dating back to Kraepelin, Bleuler, Gastaut, and more recently Blumer and Kanner have made a point of emphasizing the pleomorphic nature of the symptomatology of depressive disorders in PWE, in which symptoms of anxiety play a prominent role.[20,22,55,93,100]

Comorbid anxiety symptoms can also occur in subclinical or subsyndromic forms of depression. In the study of 199 consecutive PWE cited above,[91] 132 patients (64%) failed to meet any DSM-IV Axis I diagnosis according to the SCID and MINI; yet, using the self-rating instruments Beck Depression Inventory-II (BDI-II) or the Center for Epidemiologic Studies-Depression (CES-D), 32 patients (16% of the entire cohort) were also found to have been experiencing symptoms of depression of mild to moderate severity. Symptoms of anxiety were identified in 31 of these 32 patients with the MASE.

Screening of Anxiety Symptoms in the Clinic

Anxiety disorders in epilepsy *are not* homogeneous conditions, and often they occur in association with more than one type of anxiety and/or mood disorders. Thus, how can a neurologist identify an anxiety disorder in PWE? The use of self-rating *screening* instruments can be an *initial* step, but by themselves do not establish a diagnosis. Several instruments are available, but none has yet been validated in PWE. Self-rating screening instruments are obviously preferable to questionnaires that have to be administered by a health professional. In addition, instruments that also screen for symptoms of depression should be included for the reasons cited above. Among the multiple screening instruments available, the following can be considered:

1. Hospital Anxiety and Depression Scale[191]: This scale is specifically developed for use in patients with medical comorbidity, and consists of seven-item self-rated subscales for both depression and anxiety.

2. Beck Anxiety Inventory (BAI)[13]: The BAI is a 21-item self-report measure of anxiety severity. The scale consists of 21 items, each describing a common symptom of anxiety over the past week on a 4-point scale ranging from 0 (*Not at all*) to 3 (*Severely—I could barely stand it*). The items are summed to obtain a total score that can range from 0 to 63.

3. Goldberg's Depression and Anxiety Scales[62]: The instrument consists of nine questions assessing mood and anxiety over the previous month, and the full set of nine questions needs to be administered only if there are positive answers to the first four. The scales are devised specifically to be used by nonpsychiatrists in clinical investigations. Scores are from 0 to 9.

4. Hamilton Anxiety Rating Scale (HAM-A or HARS)[68]: This scale is a 14-item clinical interview scale (not self-reported) measuring somatic and psychic anxiety symptoms. The responses include five degrees of severity ranging from 0 (*None*) to 4 (*Frequent and severe symptomatology*). This instrument should be used with caution in PWE, given the large number of somatic symptoms included in this scale, which, in patients with epilepsy, can result from adverse effects of antiepileptic drugs (AEDs), potentially yielding false-positive suggestions of more severe anxiety symptomatology.

The Use of Screening Instruments in Research: A Cautionary Note!

One of the most frequent methodologic errors in research studies on psychiatric disorders and epilepsy is the sole reliance on *screening* instruments to establish a diagnosis. The argument for exclusively using screening instruments is that they have been “validated” to identify the condition at hand with acceptable levels of sensitivity and specificity and the severity of the depressive episodes. Yet, as stated above, patients may often experience more than one type of anxiety disorder at a given point in time and more often than not suffer from comorbid mood disorders. Accordingly, structured psychiatric evaluations are “a must,” aimed at identifying the complexity of current and past psychiatric disorders. Short of that, the conclusions that can be derived from studies that assess any treatment modality or the course of symptomatology are limited.

For example, the course and response to treatment of GAD or PD in a patient with a comorbid history of bipolar disorder is different from that of a patient with major depressive disorder or without a comorbid mood disorder. In short, *screening* instruments identify “*symptoms*”; *structured interviews* establish the presence of a psychiatric disorder, according to classifications like the DSM-IV-TR. Thus, if the aim of a study is to identify the presence of an anxiety disorder, a psychiatric structured interview is necessary. Only once the presence of psychiatric disorders have been established in this manner should screening instruments be used to follow changes of symptom severity over time.

Impact of Anxiety Disorders on Quality of Life

Primary mood and anxiety disorders have a negative impact on the quality of life in the general population. In PWE, research on the effect of psychiatric disorders on health-related quality of life (HRQOL) has been focused on mood disorders (see also Chapter 205) and five studies carried out in patients with pharmacoresistant epilepsy have consistently demonstrated depression to be *the most* powerful predictor for each domain of health-related quality of life, even after controlling for seizure frequency, severity, and other psychosocial variables.[58,59,102,105,128] Cramer et al. also found that depression was significantly associated with poor quality of life scores on the Quality of Life in Epilepsy Inventory-89 (QOLIE-89) independently of the type of seizures; these investigators found, however, that seizure freedom for the last 3 months increased (i.e., improved) the quality-of-life ratings.[35]

Few studies have investigated the impact of anxiety symptoms and/or disorders on HRQOL of PWE. In a study of 87 patients with TLE, Johnson et al. found that symptoms of depression and anxiety were the strongest predictors of poor HRQOL.[82] These investigators found an independent effect of each class of symptoms on HRQOL, however. Furthermore, the psychiatric comorbidity explained more variance in HRQOL than did combined groups of clinical seizure or demographic variables. Furthermore, in a study of 154 outpatient adults with epilepsy carried out in South Korea, Choi-Kwon et al. found that the presence of anxiety symptoms was the most important variable mediating lower quality of life in patients with epilepsy.[32]

In the study of 199 patients described above, Kanner et al.[91] found that the scores of the QOLIE-89 were significantly

lower (i.e., worse quality of life) among patients with anxiety disorders than those of asymptomatic patients. Furthermore, patients with comorbid anxiety and major depressive disorders had significantly lower scores in the QOLIE-89 than those with only major depressive episodes.

Impact of Anxiety on Suicidality

Suicidal ideation and attempts are significantly more frequent among PWE than in the general population.[84] Several studies have already established that anxiety disorders are risk factors for suicidal ideation and suicide attempts. For example, in a large population-based longitudinal study carried out in the Netherlands, Sareen et al. found that the presence of any anxiety disorder at the initial evaluation was significantly associated with suicidal ideation and suicide attempts in both the cross-sectional analysis (adjusted odds ratio [OR] for suicidal ideation, 2.29; 95% confidence interval [CI], 1.85 to 2.82; adjusted OR for suicidal attempts, 2.48; 95% CI, 1.70 to 3.62) and longitudinal analysis (adjusted OR for suicidal ideation, 2.32; 95% CI, 1.31 to 4.11; adjusted OR for suicide attempts, 3.64; 95% CI, 1.70 to 7.83).[149] Furthermore, the presence of any anxiety disorder in combination with a mood disorder was associated with a higher likelihood of suicide attempts in comparison with a mood disorder alone. Pilowsky et al. surveyed 2,043 patients attending a primary care clinic using the Primary Care Evaluation of Mental Disorders Patient Health Questionnaire, a screening instrument that yields provisional diagnoses of selected psychiatric disorders.[131] A provisional diagnosis of current panic disorder was identified in 127 patients (6.2%). After adjusting for potential confounders (age, gender, major depressive disorder, generalized anxiety disorder, and substance use disorders), patients with panic disorder were about twice as likely to present with current suicidal ideation, as compared to those without panic disorder (adjusted OR, 1.84; 95% CI, 1.06 to 3.18). After adjusting for panic disorder and the above-mentioned potential confounders, patients with major depressive disorder had a sevenfold increase in the odds of suicidal ideation, as compared to those without major depressive disorder (adjusted OR, 7.00; 95% CI, 4.42 to 11.08). Other studies have found that anxiety disorders may increase a suicidal risk only in the presence of comorbid mood disorders.[7]

The impact of anxiety disorders on suicidal ideation and suicide attempts has also been identified in children and adolescents but may not be as clear as in adults. For example, Strauss et al. carried out a study of 1,979 patients aged 5 to 19 years using the Schedule for Affective Disorders and Schizophrenia for School Aged Children–Present Episode at an outpatient mood and anxiety disorders clinic.[168] Subjects were stratified by age and categorized into mutually exclusive groups as being nonsuicidal (N = 817), having suicidal ideation (N = 768), or having attempted suicide (N = 394) in the current episode. After stratifying by age, the investigators found no differences among the ideators, attempters, and nonsuicidal youth in rates of an anxiety disorder in general or in specific rates of PD, agoraphobia, social phobia, simple phobia, and OCD. In older children (age >15 years), GAD was more prevalent in ideators (OR = 1.65; 95% CI, 1.03 to 2.66; $p = 0.03$) than in nonsuicidal patients. Whether similar findings would be identified in population-based studies is yet to be established.

The impact of anxiety disorders in suicidality of PWE has not been studied extensively. In one study by Jones et al. of 139 PWE, 17 met criteria for current suicidal ideation (12.2%), while a lifetime prevalence of suicidal attempts was found in 29 patients (20.8%).[84] Anxiety disorders were significantly more common among patients with current suicidal ideation (58.8%), while 41.2% of patients had comorbid anxiety and current major depressive disorders. On the other hand, lifetime major depressive disorder was the most frequent psychiatric disorder identified among patients with lifetime suicide attempt (51.7%).

Pathogenic Mechanisms

There are several operant pathogenic mechanisms of anxiety in PWE, which can be classified into three groups: (a) psychosocial; (b) endogenous, which include neurochemical, neurophysiologic, neuroanatomic, and functional changes related to the seizure disorder per se; and (c) iatrogenic, including adverse effects of AEDs and complications of epilepsy surgery.

Psychosocial Factors

Patients with epilepsy face multiple psychosocial obstacles that can facilitate the development of symptoms of anxiety and/or (in patients with a predisposition) full-blown anxiety disorder. Stigma, to name one of such obstacles, accounts for the development of symptoms of anxiety. For example, in a study of more than 5,000 patients living in 15 countries in Europe, Baker et al. found that 51% reported feeling stigmatized, with 18% reporting feeling highly stigmatized.[9] High scores were correlated with worry, negative feelings about life, long-term health problems, injuries, and reported side effects of AEDs. Unfortunately, PWE's perception of being stigmatized is not only a function of their “insecurity” resulting from the epilepsy, but is also a real phenomenon illustrated in a study by Harden et al.[69] These investigators developed a survey consisting of three vignettes briefly describing a coworker with depression, multiple sclerosis, or epilepsy. Of note, the epilepsy vignette *did not describe a seizure*. Each vignette was followed by eight identical questions addressing the level of comfort during interactions with the vignette subject. The surveys were hand-distributed in two companies in New York City and returned anonymously by mail. Seventy-four of 200 distributed questionnaires were returned. Respondents reported more discomfort at the thought of interacting with a coworker with epilepsy than with depression or multiple sclerosis, but this difference did not reach significance. However, worry about sudden, unpredictable behavior for the coworker with epilepsy was significantly greater than that with multiple sclerosis. Responders had a significantly lower level of comfort providing first aid for the coworker with epilepsy than for the coworkers with depression and multiple sclerosis. Lower job level and lower income level correlated with more social discomfort for all three illnesses.

People with epilepsy have also been found to suffer from more frequent comorbid physical disorders, some of which are closely associated with stress and anxiety. For example, Téllez-Zenteno et al. analyzed epilepsy-specific and general population health data obtained through two previously validated, independently performed, door-to-door Canadian health surveys, the National Population Health Survey (N = 49,000) and the Community Health Survey (N = 130,882), which represent 98% of the Canadian population.[172] PWE were found to have higher comorbid stomach and intestinal ulcers, bowel disorders, migraine, and chronic fatigue. Likewise, Strine et al. analyzed data obtained from 30,445 adults aged 18 years or older who participated in the 2002 National Health Interview Survey in the United States.[169] They identified an estimated 1.4% subjects who were told by a health care professional that they had seizures; these subjects were significantly more likely than those without seizures to report lower levels of education, higher levels of unemployment, pain, hypersomnia and insomnia, and psychological distress (e. g., feelings of sadness,

P.2145

nervousness, hopelessness, and worthlessness). In addition, they were significantly more likely to report insufficient leisure time physical activity as well as physical comorbidities such as cancer, arthritis, heart disease, stroke, asthma, severe headaches, lower back pain, and neck pain. It is likely that the comorbid medical disorders play a significant role in the generation of symptoms of anxiety in PWE.

The Role of Seizure Frequency and Seizure Severity

As part of a large community-based study, Jacoby et al. investigated the variables associated with the clinical course of epilepsy and the development of anxiety and depression symptoms in an unselected population of people who had a recent history of seizures or were receiving AEDs.[76] Epilepsy data were collected from the medical records of the treating primary physicians and information about psychosocial functioning was obtained with questionnaires mailed to identified subjects, 71% of whom returned the questionnaire. Fifty-seven percent of the sample had had at least 2-year seizure-free periods and 46% were in a remission of at least 2 years' duration. There was a clear relationship between *current seizure frequency* and levels of anxiety and depression.

Smith et al. reported a study of 100 patients with medically refractory partial seizures who completed a quality-of-life questionnaire including measures of physical (seizure severity and frequency), social, and psychological well-being (anxiety, depression, self-esteem, locus of control, and happiness).[160] Multivariate analysis demonstrated that individual psychological variables were best predicted by other psychological variables. However, when these were removed from analysis, seizure severity, *but not seizure frequency,* was the most significant predictor of anxiety and self-esteem.

Similar findings have been reported in children with epilepsy, though data have been obtained from tertiary centers and not from population-based studies. For example, in a study of 35 children and adolescents aged 9 to 18 years and 35 healthy controls, Oguz et al. investigated the relationship between epilepsy-related factors and the development of symptoms of anxiety and depression.[123] Both study and control groups were divided into two age groups (9 to 11 and 12 to 18 years) to exclude the effect of puberty on anxiety and depression scores. Children and adolescents with epilepsy displayed higher scores on the measures of depression symptoms and suicidal ideation, and the mean trait anxiety score was significantly higher in the 9- to 11-year age group of epileptic patients than the corresponding control group, while the mean state, trait anxiety, and depression scores were significantly higher in the 12- to 18-year age group of epileptic children than in the control group. Duration of the epilepsy, seizure frequency, and polytherapy were the epilepsy-related factors associated with the development of anxiety and depression symptoms. Furthermore, in a study carried out in 102 adolescents aged between 12 and 18 from Nigeria, Abiodoun et al. identified an anxiety disorder in 32 (31.37%) of the adolescents with the Diagnostic Interview Schedule for Children Version IV (DISC-IV) and a depressive disorder in 29 (28.4%).[3] As in the above-cited studies, uncontrolled seizures, polytherapy, and felt stigma were identified as predictors of anxiety and depressive disorders by regression analysis. Family factors such as parents' psychopathology and family stress also played a moderately significant role. On the other hand, Williams et al. did not find a pathogenic role of seizure frequency in the development of anxiety symptoms. In a study of 101 children and adolescents between the ages of 6 and 16 years, mild to moderate symptoms of anxiety were reported by 23% of the patients.[183] The presence of comorbid learning or behavioral difficulties, ethnicity, and polytherapy were identified as the variables associated with increased anxiety scores.

Type of Seizure Disorder

The development of anxiety and mood disorders has been associated with seizure disorders involving limbic structures, such as seizures of temporal and frontal lobe origin. In fact, ictal fear can be identified in seizures originating in the amygdala, hippocampus, and cingulate gyrus.[28] Yet, anxiety symptoms can also be identified in primary generalized epilepsy. For example, among a group of 42 patients with idiopathic generalized epilepsy in adulthood, Cutting et al. found an anxiety disorder in nine patients (21%), seven of whom had GAD and two OCD.[40]

Endogenous Changes of Anxiety in Epilepsy

While it is tempting to conclude that anxiety in epilepsy is a simple reaction to having experienced the distress associated with seizures and living with the “Damocles sword” of future seizure risk, compelling evidence in the biologic realm would argue for a much higher degree of complexity to this association. While our understanding of the mechanisms underlying anxiety disorder is still in its infancy, knowledge of areas of potential commonality between anxiety and seizures has laid the foundation for better diagnosis and treatment of this distressing comorbidity. The common pathogenic mechanisms that may be operant in the development of anxiety disorders and epilepsy include (a) neurotransmitter abnormalities and (b) structural and functional abnormalities in common neuroanatomic structures, particularly the amygdala, hippocampus, and cingulate gyrus.

Neurotransmitter Abnormalities

Several neurotransmitters and neuropeptides have been found to play important pathogenic mechanisms in the development of anxiety disorders, including γ-aminobutyric acid (GABA), NE, serotonin (5-hydroxytryptamine, 5HT), and some of the hormones and neuropeptides involved in the hypothalamic-pituitary axis, particularly CRH. Interestingly enough, these neurotransmitters also play a significant pathogenic role in mood disorders and epilepsy and may explain the high comorbidity of these three disorders.

γ-Aminobutyric Acid

One area of obvious neurochemical commonality involves the neurotransmitter GABA, which promotes inhibition of neuronal excitability by its effect upon chloride ion channels. The important role GABA plays in the pathogenesis of epilepsy is well known. For example, commonly utilized AEDs such as benzodiazepines, barbiturates, and tiagabine have anxiolytic properties through a potentiation and prolongation of GABA's synaptic inhibitory actions.[167] Barbiturates, for example, inhibit action potentials, neurotransmitter release, voltage-regulated calcium channels, and glutamate-mediated inhibitory synaptic activity.[134] By the same token, the effect of tiagabine and vigabatrin is mediated by an increase of GABA synaptic concentrations, through an inhibition of its reuptake or its metabolism, respectively. Some AEDs may indirectly enhance GABA through action upon sodium or calcium channels. For example, pregabalin, a pharmacologically active S-enantiomer of 3-aminomethyl-5-methyl-hexanoic acid, is a structural analog of GABA, although it is not active at GABA receptors, nor does it acutely alter GABA uptake or degradation. It binds with high affinity to the a^{54}–δ subunit protein of voltage-gated calcium channels in central nervous system (CNS) tissues and acts as a presynaptic modulator of the excessive release, in hyperexcited neurons, of various excitatory neurotransmitters. Binding of pregabalin to the a^{54}–δ subunit appears necessary for its demonstrable anxiolytic, analgesic, and anticonvulsant activities in animal models.[126]

The convulsant pentylenetetrazol (PTZ; a model for generalized seizures), which blocks $GABA_A$ receptor function, also promotes anxiety symptoms.[85] By the same token, anxiolytic effects of valproic acid identified in some animal models of anxiety are thought to be mediated through GABAergic processes as they can be reversed by the use of $GABA_A$ receptor antagonists.[159] Valproic acid has been reported to display antipanic efficacy and an anxiolytic effect in an open trial,[8] but no controlled studies have been carried out as of yet.

One theory posits that anxiety disorders may be due to defective neuroinhibitory processes, mediated in part through GABA, while abnormalities in the benzodiazepine receptors have also been suggested to play a pathogenic role in epilepsy.[29] The potential relationship between abnormalities in the benzodiazepine receptor system and anxiety disorder is suggested by the induction of panic symptoms in panic disorder patients, when the benzodiazepine antagonist flumazenil is administered.[121] It is further supported by the demonstration of widespread decreased binding of flumazenil to benzodiazepine receptors in panic disorder patients. Indeed, Malizia et al. compared fully quantitative, high-sensitivity positron emission tomography (PET) studies with flumazenil radiolabeled with carbon 11 between seven patients with panic disorder who had been off medication for at least 6 months and who had never abused alcohol and eight healthy controls.[108] Patients' PET studies displayed a global reduction in benzodiazepine site binding throughout the brain compared with controls. In addition, the areas with the largest regional decrease in binding (right orbitofrontal cortex and right insula) were areas thought to be essential in the central mediation of anxiety. The question is then raised whether down-regulation of these receptors is a consequence of exposure to stress or whether a pre-existing low level of benzodiazepine receptor density may be a genetic risk factor for the development of stress-related anxiety disorders.

Noradrenergic Abnormalities

There are also very important links between the noradrenergic system and anxiety, since fear activates neurons of the locus coeruleus and increases NE secretion in the locus coeruleus; limbic structures such as the amygdala, hippocampus, and hypothalamus; and the cerebral cortex. With sustained stress in the learned helplessness animal model, depletion in norepinephrine can be demonstrated.[67] Furthermore, agents such as the norepinephrine reuptake inhibitor reboxetine are effective in the treatment of PD.[178] In fact, chronic symptoms experienced by anxiety disorder patients, such as panic attacks, insomnia, startle, and autonomic hyperarousal, are an expression of increased noradrenergic activity.[47] These symptoms can be alleviated with drugs that decrease the firing of neurons in the locus coeruleus, such as benzodiazepines, alcohol, and opiates, while drugs that increase its firing (i.e., cocaine) worsen these symptoms.[47]

Disturbances in the noradrenergic system have been found in epilepsy as well. For example, in animal models of epilepsy, the pathogenic role played by NE is illustrated in studies of two strains of genetic epilepsy-prone rats (GEPR), GEPR-3 and GEPR-9, which are characterized by predisposition to sound-induced generalized tonic–clonic seizures[34,79,81] and, particularly in GEPR-9 s, a marked acceleration of kindling.[78] Both strains of rats have innate noradrenergic pre- and postsynaptic transmission deficits. Noradrenergic deficiencies in GEPRs appear to result from deficient arborization of neurons arising from the locus coeruleus,[33,146] coupled with excessive presynaptic suppression of NE release in the terminal fields and lack of postsynaptic compensatory up-regulation.[78,187] GEPR-9 rats have a more pronounced NE transmission deficit and, in turn, exhibit more severe seizures than GEPR-3 rats.[80]

Increments of either NE transmission can prevent seizure occurrence, while reduction will have the opposite effect.[78,111] For example, drugs that interfere with the release or synthesis of NE exacerbate seizures in the GEPRs, including the NE storage vesicle inactivators reserpine or tetrabenazine and the NE false transmitter *α*-methyl-m-tryosine.

Another expression of the pathogenic role played by NE in epilepsy can be appreciated in the NE-mediated antiepileptic effect of the vagal nerve stimulator (VNS) in part through activation of the locus coeruleus.[117] Furthermore, a decrease in noradrenergic neurons reduces antiepileptic effects against electroshock or pentylenetetrazol-induced seizures.[25]

Serotonergic Abnormalities

An important pathogenic role has been identified in anxiety disorders and epilepsy. Serotonin's role in anxiety

disorders is supported by the observation of potent anxiolytic effects of tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs), which enhance 5-HT synaptic concentrations. Serotonin's anxiolytic effects may relate to an inhibition of noradrenergic activation through raphe nuclei projections to the locus coeruleus, periaqueductal gray inhibition of the freeze/flight responses, hypothalamic inhibition of corticotropin-releasing factor, and the amygdala inhibiting excitatory pathways from cortex and thalamus. PET studies with the selective 5-HT_{1A} radioligand[183] trans-4-fluoro-N-2-(4-(2-methoxyphenyl)piperazin-1-yl)ethyl)-N-(2-pyridyl)cyclohexanecarboxamide (FCWAY) permitting in vivo assessment of central 5-HT_{1A} binding have been instrumental in identifying abnormal 5-HT function in PD in a study of 16 unmedicated symptomatic outpatients with PD (seven of whom also suffered from a mood disorder of mild severity) and 15 matched healthy controls.[118] Neumeister et al. found lower distribution volume in the anterior cingulate, posterior cingulate, and raphe in patients compared to controls, indicating a reduction of 5-HT_{1A} receptors in these structures. Not surprisingly, agents that mediate their therapeutic effect through an increase of serotonergic activity in the brain such as TCAs and SSRIs have become the first line of therapy of PD and other anxiety disorders.[64]

The role of 5-HT in epilepsy has also been demonstrated in the GEPR animal model of epilepsy. The brain of this animal has deficits in serotonergic arborization and decreased postsynaptic 5-HT_{1A} receptor density in hippocampus. Conversely, drugs that enhance serotonergic transmission, such as the SSRI sertraline, resulted in a dose-dependent seizure frequency reduction in the GEPR that correlates to the extracellular thalamic serotonergic thalamic concentration.[186] The 5-HT precursor 5-hydroxy-L-tryptophan has anticonvulsant effects in GEPRs when combined with the SSRI fluoxetine.[185] SSRIs and monoamine oxidase inhibitors (MAOIs) can exert anticonvulsant effects in experimental animals, such as mice and baboons, that are genetically prone to epilepsy,[104,111] as well as nongenetically prone cats,[133] rabbits,[130] and rhesus monkeys.[189] In addition, an antiepileptic effect of 5-HT_{1A} receptors has been correlated to a membrane hyperpolarizing response, which is associated with increased potassium conductance in hippocampal kindled seizures in cats and in intrahippocampal kainic acid–induced seizures in freely moving rats.[12,124]

As mentioned, AEDs with established psychotropic effects (carbamazepine, valproic acid, and lamotrigine) can cause an increase in 5-HT.[41,42,43,162,182,188] In GEPRs, the anticonvulsant protection of carbamazepine can be blocked with 5-HT–depleting drugs.[111,116,187]

Dysfunction of the Hypothalamic-Pituitary-Adrenal Axis in Anxiety Disorders and Epilepsy

As mentioned in our introduction, the hypothalamic-pituitary axis (HPA) plays a fundamental pathogenic role in anxiety, mood disorders, and epilepsy.[143] Neurons in the paraventricular nucleus of the hypothalamus secrete CRH, which stimulates the secretion of ACTH from the pituitary gland. ACTH, in turn, releases glucocorticoids from the adrenal gland, which have an impact on various brain regions, and once in the circulation they exert an inhibitory effect on the HPA axis.[137] Under normal conditions, the hippocampus and amygdala play a role in the inhibition of the HPA axis as well.[70] High levels of CRH and glucocorticoids occur in acute and chronic stress as well as in anxiety disorders, particularly PTSD, depressive disorders, and epilepsy.[177] Intraventricular administration of CRH can mimic stress-induced phenomena. These include an increase in plasma norepinephrine, epinephrine, and glucose concentrations as well as an increase in heart rate and arterial blood pressure, large bowel transit, increase of locomotor activity in familiar environment, increased acoustic startle, grooming, and shock-induced freezing. These phenomena are not reversible by adrenalectomy or hypophysectomy but can be achieved with the use of CRH antagonists, which indicate a “direct” effect of CRH on the brain. Of note, CRH receptors are found in large numbers in the amygdala, which activate fear-related behaviors.[30] CRH receptors also are widely distributed in the cortex, and their function is believed to reduce reward expectation in animal models. Furthermore, CRH inhibits neurovegetative functions involving sexual activity and food intake as well as endocrine functions associated with reproduction and growth. Several studies have shown that early life stressors result in long-term increase of CRH activity in the CNS.

By the same token, an activation of the HPA axis demonstrated by an increase in the secretion of CRH, ACTH, and cortisol has been found in humans postictally following generalized tonic–clonic and complex partial seizures, as well as interictally. Furthermore, Wang et al. found significantly higher brain concentrations of CRH in postmortem brains from children with epilepsy compared to controls.[179] A direct pathogenic role of CRH was suggested by Baram et al. in studies of infants with infantile spasms who were found to have low cerebrospinal fluid ACTH and cortisol, which reflects a high brain CRH.[10]

Abnormalities of Neuroanatomic Structures

Similarities in the nature of symptoms of panic or other anxiety disorders and symptoms of some seizure types suggest that similar brain structures and pathways are involved in both conditions. For example, the intravenous administration of procaine in healthy volunteers produced diverse emotional symptoms of euphoria, anxiety, depression, fear, and derealization, all of which may be encountered in seizures, especially those involving limbic structures. PET scanning during this procedure reveals increased metabolic activity in anterior limbic and paralimbic areas.[157]

Abundant evidence demonstrates the central role of the amygdala in the fear conditioning model. For example, administering bilateral lesions to the lateral nucleus of the amygdala of the rat attenuates fear-induced freezing response to a conditioned auditory fear stimulus.[103] Bilateral lesions of the central nucleus of the rabbit amygdala result in loss of the fear-induced bradycardia response to a conditioned auditory fear stimulus.[94] Lesions of the central nucleus of the rat eliminate fear-potentiated startle.[73]

The amygdala is primarily responsible for mediating fear (“emotional reaction to aversive events”) and anxiety (“the apprehension of an imminent aversive event”). The central nucleus is particularly crucial for this function. PET scan demonstrates increased perfusion to the amygdala when an individual is shown images of fearful as opposed to happy faces. Functional magnetic resonance imaging (MRI) can be used to show how individuals with social phobia exhibit increased amygdala activation in response to exposure to the stimulus of fearful faces, compared to healthy controls.[17]

The amygdala can be conceptually divided into three main groups of nuclei: The medial nucleus receives olfactory information and transmits excitatory signals to the hypothalamus. The lateral/basolateral nucleus receives diverse sensory information as well as information related to memories from the hippocampus. The central nucleus receives information from the lateral and basolateral nucleus of the amygdala and transmits excitatory signals to diverse regions that relate to arousal (e. g., hypothalamus, midbrain structures, pons, and medulla).[21,132]

There are numerous afferent and efferent connections to the basolateral nuclei. These connections may have important implications for response to fearful stimuli. Connections to the orbital frontal region play a role in the choice of behavioral responses to a fearful situation, providing an “emotional coloring” of events. Output to the dorsal and ventral striatum (structures believed to be integral to reward and motivation) is important for avoidance behavior and habitual behaviors. Connections to the central nucleus and/or lateral bed nucleus of the stria terminalis (BNST) lead to the "autonomic and somatic" manifestations of fear, and the individual's attention to specific stimuli.[30]

Efferent connections from the central nucleus of the amygdala may translate into many of the symptoms and signs commonly associated with anxiety. The role of the central nucleus in fear is further validated by the demonstration in animal studies of fearlike responses (freezing, shivering, and autonomic nervous system activation such as heart rate elevation and increase in blood pressure) in response to stimulation of this region.[30,60] This suggests that abnormal electrical activity, either experimental or spontaneous epileptiform in selective regions of the medial temporal lobe such as the amygdala, can produce intense sudden fear, reminiscent of the symptoms of panic disorder.[141]

Alternatively, lesions of amygdala nuclei reduce fearful behaviors. In a classic experiment in which the central nucleus is lesioned, the rat recurrently fails to react appropriately to the fearful stimulus of the ominous cat. In the face of danger, the rat no longer perceives sensory stimuli associated with the cat to be fearful and the normally expected autonomic nervous system activation is no longer produced.[18,86]

"Hyperexcitability" of fear circuits including the amygdala has been posited by some as a potential etiology for anxiety disorder. One might speculate then that seizures emanating from or involving the amygdala (as is commonly demonstrated on intracranial recordings in epilepsy surgery candidates) and its connections promote such a hyperexcitability, leading to heightened anxiety.[181]

Anxiety and the Hippocampus

Disturbances of structures other than the amygdala, such as the hippocampus, have been implicated in anxiety disorder.[129] High serum concentrations of corticosteroids, resulting from excessive CRH secretion, have been associated with damage to the hippocampal formation. Chronic exposure to high glucocorticoid serum levels has been blamed for hippocampal atrophy in patients with PTSD and major depressive disorders. Furthermore, in studies with rats and monkeys, prolonged increased concentrations of glucocorticoids have been found to damage hippocampal neurons, particularly CA3 pyramidal neurons, possibly by reduction of dendritic branching and loss of dendritic spines that are included in glutamatergic synaptic inputs.[147,153,158] Atrophy of CA3 pyramidal cells has been found following stress-induced secretion of glutamate in the hippocampus, which in turn resulted in high intracellular concentration of calcium, thus increasing the vulnerability of

P.2148

these cells and in that manner potentially increasing the risk of seizures; this effect was attenuated by *N*-methyl-D-aspartate (NMDA) antagonists. The deleterious effects of chronic glucocorticoid exposure was found to lead initially to a transient and reversible atrophy of the CA3 dendritic tree and an increased vulnerability to a variety of insults and finally to result in cell death under extreme and prolonged conditions.[147,148,153]

The interplay between the impact of high glucocorticoid levels and glutamate secretion in the hippocampus is of significant relevance in our attempts to understand the relationship between anxiety disorders such as PTSD, major depressive disorders, and epilepsy.[23,24,148,190] The role of excitatory neurotransmitters and the glutamate receptor NMDA site has been well established in epilepsy. Indeed, NMDA antagonists have been shown to have antiepileptogenic properties in the "kindling" animal model and to also display antiepileptic properties.[155]

Hypercortisolemia resulting from chronic stress or a depressive disorder has also been found to interfere with the development of new granule cell neurons in the adult hippocampal dentate gyrus. This effect is thought to be mediated by a decrease in the secretion of brain-derived neurotrophic factor (BDNF) in the dentate gyrus, pyramidal cell layer of hippocampus, amygdala. and neocortex.[161] These changes can be overturned with chronic (but not acute) antidepressant therapy, as chronic administration of antidepressant drugs increase BDNF expression and also prevent a stress-induced decrease in BDNF levels.[31,119] There is also evidence that antidepressant drugs can increase hippocampal BDNF levels in humans.[31,119] These data indicate that antidepressant-induced up-regulation of BDNF can hypothetically repair damage to hippocampal neurons and protect vulnerable neurons from additional damage. Recent studies have suggested, nonetheless, that BDNF increases cell survival by inhibition of cell cascades.

On the other hand, other studies suggest that it is those individuals with pre-existing hippocampal atrophy who are predisposed to develop anxiety disorders such as PTSD.[57,190] So similar to the controversial debate whether seizures induce or are a consequence of hippocampal atrophy, the directionality of hippocampal abnormalities and anxiety symptoms remains unclear.

Iatrogenic Mechanisms

Pharmacotherapy

Iatrogenic effects associated with AEDs can be caused by two mechanisms: (a) the introduction of AEDs with anxiogenic properties and (b) the discontinuation (often abruptly) of AEDs with positive psychotropic properties, primarily among patients with an underlying mood and/or anxiety disorder that had been "masked" or "controlled" by the discontinued AED.[92] The AEDs with known anxiolytic properties include the barbiturates, benzodiazepines, tiagabine, valproic acid, gabapentin, and pregabalin.[15,110]

The AEDs with anxiogenic properties include ethosuximide, felbamate, levetiracetam, phenytoin, topiramate, zonisamide, and vigabatrin. Paradoxically, these AEDs have a GABAergic effect, particularly and to a lesser degree topiramate, zonisamide, and felbamate.[15,110]

Abrupt discontinuation of benzodiazepines and barbiturates is known to cause severe "withdrawal" anxiety symptoms including severe panic attacks.[14] However, abrupt discontinuation of AEDs with positive psychotropic properties can also cause anxiety.[97] Such symptoms are often observed in the course of V-EEG monitoring studies in which AEDs are stopped abruptly to facilitate the occurrence of seizures.

Epilepsy Surgery

Postsurgical development of anxiety symptoms following anterotemporal lobectomy has been reported by several investigators. Fortunately, these symptoms are transitory and occur during the first 3 to 6 months after surgery. For example, in a study of 60 consecutive patients who underwent a temporal lobectomy for intractable epilepsy, Ring et al. found that half of those with no psychopathology preoperatively had developed symptoms of anxiety or depression at 6 weeks after surgery and 45% of all patients were noted to have increased emotional lability.[140] By 3 months after surgery emotional lability and anxiety symptoms had diminished, whereas depressive states tended to persist. Patients with a left hemispheric focus were more likely to experience persisting anxiety. Reuber et al. evaluated 76 patients with TLE for symptoms of depression and anxiety before and 12 months after surgery.[136] At baseline, depression and anxiety scores were high in patients with TLE, while after surgery, depression *but not anxiety* scores were significantly lower than at baseline.

Postsurgical OCD has also been reported. Chemali et al. described the case of a young woman with a simple motor tic disorder who after right temporal lobectomy for medically intractable epilepsy developed Tourette syndrome with complex motor and vocal tics, severe obsessive-compulsive disorder, and paranoia.[30a] Kulaksizoglu et al. published a case series of five patients with TLE with obsessive personality traits before surgery who underwent an anterotemporal lobectomy.[101] Within the first 2 postsurgical months two of these patients fulfilled OCD diagnostic criteria. These two patients did not differ from the other three patients with respect to age, age of onset of epilepsy, seizure types, and seizure frequency. All patients stopped having seizures postoperatively, but the OCD patients had worse quality of life postoperatively than preoperatively.

Treatment

The treatment options of anxiety disorders include pharmacotherapy, a variety of psychotherapeutic modalities (i.e., cognitive behavior therapy, desensitization behavioral therapy, supportive and psychodynamically oriented psychotherapies) and a combination of psychotherapy and pharmacotherapy. Before addressing the specific treatment strategies, it is important to review these basic principles:

1. Did the symptoms of the anxiety disorder appear following the introduction or increase in the dose of an AED known to cause psychiatric adverse events?
2. Did the anxiety symptoms follow the discontinuation of an AED with anxiolytic properties? In this case, the psychiatric symptoms may be the expression of recurrence of an anxiety disorder that had remitted with the AED that was discontinued.
3. Did the symptoms of the anxiety disorder occur after the introduction of an enzyme-inducing AED (carbamazepine, phenytoin, phenobarbital, primidone, high-dose topiramate, or oxcarbazepine) in a patient who was already taking a psychotropic drug for a previously recognized anxiety disorder? In such case, the symptom recurrence may have resulted from a pharmacokinetic interaction between the AED and the psychotropic drug on board that caused a drop in the psychotropic drug's serum concentration. Accordingly, a readjustment in the dose of the psychotropic drug may be sufficient to induce symptom remission.
4. Are the psychiatric symptoms temporally related to the seizure occurrence; that is, do they precede (pre-ictal), follow (postictal), or precede and follow; are they the expression of an ictal event; or do they occur interictally

with a peri-ictal exacerbation in severity? In the case of pre- or postictal without interictal symptoms, pharmacotherapy may fail to yield any benefit. Postictal breakthrough symptoms may occur in patients whose interictal symptoms had remitted with pharmacotherapy.
5. Is there a risk factor, other than epilepsy, for the development of the anxiety disorder, particularly a family history in first-degree relatives?
6. Is the anxiety disorder occurring in isolation or associated with other anxiety disorders (i.e., GAD and PD) and/or with a comorbid mood disorder?

Pharmacotherapy

Pharmacologic treatment of anxiety disorders in PWE follows the same drugs and dosages used in the treatment of primary anxiety disorders. Whether the anxiety disorder's response to pharmacotherapy differs between patients with and without epilepsy is yet to be established. Indeed, clinicians assume that primary anxiety disorders and those affecting patients with epilepsy are identical and hence should respond in the same manner, though such an assumption has yet to be proven. In short, pharmacotherapy of anxiety disorders in PWE remains empirical. We will therefore base our review on data from studies conducted in patients with primary anxiety disorders.

Pharmacologic treatment of anxiety disorders depends on the specific type of disorder. Five classes of drugs are typically used: (a) antidepressants, (b) benzodiazepines, (c) AEDs, (d) noradrenergic agents, and (e) buspirone. In the next section we will discuss the use of these drugs in the treatment of GAD, PD, social phobia, and OCD.

Antidepressant Drugs

Today, antidepressants have become the first line of therapy in the management of the four anxiety disorders under consideration. In patients with epilepsy, clinicians have often been reluctant to use antidepressant drugs for fear of causing breakthrough seizures in seizure-free patients or worsening of seizures in patients with refractory epilepsy.[175] Data have shown, however, that with the exception of four agents (amoxapine, maprotiline, clomipramine, and bupropion), TCAs, SSRIs, and MAOIs can be safely used in PWE with the following caveats: If TCAs are prescribed, patients need to be started at a low dose and increments must be done in a stepwise manner to avoid toxic serum concentrations.[38,98,175] In fact, animal models of epilepsy have suggested that serotonergic and noradrenergic properties of antidepressant drugs have anticonvulsant properties.[171] A study by Khan et al. supported these observations; these investigators compared the incidence of seizures in depressed patients who were randomized to placebo or the SSRIs citalopram, escitalopram, fluoxetine, and fluvoxamine as well as the α_2 antagonist mirtazapine in Food and Drug Administration (FDA) regulatory studies. Patients randomized to placebo had a significant-higher frequency of seizures.[77]

Little data are available on the safety of the newer classes of antidepressants, such as the serotonin-noradrenaline reuptake inhibitors (SNRIs) venlafaxine (Effexor) and duloxetine (Cymbalta) and the α_2 antagonist mirtazapine (Remeron). Venlafaxine has been prescribed in more than 100 adults with pharmacoresistant epilepsy at the Rush Epilepsy Center without any evidence of worsening of seizure frequency or severity (unpublished data). A detailed discussion of the safety of antidepressant drugs in patients with epilepsy can be found in Chapter 205 and on the use of psychotropic drugs in epilepsy in Chapters 204 and 214. From a safety standpoint, other than seizure-related concerns, the antidepressant drugs of the SSRI family are considered to be the drugs of choice.

The most frequent adverse effects of SSRIs include gastrointestinal and sexual disturbances.[173] The latter may be of greater significance in PWE, as these patients have a significantly higher prevalence of sexual disorders resulting from an iatrogenic effect of AEDs and/or as a direct impact of the seizure disorder. The SSRI-related sexual adverse effects include decreased libido, anorgasmia, impotence, disturbances in ejaculation, and dyspareunia and have been reported in about 20% to 30% of patients.[173] Citalopram and its s-enantiomer escitalopram have the lowest incidence of sexual adverse events. Of note, mirtazapine also has a lower incidence of sexual adverse effects. Whether the adverse effects mediated by these drugs worsen already existing sexual disturbances in PWE is yet to be investigated. Tolerance may develop over time, and at times lowering of the dose or switching to another SSRI may improve these side effects.

By the same token, some SSRIs can cause weight gain (i.e., paroxetine, sertraline) that could potentially aggravate a weight gain problem triggered by AEDs like valproic acid, gabapentin, pregabalin, and carbamazepine. On the other hand, fluoxetine can cause weight loss in the first 3 months of therapy, but patients regain the weight lost thereafter.[173]

Pharmacokinetic interactions between antidepressants and AEDs have to be considered carefully in PWE, in particular: (a) the drop in serum concentration of antidepressants following the addition of enzyme-inducing AEDs, such as carbamazepine, phenytoin, phenobarbital, primidone, topiramate, and oxcarbazepine at high doses; and (b) the decrease in the clearance of certain AEDs with some of the SSRIs and SNRIs mediated by the inhibition of some of the hepatic cytochrome isoenzymes, which may lead to an increase in the serum concentrations of AEDs that are substrates for these isoenzymes.[52,65] For example, venlafaxine and paroxetine have the potential to inhibit hepatic cytochrome isoenzymes 2C19 and 3A4, which may lead to an increase in the serum concentrations of carbamazepine, tiagabine, and zonisamide via a moderate inhibition of 3A4. Venlafaxine is minimally inhibiting of 3A4 and of 2C19 as well, which could affect phenytoin and barbiturate levels. Likewise, fluoxetine is an inhibitor of 3A4 and 2C9/10, which can result in an increase in the serum concentrations of carbamazepine and phenytoin, while sertraline is a mild inhibitor of 3A4, leading to a potential increase in carbamazepine blood levels. On the other hand, citalopram and its enantiomer, escitalopram, have no interactions with the isoenzyme systems involved in antiseizure medicine metabolism.[176]

Other Precautions on the Use of Antidepressants

1. Patients with anxiety disorders may be extremely sensitive to adverse effects of antidepressant drugs. Accordingly, these drugs need to be started at low doses.

2. The high comorbidity between anxiety and mood disorders and the efficacy of antidepressants in anxiety disorders have made these agents an attractive option that would result in the remission of depressive and anxiety disorders with the use of a single agent. However, in the case of mood disorders, the use of antidepressants is indicated in major depressive episodes that are an expression of major depressive disorders, in dysthymic disorder, or in double depression. On the other hand, the use of antidepressants is not recommended in patients with bipolar disorders, lest they are administered in the presence of a mood-stabilizing agent, since they can worsen the course of bipolar disorders, facilitating the development of rapid cycling bipolar illness (defined as more than four manic and or major depressive episodes in a 12-month period), in which case symptom remission is less likely.[72] Accordingly, prior to the start of any antidepressant drug, it is necessary to take a careful history of manic or hypomanic episode and a family

history of bipolar illness. Furthermore, a suspicion of potential bipolar illness increases in patients with a first major depressive episode before the age of 20. Indeed, Strober and Carlson

followed 60 adolescents hospitalized for major depressive episodes and followed them for a 3- to 4-year period. Twenty percent of these patients went on to develop bipolar illness.[170]

3. Discontinuation of TCAs, SSRIs, and SNRIs has to be carried out gradually through a tapering schedule to avert the development of discontinuation emergent symptoms.[152] These include somatic symptoms, such as nausea, vomiting, tremors, diaphoresis, ataxia, movement disorders, and sleep disturbances. SSRIs and SNRIs with the shorter half-lives are associated with a higher risk of developing these symptoms.

Efficacy of Antidepressants in Anxiety Disorders

All of the SSRIs have shown efficacy in GAD, PD, and OCD.[166] Given the lack of pharmacokinetic interactions with AEDs and better tolerance, we recommend the use of escitalopram or citalopram first and sertraline as an alternative.[16,45,115,142] In the case of GAD and PD, absence of efficacy with an SSRI should be followed by a trial with the SNRI venlafaxine.[46,56,139] The anxiolytic effect of these drugs may not be apparent until the first 4 to 6 weeks after the start of therapy, for which a temporary use of a benzodiazepine is often an option.

Among the older antidepressant drugs, the TCA imipramine is the agent of choice in PD with a comparable efficacy to that of SSRIs, and has also been found to be as effective as benzodiazepines in the treatment of GAD.[151] MAOIs have been also found to be effective in the treatment of PD. Their use in PWE has been relegated to third place, however.

The SSRIs are the drugs of choice in the treatment of OCD, and all have been found to show comparable efficacy. In contrast to the treatment of GAD and PD, a therapeutic effect may not be noticed for 6 to 12 weeks, however.

Benzodiazepines

Benzodiazepines occupied the first line of treatment of anxiety disorders before the antidepressants. Their efficacy has been demonstrated in GAD, PD, and anxiety secondary to life stressors or medical conditions.[39,51,122,138] The risk of physical dependence and development of tolerance after have limited their use to short-term trials. Typically, they are used in GAD and PD at the start of pharmacotherapy with antidepressants until the latter agents' therapeutic effect takes over. Alprazolam is the benzodiazepine preferred for PD, while clonazepam is used in GAD.

Noradrenergic Anxiolytics and Beta-Blockers

The “overactivity” of noradrenergic neurons underlying anxiety states and evidenced by tachycardia, tremor, and excessive sweating has been the basis for the consideration of drugs that limit the secretion of norepinephrine through stimulation of a_2 autoreceptors and for which the a_2 agonist clonidine has been used. While it is effective in blocking the noradrenergic aspects of anxiety, it is not as effective in improving its subjective and emotional aspects. The use of beta-blockers can achieve this goal in a more effective manner, and they are often used in the treatment of social phobia.

Antiepileptic Drugs

In addition to the benzodiazepines, tiagabine,[144,154,164] gabapentin,[165] pregabalin,[126] and valproic acid have been used by psychiatrists for anxiety disorders.[8,159] Tiagabine and pregabalin have been found to be effective in the treatment of GAD and gabapentin in social phobia in double-blind, placebo-controlled studies. Valproic acid, on the other hand, has been found to cause symptom remission in PD in a small study of 13 patients whose panic attacks failed to respond to antidepressant agents. These findings need to be confirmed in double-blind, controlled studies.[8] In PWE who suffer from seizures of frontal lobe origin, tiagabine should be used with caution as it can cause absence stupor.

Other Drugs

Buspirone is a 5-HT_{1A} agonist agent that has been found to be effective for the treatment of GAD.[127] It is favored over the use of benzodiazepines because it does not cause drug dependence or withdrawal with long-term use and there is a lack of any significant pharmacokinetic interactions with other agents. Its onset of efficacy is delayed by several weeks, like that of antidepressant drugs.

Psychotherapies

Various types of psychotherapy have been used for a very long time for the treatment of anxiety disorders. In the last decade, however, cognitive behavior therapy (CBT) has gained much favor among health professionals as it has been recognized as an effective treatment for anxiety and depressive disorders. This therapy involves dismantling the patient's false or exaggerated beliefs that lead to anxiety and interfere with daily functioning. This alteration in cognitive outlook is then coupled with gradual desensitization to the anxiety-provoking stimuli, in order to improve the patient's ability to cope with anxiety. For example, in a pilot study by Goldstein et al., CBT was undertaken with six adults with chronic, poorly controlled seizures and coexisting psychiatric and/or psychosocial difficulties.[63] After 12 sessions of CBT from an experienced CBT nurse specialist, participants rated their initial epilepsy-related problem as having less impact on their daily lives, and at 1-month follow-up reported less deleterious impact on everyday life in terms of their psychological difficulties. In addition, participants demonstrated significant improvements in terms of their self-rated work and social adjustment and in their decreased use of escape-avoidance coping strategies.

The efficacy of CBT as monotherapy in GAD has been shown in a recent study of 36 patients randomized to CBT and 36 to no therapy for a 25-week period. Significant decreases in anxiety were found in the treatment group compared to the untreated group using both clinician-rated and subject-rated anxiety scales.[107] The efficacy of CBT has been found to be comparable to that of pharmacotherapy in the treatment of primary mood and anxiety disorders by several investigators, and there is a consensus that a combination of CBT and pharmacotherapy yields better results than either treatment modality given alone.[37,125,145] Given its proven efficacy in patients with primary psychiatric disorders, CBT should be tested in large studies with PWE. In theory, given its efficacy, short duration, and the fact that it can be administered by health professionals from multiple disciplines (i.e., psychologists, nurses and nurse practitioners, and social workers), CBT can be expected to play a major role in the treatment of anxiety and mood disorders in all epilepsy clinics. Furthermore, it may help alleviate the pervasive problem caused by the limited access to psychiatrists.

Therapeutic Effect of Epilepsy Surgery

While no one advocates the use of epilepsy surgery for the treatment of anxiety disorders in PWE, various studies have found a marked improvement in anxiety disorders/symptoms following epilepsy surgery, particularly temporal lobectomy. Such improvements have been associated with the achievement of seizure freedom. For example, Devinsky et al. compared the rate of anxiety disorders before an anterotemporal lobectomy (ATL) in 332 patients and 278 patients 2 years postsurgically and found a drop from 17.5% to 10.4%.[48] Furthermore, epilepsy surgery has resulted in remission of OCD in several cases, as indicated above.[11,66,88]

Summary and Conclusions

Anxiety disorders are frequent psychiatric comorbidities in PWE and together with mood disorders account to a great degree for the poor quality of life of these patients. Their early

P.2151

recognition and effective treatment should be part of the overall management of PWE. We have just begun to identify their multifactorial causes and multifaceted clinical expressions, but much research is needed to better understand their pathogenic mechanisms, identify the safest and most effective therapies, and establish the differences (if any) between anxiety disorders in epilepsy and primary anxiety disorders, as well as any difference in response to treatment.

Chapter 207

Psychogenic Nonepileptic Seizures and Epilepsy

W. Curt LaFrance Jr.

Andres M. Kanner

Tim Betts

Introduction

Psychogenic nonepileptic seizures (PNES) are similar to epileptic seizures (ES) in that they present as time-limited, paroxysmal alterations in behavior, sensation, motoric activity, autonomic signs, and/or consciousness. They differ from ES, however, in that they lack electroencephalographic ictal findings on EEG during the ictus. Treating the two disorders individually can present numerous challenges; the issues are multiplied in the 10% to 30% of patients with PNES who have comorbid ES. Much of the material on the diagnosis and treatment of patients with PNES is covered extensively in Chapter 282. In this chapter, we describe the epidemiology, diagnosis, and treatment of patients with mixed PNES/ES.

How frequently is it a problem? Epidemiologic Considerations

Medical writings from the 19th century describe how to differentiate ES from PNES (then known as hystero-epilepsy). There is a great deal of interest in and controversy about whether people with PNES have an increased incidence of coexisting or previous epilepsy. Of the 1% of the U. S. population diagnosed with epilepsy, 5% to 20% have PNES.[29] It is estimated that 10% of those with PNES have mixed ES/PNES,[54] and estimates for the coexistence of ES and PNES vary from less than 10% to more than 40%.[69] The incidence of PNES has been estimated to be 3.03 per 100,000,[79] and the prevalence of PNES is estimated to be up to 33 per 100,000.[5] Patients with PNES are usually women (~80%) and are between 15 to 35 years old (~80%),[76] although children and the elderly can develop PNES. It is estimated that up to 50% of patients admitted to an intensive care unit from the emergency department in status epilepticus in fact have pseudostatus, as one manifestation of PNES.[72]

The literature on comorbid ES/PNES is confusing because different populations of patients have been studied by different investigators with diverse methodologies and because of the uncertainty about the diagnosis of PNES. In an attempt to clarify the available data, the following three questions must be addressed:

1. In a population of people with established epilepsy in whom the primary diagnosis is clear, how many might also have PNES?
2. In a population of people with PNES in whom the diagnosis is clear, how many have previously had a history of epilepsy, and could some of their seizures still be of epileptic origin so that, if anticonvulsant medication is withdrawn, epilepsy would re-emerge?
3. How often is a “misdiagnosis” of PNES made in some of the seizures of patients with an established diagnosis of epilepsy?

The following sections attempt to answer these questions.

How Often Does PNES Occur in Patients with an Established Diagnosis

of Epilepsy?

The answer to this question is not known. If the cause of a particular patient's seizures is unclear, is it possible that two different types of seizure are present, one epileptic, the other not? The literature suggests that, in the assessment of a patient with an unknown attack disorder that has two different presentations, 5% to 30% of the time both with epilepsy and psychogenic PNES may be present.[69] The prevalence rates of concurrent ES and PNES may vary from one study to another according to whether a diagnosis of concurrent epilepsy was based on the capturing of actual seizures or on the recording of interictal epileptiform discharges only. For example, Devinsky et al. identified 20 patients with ES among a group of 99 PNES patients.[21] In contrast, in a study of 1,590 patients who underwent a video-electroencephalographic (V-EEG) study, Martin et al. found 514 (32.3%) diagnosed with PNES, of whom 29 (5.3%) were found to have both PNES and epilepsy.[55] Lesser et al. concluded that PNES and concurrent epilepsy occurred in about 10% of patients with PNES.[54] Using stringent criteria (as opposed to higher estimates in the past that based abnormalities—including slowing on EEG—as ictal evidence), Benbadis et al. identified three patients with interictal epileptiform activity among 32 patients (9.4%) with PNES.[4] These investigators did not record ES so it is not clear whether the seizure disorder was concurrent or the seizures had remitted with pharmacotherapy.

Studying the surgical population, Henry and Drury conducted a V-EEG in 145 patients who had temporal interictal EEG spikes, and they reported ictal semiology characteristic of temporal lobe seizures for presurgical evaluation of medically refractory seizures. PNES were unexpectedly identified in 12 (8%) of these patients.[37] A low prevalence was reported even in patient populations at greater risk. For example, Lelliott et al. found that, over a 5-year period, 7% of admissions to an epilepsy unit in a psychiatric hospital had PNES and concurrent epilepsy.[53]

An exception must be made among patients with cognitive developmental delay. Indeed, these are patients with epilepsy who may have found that their seizure activity can be reinforced or rewarded (i.e., having a seizure allows them to get out of unpleasant situations at school or workshop). As a result, they “learn to precipitate their epileptic seizures” at times when they try to avoid uncomfortable situations. These patients, therefore, are found to have higher prevalence rates of PNES and concurrent ES. For example, Neil and Alvarez

evaluated 124 mentally retarded persons with behaviors suggestive of epilepsy.[57] Patients were monitored using an eight-channel radio-telemetered V-EEG recording system. Twenty patients (16%) were found to have only ES, 50 (40.5%) to have PNES, 11 to have both epileptic and PNES (9%), and 43 were classified as inconclusive. Among the patients with only PNES 15 had abnormal EEGs and four (37%) had epileptiform EEGs. Thus, in this study, among the 61 patients with PNES, 24.5% had a concurrent or past seizure disorder.

How Often Does PNES Develop in Patients with Prior History of Epileptic Seizures?

As for the previous question, no clear answer is obtained from the available literature. For example, in some studies it is also sometimes unclear, when the prevalence of the two conditions is compared, whether the investigator is referring to patients with PNES and concurrent ES or merely a history of past epilepsy. It is likely, as Ramsey et al. have concluded,[69] that if the history is one of past as opposed to present epilepsy, the proportion of patients with both epilepsy and nonepilepsy is likely to be higher, particularly in patients with cognitive developmental delay.[57]

A review of the literature[8,69] and the clinical studies[42,47,71] suggest that 10% to 40% of patients who appear to have established PNES also have a past history of ES. Sometimes the question can only be answered by withdrawing antiepileptic drugs (AEDs) in those patients whose interictal recordings reveal epileptiform activity or in whom a history of paroxysmal events with clinical manifestations is highly suggestive of ES (also see the next section). If epilepsy re-emerges upon discontinuation of AEDs, the possibility exists of a patient who has a seizure disorder that remitted with the use of AEDs, and who, at some point, went on to develop PNES. On the other hand, failure to record an ES upon discontinuation of AEDs does not rule out a seizure disorder that remitted with AEDs, above all in the presence of epileptiform activity in interictal recordings.

One example of patients with both PNES and a past history of epilepsy is found in those patients who have had successful temporal lobectomies and then went on to develop PNES, presumably because of an inability to adjust to a seizure-free life. Fortunately, this is not a common occurrence. In a study of 166 consecutive patients who underwent epilepsy surgery, Parra et al. found three patients (2%) who experienced postsurgical de novo PNES documented by V-EEG.[62] The interval between the date of surgery and the development of the symptoms was variable (8–47 months range). Two of the three patients had become seizure free after surgery, and one had significant improvement of her seizures. The clinical phenomena of PNES differed from those seen for the ES preceding surgery. The diagnosis of PNES had not been suspected before the diagnostic V-EEG. Following the diagnosis of PNES, spells stopped in two patients and recurred rarely in one. Davies et al. found de novo postsurgical PNES in eight (3.5%) of 228 patients who underwent epilepsy surgery.[14] PNES occurred between 6 weeks to 6 years (mean, 23 months) after surgery. Six had undergone a resection, and two had complete callosotomy. There was a significant excess of postoperative interictal dysphoric disorder (IDD) and operative complications (bone flap infections) in the PNES group. Ney et al. identified five patients (5%) with PNES among a group of 96 consecutive patients who underwent epilepsy surgery.[58] Two patients experienced operative complications. Compared with the surgical cohort, patients had a higher frequency of preoperative psychopathologic conditions, lower mean FSIQ, and a greater occurrence of operative complications. In a recent study completed at the Rush Epilepsy Center, Kanner et al. found that seven of 94 patients (7%) who underwent an anterotemporal lobectomy developed de novo PNES. As in other studies, most patients (n = 6) were women; six of the seven patients had a pre- and postsurgical psychiatric depression/anxiety disorder, whereas the seventh patient had a history of attention deficit disorder and personality disorder that was present before surgery and worsened after surgery. Three patients had gainful employment before and after surgery, whereas the remaining four did not seek or obtain work either before or after surgery. Given the small number of patients with de novo PNES, no statistical analyses were carried out (Kanner AM, unpublished data).

Glosser et al. tried to identify risk factors of postsurgical PNES by comparing the demographic, neurologic, and psychiatric variables of 22 medically refractory epilepsy patients in whom PNES was documented by electroencephalogram (EEG) after resective surgery to those of a larger series of epilepsy surgery patients.[33] Patients with PNES were significantly more likely to have a seizure onset later in life, to have undergone epilepsy surgery in the right hemisphere, and to be women, but these subjects failed to differ with respect to age, IQ, or preoperative psychiatric diagnoses. PNES tended to become apparent in the first few months after surgery.

How Often Does Epilepsy Lie Behind an Erroneous Diagnosis of PNES?

This question is difficult to answer, because it depends on the accuracy of the diagnosis of PNES, which is often impossible to determine in published series. In the literature, completely different methods have been used for diagnosing PNES, based sometimes on EEG criteria (but not necessarily EEGs recorded during the ictus itself), clinical criteria, or a mixture of both. For example, people with epilepsy often show emotional reactions to their auras, so that they may become afraid of them and develop hyperventilation or panic attacks or have an emotional reaction during the ES itself. When auras fail to evolve to complex partial seizures, and their scalp recordings fail to reveal an electrographic ictal pattern,[22] clinicians may be prone to misdiagnose these patients with simple partial seizures as having PNES. In fact, in 1885, Gowers suggested that minor seizures can elaborate into hysterical seizures.[34] A century later, Devinsky and Gordon reported the case of four patients in whom V-EEG–documented ES were temporally associated with PNES.[20] In one woman, the nonepileptic event followed an absence seizure, whereas in the other three patients, the seizures were partial and arose from right frontotemporal regions. Kapur et al. described three patients who convincingly elaborated simple partial seizures during EEG monitoring in order to ensure a result that would lead to surgery.[43] Clearly, one of the problems of assessing the cause of a seizure is that, during a simple partial seizure, some of what is observed may well be a behavioral manifestation of the patient's emotional reactions to an unpleasant epileptic experience. This understandable emotional reaction may be mistaken for a nonepileptic event.

Paradoxically, as clinicians have become increasingly aware of the existence of PNES, patients with certain types of seizure disorders are increasingly being erroneously diagnosed as having PNES. For example, Parra et al. studied 100 consecutive patients who were undergoing a diagnostic V-EEG.[61] Referring physicians correctly suspected a diagnosis of ES in only nine (43%) of 21 patients, whereas 12 (57%) patients were incorrectly thought to have PNES. This misdiagnosis was especially likely in patients with clinical seizures of mesial frontal or parietal lobe origin and stemmed from their "bizarre" or "atypical" manifestations or from the absence of any electrographic ictal activity concurrent with the event during the V-EEG.[41,56,84] Furthermore, it should be remembered that the electrographic

ictal pattern on scalp recordings of simple partial seizures is identified in only 25% of these seizures.[22] The error rate in diagnosing PNES probably lies between 5% and 10% (i.e., in up to 10% of patients firmly diagnosed with PNES, the patient really has epilepsy).[69,85] This topic is reviewed in greater detail in Chapter 284.

Strategies in the Diagnosis of PNES in Patients with Epilepsy

Clinical History

Reaching a correct diagnosis of "only" PNES versus mixed PNES with concurrent or past ES is of the essence if a patient's AEDs are to be discontinued without placing her at risk of (epileptic) seizure recurrence. Clearly, a carefully obtained history and detailed description of all events witnessed by family members and the patient's own recollections are the first step in the diagnostic process and are of great importance when the existence of the two disorders in the same patient is suspected. The next step consists of a V-EEG to confirm the diagnosis. Unfortunately, few studies have investigated in a systematic manner the degree to which PNES and ES differ from one another in the same patient. The available data suggest that the two types of event differ clinically to a significant degree. In the Devinsky et al. study, analysis of PNES and ES on V-EEG revealed that the clinical features of PNES clearly differed from ES in 18 of 20 PNES cases.[21]

Although differentiating the two often is attempted by history, or even with observation of the ictal semiology, many epileptologists and neurologists know of cases in which a high suspicion for ES and V-EEG revealed PNES, or vice versa. Therefore, PNES is best diagnosed using the "gold standard" V-EEG, performed with the greatest humility because even the best have been fooled.

Differentiating PNES from ES Based on Ictal Semiology

This topic is reviewed in great detail in Chapter 282. We will therefore only refer to some of the salient clinical differences here. In many clinicians' minds, PNES presents as opisthotonic posturing with pelvic thrusting in a young female. Gates et al. showed that any presentation that epilepsy can have, PNES may have also,[30] but bedside examination reveals differences in the characteristics of the signs and movements.

During the ictus, some signs of PNES include geotropic eye movements, in which the eyes deviate downward to the side toward which the head is turned.[36] Eyelids are typically closed at the onset of PNES, and for a longer duration when as compared to temporal lobe epilepsy (TLE) or frontal lobe seizures (FLS) (20 seconds vs. ~2 seconds, respectively).[24] Along with ictal eye closure, weeping is associated with PNES.[7,27] Postictal nose rubbing and postictal cough are found in TLE, but not in PNES.[82] Pelvic thrusting has been reported to occur as commonly in FLS as it does in PNES. PNES and FLS differ, however, in that FLS are rarely associated with the overtly sexualized, often prolonged, display seen in some cases of PNES.[32]

It was once thought that absence of physical injury sustained during a seizure was a diagnostic indicator differentiating PNES from ES; however, more than half of all patients with PNES actually have a physical injury associated with their PNES.[40] PNES patients may have urinary incontinence and may injure themselves during the ictus. Tongue biting, self-injury, and incontinence are commonly associated with generalized seizures; however, two thirds of patients with PNES report one of these three signs, typically associated with ES.[15] Rug or floor burns on a patient's cheeks or body is viewed as being pathognomonic for PNES.[80]

Using Video-EEG

How Can the Video-EEG Monitoring Studies Help?

In ES, stereotyped ictal focal and generalized patterns appear on EEG. PNES, on the other hand, have a normal

EEG background before, during, and after the events. EEG sensitivity and specificity increase with repeated tracings.[73] Although seizures associated with impaired consciousness (e. g., generalized convulsive and nonconvulsive seizures) are associated with typical, widespread ictal EEG abnormalities, some focal seizures may not show features of seizures with scalp electrodes.[69] The limitation of V-EEG is the same as that of routine EEG—that is, simple partial seizures and FLS may not show ictal patterns using scalp electrodes. Without V-EEG, a neurologists' ability to differentiate an ES from PNES by history has a specificity of 50%.[16]

The judicious use of neurophysiologic studies can help establish whether the patient experienced PNES with a concurrent or past seizure disorder that may have remitted with the administration of AEDs, surgical treatment, or spontaneously. When suspecting concurrent PNES and ES, patients should undergo a V-EEG study and not an ambulatory EEG without video, because capturing the events on video to distinguish the two types of paroxysmal episodes is of the essence. In our opinion, patients should be admitted to a V-EEG monitoring unit, and recordings should be obtained without modifying the AED dose for the first 48 hours. Indeed, as shown by several studies, PNES tend to occur within the first 2 days in more than 90% of patients.[63] The use of induction protocols with conventional activation procedures (hyperventilation and photic stimulation) can facilitate the recording of PNES without raising the ethical concerns of other induction procedures sometimes used.[6] Furthermore, no evidence suggests that the use of induction protocols based on “placebos” such as IV infusion of saline solution or the application of alcohol swabs over the carotid artery yielded a higher rate of event induction than the use of the maneuvers typically used in all EEGs to facilitate seizures[63] (see also Chapter 282).

Interictal Epileptiform Activity

The recording of interictal epileptiform activity (IEA) in the course of a V-EEG is the first clue of a potential comorbid (present or past) ES disorder in patients with PNES. Yet, the recording of IEA does not help to establish the timing of the patient's ES (i.e., remote versus present) or whether the patient's seizures may be in remission as long as the patient is on AEDs. Furthermore, IEA may be recorded in individuals who may have never experienced any ES, and who may have a first-degree relative with a history of epilepsy, above all primary generalized epilepsy. For example, in a review of the literature that looked at the prevalence of IEA in people without epilepsy, Pedley et al. identified six studies with prevalence rates ranging between 0.5% and 2.5%.[64] Of note, IEA were more common in children (1.9%–3.5%) than in adults (0.5%), and future seizures went on to occur in healthy children more often than in healthy adults. Among children, central midtemporal IEA and generalized spike-and-slow-wave discharges were among the most frequent types of IEA recorded, which is suggestive of epilepsy in siblings or other first-degree relatives or of asymptomatic manifestations of genetic traits.[64] Delgado-Escueta et al. reported the presence of IEA in nonsymptomatic siblings

P.2158

from 5 of 33 families (16%) with symptomatic probands.[17] Ultimately, the clinical significance of IEA may have to be resolved by discontinuation of AEDs.

Tapering of AEDs During V-EEG

A rapid taper of most AEDs is reasonable as long as the patient is undergoing an inpatient V-EEG. Abrupt discontinuation of AEDs, however, is known to precipitate ES. Therefore, abrupt discontinuation of AEDs in nonepileptic people should be avoided, because they may cause a false-positive diagnosis of ES. This includes primarily any of the benzodiazepines. Furthermore, abrupt discontinuation of these drugs can trigger withdrawal panic attacks and psychotic episodes, thus leading to further confusion with PNES and underlying psychiatric disorders.

Ictal Data

The recording of spontaneous seizures before tapering the AED dose clearly establishes the concurrent existence of ES and PNES. The occurrence of seizures only after discontinuation of AEDs does not rule out ES coexisting with PNES, but it raises the possibility that the ES may have remitted with AEDs. This question can be clarified by showing the video of the captured seizure to family members and inquiring about their occurrence in the present versus recent or remote past.

The issue of the specificity of EEG in the diagnosis of PNES has not been formally established. Ramsay et al. tested whether altered clinical behavior in the absence of EEG changes was diagnostic of PNES.[69] They evaluated 281 ictal recordings in 194 sequential patients who underwent V-EEG. In 46 (23.3%), the initial scalp EEG showed no epileptiform EEG changes during the clinical event. Subsequent monitoring revealed that, of the 46 with initial negative EEGs, 28 (61%) had PNES, 12 (26%) had epilepsy, and 6 (13%) had mixed PNES/ES. Of the patients with epilepsy, depth electrode recording revealed mesial temporal or inferior frontal areas of seizure onset that were not recorded with scalp electrodes.

Also, failure to record seizures even after discontinuation of AEDs does not rule out a concurrent or past ES disorder. In such cases, the patient's family is asked to make a video of the patient's events when they occur at home.

Ideally, clinicians should aim whenever possible to have V-EEG recordings of PNES and ES available to guide the pharmacologic treatment of ES. Patients, family members, and, when appropriate, friends and coworkers should be shown the two types of events so as to avoid an unnecessary hospitalization for PNES when the patient could be treated aggressively with parenteral AEDs. It is also advisable to give the patient and close family member a copy of the video demonstrating both PNES and ES events in case the patient is taken to an emergency room. The availability of such videos can help emergency-room physicians decide on the course of treatment in a more judicious manner.

Role of Neuroimaging Studies

Neuroimaging allows in vivo visualization of central nervous system (CNS) lesions causing alterations of consciousness. No static and no functional neuroimaging abnormalities have yet been found associated with cases of PNES. Abnormalities on structural neuroimaging neither confirm nor exclude ES or PNES. As shown in the data presented earlier, patients with PNES may have abnormal neurologic examinations, including abnormal MRI studies. However, in patients diagnosed with PNES, the identification of a structural lesion in mesial or orbitofrontal regions should lead the physician to seriously reconsider the diagnosis of PNES. The use of an ictal SPECT or SISCOM study can help clarify whether ES may have been misdiagnosed as PNES (see Chapter 282 as well). A lack of abnormality on scan SPECT studies report an average sensitivity of 72% for PNES and an average of 59% specificity for ES.[13] Case reports exist describing patients with other forms of sensory or motor impairments. Patients with astasia-abasia motor conversion disorder had left temporal hypoperfusion abnormalities on SPECT; however, this has not been seen in PNES.[87]

Role of Laboratory Tests

Serologic measures have been helpful in differentiating ES from PNES. Prolactin (PRL) is secreted from the anterior pituitary and is inhibited by tuberoinfundibular dopaminergic neurons in the arcuate nucleus of the hypothalamus.[31] Trimble found that elevated serum PRL in patients with generalized seizures helped distinguish ES from PNES.[81] A number of studies have since been conducted measuring prolactin in PNES and, with a lack of elevation of PRL, the average sensitivity to PNES was 89%.[13] Further, prolactin ES versus PNES studies have since shown that serum levels are elevated on average in 88% of generalized tonic–clonic (GTC) seizures, in 64% of temporal complex partial seizures (CPS), and in 12% of simple partial seizures. False positives for epilepsy include treatment with dopamine antagonists and some tricyclic antidepressants, breast stimulation, and syncope, and false negatives occur with use of a dopamine agonist or with status epilepticus, because PRL has a short half-life and may attenuate in postictal release.[2] PRL also does not rise after frontal seizures. The American Academy of Neurology's Therapeutics and Technology Assessment Subcommittee published their report on the use of serum PRL in differentiating ES from PNES. The authors reviewed the PRL seizure literature and concluded that a twice-normal relative or absolute serum PRL rise, drawn 10 to 20 minutes after the onset of the ictus, compared against a baseline nonictal PRL, is a useful adjunct in the differentiation of GTC or PCS from PNES.[12] Unfortunately, this test is not useful for differentiating those ES that are more likely to be confused with PNES (i.e., FLS) from PNES proper.

Other serum measure studies to differentiate GTC seizures from PNES have included the use of elevations in peripheral white blood count,[75] cortisol,[66] creatine kinase,[86] and neuron-specific enolase.[67] However, Willert et al. discussed the limited discriminative power of these serological tests in differentiating ES from PNES.[83] Ictal heart rate on EKG monitoring is higher, and a change in ictal heart rate is associated with ES, but not PNES.[25,59,60] Capillary oxygen saturation on pulse oximetry is lower for ES than for PNES.[38]

Role of Neuropsychometric Testing

A large number of studies exist describing the cognitive, emotional, personality, and psychomotor differences between the ES and PNES groups. Cragar et al. reviewed the literature on adjunctive tests for diagnosing PNES and reported sensitivity and specificity of the different measures.[13] A summary of their findings noted that PNES and ES patients did not differ on intelligence tests or on neuropsychological (NP) measures consistently. Both PNES and ES groups did have cognitive deficits when compared to normal controls, and patients with PNES tended to perform better than patients with ES on various NP tests. Studies examining intelligence, psychomotor function, motivational measures, and personality features in PNES suggest the following:

- Intelligence measures and cognitive testing. Comparing patients with PNES to those with ES, Binder et al. found no significant differences on tests of intelligence or learning and memory, including the Wechsler Adult

  Intelligence Scale – Revised, Wisconsin Card Sort Test, or Rey Auditory Verbal Learning Test. Control subjects were significantly superior to both the PNES and ES groups.[9] Bortz et al. studied the California Verbal Learning Test results in PNES and ES patients, and the authors suggested that "failure to explicitly recognize words following repeated exposure" may be reflective of a negative response bias and psychological denial in patients with PNES.[11]
- Psychomotor measures. Kalogjera-Sackellares and Sackellares evaluated patients with PNES compared with matched normal controls and found reduced motor speed and grip strength in the PNES patients.[39] Some have interpreted this as a manifestation of motivation, which is discussed later. Dodrill and Holmes reported that patients with PNES performed better than those with ES on measures from the Halstead-Reitan Battery, with differences between Tactual Performance Test, Seashore Tonal Memory, and Trail-Making Part B.[23] Whereas finger tapping and grooved pegboard test results differed for controls compared with PNES and ES groups, Binder did not find differences between the ES and PNES groups on these measures.[9]
- Motivational measures. Motivational tests include the Portland Digit Recognition Test (PDRT), the Test of Memory Malingering (TOMM), and others; these tests are used to detect inadequate performance on NP testing. The presence of unconscious psychological stress is hypothesized as an explanation for variable effort in patients with PNES.[78] Binder et al. found that PNES patients performed more poorly when compared with patients with ES on the PDRT.[9,10] The authors noted that frank malingering occurs rarely in PNES, and the poorer performance in PNES may reflect a lack of psychological resources necessary to persist with a challenging NP battery.
- Personality testing. Results of the Minnesota Multiphasic Personality Inventory (MMPI/MMPI – 2) and Clinical Psychological Profiles and Family tests were reported. The majority of the MMPI studies in PNES report the "conversion V" profile, with elevations in Scales 1 (Hs, Hypochondriasis) and 3 (Hy, Hysteria), and depressions in Scale 2 (D, Depression).[13] Cragar et al. also reported an average sensitivity of 70% and specificity of 73% to PNES diagnosis using MMPI – 2 decision rules. The dramatic personality of patients with PNES was illustrated in a blinded pilot study of artwork drawn by patients with ES and PNES.[1] An 80% positive predictive value for PNES existed if subjects used 10 or more colors to draw their seizures. Galimberti et al. administered the Cognitive Behavioral Assessment (CBA) psychometric battery to patients with lone PNES, mixed ES/PNES, and ES controls. The CBA, which assesses personality characteristics and emotional adjustment, is comprised of scales rating introversion-extroversion, neuroticism, psychoticism, state-trait anxiety, psychophysiological distress, and depressive and other anxiety symptoms. These researchers found that the mean scores on the Psychophysiological Distress Scale for the PNES and the ES/PNES groups were higher than the mean scores of the ES control group.[28] The Rorschach test did not differentiate patients with PNES versus ES.[26] Krawetz et al. evaluated family functioning in patients with

ES and PNES and their families.

They found that individuals with PNES view their families as being more dysfunctional, particularly in the area of communication, whereas family members of patients with PNES reported roles as being dysfunctional.[46]

In summary, compared with healthy controls, patients with ES and with PNES perform worse on a number of NP measures. However, few differences exist between ES and PNES groups on tests that would reliably differentiate ES from PNES. The impairments are thought to be due to at least three factors: (a) both the ES and the PNES patients were on AEDs, which may affect cognition; (b) structural lesions in ES patients and in some of the PNES patients with ES; and (c) emotional factors contributing to cognitive impairment in the PNES group.[78] Psychologically, patients with PNES appear to have personality characteristics of anxiety, cognitive dysfunction, and somatic distress, and they have difficulty in expressing and communicating that distress to family and others.

Role of Pharmaco-Diagnosis

Prior to the use of EEG, neurologists and psychiatrists frequently used sedatives or other pharmacologic agents to distinguish ES from PNES. One of the earliest pharmaco-diagnostic accounts from the late 1800s reads: "I administered a hypodermic injection of hyoscine hydrobromate, which caused the fits to cease and produced five hours' sleep. On awakening the patient was very emotional and far from well, but there were no return of the fits.

Hyoscine, we know, is most useful in cases of status epilepticus and in the convulsions associated with general paralysis of the insane; it appears to be of service also in this condition of hystero-epilepsy, and certainly it is much less tedious than the old chloroform method."[44]

Sodium Amytal and hypnosis were used in the mid-1900s to differentiate between ES and PNES.[52,65] Although these agents usually are not used diagnostically today, placebo saline injections and provocation techniques are used more frequently in some institutions.[3,18] The ethics of such procedures has been an issue of debate.[19,74,77] One acceptable technique incorporated at some epilepsy centers uses activation procedures (e.g., hyperventilation and photic stimulation) that are part of their routine EEG diagnostic protocol for PNES.[6]

Treatment strategies

We learn in medical school the physician's dictum, "Primum no nocere." But in the case of the PNES population, many times harm *is* done through inappropriate treatments and aggressive therapy to stop seizures. Although PNES are not responsive to treatment with AEDs, most patients with PNES receive unnecessary AEDs, and only half pursue recommended psychiatric follow-up.[45] Extensive observational data suggest that AEDs are ineffective or may worsen PNES.[48] In some cases, potentially dangerous invasive diagnostic studies, toxic parenteral medications, or emergent intubation are administered.[35,70] The patients, their families, and society bear an enormous cost if psychiatric care is not provided or if inappropriate neurologic therapy is instituted for PNES.

Pharmacotherapy Using AEDs Only Targeting Recognized Epileptic Seizures

We ask patients and their family members to give a detailed description of seizure events; many times, PNES and ES have markedly different phenomenology in the same patient.[20] Once documented historically, we give the patient a seizure calendar and ask patients and family members to chart events prospectively, noting the characteristics of the seizures and any particular triggers or precipitants. The frequency of ES and that of PNES are established and, in the following visit, the results are discussed. This process clarifies treatment targets not only for the patient, but also for the physician. We explain that, for one

P.2160

seizure type, we will use AEDs (e.g., "the seizure that occurs nocturnally, with lateral tongue biting, incontinence, and sore muscles upon regaining consciousness"). For the other type of seizure (e.g., "the one that occurs when watching a show on TV that reminds you of the past trauma of the assault, with 'zoning out' for a brief period of time and coming to just afterwards"), we will use a combination of medications for anxiety and psychotherapy. This method is a problem-oriented, practical approach that patients and their families understand and with which they can comply.

Psychiatric Treatment (Pharmacotherapy and Psychotherapeutic Interventions) for PNES

Intensive treatment using behavioral therapy, psychodynamic psychotherapy, occupational therapy, and education on an inpatient unit was the norm in earlier references to PNES treatment.[51,68] Success levels were higher than in the current outcomes reports, which incorporate a less intensive, outpatient treatment model, with up to 70% of patients with PNES continuing to have seizure events.[72]

Based on the clinical and research reports to date, we proposed the following assessment and treatment approach by a multispecialty neuropsychiatric team:[50]

- Proper diagnosis. Order a V-EEG for each patient with suspected PNES, or refractory or pharmacoresistant seizures.
- Presentation. Explain the PNES diagnosis in a clear, positive, nonpejorative manner. The patient may make the diagnosis presentation to the family members if cognitively and emotionally capable. This process helps reveal the level of understanding and initial acceptance of the diagnosis by the patient. Clarifications can be made by the physician, who is present. Communicate the diagnosis unambiguously to the referring physician and explain the need to eliminate unnecessary medications.
- Psychiatric treatment. Conduct a thorough psychiatric assessment to identify predisposing factors (including comorbid psychiatric disorders), seizure precipitants, and perpetuating factors. As diagnosis informs treatment, a dual-armed approach ensues using pharmacotherapy and/or psychotherapy, as indicated by the individual needs of the patient with PNES.

In patients with mixed ES/PNES, reduce high-dose or multiple AED therapy if possible based upon seizure calendar results. Use psychopharmacologic agents to treat mood, anxiety, or psychotic disorders. Enroll the patient in individual therapy with a psychiatrist or psychologist familiar with PNES and somatoform disorders, if a history of trauma, illness behavior, or specific interpersonal issues is identified in the assessment. Consider family therapy if the family functioning is found to be unhealthy, noting it to be a potential contributor to the symptoms.[49]

Summary and Conclusions

The majority of patients with PNES do not have epilepsy, and vice versa. In the 10% to 30% of patients who have mixed ES/PNES, diagnosis and treatment may present a significant challenge. A good history, documenting the various types of events the patient experiences, is an essential starting point. Long-term monitoring using V-EEG, to capture more than one of their typical events, aids in establishing the presence of mixed PNES and ES. Tapering AEDs during inpatient V-EEG greatly facilitates capturing the various seizure types. Provocation techniques using the routine activation procedures appear a safe and ethical procedure for seizure diagnosis.

Once the diagnosis of mixed ES/PNES is made, treatment entails addressing the patient and their family from a neuropsychiatric perspective. When ES coexists with PNES, this is most likely to occur in people with a previous history of epilepsy who have difficulty in adjusting to living without seizures and in patients who have coexisting psychiatric and physical disorders, which is not uncommon. Holistic assessment of the patient aids both diagnosis and management of coexisting epilepsy and nonepilepsy.

Chapter 208

Psychiatric Side Effects of Antiepileptic Drugs

Bettina Schmitz

Introduction

Central effects of antiepileptic drugs (AEDs) are not restricted to the modulation of cortical excitability. AEDs may also modify systems that regulate mood and behavior. Anticonvulsant and psychotropic effects are not independent. Effects on seizure control have indirect effects on the mental state. Patients who are seizure-free have no risk of developing seizure-related psychiatric complications. On the other hand, the sudden cessation of seizures may lead to an imbalance in the mental state, as in "forced normalization" (FN). Some AEDs have dose-related paradoxical proconvulsive properties that may cause behavioral disturbances through underlying nonconvulsive status epilepticus.

Psychotropic effects may be negative or beneficial in individual patients. These effects depend on the antiepileptic strength, the mode of action of the anticonvulsant, and the patient's biologic and psychological predisposition. With the increasing variety of AEDs available, behavioral drug profiles have become very important for optimal treatment choices in epilepsy. Recent quality-of-life studies have shown that measurements of depression and the tolerability of AEDs are more important to patients than seizure reduction.[16] Furthermore, the high psychiatric comorbidity in epilepsy often requires psychopharmacologic interventions, which may be avoided when those anticonvulsants used have positive psychotropic properties.

In clinical praxis, the adverse psychiatric effects of AEDs are often not recognized. Often patients don't complain about behavior or mood changes unless they are specifically interviewed. Many neurologists are not competent in the exploration of a mental state, or they don't have the additional time needed to evaluate a patient's mental state. Many depressed patients are not primarily troubled by obvious depressive symptoms such as sadness or feelings of guilt. Depression in epilepsy often presents with sleep disorders or somatoform complaints and memory problems, which makes the diagnosis difficult unless the full psychopathologic status is explored. If delayed adverse psychiatric effects occur after months or years of exposure, the causal relationship with drug treatment is often not considered and is in fact difficult to prove, unless drug withdrawal is followed by the remission of psychiatric symptoms.

The exact prevalence of psychiatric AED events is difficult to estimate. In a consecutive series of patients with epilepsy and significant depression, about 30% were considered to have AED-related symptoms.[21,39] With respect to psychoses, the percentage of episodes triggered by AEDs has been calculated to be 40% in one study.[30]

Adverse Psychiatric Effects of Specific AEDs

Conventional Drugs

Barbiturates

Several studies suggested a link between depression and treatment with barbiturates, both in adults and in children.[5,36.] Forty percent of school children treated with barbiturates were diagnosed with "major depression," as compared with only 4% of children treated with carbamazepine.[4] In children, a conduct disorder resembling attention deficit hyperactivity disorder may be provoked by many AEDs, the most frequently implicated drug being phenobarbitone. Irritability and aggressive behavior are side effects particularly often seen when barbiturates are used in mentally retarded patients. Withdrawal problems, which present with nervousness, dysphoria, and insomnia, may occur even when barbiturates are very slowly tapered down.

Phenytoin

Phenytoin may provoke schizophrenia-like psychoses at high serum levels.[32] These psychoses are dose related—and are thus toxic syndromes—but they are not associated with the cerebellar signs that are the most common central nervous system side effects of phenytoin. In a study of 45 patients with drug-related psychoses, 25 (56%) cases were attributed to treatment with phenytoin.[20] A chronic encephalopathy has also been described with phenytoin use, and has been referred to as "Dilantin dementia."[44]

Ethosuccimide

Psychoses typically following cessation of seizures and associated with a normalization of the electroencephalogram (EEG) occur in 2% of children treated with ethosuccimide. The risk of FN is higher (8%) in adolescents and adults treated with ethosuccimide for persisting absence seizures.[45]

Carbamazepine

Affective problems are rare complications of treatment with carbamazepine.[8] These complications present as either depressive disorders or mania, the latter being explained as a paradoxical effect due to the antidepressant properties of carbamazepine, which is chemically related to tricyclic antidepressants.[9]

Valproate

Rarely, valproate is associated with acute or chronic encephalopathies.[37,40,47] These encephalopathies are related to dose and perhaps polytherapy, and they are reversible with dose reduction.

Table 1. Incidence rates of psychoses and depression in controlled trials (Besag,[2] Janssen-Cilag,[18] and Levinson and Devinsky[28])

	Psychoses (%)	Depression (%)
Vigabatrin	2.5	12.1
Lamotrigine	0.2	-
Felbamate	0.02	-
Gabapentin	0.5	-

Topiramate	0.8	9–18
Tiagabine	0.8–2	5
Levetiracetam	0.3–0.7	0.5–2

Newer AEDs

Table 1 summarizes data from premarketing controlled trials suggesting a relatively high frequency of depressive reactions in vigabatrin, tiagabine, and topiramate, and relative low rates for lamotrigine, gabapentin, and levetiracetam. Obviously psychiatric risks of the newer AEDs are not the same for all compounds. Some of the drugs seem to have neutral effects, some have a relevant risk for negative effects, and some may have predominantely beneficial psychotropic effects. A general comment is that the overall psychiatric risks of newer AEDs are not lower than those of older AEDs.

Vigabatrin

The risk of psychiatric complications caused by vigabatrin has been analyzed in two meta-analyses. The overall incidence of psychoses and severe behavioral reactions leading to drug discontinuation in seven placebo-controlled European studies was 3.4% in the vigabatrin group and 0.6% in the placebo group.[13] Another meta-analysis on the psychiatric risks of vigabatrin[28] translated psychopathologic symptoms described in the investigator forms into standardized psychiatric terminology, which was then summarized into a syndromatic diagnosis. This analysis of U. S. and non-U. S. double-blind studies demonstrated a significantly increased risk for psychosis and particularly for depression. Psychoses occurred in 2.5% of patients treated with vigabatrin compared to an incidence of 0.3% in the placebo group ($p < 0.05$), and depression occurred in 12.1% of patients treated with vigabatrin in contrast to only 3.5% in the placebo group ($p < 0.001$).

Lamotrigine

Severe psychiatric complications are rare with lamotrigine, and psychosis and depression occurred only in very few cases in trials.[14] Insomnia, which may be associated with irritability, anxiety, or even hypomania, is the only significant psychiatric side effect, occurring in 6% of patients treated in monotherapy, compared with 2% in patients treated with carbamazepine and 3% in patients treated with phenytoin.[6]

When first reports surfaced of caregivers complaining that handicapped patients had become more alert and demanding, it was interpreted as reflecting inadequate rehabilitation facilities, rather than a negative side effect.[3] Besag refers to this as a “release phenomenon.”[2] There are, however, a number of reports that children with learning difficulties and adults with mental handicaps develop behavioral problems such as aggression.[1,12] Reports have also noted the induction of a reversible Tourette syndrome, which in some cases was accompanied by obsessive compulsive symptoms.[29]

Felbamate

Felbamate is at present only used in a minority of patients, particularly those with Lennox-Gastaut syndrome, due to its hematologic and hepatic toxicity. Felbamate may lead to increased alertness, thus inducing sleep problems and behavioral problems related to agitation in some patients, particularly in children with learning disabilities.[31]

Gabapentin

Beyond somnolence, negative psychotropic effects have not been demonstrated in controlled studies of gabapentin. However, a number of studies suggest that gabapentin may induce behavioral problems such as aggression in children with learning disabilities and adults with mental handicap,[26,42,46] possibly related to rapid titration. In elderly people with reduced creatinine clearance, gabapentin may cause various neurotoxic symptoms due to its renal elimination.

Tiagabine

A specific problem with tiagabine is the paradoxical provocation of de novo nonconvulsive status epilepticus due to a relatively narrow therapeutic window.[38] Therefore, EEG registrations are necessary when behavioral problems arise, particularly when clinical signs such as mutism, qualitative change in consciousness, autisms, or myoclonia suggest status epilepticus.

In placebo-controlled add-on studies, nervousness and depressed mood were both increased in the tiagabine group[27] (12% vs. 3%, 5% vs. 1%). The incidence of serious adverse events presenting as psychosis was 2% versus 1% in the placebo group.

Table 2 Positive psychotropic effects of antiepileptic drugs demonstrated in controlled trials

	Depression	Mania	Bipolar disorder	Anxiety
Carbamazepine	0	+	+	0
Oxcarbazepine	0	+	0	0
Valproate	0	+	+	0
Lamotrigine	0	0	+	0
Gabapentin	0	-	-	+/ -
Topiramate	0	-	0	0
Tiagabine	0	-	0	0
Levetiracetam	0	0	0	-
Pregabaline	0	0	0	+
Zonisamide	0	0	0	0

+, positive results; –, negative results; 0, no published data.

Topiramate

In premarketing studies, and possibly related to aggressive titration schemes, topiramate was associated with a relatively high rate of neurotoxic side effects. Psychotic reactions were, however, relatively infrequent, with a prevalence of 0.8%. In a postmarketing study comparing the psychiatric side effects of topiramate, lamotrigine, and gabapentin, psychotic episodes occurred in 12% of patients treated with topiramate compared with 0.7% of patients treated with lamotrigine and 0.5% of patients treated with gabapentin.[7] These data suggest an increased vulnerability in selected patient groups. A significant proportion of topiramate-associated psychoses are explained as alternative syndromes in patients who become seizure-free.[34]

The rate of affective symptoms is clearly dose-dependent, with an incidence of 9% and 19% with a daily dose of 200 mg and 1,000 mg, respectively, found in one premarketing study.[18] In an analysis of topiramate-related psychiatric complications, depression was significantly correlated with rapid titration and high dosages.[34] Two studies demonstrated a correlation between psychiatric adverse events and cognitive side effects, suggesting that neuropsychological and affective problems are closely interlinked.[22,34] The neuropsychological disorders caused by topiramate resemble a frontal lobe problem, and have been interpreted as regional behavioral toxicity. It would be interesting to investigate whether patients with epilepsies and frontal lobe dysfunction are more vulnerable to these effects.

Levetiracetam

Levetiracetam is not associated with a high risk for severe psychotic or depressive reactions. Significant affective episodes were reported in 2% and psychoses in 0.7% of patients treated in preclinical trials. Some of the levetiracetam-associated psychoses were explained as a manifestation of FN.

A clinically relevant psychiatric side effect of levetiracetam is the provocation of aggressive behavior and irritability, which occurs both in adults and children. In an English series of 517 adult patients treated with levetiracetam, 10% developed a psychiatric complication, most frequently presenting with aggressive behavior.[35] Aggression occurs particularly often, but not exclusively, in patients with preexisting irritability and dysphoria. Mesad and Devinsky[33] analyzed cases of severe aggressive behavior, defined by objective verbal or physical aggression, leading to withdrawal of levetiracetam. The prevalence was 18 out of 460 consecutive patients (3.9%). Seven patients had previous episodes of aggressive behavior.

Children may be at an even higher risk to develop aggression, including suicidal behavior, with prevalence rates up to 68%.[11] In children with preexisting neuropsychiatric symptomatology, levetiracetam may provoke an exacerbation of behavioral problems.[17] Kossoff[24] reported on four adolescents who developed a psychosis secondary to treatment with levetiracetam, which was reversible following withdrawal. All patients had preexisting behavioral problems, and two had become seizure-free, supporting the role of FN.

Zonisamide

Outside of Japan and the United States, there is still limited experience with this broad-spectrum AED. There are, however, indications of significant psychiatric adverse events, including affective problems and psychoses. In a Japanese series of patients with psychotic episodes, half of drug-related episodes were triggered by zonisamide.[30]

Pregabaline

Controlled trials of pregabaline show no evidence for significant psychiatric adverse events. However, clinical experience with this recently introduced drug is still limited.

Positive Psychotropic Effects of AEDs

Carbamazepine and valproate are established drugs for affective disorders, and all novel anticonvulsants have been tested in primary psychiatric disorders with respect to potential mood stabilizing properties. The advantages of anticonvulsants compared to classical mood stabilizers are the lack of proconvulsive risks, the lower potential to induce a switch from depression into mania, and a superior efficacy in atypical syndromes such as rapid-cycling bipolar disorder. So far, only lamotrigine has been approved for bipolar disorder. Pregabaline has shown efficacy in anxiety disorders and insomnia (Table 2).

The potentially positive psychotropic effects of AEDs have not been systematically studied in patients with epilepsy. This is unsatisfactory because the experience with primary psychiatric patients cannot easily be transferred to epilepsy. Many psychiatric disorders in epilepsy are different in their phenomenology and most likely also in their pathogenesis from "endogenous" disorders.

The evidence for the mood-stabilizing effects of carbamazepine and valproate when used in patients with epilepsy is based on few observations.[36,39,44] With respect to the newer AEDs, the only convincing evidence with respect to positive psychotropic effects relates to lamotrigine.[10,15,19,41]

Risk Factors for Psychiatric Adverse Events

Patients with a biographic or genetic predisposition are presumably more at risk to develop AED-related psychiatric complications such as depression and psychosis (Table 3). Patients with previous depressive episodes are more likely to develop an affective disorder, whereas patients with previous schizophrenia-like psychoses are more likely to present with a psychotic reaction, suggesting that the clinical presentation of psychiatric adverse reactions depends on the individual psychopathologic predisposition. In patients with previous psychiatric problems, rapid titration should therefore be avoided, because aggressive titration schemes further increase the risk of behavioral toxicity.

Table 3 Risk factors for depression and psychosis with vigabatrin, topiramate, and levetiracetam

	Vigabatrin* depression/psychoses *n* = 22/28	**Topiramate**** depression/psychoses *n* = 46/16	**Levetiracetam***** depression/psychoses *n* = 13/6

*Thomas,[43]
**Mula,[34] ***Mula[35]
+, significant relationship; –, no relationship; ?, not studied or too small numbers.

Some studies have shown that patients with severe epilepsies are at a higher risk for psychiatric side effects. Mula[34] demonstrated that hippocampal sclerosis is more common in patients who develop depressive episodes secondary to treatment with topiramate, compared with patients without affective side effects, another indication for the close links between limbic dysfunction and affective disorders.

Children and adults with learning disability and multiple handicaps are particularly vulnerable to the behavioral adverse effects of AEDs. In these patients, the exact psychiatric

P.2166

diagnosis may be difficult, and both depression and psychosis may manifest with aggressive behavior. Also, nonpsychiatric adverse events may lead to disturbed behavior because patients may have difficulties in otherwise expressing their discomfort. In these patients, drug changes should be monitored carefully, and it is recommended that the behavioral changes are carefully discussed with the health care/caregiver team. Occasionally, the interpretations of behavior changes are different within the team, particularly when patients become more alert and active because of positive psychotropic AED effects. These changes may be regarded as negative by some because they require attitude adjustments on the part of caregivers and make new treatment programs necessary.

Mechanisms

Four major mechanisms explain behavioral effects of AEDs: (a) dosage-dependant toxicity, (b) dose-independent idiosyncratic drug effects, (c) withdrawal effects, and (d) indirect effects via anticonvulsive actions. Of these, the two most important mechanisms are pharmacodynamic side effects related to the drug's mode of action and effects that arise with seizure control—those alternative syndromes associated with the phenomenon of FN.

Trimble's hypothesis of a link between psychiatric complications and the γ-aminobutyric acid (GABA)-ergic mechanisms of AEDs was extended by Ketter,[23] who distinguished two categories of AEDs. The first category are GABAergic drugs with sedating, anxiolytic, and antimanic properties. This category includes barbiturates, benzodiazepines, valproate, vigabatrin, tiagabine, and gabapentin. The second category are the antiglutamatergic drugs, which are claimed to have activating, an-xiogenic, and antidepressive effects: felbamate and lamotrigine. The authors suggest that anticonvulsant drugs have different psychiatric effects depending on the preexisting mental status of patients. They predict that patients who are primarily activated may benefit from drugs that belong to the “sedating” category and become worse with use of “activating” drugs. On the other hand, patients who are primarily sedated would benefit from a drug from the “activating” category, whereas the same patients would worsen with a “sedating” anticonvulsant. Taking the primary psychopathologic status of a patient into account explains the sometimes unexpected and seemingly paradoxical effects of some AEDs in individual patients. Based on clinical experiences, Table 4 suggests some "predictable" psychiatric AED risks that may depend on baseline psychopathology.

Forced Normalization

The concept of FN goes back to the publications of Landolt.[25] Cases of FN or alternative psychiatric syndromes have been reported with the use of all conventional and novel anticonvulsants, but seem to be particularly common with the more potent drugs such as vigabatrin, topiramate, and levetiracetam. FN has rarely been reported with tiagabine and lamotrigine, and is extremely rare with gabapentin. The best known manifestation of FN is a psychotic state. However, in a consecutive series by Wolf,[45] 50% of 36 consecutive patients presented with predominating affective symptomatology.

Table 4 Psychiatric risks of antiepileptic drugs in patients with preexisting psychiatric problems

Patient	Possible contraindication	Possible side effect
Dysthymia	PHB, VGB, TPM, TGB	Major depression
Paranoia	DPH, VGB, TPM	Schizophrenic psychosis
Agitation	LTG	Insomnia, anxiety, hypomania
Hypermotor	LTG	Tourette-syndrome
Dysphoric	LEV	Aggression
Learning disability	All AEDs	Behavior disorders

PHB, phenobarbitone; LEV, levetiracetam; LTG, lamotrigine; TGB, tiagabine; TPM, topiramate; VGB, vigabatrin; DPH, phenytoin; AED, antiepileptic drug.

Summary and Conclusions

The risk of AED-related psychiatric complications is likely linked to the severity of epilepsy, polytherapy, rapid titration, and high dosages of drugs. Patients with previous psychiatric problems or a familial predisposition seem to be especially prone to behavioral side effects. Another risk group includes children and adults with learning disabilities, and perhaps elderly patients. It is important to recognize patients at risk, inform them and their families about the possibility

P.2167

of psychiatric side effects, apply a careful titration scheme, and make sure that patients are seen frequently—and that the appropriate questions are asked. When recognized at an early stage, psychiatric AED complications are mild and reversible in most cases. Risk factors for psychiatric complications are not a strict contraindication for any particular drug, and it is not always necessary to completely withdraw the responsible drug. Depending on the pathophysiology and the severity of the syndrome, a dose reduction or comedication with an antipsychotic or antidepressive drug may be a good compromise.

Behavioral drug-effect profiles, both negative and positive psychotropic effects, ought to be considered in the choice of the optimal drug for an individual patient. More studies are needed specifically devoted to the psychiatric effects of AEDs in patients with epilepsy. We need these studies to better identify patients at risk of severe behavioral reactions with the use of specific drugs, and also to identify patients who have a good chance of benefiting from the potentially positive psychotropic effects of certain AEDs.

Chapter 209

Psychiatry and Surgical Treatment

Steffi C. Koch-Stoecker

Kousuke Kanemoto

Introduction

More than half a century after its development, epilepsy surgery has become a routine procedure, especially for resection of mesiotemporal sclerosis. Indications for epilepsy surgery are now well-established, and expected physical benefits following epilepsy surgery can be shown with some certainty. Nevertheless, the implicit hope of patients is that "favourable outcomes in social and psychological domains" will follow seizure relief.[82] In light of this background, any attempts at prognosis must include more than a prediction of favorable seizure outcome by epileptologic methods. A more comprehensive neuropsychiatric view of epilepsy surgery outcomes is necessary, the importance of which is also underlined by the results of numerous studies from different countries that show a high psychiatric comorbidity in candidates for epilepsy surgery (Table 1). In the last few years, an increasing number of studies support the notion that this comorbidity exists not merely as the parallel existence of two unrelated diseases, but as a common etiology for epilepsies and psychiatric disorders. Examples include the association of fear auras with postoperative mood and anxiety disorders following a temporal lobectomy,[46] the prediction of seizures in later life by a history of depression,[31] and the correlation between postoperative psychopathology and the extent of temporal resection.[4] As a result, the gap between "organic" and "psychiatric" topics has begun to shrink, forcing neurologists and psychiatrists to work together—and producing some encouraging effects, as seen in reports from epilepsy surgery centers.

The Importance of Psychiatric Evaluation in the Context of Epilepsy Surgery

What do these promising developments mean for patients? The improvement in neuropsychiatric outcome prediction as a statistical piece of data is a helpful, although insufficient, frame in which to understand the complex situation of each individual patient. We know from psychiatric outcome studies[2,3] that mental instability may complicate the process of postoperative recovery. Following seizure cessation, affected patients may still suffer from their psychiatric disorders and may even acquire new ones. These patients face psychiatric disorder–related barriers that prevent them from making use of new opportunities in their seizure-free lives after surgery. Fortunately, individual outcome is not predicted by statistical data alone. We all know patients who transcend negative prognoses, profiting from the support and positive effects of relationships or internal strengths to make their way successfully through life post surgery. The best method for outcome prediction is a synthesis—a clinical psychiatric approach based on a balanced appreciation of the individual context and statistically evaluated group-predictors. The task of a neuropsychiatric assessment, beyond the evaluation of affiliation with special risk groups, is to understand the patient's motivations and aims within the frame of personal history, match them with realistic possibilities, communicate expected complications, treat actual disorders, and search for individual support strategies. Pre-, peri-, and postoperative psychiatric support during the process of surgery requires that the professional play the complex roles of physician, counselor, and container of hope simultaneously.

The majority of studies on this topic have focused on patients undergoing a temporal lobectomy or amygdalohippocampectomy because of the high proportion of temporal lobe epilepsies (TLEs) among epilepsy surgery candidates, but also of the prominence of psychiatric symptoms in patients with TLE. However, in the small number of reports that have mentioned the prevalence rate of psychiatric morbidities in temporal and extratemporal cases, no apparent difference has been found to exist when mental disorders are summed up as an entity.

This chapter does not cover the specific problems of epilepsy surgery in children, nor does it analyze in-depth psychosocial topics and questions concerning quality of life after surgery.

The Preoperative Phase: Mental Conditions of Surgical Candidates

As shown in Table 1, the reported prevalence of psychiatric morbidities among surgical candidates varies so widely (27%–85%) that no representative figures can be presented. With few exceptions, the mean numbers of psychiatric cases in recent studies exceed 40%, which is lower than the very early data obtained during the 1970s, although still clearly higher than in normal and nonselected epilepsy populations. Recent changes in selection strategies for epilepsy surgery to more strict exclusion criteria for patients with severe psychiatric morbidities, as well as progress in the treatment of epileptic seizures and mental problems, may have decreased the total number of patients. On the other hand, the increasing attention paid to mental disorders in the context of surgery and changes in assessment strategies (such as the use of structured clinical interviews) may account for a more complete perception of the whole situation, at least in recent series that have been reported. However, there are still no generally recognized psychiatric assessment methods for use in surgical centers. Further, the insufficiency of diagnostic systems for use in epilepsy populations has complicated the problem, because it is becoming increasingly clear that some of the most common and disabling psychiatric problems in patients with epilepsy are atypical and cannot be

P.2170

classified easily within common psychiatric classification systems, such as the International Statistical Classification of Diseases and Health Related Problems (ICD) and the American Diagnostic and Statistical Manual of Mental Disorders (DSM).[11,89] Therefore, in the current situation, the variations of psychiatric morbidities among studies are due to the variety of selection methods used, improved treatment strategies, and investigation artifacts.

Although preoperative mental disorders may improve or even remit after surgery in some patients, a substantial portion of psychiatric morbidities emerge for the first time following surgical intervention, most within a few months after operation, with a limited timeframe of less than 1 year. As a net result, the prevalence rate of mental disorders after surgery tends to be close to that before surgery. Under the condition that epilepsy surgery is performed to cure epilepsy and not psychiatric disorders, practitioners should be content with these global outcome effects. However, the implicit expectations of patients, caregivers, and professionals transcend the expectation of mere freedom from seizures.

The Role of Surgical Expectations

Patients are subjected to a number of burdensome procedures during presurgical assessments. Strong motivation or a desire for surgery makes the stressful process more endurable for both patients and the doctors in charge. However, the beneficial effects of the strong desires seen prior to surgery often become a stumbling block after surgery, and might seriously undermine patient and caregiver satisfaction with a medically successful outcome, thus hindering social and psychological readaptation. Notably, Taylor et al.[84] designated such expectations as "desire beyond seizure freedom." Furthermore, in a series of insightful investigations, Wilson et al.[95] revealed that the major components of this desire beyond seizure freedom consist of various expectations of a social and psychological nature (e.g., getting married, increasing self-confidence), and that those who aimed at more "practical" benefits (e.g., driving, employment, travel) tended to be more satisfied with the results of surgery. In a similar study, Wheelock et al.[92] showed that those with realistic aims and satisfaction with postoperative results had solid family backgrounds and more stable affective situations prior to surgery. These results suggest that desire beyond seizure freedom and implicit agreements between surgeons and patients should be explored, made explicit, and clearly stated and weighted before surgery. All who are involved in surgical procedures for intractable epilepsy should be aware of the simple fact that a surgical procedure, even a successful one, does not automatically make life happier.

Anxiety and Depression

For surgical candidates, the majority of studies agree that, among psychiatric disorders, depression and anxiety prevail, although the reported prevalence rates vary greatly from 27%,[14] to 33%,[26] to 77%.[2] In this regard, it is noteworthy that the rate of preoperative depression may change substantially, depending on the classification criteria and assessment procedures used. The atypical mixed-mood disorder is commonly encountered in patients with longstanding, intractable temporal lobe epilepsy (TLE) and, when the criteria are strictly applied, this disorder does not fit easily into any single standard diagnostic categories based on ICD and DSM. Blumer and Montouris[10] revived Kraepelin's concept of "epileptische Verstimmung" and designated the pleomorphic, intermittent, rapid cycling presentation of mixed-mood disorder as "interictal dysphoric disorder." In addition to such a fundamental problem with diagnosis inevitably resulting from the insufficiency of the present standard diagnostic systems for neurobehavioral disorders, differences in assessment tools for affective symptoms as well as the observation period (whole life

P.2171

prior to the examination or a period at the time of examination) may well produce a profound effect on the results, which makes simple comparisons between studies virtually impossible.

Table 2 Outcome of preoperative psychosis (temporal lobectomy or amygdalohippocampectomy)

			Outcome of psychosis	
Author (Ref.)	Total *n*	Preoperative psychosis	Unchanged/aggravated	Improved/remitted
Simmel 1958[78]	44	11 (25.0%)	11 (100%)	
Taylor 1972[81]	100	12 (12.0%)	9 (75%)	3 (25%)

Jensen 1979[36]	74	11 (14.9%)	5 (46%)	6 (54%)
Sherwin 1981[77]	63	7 (11.1%)	7 (100%)	
Walker 1984[91]	50	5 (10.0%)	5 (100%)	
Bruton 1988[13]	248	18 (7.3%)	12 (66.7%)	6 (33.3%)
Stevens 1990[80]	14	3 (21.4%)	2 (66.7%)	1 (33.3%)
Kanemoto 2001[40]	52	12 (23.1%)	8 (66.7%)	4 (33.3%)
Cankurtaran 2005[14]	22	0 (0%)		

Supplemented and modified from Matsuura's[59] review.
Patients with postictal psychosis were excluded, if recognized as such from descriptions.
Total *n* = number of subjects.

It remains undetermined whether preoperative diagnoses of anxiety and depressive disorders are predisposed to postoperative anxiety and depressive disorders. Again, it seems plausible that a liability to depression or even a depressed personality structure will not automatically change following surgery for epilepsy, and contradicting data both for[2,68] and against[4,14,55] this argument have been provided. About one-third[26] to one-half[2] of all patients with presurgical depression experienced continuing relief from depression after surgery. In another report, virtually no overlapping was found between patients with depression prior to surgery and those after surgical intervention.[14]

As mentioned, in their study, Kohler at al.[46] added a special comment with regard to patients with ictal fear preceding temporal lobectomy. The authors observed that mood and anxiety disorders after a temporal lobectomy were more common in patients who had fear auras preoperatively, compared with patients with other auras or without auras, in particular if they were seizure-free. The role of the amygdala in fear conditioning, kindling, and the concept of forced normalization were suggested as a possible mechanism.

With regard to the laterality effect, some authors have postulated higher rates of depression in patients with left TLE at the time of the presurgical evaluation,[1,11,90] although more studies have suggested that serious affective dysfunction occurs predominantly in patients with right temporal lobe seizure focus.[22,24,26,47,81] There are also reports that deny any correlation between focus side and depression in surgical candidates.[2,55,57] However, a definitive trend is noted concerning postoperative depression, because right temporal surgery leads to a higher postoperative clinical depression index.[26,47,54,68,81]

Concerning the fate of patients with preoperative depression, the concept of "turning-in" proposed by Hill et al.[32] half a century ago is still worth noting. The authors found that some patients who had a reduction in outwardly turned aggressiveness that was apparent prior to surgery showed depressive mood swings that developed postoperatively, which recovered spontaneously in most cases within 18 months after surgery.

Thereafter, a number of authors reported results supporting that tendency for aggression and irritability to ameliorate following a temporal lobectomy.[19,35,67,81,91]

At our center in Bethel, however, we have also observed changes in the opposite direction, as patients who were emotionally withdrawn preoperatively have gained after surgery impulsive energy that turned into irritable, polemic behavior. The case of a man who lost emotional responsiveness to his family members after surgery, presented by Lipson et al.,[53] points in a similar direction.

Psychosis

Stable interictal psychotic disorders are notably absent in recent surgical series, because such patients have obviously been screened out during presurgical assessment on the assumption that they are less likely to improve functionally[36,37,71,79] or even deteriorate after an anterior temporal lobectomy.[22,36,52,54,81,86] However, since Fenwick[21] advocated surgical treatment even for patients with chronic psychoses, using the argument that seizure freedom alone can be worthwhile for patients even if their psychoses persist, this policy of excluding interictal psychosis has slowly started to change.

Recently, two multiple case studies summarized sequels of temporal lobectomy in patients with chronic psychosis. In one of those studies, Reutens et al.[71] described five patients who had been diagnosed with schizoaffective disorder or schizophrenia based on DSM-IV criteria and rendered seizure-free after surgery, with a 2- to 8-year follow-up period. In two of those patients, activities associated with daily living improved visibly. In another two patients, mental as well as social status remained stable, but unchanged. However, in one patient, psychotic symptoms continued and were so crippling that the patient needed repeated admission. Marchetti et al.[58] reported six patients, five of whom achieved Engel class I seizure outcome and relative improvement in their mental condition. Of those, four patients had a left epileptogenic lesion and two received an initial diagnosis of postictal psychosis, which developed into persistent chronic psychosis later during the course of illness. Although the psychotic symptoms were ameliorated in all four patients with a left-sided lesion, only one of the two with a right-sided lesion improved mentally.

Table 2 lists the ratios of patients with a history of episodic interictal psychosis prior to surgery and the outcome of

pre-existing psychotic symptoms after a temporal lobectomy reported in previous studies. The wide range (0%–25%) of rate of prevalence obtained at different surgical centers may well reflect different exclusion criteria for patients with intermittent (not persistent) psychotic episodes. Except for the Danish series, psychotic symptoms recurred in more than two-thirds of the patients after surgery. In our series, the average duration of postoperative psychotic disorders was far longer (7 months to 7 years; 50% longer than 2 years) than depression (2 to 17 months; 75% shorter than 6 months). It should be noted that a psychotic episode can recur even several years after surgery.[40,80]

In conclusion, treatment of interictal psychosis is not the aim of epilepsy surgery, and only seizure freedom (or improvement of seizure status) can be reasonably expected after surgical intervention. On this basis, patients should be informed that the postoperative development of their psychosis is unpredictable. However, with appropriate psychiatric support, patients can undergo epilepsy surgery and profit from seizure freedom in many respects.

In contrast to interictal psychosis, a number of studies suggest good outcomes for postictal psychotic episodes after a temporal lobectomy, thus rendering them as suitable surgical candidates.[19,22,40,74] The direct coupling of this type of psychosis to the occurrence of seizures predicts an excellent improvement under seizure-free postoperative conditions. In this regard, postictal psychosis has been described as a psychiatric indication for epilepsy surgery. However, in the postsurgical phase, those patients are especially liable to develop postoperative depression complicating their readaptation after surgery.[40] Two studies have reported frequencies of postictal psychoses in candidates for epilepsy surgery, which are rather high at 18%[87] and 13%.[40]

Other Psychiatric Disorders

In two case reports, rare associations of TLE and obsessive-compulsive disorder (OCD) were ameliorated after a right temporal lobectomy.[7,42] In contrast, Kulaksizoglu et al.[51] reported a worsening of preoperative obsessive-compulsive personality traits into a full-dressed OCD in two patients following an amygdalohippocampectomy. The authors hinted at the possible contribution of left-sided surgery to the development of OCDs.

Sexual behavior and function changes have also been listed as possible sequels after a temporal lobectomy. Postoperatively, both declines[12] and increases in sexual activity[5,6,9,12,65] have been reported, whereas abolition of aberrant sexual behaviors such as paraphilias[61] has also been noted. Postoperative sexual changes may persist several years after a temporal lobe resection and possibly more frequently after right-sided surgical intervention,[5,6] although the effect of laterality has been denied by others.[9]

Personality Disorders, Traumatic Stress, Nonepileptic Seizures

During the past decade, debate about the dubious character of the diagnostic category “personality disorder” (PD) has cooled down, possibly as a consequence of the descriptive, nonstigmatizing approach presented in the DSM classification system. Today, discussion tends toward a notion of PD as a result of maladaptive biographic developmental conditions, constitutional and/or experiential, which are expressed in behavior traits deviant from sociocultural norms. The capacity to cope with stressful life events is low in patients with a PD, and their liability to psychiatric decompensation is strengthened. It seems evident that, beyond other developmental risks, patients with chronic epilepsies are prone to additional personality problems due to their organic deficits, their epilepsy-specific social restrictions, and the side-effects of treatment. Candidates for epilepsy surgery with complex PDs could thus be expected to develop new psychiatric disorders. However, there are only a few studies on PDs in the context of epilepsy surgery. In 1957, Hill et al.[32] published a historical paper on personality changes after a temporal lobectomy. In that study, the authors investigated 27 patients both before and 2 to 5 years after temporal lobe surgery, of whom all but one had psychiatric disorders prior to surgery. Using a broad, not exactly specified definition of PD, the authors reported the following changes in personality: Loss of verbal learning abilities in dominant resections, reduction of aggressiveness by an increased tolerance of frustration, “turning-in” of aggressiveness with depressed mood (as mentioned earlier), changes in sexuality (mostly an increased sexual drive), and an increase of warmth in social relationships by a “lessening of egotism.”

Two more early, but very instructive, studies with diligent case-descriptions were presented by Horowitz and Cohen in 1968[33] and Serafetinides in 1975,[75] which focused on the meaning of PDs in the context of epilepsy surgery. However, from that time, the topic more or less vanished as a research subject in regards to epilepsy surgery. Since then, most of the studies on presurgical psychiatric morbidity have only focused on DSM axis 1, namely clinical syndromes, and excluded personality diagnoses. One study found PDs in 18% of the candidates for epilepsy surgery.[57] In a group of 100 patients who underwent temporal lobe surgery at our Bethel epilepsy center, we found that 60% had PDs. A detailed analysis revealed that 15% had a severe PD due to epilepsy—that is, directly correlated to the disease—which was formerly called “organic PD.” These patients, together with Cluster A patients (DSM-IV), showed a specific risk to develop new postoperative psychoses, whereas Cluster B patients were susceptible to dissociative disorders like depersonalization and nonepileptic seizures, but not to psychoses. The postoperative development of Cluster C patients was uncomplicated, except for those with additional cognitive deficits.[44] PDs also proved to predict severe postoperative psychiatric complications (defined by admittance to a psychiatric hospital during the first 2 years after surgery), because all psychiatrically hospitalized patients had suffered from PDs prior to surgery.[43]

As Ettinger[18] stressed in the editorial remarks to the recent re-edition of Hill's study, not only the topic of PDs but also Hill's scientific approach may need reactivation. The rigidity of the scientific community for only allowing the use of scales and scores as a basis for scientific publications too easily dismisses the detailed portrayals of patients' daily distress or missing skills, as well as analysis of their “essence.”

Another topic that remains unexplored in the context of PDs in epilepsy patients is the role of psycho-traumatization in the genesis of epilepsy and during surgical procedures. Research in this field has shown that chronic complex trauma experienced during the phase of brain development may induce borderline PD as well as dissociative disorders, and may have a damaging effect on mesiotemporal structures. It is an open question if the origin of TLE in those patients is accidental or causally related to trauma history, the latter being subjective evidence of many affected patients. As mentioned earlier, in our Bethel group, the development of new dissociative symptoms after surgery has shown a strong link to the diagnosis of borderline PD with a trauma history. This concurs with the findings of Ney et al.,[64] who reported that new dissociative nonepileptic seizures after surgery were predicted (among other factors like low IQ and surgical complications) by serious preoperative psychopathologic conditions.

It is unclear whether nonepileptic seizures should be considered an independent disorder or a symptomatic expression

P.2173

of an underlying PD. To date, there is not much data on the percentage of patients with additional nonepileptic seizures in candidates for epilepsy surgery (ranging from 5%[64] to 10%[25]). Reuber et al.[70]

followed-up 13 patients (out of 1,342 surgery candidates) with both seizure types and reported good postoperative outcomes in terms of epileptic seizure control with a good match to those without nonepileptic seizures. Similar to Henry and Drury,[27] who recommended that an operation should only be planned if nonepileptic attacks are well treated by psychotherapeutic interventions, Reuber et al. concluded that additional psychogenic seizures should not be considered an absolute contraindication for surgery.

Postoperative Psychiatric Development

De Novo Acquired Disorders and Their Treatment

In general, improvement in seizure frequency after a temporal lobectomy may increase the possibilities of participation in social life and contribute to a well-balanced psychosocial state. However, especially during the first 3 to 6 months after temporal lobe surgery, many studies indicate that even patients who experience seizure freedom should be prepared for at least transient psychiatric deterioration.[11,26,39,40,48,72] Some authors have pointed out that even over the long term, some exceptional patients continue to suffer from postoperative worsening of their mental condition.[40,80,81] Among psychiatric disorders, depression and anxiety are listed as the most frequently encountered conditions in many reports. Psychogenic seizures are not so common; however, these could become a serious problem for some individuals. Single cases of OCDs that developed following surgery have also been described. The majority of recent studies that have addressed psychotic symptoms agree that new psychosis after a temporal lobectomy is less frequent than assumed earlier.[26,60,63] However, the acquisition of a new psychosis is such a serious burden for patients that it is imperative to observe carefully if psychotic symptoms develop. These may be potentially reversed when appropriate therapy is provided.

Generally, the explanations for the occurrence of new psychiatric disorders suggested so far can be summarized as biologic and sociopsychological, a consequence of disrupted functioning within the temporal lobe structure, such as the amygdala, which is known to be involved in the modulation and expression of emotion,[72] forced normalization.[26,50,90] This system collapses under increased expectations for new role functions once seizures have been abolished or reduced.[9,23] However, these theories remain to be elucidated with further evidence.

Postoperative Depression, Anxiety, and Manic Disorders

It is widely accepted that patients are especially prone to develop depressive or anxious states during the first 3 months after surgical treatment.[9,11,17,72,89] Thus, the prevalence rate of postoperative depression in outcome studies is highly dependent on the time schedule of the psychiatric assessment (Table 3). Within 3 months after the operation, depression occurred in one-third of patients, a prevalence rate that amounted to approximately half of the patients when anxiety disorder was added in two studies.[11,72] In contrast, many studies agree that the prevalence drops to 5% to 14% at 6 months after surgery.[9,26,40.52,63] Except for the report of Anhoury et al.,[4] showing 17%, the prevalence rate of new depression ranges from 8% to 10% after 6 months. Further, Wrench et al.[96] found that temporal patients reported significantly higher rates of anxiety and depression than did extratemporal patients, stressing the pivotal role of temporal lobe involvement in the genesis of new depression.

Although the highest incidence of anxiety was achieved within 1 to 2 months after surgery, the highest morbidity of depression was found within 3 months.[55,72] Except for some exceptions,[45] many authors agree that anxiety disorders tend to have a shorter duration than do affective disorders.[14,55,72]

In extreme cases, significant levels of postoperative depression and anxiety can lead to attempted suicide, paradoxically even in patients who have been rendered seizure-free.[9,26,36] After the first alarming report of Taylor and Marsh of nine suicidal cases from Falconer's large series of 193 patients, suicide attempts have been reported (4.6%–8.1%), especially in earlier series.[36,83] Most authors agree that postoperative mood disorders are transitory, with a remission within the first year after surgery,[26,40] and that the occurrence of postoperative depression is independent of seizure outcome.[32,96]

Table 4 De novo psychosis after epilepsy surgery

Supplemented and modified from Trimble.[85]

Total *n* = number of subjects.
R/L, right/left.

In exceptional cases, mania can also occur de novo after a temporal lobectomy. Following the first case report,[38] a case control study[15] compared postoperative depression and mania

groups, and indicated that postoperative mania patients were more likely to yield findings of additional brain dysfunction in the hemisphere contralateral to the side of surgery, particularly in the electroencephalogram (EEG). Episodes of mania, just as depression, were usually transient and remitted within 1 year after onset. The prevalence rates in previous studies were 1.8%,[52] 3.8%,[39] and 3.9%.[15] Right temporal lobectomy was more common in patients exhibiting mania.[15,39]

New Nonepileptic Seizures and Somatoform Disorders

Nonepileptic seizures occurred newly after a temporal lobectomy in 1.8% to 8.8% of patients.[4,25,62,66] Following the first report of Ferguson,[23] which emphasized psychological aspects, new-onset nonepileptic seizures following surgery have been neglected in studies. However, the recognition of postoperative new seizure events as nonepileptic seizures, both in patients following a successful operation and in those with persistent epileptic seizures, is mandatory to prevent a delay in finding the most effective coping strategy. Since those patients who develop nonepileptic seizures frequently suffer from complex biographic burdens, extensive psychotherapeutic interventions may be necessary.

Previous reports agree that female patients with a right-sided temporal lobectomy are more susceptible to developing new-onset nonepileptic seizures, which tend to appear within 6 months after surgical intervention.[25] Although some reports have stressed early epilepsy onset as a risk factor for the emergence of new-onset nonepileptic seizures,[23,49] others have reported the reverse.[25] Low intelligence has been also suggested to promote new-onset nonepileptic seizures,[64] although that has been denied by another report.[25] As an explanation for that discrepancy, Glosser suggested the heterogeneity of such patients. Further, Naga et al.[62] described rare cases of postoperative occurrence of somatoform disorders other than conversion, such as pain disorder and body dysmorphia. They found new-onset somatoform disorders exclusively in patients following a temporal lobectomy, especially after right-sided resections, and not in those with an extratemporal resection.

De Novo Psychoses

Over the years, special attention has been paid to the risk of development of de novo psychosis following epilepsy surgery, because psychotic symptoms, once emerged, may decisively damage the quality of postoperative life and can become the main obstacle to social and psychological adaptations following surgery.[11,36,54,56,57,73,80,81,86] Furthermore, a new development of postoperative psychosis can be observed even in the setting of complete relief of seizures. As a result, several earlier reports stressed the risk of a development of postoperative psychosis.[36,81] However, the majority of recent studies suggest that new psychotic symptoms are less common following epilepsy surgery than assumed earlier.[26,60,63] Despite this, because of the severity of the disorder and the clinical significance of early detection and effective treatment of even subtle psychotic complaints, the new occurrence of psychotic episodes deserves special attention.

The prevalence rates of postoperative new psychosis in available studies range from 3.8% to 12.1%, except for the very high rate of 35.7% reported by Stevens[80] (Table 4). In Stevens' series, three patients who had exhibited strong paranoid behavioral patterns even prior to surgery were also included as postoperative new psychosis. By excluding those patients from analysis, the prevalence rate for that report drops to 14.3%. Several clinical parameters have been listed as predictors for the postoperative occurrence of new psychosis, and some authors have postulated that patients with ganglioglioma are more susceptible.[3,73,81] In a recent case-control study of patients with new psychosis after a temporal lobectomy, more bilateral abnormalities in preoperative EEG findings were detected, as well as pathologies other than mesial temporal sclerosis in the excised lobe and a smaller amygdala on the unoperated side.[76]

As Trimble suggested,[85] an association between postoperative psychoses and right-sided temporal lobectomy is rather clear when previous studies are listed together (see Table 4). This is all the more conspicuous when considering that schizophrenic-like psychoses are more common in patients with left or language-dominant temporal lobe seizure focus before surgery.[24,81,86]

P.2175

Some psychoses following surgery occur with postoperative freedom from seizures. They may be interpreted as "alternative psychosis" under the postoperative condition of forced normalization,[54] whereas others occur in patients with ongoing seizures, frequently as new "postictal psychosis," which has been reported to occur more often in male patients with right-sided surgery.[56] Recently, Christodoulou et al.[16] emphasized the significance of an emergence of new contralateral seizure foci after surgery, and suggested that new episodes of postictal psychosis were heralded by a new seizure type and originated from the side contralateral to the side of operation.

The Role of Seizure Outcome

Postoperative depression and psychosis can both occur with or without seizure freedom, and the relationship between seizure control and new psychiatric symptoms following surgery is still an open question. Glosser[26] noted a weak but noticeable trend that seizure-free patients may be at higher risk for the development of an early transient psychiatric worsening at 6 months after a temporal lobectomy. In contrast, seizure-free status is recognized to be the most powerful predictor of improved psychiatric and psychosocial adjustment outcome over the long term.[9,30,69,83,88,92]

On the other hand, several reports show weak but consistent evidence that the preoperative existence of a psychopathology is a negative predictor of seizure freedom. This supports the assumption of a common etiology between epileptic syndromes and psychiatric disorders.[4,63] At Bethel, we found seizure freedom in 89% of 100 patients without psychiatric comorbidities, whereas only 43% of patients with psychiatric disorders were seizure-free after temporal lobectomy.[44]

Postoperative Treatment, Role Changes, and Long-Term Adaptation

The first few postoperative weeks after epilepsy surgery are a vulnerable phase of irritability, anxiety, and the development of depression. One treatment strategy is to start early and broadly with antidepressants. Selective serotonin-reuptake inhibitors (SSRIs) are tolerated well and have been reported to be helpful, as have tricyclic antidepressants,[11] although control studies are missing.

If patients refuse to take antidepressants, it is necessary to instruct them to contact a neuropsychiatrist, at least when symptoms get stronger and indicate a manifest depressive episode. If patients, or more likely family members, should complain about withdrawal, delusions, and atypical suspiciousness, which are early symptoms of postoperative psychoses, an urgent outpatient contact is needed to plan careful treatment and convince the patient of the necessity of antipsychotic medication. Atypical substances, especially risperidone, in rather low doses are often sufficient, and instructions to the family along with clear advice about further treatment contacts are important. Generally, it is recommended to equip all patients with the phone number or e-mail address of a psychiatrist at the surgery center, which may also help to prevent suicide attempts during the first postoperative months. Although only a few patients make use of such contact offers, many report that the option to call or write is a substantial part of feeling secure during insecure times of change.

We concur with Wilson et al.,[94] in recommending a graduated return to work, starting no earlier than 6 to 8 weeks after surgery, to avoid the negative effects of early transient postoperative impairments (difficulties in word finding, memory, and concentration, distracted attention, affective lability) that may yield mistakes on the job and create a negative influence in the relationship between patients and employers.

Not only acute psychiatric complications bother patients and families after epilepsy surgery, but the complicated process of moving from chronically ill to normal and healthy. Since the early reports of Ferguson and Rayport,[23] who observed paradoxical worsening of behavior after successful surgery, and of Horowitz and Cohen,[33] who described that the loss of seizures may seem like the loss of "an old friend" during the process of readjusting to life without epilepsy, some papers have focused on the process of discarding roles associated with chronic epilepsy. Of special interest is the thoughtful application of the concept of "learned helplessness," a known trigger for depression, to chronic epilepsy patients.[28] Recurrent uncontrolled seizures support the development of a self-concept as being without personal resourcefulness and efficacy. This negative self-concept tends to persist after surgery and may lead to a poor postoperative psychosocial adjustment.[17] Ongoing feelings of helplessness, especially in the surroundings of growing external demands and the loss of being excused by the epilepsy are expressions of the "burden of normality."[9,93] Conversely, other patients have pushed themselves to their personal psychophysical limits before surgery to prove their normalcy. They may experience exhaustion after the cessation of seizures, instead of expected alleviation. Another hint that life remains complicated for patients who undergo surgery has been shown by Koch-Weser,[45] who found that the average burden of anxiety symptoms was higher in patients 2 to 7 years after surgery than in presurgical candidates. Over the long term, complete seizure relief is the best predictor of good psychosocial adaptation, and especially of an enduring remittance of depressive symptoms.[11,29]

Psychiatric Care in epilepsy Surgery Centers: History, State, and Perspectives

In the first Consensus Conference on epilepsy surgery at Palm Desert, Fenwick initiated a worldwide survey on psychiatric facilities in related centers.[20] At that time, 53 centers existed and 21 answered. The mean proportion of patients psychiatrically assessed before surgery was 31.7%, and after surgery the percentage was 41.5%. As a consequence, Fenwick advocated improvements in psychiatric facilities.

In their recommended standards, the International League Against Epilepsy (ILAE) commission on Neurosurgery (1993–1997) commented rather scantily on psychiatric necessities, saying that the preoperative workup should include "careful assessment of psychiatric state… using psychiatric rating scales when appropriate" and, with respect to the follow-up period, the recommendation was that "some form of psychiatric assessment should be used."[8]

Recently, Kanner[41] has advocated for more involvement of psychiatrists in epilepsy centers. He complains that "only a minority of (U.S. surgical) centers performs a psychiatric evaluation as part of their presurgical evaluation" and "in less than 25% of major epilepsy centers surveyed, the epilepsy team includes a psychiatrist who is available to evaluate every patient."

In the recent ILAE psychobiology commission (Trimble, Schmitz), a subcommission on epilepsy surgery (Koch-Stoecker, Krishnamoorthy, Kanemoto) has repeated a worldwide survey on psychiatric facilities in epilepsy surgery centers (unpublished data). The most important result is that 26 (43%) of the 60 responding centers stated that they perform both pre- and postoperative assessments for all patients, and another 40% at least have access to psychiatric crisis interventions. These results show substantial improvement; however, the survey did not

P.2176

cover the assessment strategies used, and it is probable that in many centers only standardized self-rating questionnaires are used which are no adequate substitute for a clinical diagnostic interview.

In times of economic pressure that lead to reductions in staff at most centers and no enhancement of psychiatric services, we recommend a psychiatric screening using rating scales for all patients, followed by an extensive interview with those who are screened out as belonging to a psychiatric risk group.

With respect to enhancement of psychiatric treatment options for epilepsy surgery patients, the development of specific psychiatric treatment manuals to be used in surgery centers as well as in local psychotherapies is desirable. These manuals should include topics such as a structured clearing of surgical expectations beyond seizure freedom; typical role-constellations and possible changes after surgery; education about symptoms of depression and psychosis; social skills training, along with instructions for the development of a reasonable self-concept; and education for coping with seizure recurrence.

Finally, psychiatric research in epilepsy surgery centers that stand at the interface between neurology and psychiatry must be promoted. In amplifying Ettinger's comments[18] on the rigidity of requirements for approval in peer reviews, more flexibility and creativity in study designs should be allowed to add new dimensions to our scientific knowledge. For example, individual case reports, in which psychosocial developments are extensively thought over and analyzed on the basis of the exchanges between patient and professional, or quality research strategies with expert discussion groups, are excellent and thoughtful means to supplement a statistically based understanding of mental disorders. Further, additional diversity in scientific exchange will inspire psychiatrists working in epilepsy surgery to participate in expanding the international network.

Summary and Conclusions

The close link between the epileptic condition and psychopathology, and the high frequencies of psychiatric disorders in epilepsy patients calls for psychiatric assessment and treatment in the context of epilepsy surgery. In addition, postoperative seizure freedom alone is no guarantee for an amelioration of quality of life, but mental stability and coping capacity are central preconditions in the challenging postoperative time of new role demands. Concerning depression, the most frequent disorder type, the predictive meaning of its preoperative existence is still equivocal, whereas postoperative depression is well-known as surgical complication during the first half year after surgery which occurs in about 10% of patients, especially after right sided resections.

Interictal psychoses are no longer seen as contraindications, because seizure relief can be of great value even if psychosis persists, and psychotic deteriorations after surgery are extremely infrequent. Postictal psychoses disappear together with seizures, but the probability of an episode of postoperative depression is high in this patient group. During the last decade the reports on new psychoses after surgery oscillate about a frequency of 2%. Despite this low incidence rate postoperative psychoses deserve special attention because of the severity of the disorder.

Personality disorders are very frequent in candidates for epilepsy surgery and complicate postoperative adaptation. The role of early traumatic experiences in the development of personality disorders, of the epilepsy causing lesion itself, and of non-epileptic dissociative attacks in epilepsy surgery candidates is not yet well understood.

In summary our knowledge about psychiatric disorders, their predictors and their treatment in the context of temporal lobe resections has grown during the last decade. Still there are many contradictory results, and conclusive etiological models are not available. Apart from future descriptive and controlled studies quality research and case studies could be helpful to create a more colourful picture of individual courses and to generate new hypotheses on psychobiological connections.

There is still too little presence of psychiatrists in epilepsy surgery units. Especially needed is more time for understanding patients' individual psychodynamics, the development of suitable assessment tools to meet the demands of atypical psychiatric disorders, and structured treatment instructions for special surgery related complications. If assessed and treated adequately mental disorders do not hinder patients on their way to a better quality of life after surgery in the long run.

Chapter 210

Psychiatric Disorders in Children

Rochelle Caplan

Christopher Gillberg

David W. Dunn

Sarah J. Spence

Introduction

The psychiatric and social aspects of epilepsy in childhood reflect the complex interaction of both general and specific illness-related factors on the child's life.[103] In terms of general factors, epilepsy is a chronic recurrent disorder and, like other chronic illnesses, this disorder affects the lives of the child and family. Among the specific illness-related factors, epilepsy involves brain function. In the developing child, chronic recurrent brief episodes of brain dysfunction might impact brain development, and, therefore, the development of behavior, cognition, and language. The maturation of these three areas of functioning has important implications for the psychiatric and social functioning of the child.

Two epidemiologic studies found a significantly higher rate of psychiatric disorders in children with neurologic disorders compared with children with chronic illnesses that do not involve the brain.[55,218] Furthermore, more specific seizure-related factors, such as type of seizure disorder, seizure control, the age of onset of seizures, and the number and type of antiepileptic drugs (AEDs) can impact the child's behavior.

This chapter summarizes the literature on these general and specific illness factors and how they are associated with psychopathology, cognition, and language in the child with epilepsy. It also presents the neurobehavioral aspects of selected early-onset epilepsy syndromes and how they affect children's behavior, cognition, language, and social skills.

The chapter then describes psychiatric disorders found in children with epilepsy. The chapter concludes by summarizing the most pertinent psychiatric and social issues of pediatric epilepsy. It also presents possible avenues for future research that would address the mental health needs of children with epilepsy.

Definition and Phenomenology

Psychological Impact of a Chronic Illness on the Child and Family

A chronic illness like epilepsy is a stress factor for the child and his family. The child and family need to recruit coping or behavioral, emotional, and cognitive strategies to decrease the illness related “mismatch” with the environment.[98,218] Adaptive or maladaptive use of these coping strategies depends on the complex interaction of a “multivariate multiprocess system”[143] that involves the child and family, as well as the social, educational, and medical environments.

Several studies have demonstrated that maternal and family functioning are important predictor(s) of psychological functioning in children with a chronic illness, whereas illness severity merely mediates (moderates) the effects of psychosocial variables; the reader is directed to two reviews on this subject.[248,269] In pediatric epilepsy, maternal depression and family functioning primarily reflect the presence of comorbid behavioral problems in the child rather than illness severity.[164,232] Limited family mastery and lower levels of confidence in managing child problems also predicted behavior problems in children with epilepsy at baseline and 24 months later.[11]

From the psychodynamic perspective, a child with epilepsy is faced with several stresses. The first stress factor, unpredictability, is a hallmark of epilepsy because the child never knows when a seizure is going to happen.[276] From the child's perspective, this unpredictability can lead to a sense of lack of control, fear, anxiety, or need to be dependent and protected by significant adults.

During development, children acquire self-esteem as they begin to master their environment and can do more things by themselves. This sense of mastery fosters a feeling of competence and control while decreasing the child's need for dependence. In contrast, the need for dependence produces a sense of helplessness and lack of self-esteem that can lead to feelings of inadequacy, poor self-worth, and ultimately to depression.[144]

In addition to unpredictability, the lapse in consciousness during a seizure or the child's experience of having his limbs do things that he has no control over further increases the sense of lack of control. Similarly, the unpleasant sensation of epigastric distress during the aura of a complex partial seizure can exacerbate the sense of lack of control, fearfulness, and dependence. Furthermore, the manifestations of a seizure are often perceived by others as frightening and grotesque.[163] The child's peers might, therefore, react to a seizure in a negative manner.[163] This could increase the child's feelings of being different.

Several older studies have shown that children with epilepsy, particularly those with temporal lobe epilepsy (TLE), were more dependent than children with other chronic illnesses.[96,109,243] In these studies, dependence was related to the presence of psychiatric disturbances,[96,109,243] a sense of lack of control, and attribution of failures and successes (particularly those in the social realm) to external unknown sources.[163] More recent studies have shown that children with newly diagnosed epilepsy feel shame and guilt about having epilepsy[196] and that adolescents with epilepsy are aware of a stigma to this illness.[9] Caplin et al.[36] demonstrated a positive correlation of self-efficacy with positive self-concept and positive attitude toward illness in youth with epilepsy and a negative association of child self-efficacy with child worries and symptoms of depression. Austin et al.[11] have shown that greater worry, negative attitude, poor self-concept, and symptoms of depression were associated with an increased sense of stigma in a large sample of children with chronic epilepsy.

Furthermore, the child has to contend with the possible behavioral and cognitive side effects of AEDs. Young children

P.2180

and sometimes adolescents are often unaware of the connection between these effects and their medication. These side effects could, therefore, contribute to the child's feeling of not being in control. Finally, despite the previously described stressors, children with epilepsy, like their peers, need to function adequately in the academic and social environment. These are far from trivial stressors.

Three main factors affect the coping skills of children with a chronic illness: the marginality of the sick status, the episodic nature of the disease, and the age of onset of the disorder.[100,202] If a child has visible physical impairments, a disease that is not episodic, and onset of the disorder from the preschool period, she self-identifies as sick and others identify her as different. If the disease has no visible impairments, is episodic, and begins after kindergarten, the child does not feel different from other children. When ill, the child tries to regain and/or achieve normal status.

The emotional burden on the child increases the less visible the handicap and the more normal the child is expected to be.[100] The need to meet these expectations becomes increasingly taxing for the child with epilepsy with recurrent rather than well-controlled seizures.

From the conceptual perspective, children's understanding of the nature of their disorder is age-related and can impact how well they cope with the illness.[220] Thus, 5- to 7-year-old children are aware of the external aspects of their disorder.[23] For example, they take medication, have repeated blood tests, and visit the doctor. Older children with epilepsy are more aware of the brain's role in their disorder, and this knowledge sometimes becomes a source of concern for them.

Sanger et al.[220] found that 41% of epileptic children and adolescents between the ages of 5 and 16 years identify epilepsy as a disease that involves the brain. Some children[10] fear that they might die during a seizure, and this fear makes them more anxious and dependent. Many children have misconceptions about seizure disorders and lack disease-related information. Only 41% of the children identified epilepsy as a disease involving the brain.[220]

Compared with children with asthma and diabetes, those with epilepsy have more unanswered questions about their illness and feel excluded from discussions with doctors.[119] Supporting this finding, McNelis et al.[157] reported that more than half of children with new-onset seizures want more information on seizures, the cause of seizures, treatment, handling future seizures, and protection from injury 6 months after their first seizure. They want to talk to other people with seizures, and need help handling seizures at school. More than 30% have fears or concerns about having another seizure and how to tell others about their seizures.

The impact and ramifications of the unpredictability of seizures is as important for the parents as for the child. It causes a sense of anxiety and is confounded by fear that the child could get hurt[10] or die[277] during a seizure. This unpredictability results in the difficult task of having to tread the fine line between what might be perceived as an overanxious or overprotective parent versus a neglectful parent. Thus, mothers of children with epilepsy are more stressed than are parents of children with other chronic illnesses.[68]

Parents vacillate between the need to protect and make sure their child is safe at all times versus the need to allow the child autonomy. The way parents cope with this stress affects the child's sense of dependence/independence, competence, and self-esteem. The findings of studies on the relationship of maternal anxiety and maternal adjustment with child quality of life, severity of epilepsy, and child adaptation highlight the role psychosocial variables play in how families cope with having a child with epilepsy.

For example, a study conducted on a relatively small sample described mothers as more emotionally involved in the lives of their children with epilepsy compared with their children without epilepsy.[111] This study also found increased maternal criticism toward the children with epilepsy, and this finding was related to more antisocial behaviors and poorer self-esteem in the children with epilepsy compared with their siblings.

Williams et al.[266] found that a significantly higher rate of parents of children with epilepsy sleep with their children than do parents of children with diabetes. They suggested that anxious parents might be more likely to perceive more risks for their children and misinterpret information about their child's condition, such as the need to sleep with the child to monitor for seizures. In a later study, Williams and colleagues[268] demonstrated that families most vulnerable to reduced quality of life were those in which a child has poorly controlled epilepsy, comorbid disabilities, and increased parental anxiety. Similarly, Austin et al.[15] reported that maternal adjustment and attitude was significantly related to the severity of the child's seizures.

In a large sample of children with epilepsy, Shore et al.[231] used a conceptual model based on prior findings in the literature to investigate the associations among maternal and child characteristics, maternal beliefs, and maternal adaptation. They found that most mothers adapt relatively well to their children having epilepsy. However, more than one-third of mothers were depressed and felt inadequate at managing their child's seizure disorder and maintaining the family's usual leisure activities. Child behavior problems, maternal satisfaction with family, and maternal learned helplessness had the strongest associations with maternal outcomes. This study did not examine the relationship between maternal and child adaptation.

In terms of child functioning and adaptation, Lotham and Pianka[154] found that measures of child–mother interaction and child self-reliance were significantly related to adjustment measures in children with epilepsy. Chapieski et al.[48] reported that poor adaptive functioning, based on the Vineland Adaptive Behavior Scale[238] in children with epilepsy was significantly associated with maternal anxiety, as well as with an overprotective and overly directive parenting style.

The few studies that have included both mothers and fathers find similar concerns in both parents of children with new-onset epilepsy.[233] Although these concerns decrease over a 6–month period, mothers maintain a higher level of concern than do fathers. Fathers have also reported that mothers are more concerned than they are about their child's epilepsy.[66] These parental differences can influence what children feel about the impact of their illness on their parents and family functioning. Therefore, studies are needed to determine how differences in parental concerns, anxiety level, and attitude are reflected in child functioning and adaptation.

In addition to the previously reviewed child and parent psychological variables, sociodemographic variables, such as social class, current and previous family stresses, and the presence of other children might also contribute to both the child's psychosocial adjustment and the family's coping skills.[110] Within the family context, there is a debate in the literature on the impact of chronic illness on healthy siblings; this topic is reviewed by Sharpe.[228] Hoare[108] demonstrated that the siblings of children with new-onset epilepsy are not more maladapted than the siblings of children with new-onset diabetes. However, the siblings of children with chronic epilepsy were more maladapted than the siblings of children with chronic diabetes. These findings led Hoare to conclude that chronic epilepsy has a marked impact on the behavior of the affected child, the siblings, and the family.[108]

In terms of the external environment, both the child and parents must deal with the school system. From the psychodynamic perspective, the occurrence of seizures at school can increase the child's sense of lack of control and present the child with the difficulty of dealing with stigma from peers and

teachers. The child is also often faced with repeated questions by peers after having a seizure at school and also with teachers' lack of knowledge and misconceptions about epilepsy.[24] Even though there is no medical indication, teachers sometimes send children home or to an emergency room when they have a seizure. As a result of repeated absences, the child has more work to catch up, and this may increase the already difficult work load.[202] Teachers also might underestimate the child's intellectual potential due to misconceptions about epilepsy.

From the parental perspective, their efforts to help the child deal with the school system might increase their stress and that of their child. Hoare and Kerley[110] have shown that families of children with epilepsy who attend special schools are under more stress than those of children in regular schools. Alternatively, Austin et al.[18] described a significant association between academic achievement and family mastery in children with epilepsy.

Regarding academic achievement, Fastenau et al.[72] demonstrated a moderating effect of family factors, particularly organized/supportive versus disorganized/unsupportive family structure, on the impact of neuropsychological deficits on the writing and reading skills of children with epilepsy. Supporting the importance of family functioning in the academic performance of children with epilepsy, Mitchell et al.[175] found that parental education rather than seizure variables plays an important role in the IQ of children with epilepsy. Taken together, these psychosocial factors could increase the demands facing the child and affect his academic functioning,[72] self-esteem,[162] and related social and school functioning.[42]

From the social perspective, the problems of adolescents with epilepsy deserve special mention. During adolescence, youth acquire more independence, yet vacillate between dependence and independence. Uncontrolled epilepsy could affect this process by increasing dependency. Alternatively, if adolescents experiment with the decision-making, they might make decisions that are potentially harmful for their illness.[33] For example, to conform to what they perceive as the expectations of peers, adolescents might be noncompliant with AEDs, go to sleep late, or use alcohol and drugs. These behaviors could lead to poor seizure control and possible denial of a driver's license. These circumstances can lead to a significant increase in family stress.[146]

In terms of coping skills, a study of a large sample of adolescents with epilepsy has shown increased negative attitude with increasing age and poor seizure control[99] using the Child Attitude Towards Illness Scale.[13] The authors of this study suggest that as youth get older, a better understanding of the restrictions and limitations of the illness might underlie the increased negative attitude. Despite seizure control, the mothers of adolescents with epilepsy report significantly more psychological, social, and school adjustment problems than do the mothers of adolescents with asthma.[14] Also, above and beyond the effects of seizure control, Sbarra et al.[224] found that adolescent perception of controlling maternal behavior was significantly associated with youth externalizing behaviors.

Dealing with the stigma of epilepsy during adolescence might also pose additional coping challenges, as reviewed by MacLeod.[157] Westbrook et al.[263] found that only one-third of 64 adolescents with epilepsy confirmed that they felt stigmatized, and this finding was associated with poor self-esteem. Similarly, using the Quality of Life in Epilepsy for Adolescents (QOLIE-AD-48), which includes a stigma scale, Devinsky et al.[57] found relatively low stigma and good quality of life in youth with epilepsy. In contrast, a 37-item questionnaire designed to measure familiarity with epilepsy, knowledge about epilepsy, and perceptions reflecting stigma filled out by 19,441 adolescents revealed lack of knowledge and misperceptions about epilepsy that suggest a high rate of stigma.[19] In addition, the finding that 70% of the epilepsy patients in the Westbrook et al.[263] study said that they do not talk with anyone about their epilepsy implies that they do not talk about their illness because of stigma.

Finally, the child and family also must interact with the medical system. Two studies, one conducted in the mid 1980s[50] and one in 2004 (Smith et al., in press) found a marked discrepancy between the concerns of parents of children with epilepsy regarding their children's needs compared to how the treating pediatric neurologists and pediatricians viewed the parents' concerns. Whereas the parents were mainly worried about their children's behavior and performance at school, physicians thought the parents were concerned primarily about the stigma of epilepsy and seizure control. This continued discrepancy, despite increasing evidence for behavioral, cognitive, linguistic, and quality-of-life difficulties experienced by children and adolescents with epilepsy, underscores the stresses faced by parents of children with epilepsy.

In summary, from the psychological perspective, the child's ability to cope with epilepsy is a function of his intrapsychic experiences, such as sense of mastery and understanding of the illness, how the child's parents and family deal with the illness, as well as how the school, peer group, and medical system respond to the illness.

The Effect of Seizure-Related Factors on the Child's Behavior

This section reviews studies on the association among seizure-related factors, such as seizure type, seizure control, AEDs, and age of onset with behavior, cognition, and language of children with epilepsy.

Psychopathology by Seizure Type

The landmark Isle of Wight epidemiologic study on psychopathology in children found an increased rate in children with TLE.[218] However, very few children in that study met criteria for TLE. Subsequent studies, albeit nonepidemiologic, of psychopathology by seizure type in childhood inconsistently found a relationship between type of epilepsy and psychopathology.

These discrepancies reflect limitations inherent in including relatively small sample sizes of children with epilepsy, and, therefore, small numbers of children with different seizure types. This, in turn, reduces the power to examine possible confounding effects of other seizure variables (e.g., seizure control, age of onset, duration of illness, type and number of AEDs), as well as of comorbid cognitive and linguistic deficits, demographic variables, and premorbid behavior problems.

Moreover, studies differ in whether they classify children by epilepsy syndrome, type of epilepsy, or localization-related epilepsy, or include type of epilepsy as one of several seizure severity measures. In addition, they also vary in the technique used to collect behavioral information on the children (e.g., structured psychiatric interviews, questionnaires), the source of information (e.g., child, parent(s), teacher), and the measures (psychiatric diagnoses, scores).

With these limitations in mind, the findings of earlier studies suggested that a relationship exists between type of seizure disorder and behavioral problems. For example, Nuffield[190] described neurotic traits in childhood absence epilepsy. Several studies suggested that children with TLE have characteristic behavioral disturbances,[94,110,151,217,241,246] particularly if they have left-sided foci.[151,241] Their behavior problems, hyperactivity, aggression, and antisocial behavior were

P.2182

associated with male gender, poor seizure control, low IQ, and childhood rages.[94,110,151,217,241] However, other researchers were unable to identify differences in measures of psychopathology between children with temporal lobe and generalized epilepsy.[103,265]

Using structured psychiatric interviews, a recent study on a large sample of children with different types of seizure disorder has demonstrated similar rates of DSM-IV psychiatric diagnoses in 60% of the children with complex partial seizures and 58% of those with childhood absence epilepsy, compared with normal children.[198] Other than schizophrenia-like psychosis in 10% of children with complex partial seizures rather than childhood absence epilepsy,[41,150] children with complex partial seizures and childhood absence epilepsy have similar rates of disruptive, affective/anxiety, and both disruptive and affective/anxiety disorders. Controlling for seizure and demographic variables, IQ was the single predictor of a psychiatric diagnosis in children with complex partial and childhood absence groups.[198]

A long-term follow-up study of young adults with a history of childhood absence demonstrated that, compared with a control group of young adults with a juvenile rheumatoid arthritis history, they had a significantly higher rate of behavioral and school/academic problems.[270] This finding was unrelated to seizure variables. Thus, childhood absence epilepsy, considered by most neurologists to be completely benign, has both a high rate of psychopathology in childhood and poor outcome regarding behavior and academics by young adulthood.

In children with new-onset seizures, those with prior unrecognized seizures and subsequent development of partial or absence seizures have higher rates of behavior problems (based on Child Behavior Checklist [CBCL],[1] parent,[12] and teacher[65] total) internalizing, attention, thought, and somatic complaints scores than those with other types of seizures. Other studies on children with new-onset seizures, however, have not shown a relationship between severity of behavioral problems and type of epilepsy.[195] In fact, prior cognitive and behavioral problems, rather than seizure variables, predicted whether children with new-onset seizures continued to have behavior problems over time.[197]

A study on localization-related epilepsy describes parental reports of behavioral problems in 39% of 63 children with TLE.[97] However, this study did not include control groups of children with other types of epilepsy. A study comparing small samples of children with temporal, frontal, and absence epilepsy found increased attentional problems based on parent CBCL scores in those with frontal lobe epilepsy.[104]

Among the localization-related epilepsies, even the so-called “benign” epilepsies, benign epilepsy with centrotemporal spikes (BECTS) or benign occipital epilepsy (BOE) may be associated with psychopathology. In the last decade, more reports focus on the subtle behavioral alterations commonly seen with these syndromes. Nonspecific behavioral problems have been reported in 30% of children with centrotemporal spikes,[275] and these may be more prevalent in those with atypical features of BECTS.[260] Symptoms of attention-deficit hyperactivity disorder (ADHD) have also been reported and may be predicted by certain EEG characteristics.[161] Parents report more problems with attention, temper, and impulsiveness in children with BECTS compared with controls.[51] Of interest, centrotemporal spikes were found in 5% to 6% of a large sample of ADHD patients without a history of epilepsy,[117] and spike frequency appeared to be related to severity of symptoms.

In summary, irrespective of type of epilepsy, children with epilepsy, both new-onset and chronic epilepsy, have high rates of a wide range of behavioral disturbances. The small study sample sizes, wide age range, and different methods of assessing behavioral abnormalities in these studies highlights the importance of conducting prospective studies of large representative samples of children to demonstrate the consistency of the behavioral problems and their course, and whether type of epilepsy plays a role in the behavioral profile of children and adolescents with epilepsy.

Effects of Seizure Control on Behavior

Historically, Lindsay et al.'s[151] long-term outcome study of 100 pediatric TLE cases revealed that poor seizure control was associated with increased antisocial behavior in these children. Remission of seizures by age 12 years was associated with a better adult psychosocial outcome than remission after age 12.[150]

Hermann et al.[103] demonstrated that seizure control was the most robust predictor of total and externalizing CBCL scores in a large sample of children with epilepsy, controlling for the effects of demographic, biologic, and psychosocial variables. Numerous subsequent studies have examined this relationship using different behavioral instruments, control groups, informants, measures of seizure control, sample sizes, and youth cognitive ability. Some of these studies were cross-sectional and few were longitudinal. Only a few studies have controlled for possible confounding seizure variables to varying degrees. Retrospective and prospective treatment studies have also investigated the relationship between seizure control and behavioral outcome following intervention with AEDs and epilepsy surgery.

Due to space limitations, this section briefly summarizes the findings of the larger cross-sectional and longitudinal studies (including postsurgical intervention), conducted in children with epilepsy, that have examined the association with seizure control. It also indicates how these findings vary by type of behavioral instrument and informant.

In terms of cross-sectional studies there was no statistically significant relationship of seizure frequency with the presence and type of psychiatric disorders, as well as with CBCL scores in a large sample of children with complex partial seizures who have average IQ scores.[43] The DSM-IV psychiatric diagnoses of these children were based on information obtained on the child by a structured psychiatric interview administered separately to the child and to the parent.

In contrast to these findings, Schoenfeld et al.[225] reported significantly higher total and internalizing CBCL scores in children with complex partial seizures with the highest seizure frequency. However, they did not examine the possible effect of IQ on these findings.

Using CBCL scores, Austin et al.[16] also found significantly higher internalizing scores in children with epilepsy, aged 8 to 13 years, who had more severe seizures, a measure that includes seizure control. Follow-up of these children 4 years later revealed significantly higher internalizing CBCL scores in the girls with epilepsy who had more severe seizures both at baseline and follow-up.[9] These authors concluded that girls with more severe seizures might be more at risk for behavior problems as they moved through the teen years.

Children with new-onset seizures and subsequent recurrent seizures have significantly higher parent-[17] and teacher-based total and internalizing CBCL scores,[62] suggesting a relationship between seizure control and severity of behavioral problems. In contrast, Oostrom et al.[195] reported lack of persistence in behavior problems based on parent CBCL and teacher reports in their 3-, 12-, and 48-month follow-up study of children with new-onset epilepsy. Despite similar mean parent and teacher ratings, Oostrom et al.[195] found no agreement between parent and teacher ratings for individual children.

In terms of surgical studies, several older studies noted that some children with TLE become less aggressive, and their behavior improves once they attain seizure control after temporal lobectomy.[54,60,89,118,149] None of these studies, however, used standardized psychiatric instruments and control groups to follow the postoperative behavioral changes of a representative

sample of children undergoing temporal lobectomy. In addition, these studies did not include a control group of medically treated children with epilepsy.

Using the CBCL,[1] Lendt et al.[145] found a significant decrease in the CBCL externalizing, internalizing, attention, and thought scores that had been within the clinical range 3 months after epilepsy surgery on 13 temporal and 11 extratemporal lobectomies, two hemispherectomies, and two callosotomies, compared with a control group of medically treated children with intractable epilepsy. Postsurgical seizure control rather than age, sex, onset, and duration of epilepsy; the site of the focus; and changes in AED regimen accounted for this finding.

In a 1-year follow-up study of a large sample of 30 children who underwent epilepsy surgery, Smith et al.[237] found no significant change in CBCL scores 1 year after surgery, compared with medically treated children with intractable epilepsy. Seizure control was unrelated to these findings.

In summary, the findings of cross-sectional and follow-up studies of children with new-onset and chronic epilepsy demonstrate an association of seizure frequency with the presence and severity of behavioral disturbances. However, recent evidence that verbal IQ predicts psychopathology, children with new-onset seizures have behavior problems prior to the onset of seizures, and children who undergo epilepsy surgery continue to have behavior problems irrespective of postsurgical seizure control suggest that psychopathology is a comorbid component of pediatric epilepsy irrespective of illness variables.

Effects of Antiepileptic Drugs on Behavior and Cognition

Although there are numerous reports on AED effects on behavior and cognition in children with epilepsy, no double-blind, randomized, controlled studies have examined these relationships in these children. For detailed information on extant studies and reports, the reader is referred to two reviews, one on the mechanisms of action of AEDs and the relevance to neurobehavioral adverse effects,[222] and the other on the cognitive side effects of AEDs in children with epilepsy (see also Chapter 201).[153]

This brief summary of the adverse effects of AEDs on cognition and behavior emphasizes the importance of controlling for these variables in neurobehavioral studies of children with epilepsy. In addition, different children appear to be vulnerable to these AED adverse effects. Thus, as described in adults with epilepsy,[138,181] increased risk for AED-related behavioral and cognitive side effects in children with epilepsy include AED polytherapy,[32,95,134,151,155] mental retardation or learning disabilities,[32,95] and a family history of psychiatric disorders.[28,30] Similarly, as shown in adults with epilepsy,[250] children with a past history of behavioral problems, as well as of prior adverse behavioral and cognitive effects to AEDs, might also be more vulnerable to these adverse effects.

It is important to note that children on high doses of combinations of AEDs might appear to be depressed because they are tired, apathetic, listless, and poorly motivated. Other children on polytherapy or high-dose monotherapy might respond with irritability, low frustration tolerance, poor impulse control, and hyperactivity.

However, AED polytherapy might also reflect the type or types of epilepsy, as well as comorbid cognitive and linguistic difficulties, all of which might increase the likelihood of behavioral problems. Therefore, clinicians should be aware that the functional impact of AED behavioral and cognitive side effects on the individual child's daily functioning and quality of life might be as severe as that of uncontrolled seizures.

In terms of specific behavioral side effects, AEDs that can trigger depression in children include phenobarbital,[28,30] primidone,[105] and valproic acid.[105] Adult studies also find depression associated with topiramate[182] and levetiracetam.[188] Manic behavior has been described in children with epilepsy treated with felbamate[45] and ethosuximide.

Case studies describe psychosis in children treated with topi-ramate,[206] levetiracetam,[134,274] vigabatrin,[35] and zonis-amide.[177] Several case reports describe irritability, hyper-activity, and aggression in children with epilepsy on gabapentin,[129,172] phenobarbital,[34,261] vigabatrin,[3,230] and benzodiazepines.[81,249]

Slowing of cognitive processes and motor reaction time are attributed to the older AEDs, such as phenobarbital and benzodiazepines.[26,34,105,261] In adults with epilepsy, these effects are dose-related for carbamazepine, phenytoin, and valproic acid.[59] However, there have been no well designed studies on the new AEDs and cognition in children. The impaired word retrieval and cognitive slowing found in children treated with topiramate,[91,229] and the possible association with the speed of titration[221] must be studied in children.

To date, most clinicians have been impressed by the lack of adverse cognitive effects in children treated with lamot-rigine.[221] The slow titration used in children with epilepsy to avoid the rash associated with lamotrigine treatment might contribute to this observation. However, well-designed studies are needed to examine the effects of the new AEDs on cognition.

In summary, double-blind, randomized studies using well-established behavioral and cognitive instruments sensitive to change are needed to determine which AEDs have behavioral and cognitive adverse effects and for which children with epilepsy. Studies of behavior and cognition in children with epilepsy, however, should include large samples of children to examine the possible role played by AEDs in the studies' findings. AED polytherapy and high therapeutic blood levels might be associated with more general behavioral problems, such as irritability, aggression, and hyperactivity, as well as slowing of cognitive processes in children.

Children with epilepsy at risk for the adverse neurobehavioral effects of AEDs are those with mental retardation, learning disabilities, poor prior behavioral and cognitive responses to AEDs, psychiatric history of past behavioral and cognitive problems, and family history of psychiatric disorders.

Age of Onset and Duration of Illness

Increasing evidence suggests connectivity and structural changes caused by seizures in the brain of young animals despite the lack of cell loss (see review by Holmes[114]), an age-related effect on synaptic function,[141] and long-term cognitive and behavioral changes.[223] Maternal deprivation in the young animal has synergistic effects, with recurrent seizures in inducing long-term damage in the developing brain.[121] Although the impact of early seizures on brain development might reflect the underlying cause of the seizures rather than the effects of seizures,[113] the findings of animal studies support the previously reviewed clinical data suggesting that the child's immediate environment (i.e., home, school), rearing practices, recurrent ongoing seizures, and AEDs might impact the development of behavior and cognition.

The age of onset of epilepsy might be an indicator of the severity of the underlying pathology. Thus, early-onset epilepsy is often associated with mental retardation, and children with mental retardation have an earlier onset of epilepsy.[218] These age relationships imply that epilepsy and mental retardation in children with early onset are epiphenomena of underlying pathologic processes in the brain.

In terms of psychopathology, two epidemiologic studies have demonstrated significantly higher rates of psychopathology

in children with epilepsy who have mental retardation[218] or complicated epilepsy, including learning disabilities[55] than those with normal intelligence or uncomplicated epilepsy. A population study of children with both mental retardation and epilepsy also revealed high rates of severe behavior problems.[239]

Nevertheless, it is still unclear how and to what degree recurrent seizures, both frequent and infrequent, and the need for high doses of AED polytherapy impair ongoing development of the brain and of emotional, social, cognitive, and linguistic skills in early childhood. It also remains to be determined through prospective studies if the behavioral, cognitive, and linguistic outcome in developmentally disabled children with earlier onset of epilepsy is worse than in children with later onset of their epilepsy. Whereas some studies suggest that epilepsy surgery and subsequent seizure control for early-onset intractable epilepsy changes the developmental course,[78] others do not.[44,133,135,237]

Regarding later onset of epilepsy, two of the most common types of pediatric epilepsy, complex partial seizure disorder and primary generalized epilepsy, typically begin in middle childhood. During middle childhood, acceleration occurs in the development of children's emotional, social, cognitive, and linguistic skills and continued maturation through adolescence. Ongoing seizures, high doses of multiple AEDs, and prolonged seizures might interrupt the functioning of the neural circuits involved in these maturational processes.

In children with onset of epilepsy in middle childhood, although the presence of psychopathology does not appear to be associated with age of onset,[43] earlier studies identify an association between early-onset and impaired cognitive functioning.[2,26,70,191] Yet, these findings might also reflect the confounding effects of poor seizure control, as well as AED polytherapy and high blood levels of treating drugs.[26]

More recent studies also find that cognition,[225] language,[225] verbal learning, and certain aspects of discourse skills[39,40] are associated with age of onset in children with complex partial seizures. For example, unrelated to lateralization of EEG findings, children with earlier onset of complex partial seizures have significantly lower scores on neuropsychological and linguistic tasks,[225] poor performance on long delay cued recall, and reduced monitoring and self-correction of errors in the organization of ideas during speech[39] than do those with later onset.

In summary, these findings suggest a dynamic interplay among brain development, age of onset, and maturation of cognition and language in children. They also highlight the importance of early treatment of seizures for optimal development of children's cognition, language, and discourse skills. Moreover, further studies are needed to determine if the higher rate of behavior problems found in studies of children with new-onset epilepsy[12] who had prior unrecognized seizures might represent the cumulative effects of early-onset seizures on the development of cognition, behavior, and language in these children.

Early-Onset Epilepsy Syndromes with Specific Behavioral, Cognitive, and Linguistic Impairments

Four early-onset epileptic syndromes, the West, Lennox-Gastaut, Landau-Kleffner, and continuous spike-and-slow wave syndromes and one disorder, tuberous sclerosis (TSC), are associated with behavioral social, cognitive, and linguistic impairments.

West Syndrome (Infantile Spasms)

The prototype for early-onset epilepsy syndromes is that of infantile spasms or West syndrome (Chapter 229). Seizure onset is usually by 4 to 6 months.[86] In the absence of seizure control, the developmental outcome for these children is usually poor both in the cognitive (see Caplan's review[38]) and behavioral domains, with varying degrees of impaired social relationships.[44,61,207]

Although the cause of the poor outcomes is still unknown, hypsarrhythmia, the severely epileptiform EEG found in this disorder, is present very early in development and has been implicated in the negative outcomes in these patients.[207] In fact, normalization of the EEG is thought to be the hallmark of successful treatment in this disorder.

Outcome studies in infantile spasms have mostly focused on cognitive rather than behavioral outcomes. Most studies show that a better cognitive profile at the onset (e.g., lack of significant regression), earlier treatment, and cryptogenic etiology are factors associated with improved cognitive outcome.[61,131,208]

More recently, early follow-up results from a large multicenter treatment trial[155] showed that the successfully treated subjects (those who showed cessation of spasms) had better scores on the Vineland Adaptive Behavior Scales than those who did not have cessation of spasms. Those with cryptogenic spasms also had better outcomes compared to those with symptomatic etiologies. But, in contrast to past results, there were no differences based on type of treatment, speed of normalization of the EEG, or time to treatment.

The behavioral or psychiatric abnormalities most strongly associated with infantile spasms are autism and autism spectrum disorders (ASD). According to a population study,[194] 6% of children with infantile autism had shown typical or atypical hypsarrhythmia with infantile spasms in the first year of life. Conversely, 13% of all children with infantile spasms were later diagnosed as suffering from infantile autism,[209] and several more showed severe degrees of autistic behavior. The autistic symptoms may be of a transient character in a large proportion of cases.[194,209] Another small prospective trial suggested that the etiology of the spasms was important in predicting later autistic behavior, with patients with symptomatic spasms showing a higher rate of autism.[8]

Given the high rate of infantile spasms in children with known genetic syndromes (e.g., TSC) and other brain abnormalities that are themselves associated with an increased rate of mental retardation and autism, this is undoubtedly a complex inter-relationship. The association with later autistic behavior in these patients, as well as the history of infantile spasms seen in ASD patients, points to the fact that epilepsy and, perhaps more importantly, epileptiform EEGs may play an important role in the development of autistic behaviors. Hyperactivity is another psychiatric disturbance seen in this syndrome. About two-thirds of those individuals with infantile spasms who have autism also meet criteria for hyperkinetic disorder. This is more than would be expected solely from the autism diagnosis.[209]

About 80% to 90% of children who had West syndrome in infancy will show cognitive delay either at the time of seizure onset or will be diagnosed with mental retardation later in childhood. Those with West syndrome, autism, and hyperkinetic disorders have mental retardation as often and of the same degree as children who do not. Thus, the well-known association of autism and hyperkinesis with cognitive impairment cannot in itself account for the link between these psychiatric disorders and West syndrome.

A meta-analysis of 67 studies showed that 17% of patients with infantile spasms developed Lennox-Gastaut syndrome (LGS).[120] The vast majority of these children will also appear severely withdrawn (autistic) and profoundly mentally retarded.

Lennox-Gastaut Syndrome

This syndrome is characterized by the early onset of intractable seizures (tonic, generalized tonic–clonic, atypical absence, atonic, and myoclonic) and bilateral slow spike-and-wave complexes on EEG (Chapter 241). Follow-up of children with LGS reveals that about half are retarded, in particular if they have minor motor seizures and multifocal independent spikes.[193] Treating clinicians all know that the behavioral aspects of this disorder are significantly impairing to the patient and family, but not much systematic study has been devoted to the area.[22] As in other cases of mental retardation, the children are sometimes irritable and hyperactive. These symptoms might decrease with seizure control or become exacerbated with some AEDs.

Landau-Kleffner Syndrome

Landau-Kleffner syndrome (LKS) is an acquired epileptic aphasia characterized by a gradual or rapid onset of aphasia that occurs in a previously normal child *plus* seizures and/or epileptiform changes on the EEG (Chapter 242).[142,257] The aphasia is often predominantly of a type referred to as "verbal auditory agnosia" (inability to understand spoken language).[205] All types of seizures have been reported in this syndrome, but nocturnal complex partial or simple motor may be most common.[21] The seizures are usually relatively infrequent and respond readily to AED treatment in most cases. EEG abnormalities frequently include focal or generalized spike-and-wave discharges that are activated during sleep.[161] At times, the patients meet criterion for electrical status epilepticus in sleep (ESES), with more than 80% to 85% of their sleep record consisting of spike-and-wave activity.[107]

The epidemiology of the disorder has not been properly studied. In clinical series, it appears to be about twice as common in boys as in girls. The etiology of LKS is unknown. There is a moderately increased rate of a family history of seizure disorder (10%–15%),[21] and the syndrome has been described in siblings. Taken together, these data suggest a genetic liability in some cases. However, it has also been described in conjunction with temporal lobe tumors,[186] cerebral arteritis,[199] and otitis media.[88] The possibility of electric dysregulation in several cortical areas as a pathophysiologic basis for this disorder has been emphasized by many authors, including Landau and Kleffner.[142]

The hallmark association is the language disturbance. This may fluctuate in severity, especially initially, when the impairment of verbal comprehension may first lead to suspicion of acquired deafness. Both receptive and expressive languages are affected.[236] Behavioral changes have also been reported. These include hyperactivity and inattentiveness,[107] psychosis and autistic behavior,[56] as well as oppositionalism, noncompliance, and frank aggression.[211,264]

LKS has been treated with traditional anticonvulsant medications,[56] corticosteroids,[147] intravenous immunoglobulin (IVIG),[173] and even epilepsy surgery[178] (see Tuchman[251] for review). Therapy that treats the EEG abnormalities has been associated with improved language[147,160] and behavior.[124,235] Robinson and colleagues reported that the duration of ESES was strongly correlated with language recovery, and that no child with prolonged ESES (>36 months) had a normal language outcome.[211] They also found that the severe behavioral disturbances in the acute phase were associated with frontal epileptiform activity during wakefulness.

On the other hand, the relationship between the seizures and/or the EEG abnormalities and the language and/or behavioral deficit is not completely clear. Many children do not begin to have seizures until after the period of regression, and some never have clinical seizures at all.[254] Some of the EEG abnormalities resolve spontaneously, and there are studies failing to demonstrate a correlation between EEG findings and the severity and course of the language impairment.[115,254,264] Van Hout[258] points out that, while the behavioral disturbances have been thought to be secondary to the severe language disturbance, there are cases where these disturbances precede the period of language regression. It has also been proposed that the epileptiform discharges are an epiphenomenon of the underlying brain abnormality rather than the actual cause of the language disturbance.[115]

Outcome in LKS is variable.[236] Seizure outcome is usually good, with resolution of seizures being the norm. But language and behavioral outcomes are more difficult to predict and range from muteness, persisting behavioral problems, and sometimes even intellectual impairment, to complete recovery in adult age. A considerable amount of variability of the clinical picture at the time of onset is supposedly a marker for relatively better outcome.

Continuous Spike-and-Wave Activity During Slow Sleep

Continuous spike-and-wave during sleep (CSWS) is the term most often used to describe a rare syndrome that strikes predominantly school-age males (Chapter 242). In 1971, Patry and colleagues[200] described the first patients, who presented with cognitive deterioration and the onset of epilepsy. The EEG showed a characteristic pattern of continuous spike-and-wave discharges during more than 85% of slow-wave sleep. The syndrome is now part of the epilepsy classification system as defined by the International League Against Epilepsy.[123] Individuals with the syndrome undergo severe language, behavioral, and global cognitive regression accompanied by epilepsy and the severely abnormal EEG pattern known as CSWS or ESES. Although the terminology is still not universal, most authors now use the term CSWS to refer to the clinical syndrome and ESES to refer to the EEG pattern.

As in LKS, this syndrome has its onset in childhood, shows a male predominance, and is associated with multiple seizure types. But unlike LKS, patients sometimes have preexisting developmental issues, the seizures are more frequent and harder to control,[236] the cognitive regression is significant and universal, and the behavioral difficulties are more prevalent.[79] Behavioral deficits include those similar to LKS (hyperactivity, inattentiveness, and aggression) but autism-like behavior has also been reported.[215] There are also motor impairments including weakness, dystonia, ataxia, and dyspraxia.[245] These more severe deficits in behavior, cognition, and motor function have been attributed to frontal and prefrontal dysfunction, perhaps as a result of the more frontal predominance of the EEG discharges.[33,215,236]

Outcomes are variable but overall are believed to be rather poor.[214] A recent study showed good behavioral outcome in all seven patients studied, but cognitive recovery (complete or partial) was seen in only three.[226] However, severe psychosis and lasting cognitive and motor impairment are also reported.[139,245]

Tuberous Sclerosis

TSC illustrates the complex relationship between brain malformations, epilepsy, behavior, and cognition. Epilepsy, both infantile spasms and partial epilepsy, and significant learning disability or mental retardation may be found in more than half the children with TSC.[52] Autistic disorder affects 25% to 50% of children with TSC.[25,94]

The severity of the neuropsychiatric problems associated with TSC seems dependent on the number and location of cortical tubers, although there are some inconsistencies in the literature. Bolton and Griffiths[25] found a strong association between temporal lobe tubers and autistic disorder. Positron emission tomography (PET) studies have shown decreased glucose metabolism in the temporal lobes, increased glucose metabolism in the cerebellar nuclei, and increased tryptophan uptake in the caudate nuclei.[7]

Age of seizure onset and seizure type also may be important. Both mental handicap and autistic disorder have been most consistently associated with infantile spasms and seizure onset before 2 years of age. Hunt and Dennis[122] found a history of infantile spasms in 40 of 45 children with TSC and autistic disorder.

The relative contribution of epileptiform discharges to autistic behavior remains a question. Tuchman and Rapin[255] found an association of autistic regression and epileptiform discharges in a population without TSC. Jambaqué et al.[125] treated seven children with TSC and infantile spasms with vigabatrin, with remission of the spasms in all the children. At follow-up, five of the six children with autistic symptoms showed improvement in behavior, and six of seven patients had improvements in developmental testing, thus suggesting some effect of epileptic discharges on cognitive function and behavior.

Thus, the brain areas that are dysfunctional in autism (and possibly certain variants of hyperkinetic disorder with cognitive impairment) may also be those that are affected in infantile spasms and in TSC with early symptom onset. According to one current theory for the development of autistic symptoms, dopaminergic (and other) nerve fibers arising in the brainstem and projecting onto structures in the striatum, medial temporal lobes, and prefrontal areas may be malfunctioning. Parts of these neural circuitries are also possibly involved in the pathogenic chain of events in infantile spasms. That they are often implicated in TSC has been known for a long time.[87]

Child Psychiatric Disorders Associated with Epilepsy

This section addresses the interface of behavior, cognition, language, social skills, and seizure variables as it pertains to psychiatric disorders commonly found in older children with epilepsy.

Autism, Asperger Syndrome, and Other Autism-Like Conditions

Autistic disorder, which occurs in about 1 to 2 children per 1,000, and about four times more often in boys than in girls,[77] is associated with a high rate of epilepsy, although reported rates have been extremely variable, with a range from 5% to 44%.[69,85,128,132,174,179,194,213,255,256,262,271] Seizure onset is usually either during the first 3 years of life,[194,262] or around the time of puberty.[80,82,218] New cases of epilepsy may also appear in early adult life.[53] The most common types of epilepsy encountered in autism are complex partial seizures, generalized tonic–clonic seizures, and combinations of seizures of various kinds.[53,194]

Autistic disorder is associated with mental retardation in approximately 70% of all cases.[76] Epilepsy is much more common in those individuals with autistic disorder who are also severely mentally retarded, but it is not a very rare phenomenon in those of low normal intelligence.[83,201,256]

The occurrence of epilepsy may also have a direct effect on language in ASD. The presence of a specific language profile (verbal auditory agnosia similar to that seen in LKS) predicts the presence of epilepsy and/or abnormal EEGs in autism.[256] Another, more controversial, association is that of language regression; conflicting reports exist regarding whether regression is or is not associated with a higher risk of epilepsy/EEG abnormalities.[128,132,148,152,156,183,184,213] For example, Tuchman and Rapin[255] found those with language regression had no increase in the frequency of clinical epilepsy, but did have significantly more isolated epileptiform EEG abnormalities compared with those without regression. Looking at this phenomenon in more detail, McVicar and colleagues[166,167] studied a sample with a high rate of ASD but that was ascertained for language regression; they showed that regression associated with pure language loss and occurring later was more frequently associated with epilepsy/EEG abnormalities than was more typical earlier autistic regression.

The variability in rates in the literature is likely due to sample heterogeneity. Factors such as differing ASD diagnostic classifications across the years,[58,210,256] variable epilepsy definitions,[85] differing age distributions in samples,[58,85,174,217,262,271] the inclusion of subjects with other specific genetic or neurologic disorders that are themselves associated with epilepsy,[201] as well as variability in the degree and type of associated cognitive or language deficits[20,253] could all influence rates of epilepsy in this population.

Asperger syndrome, which occurs in at least 3 to 4 out of every 1,000 children, and, again, much more often in boys than in girls,[67] may be associated with a slightly higher than expected rate of epilepsy,[47,81] but, to date, no large-scale epidemiologic study has been performed.

A group of autism-like conditions also exist that do not meet criteria for autism or Asperger syndrome. Some of these children are diagnosed as suffering from a “pervasive developmental disorder not otherwise specified” (PDD NOS). Others are never clinically diagnosed on the autism spectrum despite severe and typical problems, but receive diagnoses of “conduct disorder,” “attention deficit hyperactivity disorder,” or “hyperkinetic syndrome” instead, or have no other diagnosis than epilepsy (and possibly mental retardation). Just how frequently these autism-like conditions appear is not known. In a population study of all mentally retarded children with epilepsy, aged 8 to 12 years, several new cases of autism and autism-like conditions were found; these children had not been previously identified as suffering from a problem on the autism spectrum, and some had been missed in previous population studies of autism. Together they account for at least 1 in 1,000 children.[239] The gender ratio is almost equal in this group. It seems clear that the fact that they had early-onset epilepsy "deprived" them of recognition of the autistic symptoms. It is almost as though the specialists (often experienced child neurologists) treating these children for their epilepsy believed that the classical autistic symptoms evidenced were only to be expected in early-onset epilepsy and so required no additional diagnosis. The families, however, believed that, after the first year of diagnosis of the seizure disorder, they needed the most help with the autistic symptoms. However, no help was offered, because no diagnosis had been made. The children and their families were in a particularly difficult situation also because many of the AEDs (the benzodiazepines especially) tried appeared to contribute to enhancing the autistic symptoma-tology.

One of the many difficulties faced by the clinician caring for a family with a child affected by seizures and autistic behavior is to try to disentangle the effects of the neurologic from the psychiatric disorder. Many bizarre behaviors shown by children with autism are difficult to separate from clinical seizure activity. The empty, staring gaze might be mistaken for

a "true" absence. Complex facial, hand, and arm mannerisms may suggest a complex partial seizure. Tics-like movements—very common in Asperger syndrome[67]—can be virtually impossible to separate from myoclonic jerks. The diagnostic problems are further enhanced by the fact that what is sometimes a symptom of epilepsy (for example, the upward turning of the eyes), may at other times be a stereotypic-catatonic phenomenon. An individual with an autism spectrum disorder may actually show the same—or a very similar—symptom as a consequence of epilepsy in one instance and of autism in another.

The EEG (including video monitoring) is sometimes very helpful in differential diagnosis, but this examination can be extremely difficult to accomplish in a child with severe behavior problems. A sleep EEG is sometimes all that can be obtained, but even the limited information one can get from this can be an essential part of the differential diagnostic work-up.

Literature also describes epileptiform discharges on EEGs in patients with autism without clinical seizure disorders. Tuchman and Rapin[255] reported 15% epileptiform sleep EEGs in patients without a history of epilepsy. Others report 20% to 30%[85,128,262] epileptiform EEG rates. Some evidence suggests that prolonged or overnight EEGs yield much higher rates of 46% to 60%.[49,252]

The exact association between the epileptiform discharges and the social, communication, and behavioral deficits seen in autism spectrum disorders is unknown. It is tempting to think there may be a causal relationship because that would have important implications for treatment. However, this has not been proven.

Pervasive Developmental Disorders Umbrella and the Spectrum Concept

The prevalence of epilepsy may be even higher in some of the other pervasive developmental disorders (PDD) umbrella disorders from the DSM. Rates in Rett syndrome range from 63% to 94%.[46,240] Patients also show an age-specific abnormal EEG pattern that may be related to the clinical disease progression.[86] Epilepsy rates of up to 77% are also seen in childhood disintegrative disorder.[179] Paroxysmal EEGs and ESES have been reported in higher numbers in CDD than in autism as well.[137,180,216]

These epilepsy and behavioral syndromes (e.g., autism with regression and epilepsy, other pervasive developmental disorders [Rett syndrome, CDD, developmental language disorder, LKS, CSWS, TSC]) all have in common characteristic seizures and/or epileptiform EEG patterns associated with specific behavioral, cognitive, and linguistic deficits. Thus, it has been the subject of much debate whether they could all exist along a single spectrum with a common underlying neuropathology and variable symptomatic presentation.[20,79,127,159,214,251,254,255] However, the exact role of the seizures and EEG abnormalities is still not understood. Given that the EEG pattern of ESES is seen in multiple epilepsy syndromes and not believed to be specific to the clinical syndrome of CSWS[259] it may be that the EEG pattern may affect behavioral, cognitive, and linguistic performance, regardless of the syndrome with which it is seen.

A better understanding of these phenomena is important both for elucidating pathophysiologic mechanisms underlying these disorders and for the development of proper treatment strategies. Indeed, some clinicians are adopting LKS and ESES treatment strategies, including drugs associated with significant side effects[251] and even epilepsy surgery,[185] for autistic patients with abnormal EEGs.

Attention-Deficit/Hyperactivity Disorder (ADHD)

Problems with attention and symptoms of attention deficit hyperactivity disorder (ADHD) are commonly reported in children with epilepsy. As previously described, children with TLE, particularly those with left-lobe TLE, were thought to demonstrate behaviors similar to ADHD (i.e., hyperactivity, distractibility, impulsivity) and conduct disorder (i.e., antisocial behaviors).[27,112,203,218,242] Using teacher and parent scales, Stores et al.[242] found that epileptic boys were more hyperactive and inattentive than nonepileptic boys. These two groups of subjects did not differ, however, on laboratory measures of attention, impulsivity, visual scanning, and distractibility.

Kinney et al.[130] concluded that epilepsy does not influence behavior adversely, because they did not find increased behavioral or learning disturbances in epileptic children with ADHD compared with nonepileptic children with ADHD. Hellgren et al.[101] found no increased rates of epilepsy in adolescents with a history of attentional deficits in preschool. However, the histories of these children indicated a significantly increased incidence of febrile seizures. Mitchell and colleagues[176] described decreased reaction time and inattention, but no impulsivity in children with epilepsy. These findings were unrelated to AEDs, IQ scores, duration of seizures, or seizure severity.

Reviewing ten recent studies of attention in children with epilepsy, Sánchez-Carpintero and Neville[219] found evidence of sustained attention deficits, particularly in children with complex partial seizures and BECTS. Deficits in divided attention were not found consistently. Studies using DSM criteria for the diagnosis of possible ADHD in children with epilepsy have reported prevalence rates of 30% to 40%.[63,102,227,247] There has been some suggestion that the inattentive type of ADHD may be more common than ADHD, combined type, in children with epilepsy.[63] As in the general population, children with epilepsy may have ADHD comorbid with other behavioral disorders. Caplan et al.,[43] in a study of children with complex partial epilepsy, found that 17% of children had disruptive behavior disorder (ADHD, oppositional defiant, or conduct disorders) and 23% had a disruptive disorder plus a mood or anxiety disorder.

Several risk factors are possible for attention problems in children with epilepsy. Neither gender nor seizure type have been consistent predictors. Early studies found more ADHD symptoms in boys with epilepsy, but in a recent study there was no difference by gender.[63] Similarly, although attention problems are often cited in children with partial complex seizures, some studies have found a higher rate in children with generalized seizures[102] or no effect by seizure type.[63] Seizure frequency may be important. Aldenkamp and Arends[4] found slowing of processing speed in children with frequent epileptiform discharges, and slow processing and attention problems in children with frequent nonconvulsive seizures. AEDs may be a factor. Attention problems have been reported with phenobarbital, benzodiazepines, and topiramate, but are less often found with newer AEDs.[26,153] ADHD may also be a risk factor for seizures. Hesdorffer et al.[106] found that ADHD, inattentive type, was a risk factor for subsequent unprovoked seizures, and Austin et al.[12] noted increased scores on the attention problem subscale of the CBCL at the time new-onset seizures were first recognized.

Treatment of attention problems in children with epilepsy is important. Williams et al.[267] have shown that problems with attention are better predictors of academic underachievement in children with epilepsy than are socioeconomic status, self-esteem, or measures of memory function. Although there have been concerns about the use of stimulants in children

P.2188

with seizures, the more recent recommendations and studies of stimulants in children with epilepsy have shown that methylphenidate is effective for symptoms of ADHD, is safe in children with well-controlled seizures, and is probably safe in children with uncontrolled seizures.[73,90,93,244]

Affective and Anxiety Disorders

Although epilepsy markedly impacts children's coping resources,[13,64] only a few mood and anxiety disorder studies have been conducted in children and adolescents with epilepsy. They demonstrate depression and anxiety in 16% to 23% of patients, with more anxiety disorders in younger patients[42,192] and depression in older youth.[64,71] Evidence for suicidal ideation in 20% of children with epilepsy, most of whom have both affective and disruptive disorders,[42] underscores the potential morbidity of these comorbid diagnoses in this population. Moreover, the higher rate of depression, anxiety, and suicidal acts, together with the poor quality of life in adult epilepsy patients,[84,126] highlight the need for early detection and treatment of depression and anxiety disorders in youth with epilepsy.

In a large epidemiologic study, Davies et al.[55] found emotional disorders (e.g., mood and anxiety disorders) in 16% of children with epilepsy, a prevalence of more than twice that found in children with diabetes (6.4%) and four times the rate found in the general population of youth (4.2%) using a structured psychiatric interview. Based on the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS), Caplan et al.[42] found DSM-IV–based mood and anxiety disorder diagnoses in 33% of 171 children with epilepsy compared with 6% of 93 children without epilepsy. The most common diagnoses were anxiety (63%) and comorbid mood and disruptive disorders (26.1%), while only 5% had depression and 5% met criteria for both anxiety and depression.

Studies using the self-report Children's Depression Inventory[136] found depression in 25% of adolescents with epilepsy,[64] 26% of 7- to 18-year-old epilepsy youth,[71] as well as more depression in 12- to 18-year-old compared with 9- to 11-year-old children with epilepsy.[192] Although Ettinger et al.[71] reported anxiety in 16% of 7- to 18-year-old patients with epilepsy, both Caplan et al.[42] and Oguz et al.[192] found that anxiety, not depression, was more common in young children with epilepsy.

Inconsistent findings on the association of seizure variables with depression and anxiety disorders in youth with epilepsy could reflect methodological differences across studies, such as inclusion of different sample sizes and epilepsy variables, as well as use of different mood and anxiety instruments. Whereas several investigators report no association with seizure variables,[42,55,64] some find a relationship with duration of epilepsy and number of AEDs[192] and type of AED.[29,30] More children with complex partial seizures have depression than do those with absence epilepsy, who, in turn, have more anxiety disorders.[42]

Mood disorders also occur more frequently in children with epilepsy who have mental retardation[31,55] and lower average IQ scores.[42] Patients with comorbid psychopathology, depression and anxiety disorders, or disruptive and depression/anxiety disorders have significantly lower full scale and verbal IQ scores than do those with either depression or anxiety disorders alone.[42]

Finally, the association with demographic variables, such as gender and age, is similar to that described in the general population of youth with depression and anxiety disorders.[5,75] Thus, Dunn et al.[64] demonstrated more depression in adolescent girls with epilepsy. Younger children with epilepsy have more anxiety disorders, whereas adolescents have more depression.[41,192]

Psychosis

A recent epidemiologic study demonstrated a higher rate of a schizophrenia-like psychosis in epilepsy than in the general population.[204] They also found an association with both a family history of schizophrenia and a family history of psychosis. Unlike adults with epilepsy, postictal psychosis[189] has been rarely described in children. In contrast, about 10% of children with TLE[150] and complex partial seizures[37,41] have an interictal schizophrenia-like psychosis. These children present with hallucinations, delusions, and formal thought disorder, no negative signs, and poor seizure control.

Nonepileptic Seizures

Psychogenic nonepileptic seizures (PNES) can reflect a conversion disorder, a factitious disorder, malingering, or parental misinterpretation of the child's symptoms. The marked short- and long-term psychological morbidity associated with misdiagnosis of these disorders emphasizes the importance of recognizing these entities in youth with epilepsy.

Conversion Disorder (Pseudoseizures, Psychogenic Seizures, Nonepileptic Seizures)

In a conversion disorder,[8] the child's seizures or convulsions suggest that he has epilepsy and suffers significant distress or impairment from these attacks. Appropriate investigations do not confirm the epileptic basis for these episodes. Psychological factors, in the form of conflicts or stressors, however, initiate or exacerbate these attacks. The child with a conversion disorder does not intentionally produce or feign the seizures. This disorder is found in children and adolescents with normal IQ scores,[171] albeit varying degrees of learning difficulties, and in children with mild to moderate retardation.[116] Girls are affected more than boys,[74,92] and the incidence increases with age. The disorder is more common in children with a diagnosis of epilepsy and in those without epilepsy who have some exposure to epilepsy through a family member, a neighbor, or a friend.

The symptoms most commonly found in children and adolescents with PNES include: slow onset of seizures with a gradual build-up, prolonged duration, the absence of bodily injury or loss of continence, thrusting, jerking, or shaking motions rather than repeated fast flexion and extension, and the absence of a postictal period.[273]

These children often have difficulty expressing negative feelings, such as anger, or their expression of these feeling are unheard or minimized by family members. Social difficulties, strife with parents, learning difficulties,[234] or sexual abuse can give rise to the negative feelings associated with the primary conflict. The child's epileptic events increase the amount of attention the child gets and decreases demands, such as going to school. By reinforcing the child's symptoms, this secondary gain prevents the child from dealing with his problems in an adaptive manner. Although concerned about their seizures, these children minimize or deny any concern about the problems and difficulties in their lives even when these are significant.

Given the maladaptive nature of the symptoms of this disorder, a definitive diagnosis is needed as soon as possible. Wyllie et al.[273] reported a good outcome in 14 of 18 children and adolescents diagnosed with NES who had their symptoms for a mean duration of 7 months.

Factitious Disorders

Factitious disorders[8] involve intentional production or feigning of seizure symptoms specifically to assume the sick role. Unlike malingering, there are no external incentives for these

P.2189

behaviors, such as avoiding a legal responsibility like going to school. More commonly, the parent rather than the child has the factitious disorder and imposes a diagnosis of epilepsy on the child, as in Munchausen syndrome by proxy. Many of the reported Munchausen syndrome by proxy cases have presented with seizures.[140,165,212,272] In Meadow's series of 76 cases, 32 children had a primary diagnosis of epilepsy. In 21 cases, the mothers fabricated the symptoms of the illness.[168,170] In 11 cases, the mothers caused seizures by suffocation, carotid sinus pressure, or use of drugs. Sixteen of the children in Meadow's sample had medical symptoms other than seizures. In Rosenberg's series, 42% of the 117 cases presented with seizures.[212] It is important to note that Munchausen syndrome by proxy can also occur in a child with genuine epilepsy.[170]

Unlike other disorders, clinicians do not usually observe the seizures of children with epilepsy and need to rely on parental report for a description of the clinical manifestations of the child's seizure.[165] Because it is difficult to confirm parental reports, it is relatively easy for a parent to fabricate a history of seizures and a lack of response to AEDs in the child.[168]

These cases present with a history of uncontrolled seizures; an inconsistent description of the child's seizures; repeated normal EEG recordings; repeated consultation with different physicians, particularly if the physician determines that no evidence suggests that the child has epilepsy. Other than the parent, no medical or school personnel have observed the child have a seizure. The mothers of these children,[165] sometimes employed in the healthcare field, are often very knowledgeable about epilepsy, EEG findings, and the use of AEDs. They are concerned and devoted to the child, and appear at ease in the hospital, even forming close relationships with hospital staff. The fathers usually are absent or play no role in the sick process, so that they appear to be in "passive collusion"[170] with the mother. In some cases of Munchausen syndrome by proxy, the father has been described as the perpetrator.[158]

Misinterpretation of Children's Behavior

Misinterpretation of the child's behaviors as epileptic seizures can reflect parental anxiety.[169] Several investigators have shown that the primary reason for nonepileptic events in children, particularly those with impaired intellectual function, was misinterpretation of behavior by parents and caretakers.[60,171,187] These behaviors included staring episodes, abnormal reactions to environmental stimuli, and repetitive movements, such as rocking, shaking, or arm waving. Unusual movements based on abnormal muscle tone were also often misinterpreted as seizures.[187]

Unlike Munchausen syndrome by proxy, these cases usually present with fewer episodes. In addition, the parent's main concern is that their child recovers rather than need repeated medical examinations and procedures.

Summary And Conclusions

In summary, epilepsy is a chronic and episodic disease of the brain that can affect the child's emotional, cognitive, and linguistic functioning and, therefore, his intrapsychic and interpersonal functioning within the family, with peers, and in the academic and social environment of school. The response of the child's family to these stressors affects the way the child copes with the disorder. In addition to these psychodynamic and social factors, seizure-related (i.e., type of seizure disorder, seizure control, seizure duration, number and blood level of AEDs) and developmental factors (i.e., age of onset of seizures, level of cognitive and language function) affect the child's functioning and ability to cope with his illness.

The research of the past decade has demonstrated that epilepsy is a biopsychosocial disorder and that children with epilepsy have comorbid difficulties with behavior, cognition, and language. They have also shown that parents shoulder a heavy burden. Studies are sorely needed to determine optimal approaches for early identification and treatment of these comorbid problems, as well as how best to implement them.

Chapter 211

Suicide: Incidence, Psychopathology, Pathogenesis, and Prevention

Dietrich Blumer

Introduction

Suicide among patients with epilepsy has been widely recognized as a serious problem. In modern times, its frequency appears to approach the frequency of death from seizures. However, the frequency of its incidence is still debated, its psychopathology and pathogenesis remains unclear, and no proper method of prevention has been established.

Review of Literature

Frequency of Suicide

In a recent paper, Jallon[28] reviewed the significantly higher mortality of patients with epilepsy by status epilepticus, sudden unexplained death, and suicide, compared with the general population. He expressed concern that the reports on suicide were based on small samples from different populations and from highly selected groups of patients and used different methods of analysis. However, an analysis of the populations that differed in the numbers of suicide and an investigation (published in 2005) of the frequency of suicide in 29 cohorts of patients with epilepsy[44] provide answers to this concern.

Suicide is a rare event, occurring only slightly more than once among 10,000 persons annually in the United States.[41] In a review of completed suicide in manic-depressive patients, Goodwin and Jamison found a mean of 19% of deaths secondary to suicide in this population.[22] A similarly high suicide rate among patients with epilepsy has been documented: In a Danish study,[26] 164 of 2,763 patients with epilepsy suicided (an excess mortality rate of 273% compared with the number of deaths expected in Denmark); the case material included all adult patients discharged with the diagnosis of epilepsy at four neurologic clinics over 14 years, and any patient with a handicap other than epilepsy was excluded from the study. Although epilepsy was the immediate cause of death in 26%, suicide was the second leading cause of death in 20% (an excess mortality rate of 300%) at an average age at death of 32 years. According to eight reports, death by suicide occurs in 5% of patients with epilepsy, compared with 1.4% in the general population.[36] Based on a wider review of the literature, a fivefold increase in suicides among patients with epilepsy over the rate in the general population was found among those attending special clinics and was magnified to as much as 25-fold among patients with temporal lobe epilepsy (TLE).[1] A study by Hauser et al.,[24] on the other hand, included a general population of patients with epilepsy followed from the time of diagnosis, and not from the time of registration in a neurologic clinic; their patients were less severely affected, and they reported no suicides in excess of expected numbers. Suicide appears to represent a serious problem not in the general population of patients with epilepsy, but among those with more difficult epilepsy who require treatment in specialty clinics.

Since Jallon's review, Pompili et al.[44] investigated 29 studies of suicide in epilepsy, comprising 50,814 patients, of whom 187 committed suicide. Their meta-analysis showed that suicide in epilepsy is indeed more frequent than in the general population, but with significant exceptions. A study by Cockerell et al.[12] included patients with newly diagnosed or suspected epilepsy who were ascertained when attending a general practice, with a median follow-up of less than 7 years; a single suicide was registered among 792 patients. As in the study by Hauser et al.,[24] few severely affected patients were included. In contrast, the largest study cited by Pompili et al., 10,739 patients from our Epi-Care Center,[8] registered only five suicides (a rate lower than in the general population), not because of lack of severity of the epilepsy in the population, but because all patients with psychiatric complications were treated, at intake or as soon as needed, with proper psychotropic medication. This study will be fully reviewed, for a better understanding of suicide in epilepsy and to establish specific guidelines for its prevention.

Psychopathology Associated with Suicide in Epilepsy

The generally difficult psychosocial circumstances of patients with chronic epilepsy have often been considered the leading factor responsible for their elevated suicide rate, more important than the presence of psychiatric illness or the availability of drugs.[15] However, in general, psychiatric illness has been identified as the nearly universal antecedent of suicide, and psychosocial circumstances cannot be considered causes for suicide.[35,41] Very few reports have attempted to clarify the nature of the psychiatric disorder that may lead to suicide among patients with epilepsy.

Nilsson et al.[42] pointed out that studies are lacking in which persons with epilepsy who have committed suicide are compared with relevant controls to identify risk factors for suicide. In their case-control study of risk factors for suicide in epilepsy, they compared 26 cases of suicide and 23 cases of suspected suicide with 171 controls, within a cohort of 6,880 registered with a diagnosis of epilepsy in the Stockholm County Inpatient Register. They found a ninefold increase of suicide with mental illness and a tenfold increase in relative risk with the use of antipsychotic drugs. They arrived at a profile of the epilepsy patient who commits suicide as one with early onset, but not necessarily severe, epilepsy and with psychiatric illness (depression, psychosis, substance abuse).

Mendez et al.[40] studied the causative factors for suicide attempts by overdose in 22 patients with epilepsy (from 711 patients hospitalized for a suicide attempt) and concluded that interictal psychopathologic factors were of primary importance. A comparison of suicide attempts among patients with epilepsy and comparably handicapped controls with other chronic disabilities found that 30% of patients with epilepsy had attempted suicide, as compared with 7% of the controls.[38]

In 1992, Mendez and Doss[39] reported on the suicides in a substantial population of patients with epilepsy *and* included clinical details of all fatal outcomes. They documented the neuropsychiatric aspects of the four patients who died by suicide out of 1,611 patients with epilepsy followed in a neurology clinic over a period of 8 years: two male patients with chronic psychosis, depressive moods, and good seizure control; one male patient with brief psychotic episodes associated with confusion and increased bitemporal spikes and diffuse slowing on electroencephalogram (EEG) in the absence of seizures; and one female patient with episodes of profound ictal and postictal depression who suicided after three witnessed staring spells. The patient with brief psychotic episodes and one of the patients with chronic psychosis experienced voices commanding them to commit suicide. All four patients had suffered from complex partial seizures since childhood and committed suicide by medication overdose at a time when their seizures were controlled, except for the patient who suicided in a state of postictal depression.

Fukuchi et al.[17] reviewed the case records of all outpatients of two epilepsy centers who had died. Patients in one center were followed for 10 years and in the second center for 7 years. Those who had unclassified epilepsy or who died as the result of an underlying disease (such as neoplasm) were excluded. More than 4,000 subjects were reviewed, and the records of 43 deceased patients with well-classified epilepsy were analyzed. Suicide occurred in six patients (14% of the deaths), all with TLE, and three suicided by throwing themselves in front of an oncoming train in the midst of an episode of postictal psychosis. The authors noted the agreement of their findings with those of Mendez and Doss.[39] While providing fewer details, they concluded that most suicides in epilepsy were the result of an immediate causal relationship with ictal or interictal epileptic manifestations. The authors referred to reports of violent behavior directed outward following complex partial seizures, and proposed that this violence may eventually turn into a paroxysmal self-destructive impulse.[20,31]

Suicides After Successful Treatment of Seizures and After Surgical Treatment of the Epilepsy

For an understanding of the pathogenesis of suicide in epilepsy, evidence for the role of predominant inhibition ("forced normalization")[21,33,34,51] must be reviewed.

In 1969, Janz[29] stated that suicide does not occur among patients with severe epilepsy but does occur not infrequently among those patients who have just become free from seizures. With the guidance of Janz, Haltrich[23] studied the causes of death among 909 patients with epilepsy who had been treated at the neurology clinic of a German university during the preceding 8 years (1946–1953); his report includes a large number of suicides with highlights of their psychopathology. Of the 83 patients with symptomatic epilepsy, 51 died from brain tumors. The 11 recorded suicides all occurred among the 78 patients with cryptogenic epilepsy, and at 14.1% surpassed any other cause of death in this group; eight patients (10.3%) died from seizure status and six patients (7.7%) from single seizures. Among the 11 suicides, eight patients had complex partial seizures. Increased irritability was reported in six of the seven males (four with episodes of violence) and in one of the four females; four patients had a history of previous suicide attempts, and another three patients had experienced depressive moods with or without suicidal thoughts. Only one patient suicided during a psychotic state after three previous suicide attempts in psychotic or dysphoric states; he had been violence-prone and was the only patient requiring institutionalization among the 11 who suicided. Haltrich included three later cases of suicide when he reported that the 14 patients had responded well to treatment of their seizures; at the time of suicide, three had experienced only minor attacks, seven only very rare or no major seizures, and four had rare or no seizures of any type.

Taylor and Marsh[49] reported on the occurrence of suicide among 193 patients who had undergone temporal lobectomy and who were followed from 5 to 24 years. Of 37 deaths, nine were by suicide (24.3%). Including an additional six patients who died in unclear circumstances would have raised the suicide rate observed from 25-fold to 50-fold of that expected.[48] Five of the nine who definitely suicided had been rendered seizure-free by the surgery. The authors did not describe the mental state of the victims and merely documented the very high risk of suicide in their particular population.

In another series of surgically treated patients with epilepsy, Hennessy et al.[25] reported only one suicide among 20 deaths in their cohort of 305 consecutive patients who had TLE surgery over a 20-year period. A second patient ran onto a road and was killed by a passing car; both patients were seizure free. The authors suggested that the early series of Taylor and Marsh,[49] with its much higher postoperative suicide rate, had included many patients referred from the Maudsley psychiatric institution. However, the origin of the populations of patients surgically treated and with reports of postoperative mortality is usually not well defined. A large group surveyed from 1928 to 1973 by Jensen[30] includes 2,204 patients who had unilateral temporal lobectomy, with 164 postoperative deaths: due to epilepsy in 26%, suicide in 20%, and accidents in 11%; no details were provided about the suicides.

Of interest is the report by Bladin[2] who reported, with remarkable details of the psychosocial outcome, the results after temporal lobectomy of a series of 115 consecutive patients. They were followed as closely as possible for a mean of 4 years after temporal lobectomy. Five patients showed significant episodes of depression after the operation. In three of them, recognition and antidepressive therapy produced prompt improvement. Another patient, who was seizure-free, was rehabilitated by friends in a religious organization after two suicide attempts. The fifth patient, who lived at a distance and could not participate in the routine postoperative follow-up, was also free of seizures yet committed suicide following the unexpected death of mother and sibling. Three patients showed psychotic episodes more than 3 months after the operation and responded to appropriate therapy, including a neuroleptic. Postoperative anxiety was noted in about half the patients and responded to counseling, medication, or brief hospitalization. Increased sexual drive was reported only upon optimal seizure control. Bladin's report is unique in its report of the use of psychotropic medication for patients with epilepsy.

Psychopathology, Pathogenesis, and Prevention of Suicide: the Study of Patients Treated at the Epi-Care Center

In Chapter 205 on affective disorders of epilepsy, we concluded that the pre-modern psychiatrists, who commonly observed patients with epilepsy on a daily basis, were correct when they

P.2197

recognized the interictal dysphoric disorder with its intermittent and pleomorphic symptomatology as the predominant specific psychiatric disorder of chronic epilepsy. The interictal dysphoric disorder includes episodes of anxiety, fear, elation, insomnia, anergia, pain, explosive irritability, and depressive moods that may be intense and associated with suicidality. The disorder, in its entirety, is well treated with low doses of antidepressant medication. Subsequent to the detailed report of our experience with suicide in a large population of patients attending our epilepsy center, the psychopathology, pathogenesis, and prevention of suicide in epilepsy will be discussed.

A total of 10,739 patients with epilepsy were treated at the Epi-Care Center in Memphis during a 12-year period (1987–1999). The population included a large number of referrals from the mid-South area and beyond. About 900 patients were surgically treated during this period. The comprehensive professional team of the Center consisted of a neurologist, neurosurgeon, electroencephalographer, neuropsychologist, and the same psychiatrist (D.B.) during the entire period. The tasks of the psychiatrist included evaluating all patients admitted for intensive neurodiagnostic monitoring (as candidates for surgical treatment of medically intractable epilepsy or for clarification of the differential diagnosis between epilepsy and nonepileptic seizures) and of every patient at the center who was judged by the team to have psychiatric difficulties. Every patient in need of psychiatric assistance was followed at the Center with the appropriate psychopharmacologic and supportive treatment regardless of geographic distance, as long as the patient and family were able to come for return visits. Patients who required psychiatric hospitalization were admitted under the care of the team psychiatrist in the same hospital where the team admitted its patients for evaluation and treatment of the epilepsy. The presence of a team psychiatrist at the Epi-Care Center and the effectiveness of the psychotropic treatment employed assured prompt referral of patients with psychiatric complications, who were not routinely evaluated by the psychiatrist, for early treatment beyond antiepileptic treatment. Neuropsychological testing of all patients admitted for intensive monitoring and of a large number of outpatients, as well as a weekly case conference, greatly facilitated the teamwork and the referrals to the psychiatrist for early treatment.

The gradual development of a standardized psychiatric evaluation by a comprehensive questionnaire for seizure patients using a semistructured interview of patients and next-of-kin and of an increasingly effective psychopharmacologic treatment has been reported elsewhere.[5,9,10,11] Initially, most patients with psychiatric complications of their epilepsy were treated by adding a modest dose of tricyclic antidepressant to the antiepileptic medication. With the development of treatment by double antidepressant medication (tricyclic plus serotonin-specific reuptake inhibitor) and the addition, if necessary, of a small dose of an atypical antipsychotic drug (risperidone), it became possible to treat successfully the vast majority of patients with any degree of psychopathology, including psychoses and suicidality.

The death of a patient with epilepsy at a treatment center is a memorable event. The number of patients who suicided was ascertained from medical records and the combined memories of the treatment team. The Epi-Care Center was the major center for treatment of epilepsy in the Mid-South and had a policy of careful follow-up of all patients. Thus, the death of one patient who had moved to a distant state about 1 year before her suicide (case 3) is included, as we had attempted to remain helpful.

Results

A total of five (four males, one female) of 10,739 patients attending the Center during the 12-year period committed suicide. The circumstances of these five treatment failures are reported here.

Case 1 (1989)

This male patient had had seizures since age 10. Following a 6-month marriage in late adolescence, he married two more times. His second wife had suicided following childbirth after 1 year of marriage; at that time, the patient became suicidal himself and required 2 months of psychiatric hospitalization. During the third marriage that lasted 4 years, he became suicidal when his wife left him with their child; he blamed his bad temper for the final breakup that had occurred 1 year prior to referral to the Center. His seizures became increasingly more frequent, occurring as often as three times daily. He was then treated by right temporal lobectomy at age 32.

After the operation, he experienced epileptic seizures on only two occasions after missing his medication. There had been a brief episode of feeling suicidal shortly after surgery, but soon he became enthusiastic about the success of the surgery, volunteered to talk to patients who were candidates for surgical treatment of their epilepsy, was active in the local chapter of the Epilepsy Foundation, and was working on a book about epilepsy. When he experienced an episode of dissociation with amnesia 12 months after his surgery, he was scheduled for psychiatric evaluation. Shortly thereafter, he developed frequent nonepileptic seizures.

He was first evaluated psychiatrically at age 33, 14 months after surgical treatment. He presented as an intensely emotional individual who felt he had a special mission in life and reported big mood shifts from very happy to very sad. He was at first treated with doxepin because of insomnia, then with the better-tolerated imipramine to 100 mg at bedtime, and he showed improvement. However, after 6 months of monthly visits, he felt accused of having "fake seizures," abruptly severed his relationship with the Center, moved to a neighboring state, and discontinued the antidepressant medication. On two occasions, at 7 and 11 months after he had discontinued his visits, he returned to the Center for only neurologic follow-up visits, stating that he had no seizures and was doing well. Six months after his last visit, he called the Center from out of state. He stated that his girlfriend had left him, he feared going off in a rage attack, and for the past 8 days he had been driving around with a rope in his car looking for a tree to hang himself. He refused any help and, 10 days later, 3 years after the operation, committed suicide by hanging.

Comment: This patient had a dysphoric disorder with marked depressive moods, irritability, and insomnia. The occurrence of nonepileptic seizures is not uncommon in patients who have become free of seizures after surgery.[13] We did not have the experience to deal with this predicament at that time; the patient became noncompliant and discontinued the antidepressant medication.

Case 2 (1990)

This male patient had had frequent seizures since the age of 6 weeks. He had three to five seizures per week, lived with his parents, and was active in church life. When he became unable to work because of back pain, he became depressed, with marked anergia and recurrent episodes of feeling suicidal, which required a brief psychiatric hospitalization.

Four months after onset of his pain, at age 34, he was evaluated at the Epi-Care Center. No pathology was found for his back pain, but a right temporal tumor was detected, and a right temporal lobectomy for a ganglioglioma was carried out.

Subsequent to the operation, he remained seizure free. At discharge, he was prescribed imipramine but discontinued the drug when it did not help his insomnia. He was referred for psychiatric follow-up near his home. Initially, he seemed improved

P.2198

but then continued to be depressed and preoccupied with his back pain. The psychiatric treatment consisted of counseling, fluoxetine, and a period of inpatient treatment 8 months after the operation. One year after the operation, he drowned himself. His family did not understand why this happened.

Comment: This patient had a dysphoric disorder with depressive moods, anergia, insomnia, and pain. He was treated psychiatrically near his home and, at that time, we did not have a more effective treatment to initiate or to recommend.

Case 3 (1991)

This female patient had had seizures since grammar school but was diagnosed only at age 18. After 18 years of education, she married but remained childless. She made one suicide attempt at age 38, and had several car accidents due to seizures.

She became a patient at the Epi-Care Center at the age of 43, initially for psychiatric treatment. Her main complaint was chronic pain with anergia and depressive moods of at least 5 years' duration; she also had insomnia and was hypochondriacal. Her primidone was phased out, and her pains and dysphoric symptoms vanished when the combination of carbamazepine and amitriptyline at 100 mg was prescribed. When her husband insisted on divorce, she regressed and had to be hospitalized for 1 month with a mixed manic and depressive state with recurrence of her pains. She again improved with the temporary addition of lithium.

Her seizures occurred perhaps every few weeks and, following finalization of the divorce, she had a right temporal lobectomy at age 45. The specimen showed hippocampal sclerosis, and she remained seizure-free. Six months after surgery, she felt great and decided to move to her far-away home state, where she did not find a supportive environment. Her pains and depression resumed, even though she maintained an antidepressant (trimipramine 100 mg daily). She returned to her original neurologist, who replaced the carbamazepine with primidone when she was found to have a low sodium level. At the age of 46, 18 months after surgery, she committed suicide by shooting herself.

Comment: This patient had a dysphoric disorder with depressive moods, anergia, insomnia, and pain. She did not seek local psychiatric help after her departure from the Center. The reintroduction of primidone possibly made her depressive moods worse.

Case 4 (1998)

This male patient began to have seizures at age 10, and was treated at the Epi-Care Center beginning at age 23. He underwent a left temporal lobectomy that showed hippocampal sclerosis, but he continued to have daily (although shorter) complex partial seizures. A further resection of the left hippocampus 6 months later was similarly ineffective. He was a serious and very religious young man, who admitted to some temper but showed no troublesome dysphoric symptoms at the time of his presurgical psychiatric evaluation at the Center, and he was not followed psychiatrically. He worked for 2 years after the operation and, after a failed marriage, resumed living with his parents. Over the subsequent 6 years, he was treated with all the latest antiepileptic drugs without any success until his seizures finally became controlled by the combination of zonisamide, gabapentin, and phenytoin. The subsequent follow-up was entirely by phone contact with the patient and his family. He resumed work and reported enjoying it. Following an unprecedented outburst of rage toward his parents 2 weeks after he had become seizure-free, he began to live in separate quarters on the family property. Antidepressant treatment suggested by our neurologist was not felt necessary by the family since he did well at work. Three months after becoming free of seizures, he was found dead, having inflicted a gunshot wound to the abdomen.

Comment: The first symptom of a dysphoric disorder in the form of an unexpected outburst of rage was reported after he had become seizure-free. There was no further warning or call for help.

Case 5 (1999)

This male patient suffered a head injury at age 6 and started to have seizures at age 17. He worked until age 35, and went to church faithfully. After age 41, he attended a family therapy center for a few years for depression and marital conflicts and took a drug overdose at the time of his divorce at age 45.

At age 48, he began treatment at the Epi-Care Center for complex partial seizures that tended to occur several times daily. On first evaluation, he was recognized as having a dysphoric disorder with intermittent depressive moods and occasional suicidal ideas, anergia, irritability, and anxiety. He refused antidepressant treatment. An anterior partial callosotomy early in his treatment at the Center did not improve the high daily frequency of his seizures.

At age 50, he married a domineering woman who had a history of skull fractures inflicted by her former husband and who had been treated for her own violent temper. Shortly thereafter, the couple elected treatment by vagal nerve stimulation (VNS) for his seizures, and he was reevaluated psychiatrically. Both the patient and his new wife admitted to being “hotheaded,” but they adamantly refused to comply with advice given for the treatment of his dysphoric disorder. His seizure frequency gradually decreased over the initial 15 months of VNS until it diminished to only two complex partial seizures per day. At that point, the VNS was increased. Four months later, we learned from his local physician that he had become seizure-free for the first time since the onset of the epilepsy 35 years earlier and that he had killed his wife and then himself.

Comment: This patient had a dysphoric disorder with depressive moods, anergia, anxiety, and irritability. Whereas irritability to the point of paroxysmal outbursts of anger is a key symptom of the dysphoric disorder, dysphoric patients, like the majority of patients with epilepsy, tend to be very conscientious and often highly religious, and their outbursts are followed by genuine remorse. Their extreme rage tends to be turned against themselves, and homicide, as opposed to suicide, is an exceptionally rare occurrence in epilepsy.[6]

Discussion

The five suicides among the population of 10,739 patients seen at the Epi-Care Center over the period of 12 years share a surprisingly common pattern. All had a history of early onset (mean age 9.5 years) of long-standing complex partial seizures (mean duration 29 years) with very high (often daily) seizure frequency in all but one. Suicide occurred in all patients after a short interval (3 months to 3 years, mean 13 months) of having obtained full control of seizures for the first time by temporal lobectomy (three patients), medication, or VNS. All had symptoms of an interictal dysphoric disorder, and three of the four males had a significant problem with episodes of violent anger. All but one (case 4) had a history of previous suicidal moods or suicide attempts, but in three of the five, the suicidal act was precipitate and not anticipated at the time. All had experienced worse psychosocial predicaments in the past than were present at the time of completed suicide.

The four patients from the series of Mendez and Doss[39] likewise all had an onset of epilepsy in early life, with a mean duration of the seizure disorder of 25 years, and two of the three patients who committed suicide in a psychotic state were under good seizure control. The third patient suffered from unusual psychotic episodes that coincided with the presence of increased electroencephalographic epileptiform potentials in the absence of seizures; he will be discussed in the section on pathogenesis. The fourth patient suicided in a state of postictal depression. The patients from the series of Taylor and Marsh[49] who suicided after temporal lobectomy were reported without any details of their psychopathology, but five of the nine had been rendered seizure-free after surgical treatment.

Among the three series, 12 of 18 patients committed suicide after a long-standing seizure disorder was under control. This finding confirms the early reports by Janz[29] and Haltrich.[23] Janz was already well aware of the finding of forced normalization noted by Landolt[34]: Control of seizures may usher in dysphoric or psychotic disorders. Particularly notable is Haltrich's finding that six of the seven male patients had been markedly irritable, with a majority suffering from episodes of violent temper. The same finding is evident in three of our four male suicides.

Suicide among patients with epilepsy clearly is not the result of psychosocial difficulties caused by having seizures, but rather occurs in the presence of significant interictal and at times postictal psychopathology. Prior to reviewing the pathogenesis of suicide in epilepsy, the phenomenology of the interictal and peri-ictal psychopathology and their relationship to suicide must be clarified.

Psychopathology Associated with Suicide in Epilepsy

Premodern psychiatrists recognized an intermittent and pleomorphic disorder, termed the *dysphoric disorder*, as the most common psychiatric disorder of epilepsy. The interictal dysphoric disorder is a distinct disorder that had to be rediscovered.[6] One of its key symptoms—intermittent depressive mood—is associated with the episodic suicidal moods of patients with chronic epilepsy, primarily those with mesial TLE.[3,6,9,18,19,37] Kraepelin[32] precisely described the dysphoric disorder of patients with epilepsy: Dysphoric episodes present with depressive moods ("very frequently with utter disgust of life and suicidal bent"), irritability, anxiety, headaches, insomnia, but also with euphoric moods. The dysphoric episodes occur without external triggers, with rapid onset and termination, and recur fairly regularly in a uniform manner in the absence of clouding of consciousness. Dysphoric symptoms commonly can be observed as prodrome or aftermath of an attack but, most important, they appear as phenomena independent of the seizures, as interictal dysphoric episodes, with a frequency varying from every few days to every few months. As a rule, the dysphoric state lasts from 1 to 2 days but may dissipate after just a few hours.

Based on our own observations, we added anergia and phobic fears to Kraepelin's six key symptoms of the dysphoric disorder and have defined it by the presence of at least three of the eight key symptoms, each present to a troublesome degree.[9]

The risk of suicide in patients with epilepsy is primarily associated with the often sudden episodes of intense depressive mood of the interictal phase; therefore, suicide in epilepsy tends to occur in a precipitate manner. As noted by Haltrich[23] and in our own series, the occurrence of marked irritability with outbursts of violent behavior appears to represent a particular risk factor for suicide among male patients. As noted early by Kraepelin, the dysphoric symptoms also tend to occur peri-ictally, during the prodrome or aftermath of a seizure. The postictal phase in particular may be associated with marked depressive mood.[4] A high suicidal risk has been observed in patients who experience ictal depressive mood that extends into the postictal phase for a period of 1 hour to 3 days. Williams[52] reported 21 such cases among his 100 patients with ictal emotional experience, and five of the 21 patients had made suicide attempts during their postictal phase. The fourth case of Mendez and Doss represents a well-documented postictal suicide.[39]

As noted earlier by Kraepelin, interictal psychoses tend to develop as expansions of interictal dysphoric disorders.[32] The dysphoric disorder persists during the psychotic state, and suicidal depressive moods may occur in the course of an interictal psychosis when reasoning is impaired. Presence of the hallucination of voices commanding a patient to suicide represents a particular risk.

Pathogenesis of Suicide in Epilepsy

The treatment of seizures during the first four decades of the 20th century consisted chiefly of potassium bromide; phenobarbital, available since 1913, was widely shunned by psychiatrists because of its psychotoxic effects. In a modern era that considers epilepsy a neurologic disorder and has focused with growing success on the control of seizures with an expanding score of antiepileptic drugs and surgical procedures, dysphoric symptoms and psychotic episodes appear to have become more severe and chronic. Kraepelin[32] had noted a very brief duration of the dysphoric episodes, and stated that interictal psychotic episodes as a rule last only a few days and may persist for weeks or even months only in isolated cases; he noted a very frequent suicidal urge, but not completed suicide, associated with dysphoric episodes. The relative infrequency of suicide in the premodern era is documented by Prudhomme,[45] whose research included approximately 77,000 patients with epilepsy from the period of 1893 to 1940.

The emergence or worsening of psychopathology upon suppression of seizure activity has been widely reported. Since the early reports by Gibbs,[20] Hill,[27] and Landolt,[34] evidence has been increasing that the interictal psychopathology may emerge or worsen upon improvement of the epilepsy, as measured by seizure frequency and EEG abnormalities. Persuasive evidence suggests that the psychiatric disorders of epilepsy may result from the inhibitory activity that develops in reaction to the excessive excitatory activity of the chronic seizure disorder, as postulated by Stevens[47] and Engel.[16] The precise nature of the seizure-suppressing mechanisms is insufficiently understood, and the phenomenon of emergence of psychiatric disturbance with normalization of the EEG or with suppression of clinical seizures, has been usually referred to as *forced normalization* or *alternating psychosis*, respectively.[10,34,50] Landolt's early observations included dysphoric disorders upon normalization of the EEG,[34] but when the concept of the dysphoric disorder was forgotten, psychiatric observations began to focus on the psychotic disorders and to a lesser extent on isolated symptoms of the dysphoric disorder.[46] Early reports that suicide may occur as an alternating phenomenon when seizures are suppressed[29] were widely ignored.

The evidence of a linkage of the psychiatric changes to inhibitory mechanisms can be summarized as follows: (a) The development of interictal dysphoric and even more so of psychotic disorders is delayed following onset of epilepsy,[18,19] as inhibitory mechanisms become increasingly established; this predicament accords with the particular linkage of the psychiatric disorders of epilepsy with its most prominent chronic form (i.e., mesial TLE). (b) Upon decrease, and particularly upon full control of seizures, dysphoric symptoms and psychosis tend to be exacerbated or to emerge de novo.[6,10,21,27,34,50,51] (c) The same psychiatric changes emerge also at times when

acute exacerbation of the seizure activity engages an enhanced inhibitory response, commonly in the prodromal and postictal phases, and rarely upon increased seizure activity as paraictal psychosis —a seeming opposite of forced normalization or alternating psychosis.[4,6,32,46] (d) After optimal surgical elimination of the epileptogenic zone, a delay of 6 to 18 months occurs before the psychiatric changes become phased out, presumably with only gradual fading of the inhibitory mechanisms.[10]

If predominance of inhibition results in persistent suppression of seizures in chronic epilepsy, some patients are at risk to develop the most severe psychiatric complications: A dysphoric disorder with suicidal depressive moods, psychosis, or a combination of both. On the other hand, the *acute* engagement of inhibitory mechanisms by the seizure event tends to result in peri-ictal dysphoric symptoms that may include postictal depressive mood with suicidality. The third case of Mendez and Doss[39] is exceptional: The patient's brief psychotic episodes would occur in the presence of *increased* epileptiform activity in the EEG in the *absence* of seizures, and the psychotic confusion was associated with voices commanding him to commit suicide. Demers-Desrosiers et al.[14] reported similar psychotic episodes in two patients who became psychotic shortly after discontinuing their antiepileptic medication, in association with *increased* epileptiform activity of the EEG in the *absence* of seizures; their psychotic state remitted upon resuming the antiepileptic medication. The authors correctly considered their findings as the antipode of forced normalization, since forced normalization is understood as the emergence of psychotic disturbance when the EEG is normalized. The three cases have in common that, in the presence of increased EEG abnormality, no seizures occurred, presumably as inhibitory mechanisms were acutely engaged, provoking psychotic episodes and suicidality as alternating phenomena.

A psychodynamic aspect in the pathogenesis of suicide is noteworthy. A core symptom of the dysphoric disorder, termed *irritability*, consists of the paroxysmal affect of anger that may be overcontrolled or range from short temper to the point of explosive rage; excessive anger conflicts with the notably conscientious and even hyper-religious personality of patients with epilepsy and may become intolerable,[6] prompting a precipitate and often unexpected act of suicide. Janz noted that a violent form of suicide (plunge from great height, throwing self under a train, drowning) occurred more frequently among patients with epilepsy than in the average population of suicides in Germany,[29] and similar reports came from Japan.[17]

Prevention of Suicide

If the hypothesis is correct that inhibition in chronic epilepsy may have a psychotoxic effect in many patients, then the treatment of psychopathology in epilepsy must aim to moderate the inhibitory mechanisms. Avoiding the antidepressant drugs that are most effective for this task for fear of lowering the seizure threshold of patients with epilepsy is ill-advised and carries the risk of fatal consequences.

The use of antidepressants for interictal psychiatric disorders was advocated as early as 1983.[43] We have successfully used antidepressants in modest doses for the psychiatric disorders of epilepsy for over 15 years in a large number of patients without increasing the seizure frequency, except in a rare patient with primary generalized seizures.[5,6,11] The proconvulsant antidepressant drugs at modest doses appear to serve as effective antagonists to the excessive inhibition and, in fact, are indispensable for successfully treating the interictal dysphoric and psychotic disorders. Gastaut et al.[19] pointed out that the interictal seizure threshold of patients with TLE (as measured by the response to Metrazol), in contrast to that of patients with primary generalized epilepsy, is higher than in nonepileptic individuals. The bias against the use of antidepressants for the psychiatric disorders of epilepsy, because they may lower the seizure threshold, is erroneous both on empirical and theoretical grounds. However, patients with primary generalized epilepsy who occasionally may experience dysphoric symptoms (presumably as a result of involvement of mesial temporal structures) still may have a lowered seizure threshold and need a more cautious dose of antidepressant medication.

In general, three of the eight key symptoms of the dysphoric disorder must be present before we initiate treatment with antidepressant medication. We add 100mg (up to 150 mg) of imipramine at bedtime to the antiepileptic medication, making sure that the sleep disturbance is corrected; amitriptyline, doxepin, trimipramine, or nortriptyline may have to be substituted for that purpose. If the patient does not respond well, we add a serotonin-selective reuptake inhibitory antidepressant (SSRI) to the tricyclic, which is usually kept at a dose of 100 mg. Paroxetine has been our preferred SSRI, at 20 mg once to twice daily, but at times a different SSRI may be more effective. One may also proceed in the reverse order by starting with the SSRI and then adding a tricyclic drug if necessary. As a third step, for severe dysphoric disorders, risperidone at about 2 mg daily may have to be added. The response to this treatment extends to all the symptoms of the dysphoric disorder, including the depressive moods as well as the irritability, and occurs within days once a therapeutic dose is reached, allowing a rapid escalation of the prescription if necessary. If an interictal dysphoric disorder is associated with suicidality or with psychotic features, treatment should be started promptly with double antidepressant medication; a small dose of neuroleptic (risperidone 1 to 4 mg daily) may need to be added. Treating the interictal psychoses—dysphoric disorders with predominant psychotic features—should generally be carried out in identical fashion as for the severe dysphoric disorders and not simply by neuroleptic drugs.[10]

The number of suicides at the Epi-Care Center is a fraction of what is expected from previous surveys. When the three early patients (cases 1–3) from the Epi-Care Center suicided after successful epilepsy surgery, we had not yet learned to use the more effective augmented antidepressant treatment for severe dysphoric disorders. Mendez and Doss[39] reported the low rate of four suicides out of 1,611 patients (0.25%) followed for epilepsy in a neurology clinic over a period of 8 years. We had two suicides among the estimated 7,160 patients (0.03%) followed at the Epi-Care Center over the last 8 years of the study period, when we had the more effective psychotropic treatment in place; both patients had eluded this treatment (cases 4 and 5). Case histories of patients with the highest suicide risk but successfully treated at the Center have been previously reported.[5,7]

Suicide in epilepsy tends to be precipitate, but there may be recurrent warning from earlier dysphoric episodes with suicidal mood. All such patients require prompt and vigorous intervention with augmented antidepressant medication to stabilize their dysphoric disorder. However, a suicidal mood may emerge without a previous occurrence in a patient who had shown other symptoms of a dysphoric disorder (e.g., the outburst of rage in case 4). Prompt treatment of significant dysphoric symptoms assures not only an improved quality of life but prevents a suicidal outcome. Finally, patients with severe postictal depression, in our experience, can be protected from a suicidal impulse if they are maintained on antidepressant medication.

Summary and Conclusions

The increased risk of death by suicide among patients with epilepsy, while rarely disputed, has often been viewed as the

P.2201

unfortunate result of the psychosocial difficulties imposed by a chronic neurologic disease and has received scant psychiatric attention.

The study of suicides among 10,739 patients seen at the Epi-Care Center over 12 years confirms earlier findings[23,39] of suicide in epilepsy resulting from the specific neuropsychiatric disorders that are associated with epilepsy. These disorders include intermittent depressive moods with suicidal intensity among patients with interictal dysphoric disorder, psychotic episodes with concomitant dysphoric disorder and at times with command hallucinations, and severe postictal depressive states. The suicides may occur particularly in patients with long-standing TLE with high seizure frequency once seizures finally became controlled. Although a majority of patients with epilepsy will reach long-term remission, some patients with chronic epilepsy experience serious psychiatric complications when their seizures become controlled. Mendez and Doss implied that interictal depression may be relieved by having seizures, similar to the effect of electroconvulsive therapy.[39] The evidence suggests that a predominance of inhibitory mechanisms, interictally or postictally, may be psychotoxic, favoring the emergence of dysphoric and psychotic states and of a suicidal risk. The findings from the Epi-Care Center indicate that the early treatment of patients with epilepsy and dysphoric symptoms by the appropriate psychotropic medication can prevent suicides.

Suicide is only the most striking problem among the sizable number of patients with chronic epilepsy who suffer from dysphoric and psychotic disorders, and are well treatable by modern psychopharmacologic intervention. A much improved collaboration is required between neurologists who recognize the scope of the psychiatric complications of epilepsy and of psychiatrists who do not shun the field of epilepsy as alien to their specialty. The modern advances in suppressing seizures must become paired with the competence to treat the psychiatric consequences of improved seizure control in order to achieve optimal quality of life and to prevent fatal outcomes.

Chapter 212

Disorders of Impulse Control

Ludger Tebartz van Elst

Michael R. Trimble

Introduction

Impulsivity in general is a frequent clinical problem that is related to many different primary psychiatric disorders as, for example, attention-deficit-hyperactivity disorder (ADHD), borderline personality disorder, bipolar disorder (in particular in hypomanic or manic states), and schizophrenia.[1,2] Furthermore, it is a common management problem in patients with mental retardation or organic brain disorders. Although the International Statistical Classification of Diseases and Health Related Problems (ICD-10) does not recognize specific independent disorders of impulse control,[1] the American Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) defines the category of impulse-control disorders not elsewhere classified[2] and includes the entities of intermittent explosive disorder (IED; DSM-IV 312.34), kleptomania (DSM-IV 312.32), pyromania (DSM-IV 312.33), pathologic gambling (DSM-IV 312.31), and trichotillomania (DSM-IV 312.39).

Because impulsive aggression is the most clinically important and most troubling form of these impulse control disorders (see also Chapter 283 and the review by Tebartz van Elst[73]), in this chapter we will concentrate on the problem of aggression in the context of epilepsy. This issue has been the topic of other recent publications.[73] We discuss the putative relationship between epilepsy and the other aforementioned impulse control disorders briefly at the end of the chapter.

Impulsive Aggression in Epilepsy

The relationship between epilepsy and aggressive behavior is a particularly controversial issue.[33] In Chapter 283, we discussed the issue of episodic dyscontrol and IED in the context of the differential diagnosis of epilepsy, and also as an independent psychiatric entity. Here we want to dwell on the more general and less specific forms of impulsive aggression that do not fulfil the criteria of episodic dyscontrol, but still are seen in patients with epilepsy.

The precise prevalence of aggressive and violent behavior in the context of epilepsy is very difficult to assess and subsequently is still unknown. In patients with episodic affective aggression, a history of epilepsy is reported to be more common.[4] On the other hand,[22] most of the community-based studies did not find an increased prevalence of aggressive behavior in patients with epilepsy.[43,48] Different papers report wide-ranging prevalence figures of aggression in epilepsy in general, do not note the specific epileptic syndrome, and cite figures from as low as 4.8%[65] to as high as 50%.[31]

Currie et al. reported aggression in 7% of the patients in a large survey of 666 patients with temporal lobe epilepsy (TLE).[15] Falconer's group reviewed 100 patients from London's Maudsley Hospital referred for temporal lobectomy and found a prevalence of outbursts of aggressive behavior in as many as 27% of these patients.[24] However, like most of the other studies addressing this issue, these studies were hampered by selection bias, and thus the real prevalence of aggressive behavior in epilepsy remains controversial.[48]

In epilepsy, three different types of aggressive behaviors should be distinguished on the basis of their relationship to the seizures: ictal, postictal, and interictal aggression.[27,42,73,74]

Ictal Aggression

Ictal aggression is very rare.[36,66] Delgardo-Escueta et al. found an incidence of about 1 in 1,000 seizures with ictal aggression in a large survey of several thousand seizures documented by video-telemetry.[18] However, it can be argued that as such, looking for ictal aggression in the context of the tightly controlled arena of an electroencephalogram (EEG) suite is not going to provide a true view on the frequency of the problem. This is because patients with aggressive episodes are less likely to be accepted for evaluation, and such episodes of aggressive release are more likely to occur in a community rather than a laboratory setting. In ictal aggression, hostile and verbal or physical aggressive behavior is often directed toward nearby objects or persons and may or may not be provoked.[27] The patients are generally amnesic for these aggressive episodes and often express remorse or feelings of shame for their behavior after the event.[19,28]

Postictal Aggression

Postictal aggression is more common than ictal aggression and, although it is still believed to be rare, it may be under-recognized and unreported.[77] Postictal aggressive behavior usually follows a cluster of complex partial seizures or secondary generalized seizures in patients in whom such episodes are not the usually expression of their epilepsy. Some evidence points to ictal pain or dysphoria as predisposing factors for the later development of postictal aggressive behaviour.[32] If the episode occurs in the context of a postictal confusional state, poorly structured aggressive behavior is not that rare. This aggression is poorly directed, and the patient, rather than someone who is attacked, is most likely to come to harm. If postictal aggression is part of a postictal confusional state, the disruptive behavior immediately follows the seizure without a lucid interval intervening between the ictus and the outbreak of the disruptive behavior. In this state, patients are often resistive, but within their confusion can be very aroused, angry, and fearful.[41,46]

Postictal psychosis typically follows a cluster of complex partial or secondary generalized seizures in patients with longstanding chronic and often therapy-refractory epilepsy. Generally these states follow a lucid interval—the calm before

P.2204

the storm—which might last anywhere between hours and days up to 1 week. Observers may notice an insidious onset of affective symptoms with arousal, restlessness, agitation, and often anxiety, fear, and anger, although the behavioral state can erupt quite suddenly. Subsequently, overt psychotic symptoms with delusions and hallucinations might follow. The latter might be accompanied by aggressive behavior that sometimes is very dramatic and dangerous.[29,40,49,78] Although aggressive behavior in the context of a delusional state is often rather disorganized if there is some clouding of consciousness, this is not necessarily the case. Over 50% of patients with postictal psychotic states have minimal or no such associated confusion, and aggressive behavior can be well-structured and goal-directed. Patients often feel angry and aroused, although they may appear calm and concentrated to the observer.[41,72]

Kanemoto et al. make the important observation that well-directed and self-destructive behavior might even be a hallmark of postictal psychosis.[41] The psychosis may be missed, either because it is not probed for, or because the behavior is such that it is not possible to obtain a good mental state evaluation. The latter is the more problematic in those with learning disabilities. The aggressive behavior might then be structured and goal-directed, but without any obvious sign of delusions or hallucinations.[41,46,72] The awareness of the problem of postictal psychoses and associated aggressive behavior is of particular importance for epilepsy-monitoring centers because, in this context, many patients with chronic therapy-refractory epilepsy are seen and diagnosed following an acute reduction of their medication for diagnostic purposes. If a history of previous postictal events exists, doctors should be aware of the risk of postictal psychosis and aggression, and should closely monitor the behavior of these patients. Outbursts of aggression, especially with psychotic intensity, are dangerous not only for the patients but also the nurses and attending physicians themselves.

Interictal Aggression

Interictal aggressions are the most common, but generally less dramatic forms of aggressive behaviors in patients with epilepsy. These can be seen in the context of an antisocial personality disorder which, in turn, might be the consequence of the sometimes difficult psychosocial background and upbringing of patients with epilepsy, Or it might be part of a prolonged psychotic episode, an interictal affective disorder, or a psychosis of a paranoid- or schizophrenia-like type.[49,41]

In patients with epilepsy and mental handicap, interictal aggression is a common management problem. In these patients, the aggressive behavior is often the result of poor social and communication competence in expressing personal needs and rarely results in severe violence.[37]

An interictal syndrome of episodic affective aggression, independent of observable ictal activity, major psychiatric disorder, or antisocial personality disorder, is well described and has been referred to as *episodic dyscontrol* or *IED.*[4,23,47,52,64,71] Episodic dyscontrol is characterized by several discrete epi- sodes of extreme arousal and rage that are out of proportion to any precipitating psychosocial stressor, but that result in severe aggressive and violent behavior. As mentioned earlier, this form of possible epilepsy-related aggression has been described and discussed in Chapter 283.

Irritability and impulsivity, in particular verbal aggression of mild to modest severity, might be a symptom of the dysphoric disorder of epilepsy (DDE). DDE is a specific form of epilepsy-related affective disorder characterized by symptoms like irritability, mood swings, anergia, diffuse pain, anxiety, fears, and disturbances of sleep. The paroxysmal affects, ranging from irritability through anger to rage, play a major role in DDE and make it an easy-to-recognize pattern of psychopathology for the experienced clinician.[10] Based on the relationship to the ictus, DDE can be subclassified as preictal, interictal, and postictal DDE.[44] In particular, in patients with learning disability, irritability and aggressive behavior might dominate the clinical picture of DDE and thereby obscure the diagnosis.

Finally, interictal aggression in the context of epilepsy can be a side effect of antiepileptic medication. Reports have been published, for example, for substances such as phenobarbital, several benzodiazepines, gabapentin (especially in adolescents), vigabatrin, topiramate, and levitiracetam.[3,8,16,20,30,54,57,67] This may be a part of a syndrome of forced normalization, an idiosyncratic reaction representing the precipitation of a nonconvulsive status epilepticus, or a manifestation of intoxication. However, from a different perspective, anticonvulsants may be quite helpful in treating impulsive aggression in patients with epilepsy, in whom aggression is postictal in nature or interictal as part of a mood instability syndrome, as they are in other aggressive patients without epilepsy.[5,6,39,58,59,68,69,75]

This complex constellation illustrates the need for a careful neuropsychiatric assessment of patients in whom impulsive aggression is a clinical problem, be it in the context of epilepsy or not.

Treatment of Aggression in Epilepsy

Establishing a correct diagnosis is the most important point in treating problems with aggression in the context of epilepsy (Fig. 1). A careful neurologic, psychiatric, and medical history and examination is a prerequisite to answer the following questions: Is there any medical condition that contributes to the aggressive behavior, such as an endocrinologic disease? Is there any medication that might contribute to the aggressive behavior—antiepileptic or otherwise? What is the correct neurologic diagnosis? Does the patient have epilepsy? Are there any other cerebral problems in addition to the epilepsy? Is there any specific epilepsy-related psychiatric disorder, either ictal or postictal, that might explain the aggressive behavior? Are any psychiatric diagnoses present, but possibly independent of the epilepsy, such as bipolar disorder or antisocial personality disorder?

With regards to the latter question, if the epilepsy started early in life, it is often impossible to establish if, for example, the clinical picture that fulfils the criteria for an antisocial personality disorder is or is not independent of the organic brain disease indicated by the epilepsy: Does the patient have an unassociated personality disorder or, alternatively, is the problem an organic personality disorder? A careful behavioral analysis, thorough anamnesis, and possibly video-telemetry should clarify if the aggressive behavior is ictal, postictal, or interictal and whether it occurs in the context of altered states of consciousness or psychosis.

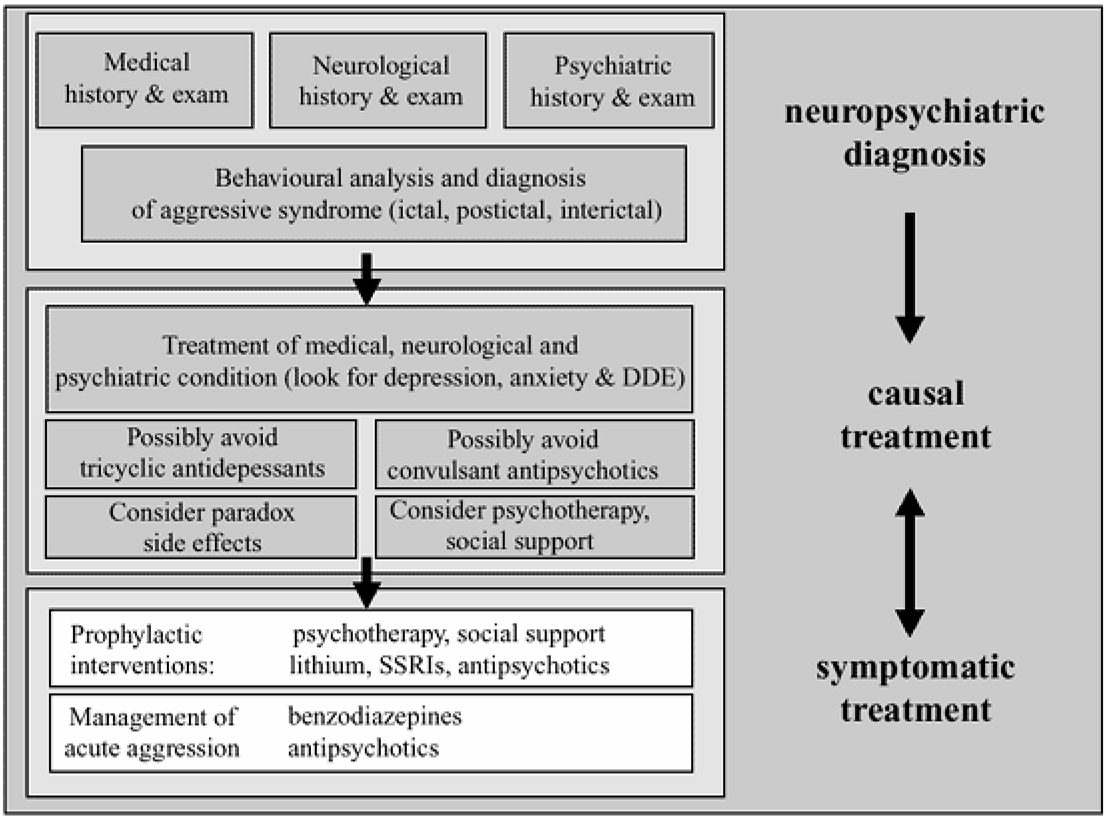

FIGURE 1. Therapeutic guidelines for the treatment of aggression in patients with epilepsy. (From Tebartz van Elst L. Aggression and epilepsy. In: Trimble M, Schmitz B, eds. *The Neuropsychiatry of Epilepsy.* Cambridge: Cambridge University Press; 2002: 81–106, with permission.)

Following syndromic and possibly nosologic diagnosis, treatment should be targeted to any treatable causes if possible, such as intervening medical problems like endocrinologic disorders. Neurological syndromes, such as the epilepsy itself, should be treated effectively, with as few medications as possible to avoid seizures, and with avoidance of medications most linked with alteration of mood and the release of aggressive behavior. Particular care should be taken to establish signs of depression, anxiety, or the common dysphoric disorder of epilepsy, because a close link exists between these psychopathologic states and affective aggression in epilepsy.[74] Affective symptoms should be treated medically and with psychotherapy at the same time.[34,50] In the medical treatment of depression in patients with epilepsy, selective serotonin reuptake inhibitors (SSRIs) or other new antidepressants such as

venlafaxine should be preferred to the older tricyclic antidepressants (TCA) because the latter are more likely to provoke seizures.[9,45] The anticonvulsant effect of the SSRIs is well documented in animal models of epilepsy,[12,51,60,79] and is also described in humans.[26]

Following treatment of all medical, neurologic, and psychiatric conditions that may or may not contribute to the aggressive psychopathology, a symptomatic treatment of the aggression is mandatory. However, this depends on whether the aggression is an ictal, postictal, or interictal phenomenon.

Ictal aggression requires immediate attention to the seizures, and a nonconvulsive status epilepticus can be interrupted using, for example, benzodiazepines.[27] Apart from that, a patient who displays agitation and aggressive during a seizure should not be overly restricted, because defensive violence is more common in such situations, and the aggressive behavior is self-limited, as is the seizure.

The same is true for postictal confusional states: Even aggressive behavior in the context of postictal psychosis is self-limited. However, if the aggression is severe and disturbing or self-harming, medical treatment using benzodiazepines such as diazepam or clobazam and/or antipsychotics (usually one of the atypicals) should be started. Good seizure control that avoids clusters of complex partial or secondary generalized seizure is the best prophylactic intervention, because postictal confusional and psychotic states are more common after such episodes. If, after for example a cluster of attacks, the impending abnormal behavior can be predicted, the use of a benzodiazepine for about 48 hours may well be sufficient to abort the event. Patients or caregivers should have a supply of such medications and be given advice on how to use them judiciously.

In treating interictal aggression, one should again distinguish prophylactic and acute treatment. For the treatment of severe and etiologically unclear acute hyperarousal-dyscontrol syndromes, a combination of benzodiazepines, such as diazepam, and antipsychotics, such as haloperidol, is still the most effective and safest intervention. In cases of interictal psychoses, however, the antipsychotic medication should eventually be switched to one of the atypical antipsychotic agents with little proconvulsant potential, because these drugs are better tolerated. A good control of the psychosis is the best way to prevent aggression if it is part of the psychosis.

In cases of interictal aggressive syndromes like IED, no well-established medical prophylactic therapies are available. However, many anecdotal reports document the effective use of substances such as lithium, valproate, carbamazepine, phenyt-oin, antipsychotics, ß-blockers, clonidine, and even psychostimulants (see Chapter 283 and several reviews[25,35,81]). However, because there are hardly any well-conducted systematic treatment studies at the moment, the medical treatment still is very experimental and single-case driven. Nevertheless, in the light of the very severe burden that is put on the patients, their relatives, and caregivers by the sometimes devastating behavioral episodes, a systematic trial of these agents seems justified.

If aggressive behavior is part of interictal DDE,[10] this should be treated with SSRIs in the first instance. Substances such as citalopram or escitalopram have few interaction problems with other antiepileptic drugs and have a minimal problem with lowering the seizure threshold. If these drugs are not effective in controlling dysphoric depression, one should consider others, such as venlafaxine, a TCA, or even a combination of the two. In some cases, additional treatment with a very low-dose atypical antipsychotic might also be helpful. However, one should always avoid high doses of these drug and be very careful with combination therapy, because this might lower the seizure threshold,[9] provoking further irritability or further postictal episodes.

Finally, as mentioned in Chapter 283 in the context of episodic dyscontrol, it must be stressed that anger management, contingency management, and psychotherapy all can be very helpful and successful in treating impulsive aggressive behavior. Particularly in the context of mental handicap and personality disorders, aggression and impulsivity might be part of attention seeking behavior and role testing. In these cases, feedback strategies and the reactions of relatives and caregivers are very important, and methods of contingency management may be a critical element of any successful treatment.[7,14] Behavioral therapy, in particular in patients with epilepsy and mental handicap, has been proven very effective.[17,38,63]

Different methods of anger management, cognitive behavior therapy, or skills training that have been developed irrespective of the context of impulsive behavior may be very helpful in the therapy of aggression.[17,70,76,80]

Epilepsy and Other Disorders of Impulse Control

To our knowledge, no papers in the literature address the question of a specific link between epilepsy and syndromes such as kleptomania and pathologic gambling. However, a few case reports discuss a putative link between very specific forms of epilepsy and trichotillomania and, in particular, pyromania or arson.[11,13,21,53,55,56,61,62] The latter has been discussed to be possibly triggered by a putative mechanism called the *limbic psychotic trigger reaction* (LPTR). This is believed to be a form of nonconvulsive behavioral seizure (NCBS); following this theory, seizure-like limbic pathomechanisms that are kindled by memory stimuli result in brief psychotic episodes in which the affected patients impulsively set fire.[61,62] However, it should be stressed that these hypotheses are purely based on a few case reports, and that no solid epidemiologic data support the theory that these forms of impulse control disorder are truly more common in epilepsy as compared to the general population.

Summary and Conclusions

Aggression in the context of epilepsy is not common but, when it occurs, it often imposes an immense burden on the patient, his relatives, and caregivers. The neurobiology and precise pathomechanisms of aggressive behavior, be it in the context of epilepsy or not, are most likely heterogeneous and very complex. Nevertheless, it is important to appreciate the interplay of social, psychological, and neurobiologic factors, all of which may contribute to aggression and violent behavior in any given case.

Clinically, it is crucial to first establish a correct diagnosis. Intervening medical, neurologic, and psychiatric disorders—in particular, depression, anxiety, and DDE—should be recognized and treated adequately. A correct syndromic diagnosis of the aggressive syndrome and its relation to the seizures should be made. Treatment should aim at possible underlying medical, neurologic, or psychiatric disorders. In symptomatic treatment of aggressive outbursts, the management of acute aggression and prophylactic treatment to prevent further episodes should be differentiated.

Pharmacologic treatment is often the mainstay of therapy, but psychological therapies in the form of anger management or other variations of cognitive behavior therapy are an integral part of management in many patients.

Chapter 213

Psychiatry and Residential Care

Stephen W. Brown

Frank M. C. Besag

"Do poor Tom some charity, whom the foul fiend vexes."

—William Shakespeare, "King Lear," Act III, Scene IV

"What doubtless remained longer than leprosy, and would persist when the lazar houses had been empty for years, were the values and images attached to the figure of the leper as well as the meaning of his exclusion, the social importance of that insistent and fearful figure which was not driven off without first being inscribed within a sacred circle."

—Michel Foucault, *Madness and Civilization: A History of Insanity in the Age of Reason*[11]

Introduction

Historical Perspective on the Rise and Fall of Confinement

Development of Institutions

Hospitals, hostels, and hotels share functions that are reflected in the common Latin root of these words (*hospitalia*, "guest chambers"). It is possible that in Europe during the Middle Ages some cities kept hostels for local people who were not capable of looking after themselves. Also, some people with behavioral problems that would now be attributed to psychosis, brain damage, or other psychiatric conditions might congregate around certain religious shrines. Custodial institutions that were separate from prisons appeared in Europe from the late 17th century onward and, during the 18th century, there emerged specialized asylums for the insane. The reason for the growth in asylum building during that period of history has been a subject of speculation in this century. One argument has been that a real increase occurred in the population with psychosis.[12] Alternatively, sociologic explanations have been advanced, suggesting that the development of psychiatry was a self-perpetuating means of social control.[25] For example, Foucault, noting that leprosy had recently disappeared from Europe, postulated that the "formulas of exclusion" persisted, so that "…poor vagabonds, criminals, and 'deranged minds' would take the part played by the leper …," and he refers to "…that major form of a rigorous division which is social exclusion but spiritual reintegration."[11] Houses of correction were established in England in 1575 by an act of Parliament for "the punishment of vagabonds and the relief of the poor," and in 1656 the Hôpital Général was founded in Paris to confine the poor. Foucault notes that this confinement included "the debauched, spendthrift fathers, prodigal sons, blasphemers, men who 'seek to undo themselves,' libertines, and, in about one-tenth of cases (Paris), the insane." There was, however, a gradual process of categorization whereby those in need of asylum were recognized as being respectively poor, insane, handicapped, or epileptic, and these groups in turn came to be regarded as separate from criminals. As asylums increased in number and became more concerned with mental illness, a more humane approach to care appeared. This was typified by the work of William Tuke (1732–1822) in York (who founded the York Retreat after the death of a fellow Quaker in the county asylum), and Philippe Pinel (1745–1826) in France. Both stressed moral aspects of treatment and advocated the avoidance of methods of physical constraint, such as chains. Pinel's pupil Maisonneuve studied epilepsy, and wrote that "…epilepsy, like all chronic diseases, can be studied well only in the hospitals; there alone is it possible to find all its varieties together, to see all its nuances, and to acquire in short time more experience of this disease than in the whole course of ordinary practice."[16] Another physician of Maisonneuve's generation, Jean Etienne Dominique Esquirol (1772–1840), advocated special facilities for people with epilepsy apart from the other asylum inmates. The reason for this, however, was not to protect those with epilepsy, but to protect the insane, for he believed "…that the sight of one epileptic attack might suffice to make a healthy person epileptic. Now if this held true of healthy people, how much greater was the danger for the mentally deranged, who were so much more impressionable."[27] Consequently, with the growth of provision for the insane there also came separate facilities within the asylums for people with epilepsy. It is not surprising that the next stage was the establishment of entirely separate institutions for people with epilepsy.

Epilepsy in Institutions and the Move Toward Colonies, Villages, and Schools

European writers of the 19th century became interested in the ways in which epilepsy might act on the mind and cause mental disorder. Morel[23] suggested that the disease could exist in a masked form (*epilepsie larvée*), in which the main features were of insanity, not seizures. Falret[10] attempted to classify the psychiatric disorders of epilepsy and, in addition to acknowledging the existence of interictal and peri-ictal phenomena, he followed Morel in proposing a category of epileptic insanity that was manifested as an alternative to seizures, the *folie épileptique*. Morel also offered the view that the behavioral disorders associated with epilepsy, in particular the "epileptic furore," might be a consequence of bad treatment, and that improvement of the patient's environment by segregation, recreation, and occupation would bring about improvement.[22] This debate added to the intellectual climate from which the argument for separate institutions for epilepsy was to emerge.

In 19th century Europe, the word *colony* did not carry a pejorative connotation. The notion of establishing separate living space for people with epilepsy was based on a belief that this would be therapeutic in itself. There was an understanding that the condition was perpetuated by restrictions placed on the activities of normal life, especially the opportunity to take part in work. This was the rationale for the colony movement,

P.2210

exemplified by the foundation in 1867 of Bethel, near Bielefeld in Germany, and by the foundation later in England of the Chalfont, Lingfield, and David Lewis colonies, and in the United States of the Craig colony. The emphasis was on social management, with early intervention by admission to the colony; discharge back to society was a possibility. Alan McDougall, the first medical director of the David Lewis colony, wrote, "Most of our colonists come to us too late to be cured of their fits. The children give brilliant results; one third of them become free from fits. Our… experience seems to show that if all epileptic children, whatever their social position, were sent on the first appearance of epileptic symptoms to an epileptic colony, and kept there till the end of their school life, the benefits to themselves, to their relatives, and to the State would be enormous."[19] These epileptic colonies were sometimes, but not exclusively, situated in the countryside. They typically created a village-like atmosphere, and often included a residential school for children with epilepsy. Attention to lifestyle, as well as physical treatment, was considered important: "Most of the colonists take daily a 30-grain dose of Potassium Bromide. This appears in many cases to diminish the frequency of the fits, and the tendency to status. But other therapeutic means are even more important. Among these is the combined concert and dance that has been held without intermission every Saturday night of the year. Dancing (particularly the 'Lancers') is a valuable means of treatment, provided that it be practised frequently. On the first few occasions a fit may follow the dancing, but the patient soon becomes able to dance without unpleasant side effects. Classical treatment of Epilepsy follows the lines of forbidding the patient to do the things that might cause a fit; colony treatment attempts to rid the patient of fits while he is performing the acts of a normal person. The latter plan gives the better results."[17]

The development of colonies was the consequence of a philanthropic movement spearheaded by the social and religious conscience of the aristocracy and upper middle classes. Increasingly, the new wealthy class—the industrial bourgeoisie—undertook a scheme of building model villages for the working classes, exemplified by the work of the Cadburys in Bournville in the English Midlands, and in the building of Styal Village for the workers of Styal Mill in Cheshire. Also at this time, arts and crafts colonies developed, where a particular creative lifestyle could be followed, away from a society that Crichton-Browne described as "…a feverish and fidgety age in which an unappeasable restlessness pervades all ranks and classes."[7] This movement was not in any way the consequence of an overt desire to segregate or discriminate against elements of society regarded as difficult, dangerous, or undesirable. Thus, at this point, the history of the institutional management of epilepsy should diverge from that of institutional psychiatry. In particular, the epilepsy colonies (in Europe at least) were concerned from the beginning with destigmatization and normalization, with attaching value to people's social roles. The evidence is in stark contrast to that often offered by historians as explanations for the great confinement of the mentally ill in the 17th, 18th, and 19th centuries. Why is this? One explanation might be that some of the accepted historical cases in psychiatry have been overstated. Bynum wrote of Foucault, "…the power of his dark vision remains, although its empirical base has been questioned,"[3] and another modern historian noted, "…the view that the 17th and particularly the 18th centuries were a disaster for the insane in England has to be qualified…."[24] Alternatively, perhaps the epilepsy colony movement then was in opposition to social attitudes at the time. Indeed, the views of those advocating colony treatment are not congruent with ideas expressed by eminent psychiatrists much later in the 20th century. For example, in 1977, a leading English-language textbook of psychiatry contained the following passage describing personality deterioration in epilepsy: "There are also more constant and lasting affective changes. Most frequently these take the form of a mulish moroseness and rancour. Slights are felt to the quick, and malice is borne for months or years. In an epileptic ward gossip, lying or slander will all too easily reign…. Chronic epileptic patients are capable of actions of the most malicious and petty spite, and of combining them with self-justification and self-praise."[26]

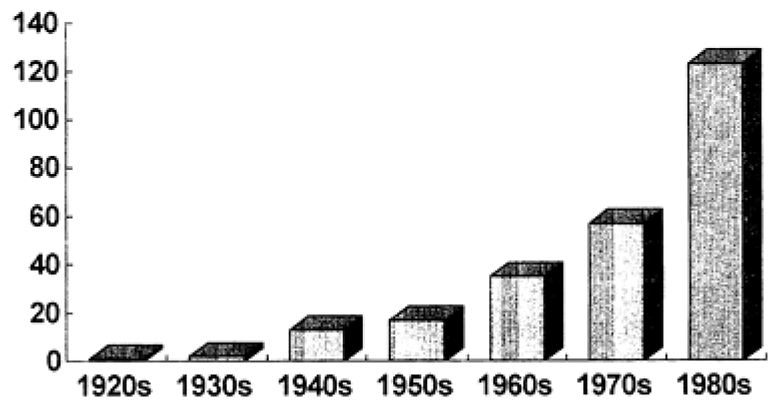

FIGURE 1. Admission rates to the Davis Lewis Centre for Epilepsy, 1920–1989.

Seven decades earlier, in 1909, Alan McDougall had noticed the opposite: "Each succeeding year, in spite of the constant increase in the population, there is less and less quarrelling among the colonists. Our experience leads us to believe that many of the unpleasant characteristics commonly ascribed to epileptics are due not so much to the disease as to the mishandling that the patient has received. When living with those who understand his special requirements, the epileptic is a very likeable person."[19] McDougall, however, did have a sanction that was not available to the alienist and, in the 1906 colony report, he noted, "Four have been discharged as unsuitable. Their persisting lack of consideration for their fellow colonists made it impossible to retain them. Yet had they entered a colony at an early stage of their illness, they would probably have been excellent colonists."[17]

Colonies for People with Epilepsy: Their Role and Development

Special Schools, Centers, and Villages: Their Maximum Development and Subsequent Decline

The epilepsy colonies of Europe have not died; rather, their work has changed to keep pace with new developments in treatment and social expectations. Their achievements have been recognized and envied in other parts of the world: "Residential and treatment facilities must be built and improved to accommodate the unique problems of persons with epilepsy and associated disorders, perhaps on the model of the many splendid public epilepsy comprehensive treatment centers of western Europe, which have not a single counterpart anywhere in the United States."[28]

The demand for services has not diminished. For example, analysis of admission rates to the David Lewis Centre from 1920 to 1989 shows an almost exponential rise (Fig. 1). Although during this period there was some rise in the overall numbers of residents, most of this increase was matched by a corresponding rise in the rate of discharges, as the length of stay decreased. The founding fathers of the colonies had apparently believed that a return to the terrors of the outside world

was best avoided until cure was absolutely established: "It is very unwise to be hasty in removing from Colony conditions an improving patient; it is far wiser to wait till the improvement has become firmly established; otherwise there is great danger of relapse."[18] In these early days, however, probably the only effective medical treatment was bromide. Three factors developing during the 20th century were to influence the length of stay. These were treatment advances, secular social trends, and economics.

Treatment Advances

The introduction of barbiturates just before World War I, and of phenytoin just before World War II, made available a wider range of treatment options with potentially fewer side effects than bromides. Thus, an expectation of prolonged remission came to be part of the medical approach to epilepsy, with less medical objection to earlier return to the community. Those who still stayed behind would include a mixture of "good" colonists who had adapted well to colony life, so that neither the managers nor the clients themselves desired a change, together with those whose epilepsy or its associated problems failed to remit.

Secular Trends

The great confinement of the mentally ill began to end after World War II, probably mainly as a consequence of the introduction of phenothiazines in the 1950s, although the medicalization of psychiatry preceded this development by a century or so, with much of the intellectual impetus coming from the German-speaking world.[4] Similarly, the development of effective antituberculosis treatment at about the same time reduced the need for sanatoria. Thus, the concept of going away for long periods of time because of illness began to wither. It remained appropriate for sick people to spend time in the hospital for purposes of diagnosis and initiation of treatment, but after that the expectation was generally to return home. Although advances in epilepsy treatment were more modest, and despite the increased need for the services provided by epilepsy institutions as a consequence of increased numbers of cases of posttraumatic epilepsy resulting from two world wars, a view gradually began to emerge in parallel with these other developments, in which the emphasis shifted from fear of discharging too soon to fear of keeping patients too long.

Economics

Although most colonies were run as charitable institutions, and efforts were made to be as self-sufficient as possible in regard to providing food and services, residence always had to be paid for. Staffing and equipment costs increased along with the expectations of investigation, treatment, and care. Sponsors (families, insurance companies, national and local government agencies) were obliged to exert pressure to limit time spent during an admission.

Faced with these pressures, some establishments became smaller and a few closed, whereas others diversified their activities to meet the perceived needs of the changing market. During the 1960s, special short-stay assessment centers for epilepsy began to emerge within the colonies. Medical staff from epilepsy colonies became more involved in providing specialized epilepsy services in hospital settings. At about the turn of the decade, a significant change occurred; these venerable institutions faced the 1970s and beyond as "epilepsy centers," and the term *colony* was dropped forever. Since then, the larger centers have continued to provide more and more specialized facilities. The number of special residential schools declined, and those that remained came to include in their population an ever-larger proportion of children with severe learning disabilities. The charitable foundations responsible for the epilepsy centers began to become involved in wider issues, such as professional education and general public consciousness raising. In The Netherlands, the various epilepsy organizations, centers, and charities cooperated in producing an integrated epilepsy service for the nation that has remained a model of excellence. In the United Kingdom, the strength of the centers lay in their continuing independence from the state system in terms of business development, but their increasing reliance on statutory sources remained a weakness. In most parts of the world, an artificial distinction is made between health-related and social aspects of care, with different budgets available. A possibility arises for budget holders in health care or social services to attempt to shift the responsibility to the other area. No clearly accepted boundary exists at which social care takes over from "health." The situation is more complicated for children of school age in those areas where education authorities, faced with a bill for special education for a child with epilepsy, may be reluctant to fund aspects of care that are perceived as "medical" or "social." Thus, artificial difficulties may be put in the way of providing an integrated service. This is partly a consequence of social welfare and insurance systems that make no recognition of the particular issues in epilepsy. For example, the government of the United Kingdom, as part of a process of laying down minimum standards, sponsored a code of practice for residential care.[14] In this document, individual client groups are discussed, including the physically disabled, mentally ill, mentally handicapped, children and young people, the elderly, and people recovering from drug addiction and alcohol abuse. There is no mention of epilepsy. Therefore, there is no official "policy" for epilepsy—despite a number of expert reports, the recommendations of which have been largely ignored.[1,5,6,8] More recently, a further attempt at defining the scope of epilepsy services in the United Kingdom does seem to have had more impact, largely because of pressure from informed consumers.[2]

Current Residential Centers

At the beginning of the 21st century, the remaining residential epilepsy centers are the result of a heterogeneous evolution. The admission and discharge criteria and the range of services vary from country to country, and often from region to region, according to the prevailing social culture and the organization of health, education, and social services. Even so, some general themes are shared by most centers. The range of services includes (a) residential education for children, (b) residential assessment for children and adults, (c) long-stay provision and rehabilitation for adults, and (d) new areas of business.

Residential Education for Children

Some centers include a residential special school for children with epilepsy. There are, for example, currently three such schools in the United Kingdom, two of which are part of a larger center that also provides residential adult services. Admission criteria are the presence of a seizure disorder and educational failure. Many children arrive at residential special schools for epilepsy after a career of repeated failure in other settings. Frequently an additional psychiatric morbidity is present, manifested as a disorder of conduct, emotion, or both; however, in those cases where this has been studied, it seems that the rate of psychiatric disorders decreases with admission. This is probably a consequence of a mixture of efficient management of the seizure disorder, appropriate educational approach, and absence of stigmatization.[13] There is,

P.2212

therefore, a possibility of return to mainstream education after a period in a residential school, and this is achieved in some cases. Geographic separation from the home area may be beneficial in the initial stages but can restrict opportunities for reintegration.

Residential Assessment for Children and Adults

Since at least the 1960s, epilepsy centers have developed a role in short-term residential assessment. Access to high-quality neurophysiologic investigations is often available, which allows the possibility of electroencephalographic (EEG) monitoring in a homelike, nonhospital environment. Each case of epilepsy can be investigated, and the most appropriate medical treatment plan agreed. Such an admission is also an opportunity to assess living skills and determine the level of care and rehabilitation needs. The individual's and the family's knowledge (or lack of knowledge) of epilepsy can also be addressed. Admission criteria include the presence of a refractory seizure disorder with or without other problems of living, and the outcome might include rediagnosis, a medical treatment plan, and a personalized statement of care and rehabilitation needs. In some centers, short assessment admissions are also used as part of an evaluation for epilepsy surgery.

Where units for assessment of children exist, the relationships between epilepsy, interictal EEG activity, drug adverse effects, behavioral problems, speech and language development, and learning difficulties (both generalized and specific) can be studied in classroom and home-type situations, so that an optimal educational approach can be developed for each patient. This information can then be used to identify the most appropriate placement after the child leaves the assessment unit.

In the case of both children and adults, assessment units may offer specialized services for patients with epilepsy and learning disabilities or other coexisting psychiatric morbidity. Assessment units are therefore staffed by epileptologists, specialist nurses, educational and clinical psychologists and neuropsychologists, speech and language therapists, and social workers. Some centers also provide nonverbal approaches, such as art therapy and music therapy. Periods of admission for assessment vary from 2 to 12 weeks, and may depend on the reason for referral.

Long-stay Provision and Rehabilitation for Adults

Despite the trend toward deinstitutionalization in the last few decades, a long-stay residential population still remains in the epilepsy centers. It is slowly dwindling in size (Fig. 2), and comprises two groups of patients. First, there is an old long-stay group of patients who were admitted many years ago (and who would not have been admitted in modern times). These are people who have spent a large part of their lives in the epilepsy centers, are now growing old, and know no other home. Their numbers will continue to decrease, and this group will eventually disappear. Although their needs for care will increase with age, they do not make high demands on services compared with other groups in the epilepsy centers. Second, a new, small, but significant long-stay group of people is emerging who have particularly complex care needs as a result of refractory epilepsy, learning disability, challenging behavior, coexisting organic psychosyndromes, or any combination of these. Members of this group may eventually be able to return to the community as a clinical and social rehabilitation program achieves slow progress over a number of years. The final size of this group has yet to be determined.

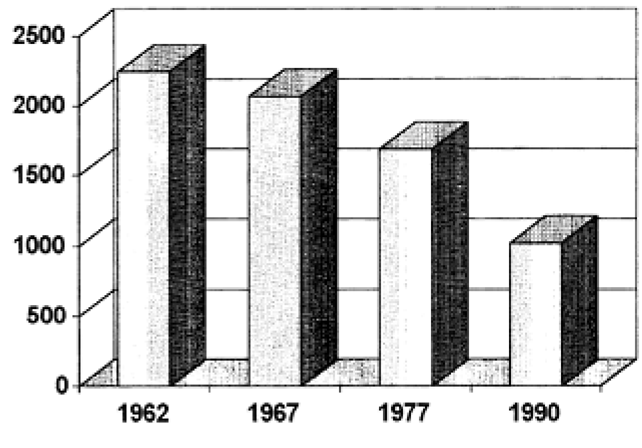

FIGURE 2. Numbers of patients living in epilepsy centers on a long-term basis. (From Duncan JS, Hart YM. Medical services. In: Laidlaw J, Richens A, Chadwick D, eds. *A Textbook of Epilepsy*. 4th ed.

New Areas of Business

Keeping pace with secular trends in social care policy as well as advances in epilepsy management, the medical staff of epilepsy centers have developed working relationships with established neurology and psychiatry units, both academic and clinical. Epilepsy centers are now often involved in research and teaching in epileptology, and in the management of tertiary outpatient facilities. In some areas, epilepsy center staff members have started working directly with primary care physicians. Some residential epilepsy schools have developed links with mainstream education and send staff members to advise on educational approaches to children with epilepsy in mainstream schools, and they have also become involved in training teachers who will work in the educational mainstream. Finally, there is a trend to replace, wherever possible, the large, institutional-type housing of the long-stay clients with small, family-sized units that may be situated within the local community close to the facilities of the epilepsy center.

Current Trends and Purposes in Epilepsy Institutions

Discharge of People with Epilepsy into the Community

Although actual discharge rates are difficult to determine on a large scale, the decline in total numbers of beds in the United Kingdom during the last years, set against the rise in overall admission rates mentioned previously, indicates a fairly marked process of deinstitutionalization (Fig. 2). The population remaining in residence does so for any of the following reasons: (a) A patient does not wish to be discharged; (b) there is no appropriate facility in the home area, even though the care needs are not excessively high; (c) care needs—whether social, medical, or both—are high, and the local services would be

unable to provide the same level of support and, when appropriate, medical intervention.

Coassessment of Learning Disability (Mental Handicap)

Another problem arises in some cases for which service must provide guidance. Different professional groups may have varying views about a patient's primary problem; for example, neurologic services may see the main problem as psychiatric or social, and so on. This is why, in the United Kingdom, mental handicap (learning disability) services are increasingly taking on the management of learning disabled patients with complex epilepsy, although this currently identifies a need for training in staff working in this area. People with learning disability should have the same quality of investigation and treatment as the rest of the population. Epilepsy is very common among these individuals and, because of their special needs, intensive investigation may be necessary. The residential centers have the capacity to offer an integrated approach in which epilepsy and learning difficulties are assessed together. Medical assessment involves detailed observation of behavior and seizures in conditions that approximate those of everyday life. Education of both caregivers and clients can be achieved, and the needs of caregivers taken into account.[15] With children, the residential setting can provide a detailed multidisciplinary assessment for a prolonged period in a nonclinical environment, and then continued management with a true 24-hour curriculum. A detailed neuropsychiatric study of the children in one residential special school for epilepsy showed that, although nearly two-thirds had been referred because of behavioral problems, the rate of observed psychiatric disorder while they were at the school was only 42%. Given the overall disabilities of the sample population, (low IQ, brain damage, frequent seizures, poor family background), it was considered surprising that the prevalence of psychiatric disorder was not higher. The authors commented, "It may be that the stable environment of a residential school involves fewer stresses that might precipitate or maintain psychiatric disturbance…. Absence of stigma, efficient management of seizures and minimizing their effect on school attendance could also be beneficial in this respect."[13]

Outcome on Discharge from Special Schools, Centers, and Hospitals

Surprisingly little follow-up research has been done on the results of discharge from residential centers. Meyer and Gray[21] drew attention to the lack of community provision for people with epilepsy, which affected quality of life in their sample. Nearly a quarter of former residents were living independently, whereas half were in supported accommodation. Regular employment had been found only in 5% of cases. On the other hand, 50% reported a continuing decrease in seizure frequency, and 32% felt more alert. Medagoda and Brown[20] found that failures of successful rehabilitation were mainly related to inadequate medical follow-up or the inability of caregivers in the community to cope with behavioral problems or seizures. Breakdown of community placement after discharge was caused by a combination of inappropriate selection of placement by the receiving social services and a lack of appropriate medical services for epilepsy. It was possible, however, to readmit patients to the epilepsy center and achieve a successful, planned discharge later when these needs were met.

Summary and Conclusions

The former colonies remain repositories of expertise in the multifactorial assessment and management of epilepsy because they continue to carry a positive culture of destigmatization. The need for their services has not diminished, but the environment in which those services are provided is changing. On the site of the traditional countryside residential setting, services are being developed to provide residential assessment away from the clinical atmosphere of the hospital. People with epilepsy who also have challenging behavioral and learning disabilities can undergo specialized assessment and treatment in this setting. A special role in the future might be found for work in the field of forensic neuropsychiatry. Certainly the trend to shorter, focused admissions will continue, with the center at the same time reaching out into the community and offering preadmission services and postadmission follow-up. Some epilepsy centers in Europe are actively developing in-community care projects by establishing small living units that are closer to patients' friends and families. This last development, if successful, will further integrate the long-stay residential facility, which has the advantage of being able to provide prompt, appropriate medical and social care, in the tradition of the best colonies, into the mainstream of the community. Although residential schools are taking on the function of short-term assessment and rehabilitation, it is likely that at least some children with complex epilepsy and associated neuropsychiatric problems will receive a large part of their education in such places. Epilepsy centers will continue to be involved in teaching and research. The question remains whether truly integrated services comprising health, social work, and education can continue to thrive in a social market. Only time will tell.

Chapter 214

Psychopharmacology of Patients with Behavior Disorders and Epilepsy

Michael R. Trimble

Marco Mula

Introduction

Psychiatric disorders are common in patients with epilepsy, and they encompass the spectrum of conditions from those that are a direct consequence of the epileptogenic activity to others that are simply comorbid.[45]

Therapy for behavioral disorders still remains unsatisfactory, and many patients with epilepsy receive psychotropic medications (Table 1) not always based on their psychiatric symptoms.[81] Effective therapy depends on a correct diagnosis and a combination of psychotropic drug treatments and behavioral interventions when other factors, such as emotional stressors, are present. In addition, antiepileptic drugs (AEDs) are important psychotropic agents with positive and negative psychotropic properties in their own right that should be taken into account when evaluating psychiatric symptoms in patients with epilepsy.

The present chapter focuses on the main problems that a clinician may encounter when treating psychiatric disorders in patients with epilepsy. We examine the effects of AEDs on mood and behavior, and we briefly review main factors that may affect choice of therapy, and patient's response and compliance, when prescribing antidepressants or antipsychotic drugs. In reviewing these agents, we concentrate specifically on drug interactions and any potential proconvulsive risk they may pose.

Antiepileptic Drugs as Psychotropic Agents

During the last 15 years, the number of AEDs available clinically has nearly trebled,[71] thus providing the possibility of providing better-tailored therapy according to patients' needs but also revealing a wide spectrum of adverse effects.

In some cases, emergent psychiatric symptoms may be side effects of the AED therapy,[5,42] the result of interactions between the drug and some biologic vulnerabilities of the patient. Subjects with more severe forms of epilepsy are generally more at risk to develop psychiatric adverse events (PAEs),[60,62] whereas specific lesions in the limbic system, such as hippocampal sclerosis, seem to be associated with the liability to develop depressive symptoms.[61] The *forced normalization phenomenon* is well known to be an idiosyncratic reaction to a sudden seizure cessation that may happen with different AEDs in predisposed patients, but whose characteristics are largely unknown.[59]

On the other hand, we have to take into account the fact that AEDs are extensively used in psychiatric practice for a broad spectrum of psychiatric disorders, especially bipolar disorders, and some are well known to stabilize mood. Since its introduction into the clinical management of epilepsy, carbamazepine has been reported to have psychotropic properties. Over time, several controlled studies have been carried out comparing the effects of carbamazepine in acute mania with placebo, lithium, or neuroleptics.[15] These studies have shown that carbamazepine is equivalent to lithium over a period of 8 weeks, and that the time course of the antimanic effect is a little slower than with neuroleptics but equivalent to lithium. This is relevant for those patients who are refractory to lithium and require an alternative to it. Carbamazepine has also been shown to be an effective treatment for the prophylaxis of bipolar disorder, with controlled studies suggesting that patients who are referred to as rapid cyclers (namely, patients with an unstable bipolar disorder with rapid fluctuations of more than four episodes a year), do best on carbamazepine or a combination of carbamazepine and lithium.[93] This approach has several advantages over the use of neuroleptics for such conditions, such as the avoidance of tardive extrapyramidal symptoms.

Valproate has been used in manic episodes, depressive episodes, and the maintenance therapy of bipolar disorder.[96] The strongest supporting evidence is for it use in acute mania, with somewhat less supporting evidence for the other conditions. Valproate may have an adverse effect on behaviors such as affective lability, aggression, and impulsivity across a range of different clinical contexts but, at the moment, controlled studies are available mainly for bipolar depression.

Among the new AEDs, some of them (e.g., tiagabine) have failed to show any efficacy in primary psychiatric disorders whereas others (e.g., topiramate) may have adjunctive uses, such as weight loss in the management of obesity. The data on the effects of oxcarbazepine on psychiatric disorders are limited and definitely less conclusive than those regarding carbamazepine. However, oxcarbazepine seems to be less effective than lithium but as effective as carbamazepine in acute mania; oxcarbazepine is probably better tolerated than carbamazepine.[94] The lack of efficacy of gabapentin in bipolar disorders has emerged from controlled studies have failed to detect such an effect.[29]

During clinical trials in the development of lamotrigine as an AED, it was observed that it had antidepressant properties. The cumulative results of the studies done so far provide evidence that lamotrigine is effective in the management of the depressed phase in bipolar disorder type II and in the long-term stabilization of mood in patients with rapid-cycling bipolar disorder.[36]

Among AEDs in development, pregabalin is probably the most interesting molecule. Controlled studies have demonstrated that it is better than placebo in anxiety disorders such as generalized anxiety disorder.[69]

Table 1 Brief classification of psychotropic drugs

ANTIDEPRESSANTS
Mono-Amino-Oxidase Inhibitors (IMAOs)
Moclobemide
Tricyclic antidepressant drugs (TCAs)
Amitriptyline, nortriptyline, clomipramine, imipramine, desipramine
Selective Serotonin Reuptake Inhibitors (SSRIs)
Fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram, escitalopram

Noradrenergic uptake inhibitors (NARIs)

Reboxetine

Noradrenaline-Serotonin Uptake Inhibitors (NSRIs)

Venlafaxine, duloxetine

Noradrenaline-Selective Serotonin Antidepressants (NASSAs)

Mirtazapine

Serotonin Antagonist and Reuptake Inhibitors (SARIs)

Trazodone, nefazodone

ANTIPSYCHOTICS

Typical

Phenothiazines

Thioridazine, mesoridazine, chlorpromazine, prochlorperazine

Butyrophenones

Haloperidol

Atypical

Benzisoxazoles and benzisothiazoles

Risperidone, ziprasidone, perospirone

Thienobenzodiazepine, dibenzothiazepine, dibenzothiazepine derivatives

Clozapine, olanzapine, quetiapine

MINOR TRANQUILLIZERS – Barbiturates, Benzodiazepines, Others

MOOD STABILIZERS – Lithium

OTHERS – ß-Blockers, buspirone

Thus, data published to present suggest an important role for AEDs in psychiatric disorders. Unfortunately, it is difficult

to extrapolate findings from these studies, performed with psychiatric patients, directly to patients with epilepsy. Obviously, it would be very useful to know whether AEDs have a positive influence on the psychic status of patients with epilepsy beyond their influence on seizure activity. However, there is little scientific evidence for this; most of the studies are uncontrolled and based on quality-of-life parameters rather than on a formal psychiatric evaluation. Because the simultaneous use of an AED as an anticonvulsant and antidepressant or mood stabilizer should be an important option for a rational pharmacotherapy in patients with uncontrolled epilepsy and comorbid psychiatric disorders, the need is great for further studies.

During the last few years, lamotrigine is the only AED investigated also as a psychotropic drug in patients with epilepsy. A randomized, placebo-controlled, double-blind, cross-over study of lamotrigine in 81 patients with refractory partial seizures showed some improvement in two subscales (happiness and alertness) in a health-related quality of life model but not on the other four scales specific for self-esteem, mood, anxiety, and depression.[82] Two double-blind studies of la-motrigine verus, respectively, carbamazepine[27] and valproate[16] demonstrated some improvement in quality of life outcomes. An open study[40] reported a significant antidepressant effect of lamotrigine in 13 patients with uncontrolled epilepsy and depression. Moreover, in two different studies, we have observed that lamotrigine significantly reduced the occurrence of PAEs during therapy with topiramate[60] or levetiracetam.[62] All these studies taken together suggest a possible role of lamotrigine as an antidepressant or mood stabilizer in those patients with uncontrolled epilepsy and depressive symptoms.

Pharmacokinetic Interactions Between Antiepileptic Drugs and Psychotropic Drugs

Pharmacokinetic Interactions with Antidepressants

Several factors must be taken into account when predicting the outcome of a potential interaction: Patient-related (sex, age, ethnicity) and drug-related (the presence of active metabolites, the activity and potency at the enzyme site, the therapeutic window).[70] The role of the CYP450 enzyme system and glucuronosyltransferases (UGTs) in clinical psychopharmacology is increasingly recognized, and many papers have been published about pharmacokinetic interactions between AEDs and psychotropic drugs.[55,57,58]

Tricyclic antidepressants (TCAs) such as amitriptyline, clomipramine, and imipramine, are mainly metabolized by CYP1A2, -2D6, and -3A4 (Table 2). Nortriptyline and desipramine are, respectively, the active metabolites of amitriptyline and imipramine and are subsequently metabolized by CYP2D6.[80] Moclobemide is primarily metabolized by the CYP2 C subfamily, of which it is probably an inhibitor,[28] whereas the atypical antidepressants mianserin and trazodone are metabolized by CYP2D6.[11]

The selective serotonin reuptake inhibitors (SSRIs) fluoxetine and paroxetine are metabolized by CYP2D6, whereas sertraline, fluvoxamine, and citalopram are respectively metabolized by CYP3A4, -1A2, and -2 C.[64] Paroxetine and fluvoxamine are inhibitors of CYP2D6[74] and -1A2,[7] respectively (Table 3). Fluoxetine is a moderate inhibitor of CYP3A4, but, like paroxetine, is a potent inhibitor of CYP2D6. No clinically significant induction-inhibition properties have been demonstrated for sertraline and citalopram.[64]

Among the new generation of antidepressant drugs, venlafaxine is primarily metabolized by CYP2D6,[17] whereas CYP3A4 metabolizes nefazodone and reboxetine.[87] Nefazodone is a potent inhibitor of this enzymatic pathway.[87]

Generally, phenobarbital, carbamazepine, and phenytoin stimulate the metabolism of TCAs, whereas valproate can increase their plasma levels[55] (Table 4). An open-label study investigated the effect of valproate on amitriptyline and its active metabolite nortriptyline.[97] The mean area under curve (AUC) and the peak plasma concentration, for the sum of nortriptyline and amitriptyline, was 42% and 19% higher, respectively.

In a case series of 13 patients with major depression, the effects of carbamazepine on imipramine and desipramine serum concentrations have been investigated.[89] The authors demonstrated that carbamazepine affects not only the metabolism of both drugs but also their protein binding, thus leading to a significant increase in the free fraction.

Table 2 CYP enzymes involved in psychotropic drug metabolism

CYP1A2	CYP2C9/10	CYP2C19	CYP2D6	CYP3A4
Antidepressants	**Antidepressants**	**Antidepressants**	**Antidepressants**	**Antidepressants**

CYP3A4	Norfluoxetine Nefazodone Fluvoxamine	Chlorpromazine Thioridazine Haloperidol Risperidone	Carbamazepine Barbiturates Phenytoin St. John's wort

Data about fluoxetine-carbamazepine interactions are contradictory and are still based on two old studies. The first one is a formal pharmacokinetic study using healthy male volunteers, in which the authors observed a slight increase in carbamazepine AUC levels and a decrease in 10,

P.2217

11-carbamazepine epoxide AUC.[30] The second study is a small series of eight patients with epilepsy who showed no modifications in carbamazepine plasma levels before and after fluoxetine administration.[85] These two studies are not comparable mainly because the activity of CYP enzymes is influenced by different factors, namely age, sex (in the first study the authors used only male patients), ethnicity, and so on.

The inhibition properties of several SSRIs on phenytoin metabolism have been tested in an in vitro study with human liver microsomes.[86] The risk for a phenytoin-SSRI interaction seems to be higher with fluoxetine and less likely with the others (paroxetine and sertraline).

Table 4 Pharmacokinetic interactions between anticonvulsant and antidepressant drugs

Possible kinetic interactions between paroxetine and carbamazepine, valproate, and phenytoin have been investigated in a single-blind, placebo-controlled, cross-over trial.[3]

Paroxetine caused no change in plasma concentrations and protein binding of the anticonvulsants. Studies of paroxetine plasma concentrations are lacking, but the major enzymatic pathway is a non-inducible enzyme (CYP2D6); therefore, modifications in plasma levels are unlikely when paroxetine is coadministered with AEDs with inducing properties.

Leinonen et al.[51] observed an increase in citalopram levels when carbamazepine was substituted with oxcarbazepine in two patients, demonstrating a significant induction effect of carbamazepine on citalopram metabolism. Steinacher et al. confirmed this observation in an open study of six patients, showing that a 4-week treatment with carbamazepine decreased the plasma concentration of S-citalopram and R-citalopram by 27% and 31%, respectively.[88]

The potential interaction between carbamazepine and fluvoxamine has been evaluated in a small open study of eight patients with epilepsy in steady-state for carbamazepine; no significant changes in carbamazepine and carbamazepine-10,11-epoxide occurred.[85] There are no studies of valproate-fluvoxamine interactions.

In the literature, two studies have investigated a possible effect of sertraline on phenytoin and carbamazepine metabolism. A double-blind, randomized, placebo-controlled study with 30 healthy volunteers showed no modifications in phenyt-oin pharmacokinetics.[77] The same authors, in a double-blind, randomized, placebo-controlled study on 14 healthy volunteers, observed no significant effects of sertraline on carbamazepine metabolism.[78] Conversely, Pihlsgard and Eliasson clearly showed that phenytoin and carbamazepine significantly reduced sertraline plasma concentrations.[72] Bonate et al.[6] demonstrated no drug interaction between clonazepam and sertraline in a randomized, double-blind, placebo-controlled, cross-over study with 13 subjects.

No clinical studies are available about potential interactions between venlafaxine and AEDs, whereas a randomized, cross-over study with 18 male subjects showed no pharmacokinetic interactions between venlafaxine and diazepam.[92]

Laroudie et al.[48] investigated kinetic interactions between nefazodone and carbamazepine in 12 healthy subjects. They observed a significant decrease in nefazodone AUC and an increase in carbamazepine AUC, demonstrating a potential inhibition property of nefazodone on carbamazepine metabolism.

An open-label, randomized, parallel group study in healthy male subjects investigated the possibility of pharmacokinetic interactions between mirtazapine and phenytoin. Coadministration of the antidepressant does not alter the steady-state pharmacokinetic of phenytoin, which, conversely, can decrease mirtazapine plasma levels by 46% on average.[83]

Ketter et al.[41] investigated the safety and efficacy of carbamazepine-moclobemide cotreatment in a double-blind study. The combination was well tolerated, with no modifications in carbamazepine kinetics, but they did not assess moclobemide plasma concentrations.

It has been well established that AEDs with induction properties determine a significant reduction in mianserin plasma concentrations.[58]

↑ Increased plasma concentration, ↓ decreased plasma concentration, = unchanged plasma concentration.

*Theoretical data, no studies available.

Table 5 Pharmacokinetic interactions between anticonvulsant and antipsychotic drugs

The use of bupropion is limited in patients with epilepsy because of a high seizure risk. Carbamazepine is a potent inducer of its metabolism, reducing the antidepressant plasma concentrations to undetectable levels.[75] On the other hand, bupropion has shown marked inhibition properties on valproate[75] and phenytoin metabolism.[90] In a randomized, open-label, cross-over study with 12 healthy subjects, the kinetic parameters of a single 100-mg lamotrigine dose were not modified by steady-state, slow-release bupropion therapy.[65]

Pharmacokinetic Interactions with Antipsychotics

Neuroleptics, such as phenothiazines, are metabolized by intestinal sulfoxidases, although CYP2D6 plays an important role in chlorpromazine and thioridazine metabolism.[67] They are also partially metabolized by CYP1A2 and -2C, respectively, and partially inhibit CYP3A4.[12] Phenothiazines, in particular thioridazine, are potent inhibitors of CYP2D6.[67] Haloperidol is metabolized by CYP3A4 and -1A2, and only partially by -2D6.[46]

Among the atypical antipsychotics, clozapine undergoes extensive hepatic metabolism; multiple CYP enzymes are involved, however, the two most prominent are CYP1A2 and -3A4.[76,77]

The newer generation of antipsychotic drugs seem to have more favorable pharmacokinetic profiles. Risperidone is primarily metabolized by CYP2D6, although a correlation study using a panel of human microsomes suggested that CYP3A4 may also be involved.[22] Olanzapine undergoes extensive hepatic metabolism and shares some of its metabolic routes with the structurally and pharmacologically related clozapine, but UGTs appear to be a major metabolic pathway.[79] Quetiapine shares some pharmacologic and structural characteristics with clozapine and olanzapine, but CYP3A4 is most likely the main isoenzyme involved in its metabolism.[17]

Thioridazine is metabolized by intestinal sulfoxidases that are induced only partially by AEDs such as carbamazepine, phenytoin, and phenobarbital, but some authors have reported an increased clearance of thioridazine and a relevant decrease of mesoridazine (the active metabolite of thioridazine) levels in patients taking carbamazepine and or phenytoin.[70] On the other hand, thioridazine, as chlorpromazine and prochlorperazine, inhibits phenytoin, phenobarbital, and valproate metabolism[31] (Table 5).

Several studies have shown that haloperidol plasma levels decrease by 50% to 60% after carbamazepine coadministration, with concomitant worsening of the psychiatric clinical features.[37,38,43] In one study, therapeutic drug monitoring data from 231 schizophrenic inpatients demonstrated that haloperidol levels were 37% and 22% lower in patients comedicated with carbamazepine or phenobarbital, respectively.[35] Carbamazepine seems to decrease haloperidol concentrations in a dose- or concentration-dependent manner, even at subtherapeutic doses of the drug.[100] Interestingly, Iwahashi et al.[37] observed that serum carbamazepine concentrations in patients treated without haloperidol were significantly decreased (on average 40%), as compared with those treated with both carbamazepine and haloperidol. In a controlled clinical trial on the effects of carbamazepine and valproate cotreatment on the plasma levels of haloperidol and on the psychopathologic outcome in schizophrenic patients, valproate led to no significant effects on haloperidol plasma levels, and its use was associated with a better psychopathologic outcome.[34]

As far as new AEDs are concerned, the use of topiramate did not lead to clinically significant modifications on haloperidol pharmacokinetics in a formal pharmacokinetic study with healthy volunteers.[14]

Spina et al.[84] compared the risperidone total active moiety (risperidone plus its active metabolite, tamoxifen steady-state plasma concentrations in patients treated with risperidone alone and in patients comedicated with carbamazepine or valproate, matched for age, sex, body weight, and antipsychotic dosage. Although carbamazepine caused a significant decrease in active moiety concentrations, valproate (at dosages up to 1,200–1,500 mg/day) had minimal and clinically insignificant effects on plasma levels of risperidone-tamoxifen, suggesting

that valproate could be added safely to an existing treatment with risperidone.

Recently, the relationship between CYP2D6 genotype and carbamazepine-risperidone interaction has been investigated, suggesting that the decrease in risperidone concentration is dependent on the CYP2D6 activity.[66] In an open study with eight patients with epilepsy, a mild increase in carbamazepine plasma levels has been described after the addition of risperidone 1 mg.[57] Although this interaction seems not to be clinically relevant, it may suggest that the antipsychotic, or more likely its metabolites, could modulate CYP3A4 activity and, interestingly, a different enantioselective 9-hydroxylation of risperidone by CYP2D6 and CYP3A4 has been shown in a separate study.[26]

Ziprasidone and perospirone are newly available antipsychotic drugs, and there are few clinical studies about their interactions. An open, randomized, parallel-group study using healthy volunteers showed a clinically insignificant reduction (<36%) in steady-state ziprasidone levels after carbamazepine prescription.[54]

Generally, phenytoin, phenobarbital, and carbamaze- pine[21,77] cause a decrease in clozapine plasma concentrations. However, carbamazepine is rarely used in combination with clozapine because of the high risk of hematologic side effects. Existing data on the effect of valproate coadministration are contradictory.[8,20] According to some authors, valproate may have a moderate inhibiting effect on the demethylation of clozapine (catalyzed by CYP1A2 and -3A4), but clozapine disposition is characterized by a large interindividual variability, being affected by age, gender, body weight, dose per kilogram, smoking habits, and ethnicity.[10]

Olanzapine plasma concentrations are decreased by carbamazepine,[53] but the authors of the study did not consider this interaction clinically relevant because of the wide therapeutic index of the antipsychotic. However, other authors have pointed that carbamazepine increases the metabolism of olanzapine, with a decrease in plasma concentrations of the latter by 38%.[52]

Quetiapine is a newly introduced atypical antipsychotic, and clinical data about pharmacokinetic interactions are lacking. Phenytoin seems to induce the metabolism of quetiapine, suggesting that dosage adjustment of quetiapine may be necessary when it is coprescribed with other AED enzyme inducers such as carbamazepine or phenobarbital.[98] Interestingly, Fitzgerald and Okos reported two patients who experienced markedly elevated levels of the carbamazepine active metabolite (carbamazepine-10,11-epoxide) with the occurrence of symptoms of neurotoxicity such as ataxia and agitation. The authors suggested that quetiapine may inhibit the epoxide hydrolase and/or glucuronidation of carbamazepine-10,11-trans-diol in the same way as valproate and lamotrigine possibly do.[23]

Pharmacokinetic Interactions with Anxiolytics

Generally, anxiolytics have a wide therapeutic index; therefore the clinical relevance of pharmacokinetic interactions is very limited. AEDs with enzyme-inducing properties may stimulate the biotransformation of many benzodiazepines. Carbamazepine has been reported to induce clobazam and diazepam metabolism,[86] and has also been demonstrated to enhance the clearance of clonazepam and alprazolam.[25,81] A clinically relevant interaction occurs between AEDs-inducers and midazolam and triazolam,[4] which are extensively metabolized by CYP3A4. Conversely, newer hypnosedatives such as zopiclone, zolpidem, and zaleplon are biotransformed by several CYP isoenzymes in addition to CYP3A4, resulting in CYP3A4 inducers having a lesser effect on their biotransformation.[33]

The Risk of Seizures with Psychotropic Drugs

Antidepressants

The association of antidepressants with the provocation of seizures is quite well known in medical literature. However, most of the data arise from studies using in vitro techniques, animal studies, and clinical observations; few specific clinical studies exist.[91] Within the therapeutic range for serum levels, the incidence of seizures is less than 0.5% for most antidepressants when other risk factors are excluded.

Table 6 Seizure risk for some antidepressant and antipsychotic drugs

High risk	Intermediate risk	Low risk
Antidepressants	Mianserin	SSRIs
Bupropion	Amitriptyline	Trazodone
Clomipramine	Imipramine	Venlafaxine
Maprotiline		IMAOs

		Mirtazapine Desipramine Nortriptyline
Antipsychotics	Haloperidol	Risperidone
Chlorpromazine (dose related)	Quetiapine	Ziprasidone
Clozapine (titration and dose related)	Olanzapine	

It has been known ever since their introduction that TCAs are proconvulsant and lead to seizures. This predilection, for example in overdose, is one method of fatality.[73] However, the mechanism responsible for inducing seizures with these heterocyclic antidepressants remains unclear. The most obvious explanation would be that the increase in serotonin and noradrenaline neurotransmission mediates this effect, because all antidepressants appear to display one or both of these properties. However, both these neurotransmitters have also been demonstrated to have some anticonvulsant effects in animal and human models. Such findings may explain those papers that suggest a possible therapeutic effect of antidepressants such as TCAs and newer antidepressants in low doses in the treatment of seizures.[99] Such observations have led to the suggestion of a biphasic effect, with lower levels being anticonvulsant and higher levels proconvulsant. Further, Leander[49] demonstrated, in an animal model of epilepsy, that the selective inhibition of serotonin uptake by fluoxetine can enhance the anticonvulsant potency of phenytoin and carbamazepine.

Antidepressants that pose a higher risk of seizures include mianserin, clomipramine, and maprotiline (Table 6). The risk associated with bupropion appears to be acceptably low when recommended prescribing practices are used. Of the newer generation of drugs, the SSRIs are considered to provoke less in the way of seizures than do TCAs.[32] Extensive clinical and research experience with all the SSRIs suggest that the epileptogenic potential of this class of drugs is quite low and not much different from placebo. However, a special caution

P.2221

should be mentioned with regard to the risk of hyponatremia. This idiosyncratic phenomenon has been associated with all the SSRIs and represents an important variable that may precipitate seizures.

Antipsychotic Drugs

Traditional antipsychotics have long been recognized as a class of drugs that can increase the risk of seizures. To determine the risk for drug-induced seizures, different approaches have been adopted: Observational studies (case-control studies and case reports), drug-induced electroencephalographic (EEG) changes, animal models, and in vitro techniques in isolated tissue samples. One of the problems of the recent literature is that most of the studies have been performed on psychiatric patients, and it is not known whether drug related seizures in non-epileptic patients really predict risk in patients with epilepsy, and whether different epileptic syndromes have different risks for psychotropic-induced seizures.

Generally, chlorpromazine and clozapine are considered proconvulsant in epileptic patients, the former only at high doses (1,000 mg/daily) and the latter at medium and high doses (>600 mg/daily).[2] Clozapine frequently causes epileptiform EEG changes and seizures in 3% to 5% of patients treated, even at therapeutic doses. Devinsky et al.[13] observed a mean prevalence of seizures of 2.9% with clozapine and, considering different doses, the prevalence was respectively given at 1%, 2.7%, and 4.4% for doses of less than 300 mg, 300 to 600 mg, or 600 to 900 mg per day. Pacia and Devinsky[68] analyzed only patients without a previous history of seizures, and the prevalence of seizures was respectively 0.9%, 0.8%, and 1.5% for the same range of doses as in the previous study. Thus, with clozapine, the proconvulsant effect seems to be a dose-related phenomenon but the role of the titration time and rate of increase of dose probably is also important.[47] Although the incidence of seizures rises to about 5% at doses 600 mg and EEG changes may be recorded at lower doses, it should be noted that these results emerge from patients with schizophrenia, and not epilepsy.[2] The seizures are often myoclonic, but can be generalized tonic–clonic or partial, depending on the individual patient.

Although, olanzapine is structurally related to clozapine, it is in the thienobenzodiazepine class of atypical antipsychotics and, along with quetiapine, premarketing studies showed a seizure rate of 0.9%.[50] Risperidone seems to have a low risk of seizures (about 0.3%), but data are taken from premarketing and postmarketing studies[2,50] (Table 6).

The use of Lithium in Patients with Epilepsy

Lithium carbonate is frequently used for manic episodes in bipolar disorder, in association with valproate and carbamazepine. Carbamazepine also demonstrates antimanic properties, and a possibly favorable pharmacodynamic interaction could be suggested; however, carbamazepine can increase the incidence of lithium toxicity. Kramlinger and Post[44] studied the effects of this combination in 23 patients with affective disorders. They observed a significant increase in many hematologic parameters (mainly the mean white blood cell count; lithium likely counteracts the neutropenic properties of carbamazepine) and a significant modification in thyroid function, with decreases in T4 and free T4. The opposing effects of carbamazepine and lithium on electrolyte regulation are well-known, with the potential occurrence of severe hyponatremia when lithium alone is stopped.[95]

The combination of lithium and valproate is widely used in rapid-cycling, manic, depressive, and mixed episode in bipolar disorder. This combination has a higher tolerability than the coadministration with carbamazepine, and a pharmacodynamic synergistic interaction has been suggested.[32] However, the combination of lithium and valproate may induce additive side effects, such as weight gain, sedation, and tremor.[24]

Chen et al.[9] investigated lithium pharmacokinetics when coprescribed with lamotrigine in 20 healthy subjects. There were no significant differences in lithium pharmacokinetic parameters. Abraham and Owen described a single case of lithium toxicity associated with topiramate cotherapy.[1] The authors suggested that topiramate, as a carbonic anhydrase inhibitor, may reduce lithium clearance and lead to toxic plasma levels.

The neurotoxic and convulsant effects of lithium are well known, but seizures are most common when plasma levels exceed 3.0 mEq/L. At therapeutic levels, the effect of lithium on seizure frequency in individuals with epilepsy is inconsistent.[19,39] Thus, although reports are conflicting, it appears that lithium can be prescribed in patients with epilepsy when mood-stabilizing therapy is necessary and alternative agents either fail or are not tolerated. In these situations, vigilant monitoring of lithium blood levels and for clinical signs of neurotoxicity is warranted.

Prescribing Psychotropic Drugs for Patients with Epilepsy

As noted earlier, most studies on the effects of AEDs on mood, or of psychotropic drug effects on seizures have been gathered from patients with psychiatric disorders and not from patients with epilepsy. However, some cross generalizations may be expected; for example, there is little reason to believe that a drug that is proconvulsant in psychiatric populations will not also be proconvulsant in people with epilepsy.

To minimize side effects and increase compliance, it is important to first of all discuss potential problems with the patient and, in particular, to settle any worries that the patient may have difficulty getting off the drugs because they may be addictive. Actually, the addictive potential of the antidepressant and the antipsychotic drugs is negligible, and some AEDs such as phenytoin are much more likely to be addictive and cause problems of abuse.

The psychotropic drugs should be introduced at low dosages, and the escalation rate should be slow (low and slow adage), but the patient's clinical progress must be carefully monitored. There is no point in prescribing the psychotropic and not seeing the patient again for several weeks.

Choice of drug is always difficult, especially because of so many newer agents from which to choose. The SSRIs are the favored antidepressants, and the atypical antipsychotics are best chosen for psychoses and in some settings for mood stabilization. If a patient has responded to a particular drug before, then it is sensible to opt for that prescription again.

The risk of an increase in seizures must always be mentioned, but this is not usually a problem in clinical practice, partly because patients are on AEDs, and partly because patients most susceptible to depression and psychoses are likely those with difficult-to-treat epilepsy, who have quite frequent seizures. In some patients who respond to the psychotropics but who do experience an exacerbation of seizures, a judicious increase in the AED therapy may be warranted.

A problem arises in the patient who has been seizure-free for a long time, but who develops a psychiatric disorder requiring treatment. Such patients are susceptible to the provocation of a seizure either on account of the proconvulsant potential of the drugs or because of a pharmacokinetic interaction. Careful discussion of the possibility of a seizure with the patient is mandatory.

Pharmacokinetic interaction possibilities are legion, as this chapter has demonstrated. Psychotropic drugs are not equivalent in their potential for drug interactions with AEDs. Each combination should be carefully considered, while taking into account all relevant variables related to the patient such as gender, age, ethnicity, smoking habits, body weight, and any associated renal or hepatic diseases.

Among antidepressants, the combination of nefazodone-carbamazepine is contraindicated because of the occurrence of toxic concentrations of the anticonvulsant. In other cases, from a clinical point of view, there are no particularly troublesome combinations. However, clinicians must be aware that fluoxetine has a long half-life, and the clearance of most antidepressants can be accelerated by enzyme-inducing AEDs.

As far as antipsychotic drugs are concerned, it must be kept in mind that the doses of neuroleptics should be always tailored on the patient's response. In almost all cases, enzyme inducers reduce the plasma levels of these drugs. The use of clozapine must be carefully monitored because its metabolism has high inter- and intraindividual variability and, especially in combination with valproate, interactions are difficult to predict. If there is concern about possible interactions, then serum AED levels should be taken before the administration of the psychotropic for later comparison.

Antidepressants must be given for at least 6 months to patients who have developed major depressive disorders, but variants, such as interictal dysphoric disorder (see Chapter 205), may resolve without therapy after a few days, or become repetitive and persistent, requiring longer-term mood stabilization. Antipsychotic drugs will be given at various schedules depending on the classification of the psychoses (see Chapter 204) and the severity. Stopping, as with starting these drugs, should be carried out slowly, and under adequate supervision.

Finally, the special role of clozapine in the psychoses should be noted. This drug may seem contraindicated in patients with epilepsy, especially on account of its proconvulsant liability. However, it has been used successfully in the management of the interictal psychoses of epilepsy, with certain provisions.[47] It is a remarkably useful antipsychotic in patients whose psychosis fails to respond to other atypical antipsychotics. The side effects of drooling and weight gain are further problems to its use, and it should not be used in patients who are on carbamazepine. However, a change of the latter to oxcarbazepine is an acceptable clinical maneuver. An EEG should be done before the administration of clozapine, in case of a deterioration of behavior, so that the development of a nonconvulsive status epilepticus can be identified and managed appropriately. The clozapine should be introduced slowly, white cell counts monitored, and increased in dose to between 300 and 600 mg if necessary, although some patients respond to lower doses.

The use of clozapine is most successful when given to a patient who has developed a psychosis and become seizure free, suggesting some variant of the theme of forced normalization and requiring perhaps a more proconvulsant antipsychotic for a clinical effect.

Summary and Conclusions

Although the mainstay of drug therapy in epilepsy relates to antiseizure medications, many patients have an associated psychopathology and receive psychotropic medications. In the past two decades the choice of such agents has increased considerably, and the introduction of new antidepressants such as the SSRIs and the atypical antipsychotics has allowed more patients to receive such drugs with a lessening of side effects. However, no psychotropic is free from treatment emergent effects, and they should only be prescribed when the clinical situation justifies it. It seems to be the case that many patients with epilepsy have unidentified psychiatric needs, and if anything psychotropic drugs are underprescribed.

Used judiciously, antidepressants and antipsychotic drugs can help bring resolution of psychopathology, but their use is always seen as part of a package of care which must also address social and psychotherapeutic needs.

Chapter 215

Overview: Social Issues

Robert T. Fraser

Introduction

There has been longstanding concern in the field of epilepsy that, although progress continues to be made relative to medical management of the disability, including the development of new generations of antiepileptic medications, attention is less focused on the social adjustment of individuals with the disability. A survey of 420 individuals drawn from affiliates of the Epilepsy Foundation of America[17] suggests a number of ongoing concerns, including employment, marriage and money management, and diverse health-related concerns. An earlier study by Schacter et al.[16] indicates that 65% of the 150 respondents in an Epilepsy Association of Massachusetts study responded that they were psychosocially adversely affected by seizures and that this was true for even half of those with one seizure or less per year. A recent review by Theodore et al.[18] regarding epilepsy in North America describes poor quality of life, a high number of depression and anxiety days, marked unemployment and underemployment, continuing perceived stigma, and higher suicide rates. Although adults with well-controlled epilepsy[8] may not be as significantly affected as those with more active seizure conditions, this appears to be the minority of the epilepsy population.

The field of epilepsy is at a crossroads relative to addressing the psychosocial needs of people with this disability and their significant others. The impact of managed care, a lack of U.S. federal support for multidisciplinary centers, and other factors are reducing the emphasis on diverse aspects of social adjustment and needed psychosocial interventions. There is an increasing concern, however, about quality-of-life assessment related to medication or surgical intervention and diverse aspects of neuropsychological functioning, but a review of the presentations at the American Epilepsy Society's 2005 Annual Meeting in Washington, D.C., suggests less coverage and research investment in some of the areas discussed in this section of the book. There were almost no studies relating to psychosocial intervention. This underscores that clinical service demands and financial constraints are affecting the investment in psychosocial research and demonstration projects.

Overall, there are a number of areas in which the epilepsy population appears to be making some significant gains. In Chapter 216, Jacoby, Snape, and Baker make a helpful distinction between "felt" and "enacted" or actually experienced stigma. On an overview, attitudes toward people with epilepsy are continuing to become more positive. There are a number of mediators of attitudes toward epilepsy, including the educational levels of respondents and their perceptions of disability-related limitations. Jacoby et al. stress the importance of family support and clear intrafamily communication as being preventive of perceived stigma by offspring. They also endorse the importance of "target-specific change models," for example, geared to adolescent attitudes, involving multiple and multitiered strategies within each efforts.

Although employment continues to be an international concern, in Chapter 219, Thorbecke and Fraser highlight the various aspects of the vocational assessment process, workplace accommodation, different model programs, and relevant national legislation that affect employability for those with epilepsy. Employment rates through specialized programs have been recorded to be as high as 89% for referrals with "epilepsy only" as a disability.[6] There is no question, however, that associated cognitive deficits, behavioral difficulties, and so on, are making successful employment outcomes more challenging. Specialized epilepsy vocational programs, however, will continue to be more effective, particularly for individuals with more involved epilepsy and associated disabilities. Unfortunately, there has been a lessening of emphasis on provision of employment services by the national Epilepsy Foundation (EF) in the United States. Today in the United States, specialized epilepsy vocational programs exist only at the University of Washington-Seattle, the University of California-San Francisco, and some EF affiliate agencies. Germany and Holland are among the few other countries that have specialized programs of this nature.

As Beran and colleagues indicate in Chapter 221, a number of gains have been made in the areas of legislation, driver licenses, and access to insurance. The Americans with Disabilities Act (ADA), signed into law in 1990, not only forbids discrimination in employment, but also requires reasonable accommodation (e.g., job restructuring) if an individual cannot perform the essential functions of a job. This type of legislation, although not necessarily affecting initial hiring decisions, can assist people with epilepsy to maintain their job position within the context of discriminatory or whimsical employer decisions to terminate. Eligibility for coverage under ADA has been difficult to establish for persons with good seizure control, but advocacy efforts by the U.S. EF and collaborators are being made to rectify this situation.

In relation to driver licenses, there is a general trend toward shorter seizure-free periods and a review of favorable modifiers prior to categorical driver licensing suspensions. This is not to say that advocacy and targeted physician effort will not be necessary in different areas of the world or within some U.S. states. Some countries, such as Japan and Russia, preclude driving after one seizure.[4] There remains a delicate balance between patient benefit and acknowledging risk factors and general safety.

Within the area of legislation, however, there is a continuing international need for advocacy, specifically in relation to health care coverage and reform. A number of U.S. insurance companies have used outdated actuarial data and failed to note the advances in diagnosis and treatment of epilepsy in making their health care access and financial rate decisions. This issue is not unique to the United States. Beran et al. emphasize the need to advocate in other areas such as epilepsy research and development and services to families. They end their chapter with a helpful section on strategies for use with political representation.

Over the years there has been a growing recognition of the need for social support for individuals with epilepsy. In Chapter 217, Austin, de Boer, and Shafer review the plethora of issues

P.2226

affecting psychosocial adjustment in epilepsy and a range of issues that can be targeted for intervention. Of particular value are guidelines for dailing living both inside the home and within the community. They also draw attention to the need for more “self-management” education in relation to the disability and research into the value of group versus individual educational programs or programs combining education, counseling, and even recreation, among other isues.

Despite the fact that psychosocial gains are being made in a number of areas, certain issue areas deserve increasing attention. Although there is a dramatic increase in quality-of-life assessment and an effort to measure the impact of seizure severity on patients' lives, there is a continuing theme in the literature[1,2,7] that patients feel poorly educated not only about epilepsy, but also about medications and potential side effects. As Buck et al.[2] indicate, patients place a significant premium on physicians who are not only knowledgeable, but are also communicative and approachable. Within the current managed care context in a number of countries and given the institutional demands on the physicians' time, it can be very difficult for physicians to make the effort carefully to explain epilepsy and issues in medical management to a patient and family members. Somehow, however, this needs to be done because it directly relates to patient compliance, among other care variables, in the prevention of the disabling condition. Several studies[5,10] show sample noncompliance rates exceeding 50%. It appears that time spent educating each patient about epilepsy and medication is well spent.

In general, there is a need for more educational programs for individuals with epilepsy and their significant others. In Chapter 217, Austin et al. point out that although the literature supports the need for epilepsy education, few educational programs (exceptions are the Modular Service Package Epilepsy [MOSES] and Sepulveda Epilepsy Education [SEE] programs) have been presented and systematically evaluated. Internationally, only a few clinics have formal educational programs for their patients with regard to their epilepsy and medications, and only one program could be identified in the literature[11,12] for children with epilepsy and their parents. The SEE program[17] has shown some very beneficial results on quality of life and seizure management for adolescents with epilepsy and their parents.

Although the U.S. Epilepsy Foundation and other national epilepsy associations have quality educational materials available (e.g., on cognition and epilepsy), significant marketing efforts through the media might be needed to promote their utilization. An obvious role for epilepsy organizations internationally is the development of formal educational programs about epilepsy and associated issues that also help physicians to take the time required to discuss their patients' concerns. Medication noncompliance and continuing advances in medication management are areas that need to be attacked simultaneously.

Marriage and family concerns also deserve continued emphasis. Educational programs for both patients and the general public could be very helpful in improving the prognosis for marriage—particularly for men. As Thompson and Upton indicate,[19] levels of stress and dissatisfaction within families can be high because those with epilepsy often face difficulties in maintaining primary work careers or even receiving respite care for their children. Within the context of psychosocial research, interventions with families and their impact on medical and social adjustment have been largely overlooked.

In Chapter 218, Seidenberg and Clemmons discuss issues relating to school functioning and school-to-work transition. They present a comprehensive review of seizure and neuropsychological correlates of academic dysfunction and discuss subtypes of learning disabilities and a comprehensive perspective on educational and vocational assessment. They also offer approaches to working with parents, teachers, and state vocational rehabilitation representatives. Again, there is a paucity of recent research on school functioning or successful school-to-work transition.

Of particular interest in this section is Chapter 220 by Rubin, Wiebe, and Gilliam on health outcomes. The chapter underscores the importance of adverse medication effects and depression/anxiety on quality of life and the need to assess and intervene with regard to these issues. Although it is understood that other health-promoting behaviors such as sleep quality and exercise also can affect quality of life, we do not yet have an integrated model of effects on quality of life.

Summary and Conclusions

Although progress has been made relative to the social adjustment of people with epilepsy, there remains much to be done. Considerable challenges face those in less industrialized countries, in which some of the issues in discrimination, employment, and so on, are only recently becoming obvious and receiving media attention. As discussed by Collings,[3] we remain at the early stages of examining international differences in psychosocial well-being and quality of life for this population. The challenge remains not only to identify these differences, but also to find funds to mount education and other psychosocial intervention efforts that currently are lacking. Although it appears that intervention during childhood and particularly adolescence[15] is crucial within this population, most existing intervention efforts appear to be conducted within short-term summer camp structures.[5] Although these are valuable, they are insufficient. More comprehensive and sustained psychosocial interventions need to be pursued and evaluated.

Chapter 216

Social Aspects: Epilepsy Stigma and Quality of Life

Ann Jacoby

Dee Snape

Gus A. Baker

Introduction

In this chapter, we turn from consideration of epilepsy as a biomedical condition and the province of health professionals to consideration of epilepsy as a negative social label and the concern of social theorists, social policy makers, and disability activists. Epilepsy has long been considered as "undesired differentness,"[44] and, as a consequence, it has involved the application of formal and informal rules and sanctions against those affected by it. Legal discrimination against people with epilepsy dates back centuries and operates still,[56] even though in many countries persons with epilepsy are now considered as having a prescribed disability and so are offered protections under the law. A significant literature traces the history of epilepsy as stigma and documents the role of stigma and discrimination in its present-day social reality. From this, it is clear that the social problems arising from a diagnosis of epilepsy and the repercussions for quality of life, especially for those in whom it proves to be clinically benign, can represent a greater challenge than its medical management. How these problems can be minimized thus represents an important aspect of the overall management of epilepsy.

Epilepsy as a Social Label

Although considered the "sacred disease" by the ancient Greeks, in many ancient and primitive societies epilepsy was believed to originate from malignant causes and to be associated with sin and demonic possession. Seizures were often considered bad omens. There are references in the New Testament to epilepsy as a form of madness, and the notion of people with epilepsy as "lunatic" held widespread currency throughout the mediaeval period. Theories of epilepsy as contagion can also be traced back to antiquity.[108] Temkin[108] saw epilepsy as representing the historical struggle between magical and scientific conceptions of disease, with its medicalization in the Western world a victory for the latter. It is apparent, however, from studies of lay attitudes and beliefs toward epilepsy (see later discussion) that remnants of the former attitude continue to inform popular concepts of the condition even through to the present day. What is more, even when biomedical explanations for epilepsy emerged as triumphant during the Enlightenment,[82] the evolution of epilepsy from "badness to sickness"[22] brought with it its own associations to stigma, with studies linking epilepsy to aggressive or even criminal behavior, abnormal sexual activity, hereditary degeneracy, and a specific "epileptic personality," all of which have had power to reinforce negative stereotypes and hence perpetuate stigma.

Although the biomedically driven concept of the epileptic personality may have been discounted in recent years, Scambler[97,98] proposed an alternative sociologic construct of "epileptic identity" resting firmly on the view of epilepsy as not just a clinical problem but also a social label. Scambler suggested that people with epilepsy react symbolically to having seizures and develop a special identity or "view of the world" underpinned by their expectations of stigma. This world view is not generally present in their lives, and is triggered by particular events; when it is triggered, however, it has the effect of predisposing them to try to cover up the signs of their condition and pass themselves off as "normal." Scambler found that almost everyone he interviewed was distressed by receiving a diagnosis of epilepsy because "they showed a more or less clearly defined awareness that a physician's diagnostic statement… had transformed them from 'normal' persons to 'epileptics' and this was first and foremost a stigmatising condition." Their perceptions of epilepsy as stigmatizing were clearly anchored in what they believed to be the predominantly negative attitudes of others, which constituted a major source of anguish to them, but for which, Scambler argued, there was actually little empirical support.

Based on his analysis, he proposed a "hidden distress" model wherein the stigma of epilepsy and its repercussions for quality of life are best understood by making a distinction between "felt" and "enacted" stigma.[100] Felt stigma here refers to the shame of being epileptic and the fear of encountering epilepsy-linked enacted stigma, that is, enacted stigma to actual episodes of discrimination against people with epilepsy *solely* on the grounds of them having epilepsy. Scambler concluded that felt stigma was far more prevalent than enacted stigma, with almost everyone in his study appearing to suffer from it, even if only intermittently. It was also, in effect, a self-fulfilling prophecy inasmuch as their fear and shame about epilepsy led people to attempt to conceal their condition from others, denying themselves the opportunity to test whether the enacted stigma and discrimination they expected would, in fact, materialize.

The power of the social label of epilepsy is also illustrated in the work by Schneider and Conrad,[101] who reported that the people they interviewed with epilepsy saw it as a kind of "moral weight" they had to carry and so was far worse than simply having seizures. Some, described as "unadjusted" to their diagnosis, appeared to be overwhelmed by the shame of having epilepsy; they saw it as precluding or limiting their access to important personal and social resources, negatively affecting different aspects of their quality of life and preventing their happiness. For some people, referred to by Schneider and Conrad as "debilitated," it appeared that the label of epilepsy totally defined them, and their response was often to withdraw from contact with the nonepileptic world.

Table 1 Dimensions of stigma according to jones et al.[66]

Concealability	Extent to which the stigmatizing condition is visible to others
Course of the mark	Whether the condition becomes more salient over time
Disruptiveness	Degree to which it interferes with social interactions
Aesthetics	Subjective reactions of others to the unattractiveness of the stigmatizing condition
Origin	Whether seen as congenital, accidental, or intentional
Peril	Perceived danger of the condition to others

Theories of Stigma in the Context of Epilepsy

Goffman[44] defined stigma as "an undesired differentness." People are stigmatized because they possesses an attribute, such

as epilepsy, that is undesired and deeply discrediting and by virtue of which they represent a discrepancy between the persons they might be and the persons they are—in Goffman's words, between their virtual and actual social identities. Goffman identifies three different types of stigma: (a) the tribal stigmas of race and religion, (b) blemishes of individual character, and (c) what he refers to as abominations of the body. Whichever of these prevails, Goffman argues that those who are stigmatized are seen by others as “not quite human” and the legitimate target for discrimination. Goffman notes that even though people who are stigmatized may attempt to rid themselves of their “contaminated” social identity, they cannot reacquire the status of normal, only that of someone who was once “contaminated.” This problem is thrown into relief in the context of epilepsy by the fact that, in clinical terms, the condition may not be considered curable, only controllable, so that the threat of “contamination” can never be entirely eliminated. Because the possibility exists “that the offensive behaviour will recur,”[2] the stigma of epilepsy is irreversible and ineradicable.

Recent theoretical work on the concept of stigma has tended to emphasize two key dimensions, visibility/concealability and course/controllability,[29,65,66] both of which are highly relevant to epilepsy. Seizures, the “symptoms” of epilepsy, may be difficult to conceal and may become more salient over time depending on the clinical course of the condition and the degree to which it can be controlled. Four further dimensions, within each of which the stigma of epilepsy can be located, are disruptiveness, aesthetic aspects, origin, and peril (Table 1).[66] Seizures are clearly often highly disruptive to social interaction, causing those observing them to stand by powerlessly as “the terrified watcher.”[116] Depending on their specific manifestations, they may also be aesthetically unpleasant to those observing them. The legacy of the old ideas about epilepsy as the product of malign forces or sinful behavior results in the issue of origin remaining ambiguous: It might be thought that people with epilepsy are somehow morally culpable for their condition. Moreover, although seizures present far greater dangers to those with epilepsy than to bystanders, the issue of peril is echoed in old ideas of epilepsy as contagion. Such ideas are still often dominant in resource-poor countries where the majority of those affected by epilepsy live, which commonly leads to their social ostracism.[21,64,83]

Table 2 Components of stigma according to link and phelan[73]

Component 1	People distinguish and label *socially relevant* human differences
Component 2	Dominant cultural beliefs link labeled persons to *negative* stereotypes (e.g., “People with mental illness are a danger to others”)
Component 3	Labeled persons are placed in distinct categories (e.g., “fat,” “disabled,” “epileptic”) to separate them from others
Component 4	Labeled persons experience status loss and discrimination (and unequal health and socioeconomic outcomes)
Component 5	Social, economic, and political power allows components 1–4 to operate (those in positions of *low* power cannot impose labels, stereotypes, separation, status loss)

Even in resource-rich countries, the fact that often no definitive cause for epilepsy can be found creates the possibility for continuing misattributions. As shown in a recent study by Austin et al.,[5] 22% of American adolescents were uncertain whether epilepsy was a contagious condition.

Social theorists have commented that a reason that conditions such as epilepsy are almost universally stigmatizing is that they represent some kind of tangible or symbolic danger either to individuals or entire cultures, including physical, moral, and health dangers.[32,104] With regard to epilepsy specifically, it has been argued[1,6,98,112] that seizures can be seen as uniquely dangerous to normal social interaction both by violating cultural norms or values and by representing human weakness and unpredictability and even “anomic terror.” Recently, stigma theorists have also recognized the previously neglected role of power relations in the social construction of stigma.[73,99] Link and Phelan[73] commented, “it takes power to stigmatise.” The social labeling, stereotyping, separation from others, and consequent status loss that are the key elements of stigma are only relevant in a power situation that allows them to unfold; in other words, they cannot be imposed by those in positions of low power (Table 2). How does this play out in epilepsy? Certainly within the current culture of biomedicine, clinicians hold power to impose a diagnosis of epilepsy on a set of often nebulous neurologic events or symptoms and, in so doing, to legitimize a historically based negative social label and its associated stereotypes. This then allows imposition of rules and sanctions that reinforce the differentness of having epilepsy.

Because it was developed in the context of epilepsy stigma specifically, it is worthwhile reevaluating Scambler's “hidden distress” theory in view of subsequent epilepsy-related research. Jacoby[54] revisited the concepts of felt and enacted stigma and found, like Scambler, that the former was far more commonly experienced than the latter, with few people able to recall any instances of enacted discrimination. Other research on epilepsy stigma in similar cultures supports this. It has been argued, however,[90] that much of the research reported has been concerned with identifying episodes at the hard end of enacted stigma only, for example, in relation to employment, while failing to document its more subtle expressions.

Furthermore, whereas felt stigma appears to be a much more pervasive element in North European cultures, it should not be assumed to be universally of greater relevance.[89] In some cultures, for example, sub-Saharan African ones,[87] enacted stigma may be of far greater concern, perhaps in part because the treatment gap increases the visibility of epilepsy. If we are to advance our understanding of the nature of epilepsy stigma, it will

P.2231

therefore be important to develop a shared theoretical framework and set of measurement tools that allow for cross-cultural and contextual adaptation.

Views About Epilepsy as a Social Label

Views of People With Epilepsy

Labeling theorists maintain that the impact of a negative social label, for example, being “epileptic,” can be quite profound inasmuch as the label overrides other aspects of a person's identity. In a sense, it becomes what has been termed the “master” status,[72] making it difficult for the affected person to continue to think of himself or herself as just “like everybody else.”[30] Given that all illness can be defined negatively as a state of “deviance” from good health,[81] having epilepsy can be said to represent a state of double deviance,[55] its particular characteristics and social connotations ensuring that deviance also attaches to the condition per se. The process by which people with epilepsy come to acknowledge their deviant status and accept that they are not like everyone else has been the focus of attention of several authors.[98,101,118]

Parents emerge as key figures in these analyses because their reactions to a diagnosis of epilepsy in their child seem effectively to set the stage for the child's subsequent interpretation of its significance. When parental reactions are negative, their affected child learns to think of epilepsy as something shameful; when parental assumptions are that epilepsy will inevitably attract hostile reactions from others, their affected child learns to think of it as something to keep quiet about. Other key figures are likely to be teachers and health care professionals, both of which groups are known as sometimes having less-than-positive attitudes about the condition and limited knowledge about its implications (see later discussion).

It is not surprising, consequently, that people with epilepsy sometimes resort to trying to "renegotiate" the diagnosis into something more socially benign[98] or to taking active steps to conceal it from others.[74,98,101,120] Among the adult participants in the studies by Schneider, Conrad, and Scambler, concealment constituted a key management strategy. Similarly, in their study of adolescents with epilepsy, Westbrook et al.[119] found that more than half kept their condition a secret from others and almost three fourths said they rarely or never talked about it to others, even though denying that having epilepsy affected their friendships and perceived likeability among their peers.

Views of Other Groups

As noted, even today epilepsy remains shrouded in misinformation and misbeliefs.[78] Misattributions about the causes of epilepsy, for example, are common (Table 3). Historically, studies have presented a less-than-favorable picture for people with epilepsy. For example, Bagley[6] compared public attitudes toward people with epilepsy with those toward people with cerebral palsy and mental illness and found that people with epilepsy were much more often rejected than the other two groups. Both Vinson[115] and Harrison and West,[47] who interviewed people in two cities as part of the U.K. National Epilepsy Week, found that significant numbers of the people with whom they talked held images of people with epilepsy that were essentially negative. These included the views that people with epilepsy were violent, retarded, antisocial, and physically unattractive. Similarly negative traits were identified as peculiar to people with epilepsy in later street surveys carried out in the United Kingdom.[67,96]

Table 3 Lay understanding of causes of epilepsy

Resource-rich countries	Resource-poor countries
• Stress/pressure	• Sorcery, witchcraft
• Tiredness	• Possession by devils, ancestral spirits
• Heat	• Infection, contagion
• Mental illness	• Saturation by foams
• Brain/nervous system disorder	• Insect/lizard in stomach/head
• Congenital problem	
• Old age	

In the United States, Baumann et al.[10] found that one fourth of respondents to a telephone survey believed there would be deterioration in the classroom environment were a child with epilepsy to join it. In the 1987 American Institute of Public Opinion survey,[70] 7% thought people with epilepsy were dangerous, 12% that they should not have children, and 33% that people think less of a person with epilepsy and their families. With regard to particular groups within the general population, research has also identified lack of knowledge and accompanying negative attitudes among employers,[40,50,91,94] coworkers,[46] health professionals,[11,109] and teachers.[13,31,42,75]

Rather more encouragingly, numerous surveys have documented improvements over time in attitudes to epilepsy,[19,20,33,39,51,52,61,63,79,80] indicating that its weight in some, if not all, "local moral worlds"[32] has lessened. For example, in the United States,[20] affirmative responses to questions asking people whether they would object to a child of theirs playing with one who had epilepsy and whether people with epilepsy should be barred from employment in the same jobs as others declined between 1949 and 1979 from 24% to 6% and from 35% to 9%, respectively. Jensen and Dam[63] reported that social acceptance of people with epilepsy was high in Denmark; Dawkins et al.[33] reported similarly in the United Kingdom. In a recent study carried out as part of the U.K. Omnibus Survey and involving >1,600 randomly selected members of the general public,[61] those questioned appeared generally well-informed about epilepsy, its causes, and its treatment, and most held highly favorable attitudes toward people with epilepsy, although one fifth thought people with epilepsy were more likely to have personality problems. Likewise, increasingly positive attitudes have been noted among key subgroups. For example, among primary and secondary level teachers surveyed in Greece,[68] most believed that children with epilepsy were as capable as others of achieving academically. Nonetheless, the continuing challenge of stigma is highlighted by a study published in the same year[95] documenting persistent widespread negative attitudes and bias toward epilepsy among teachers in Nigeria.

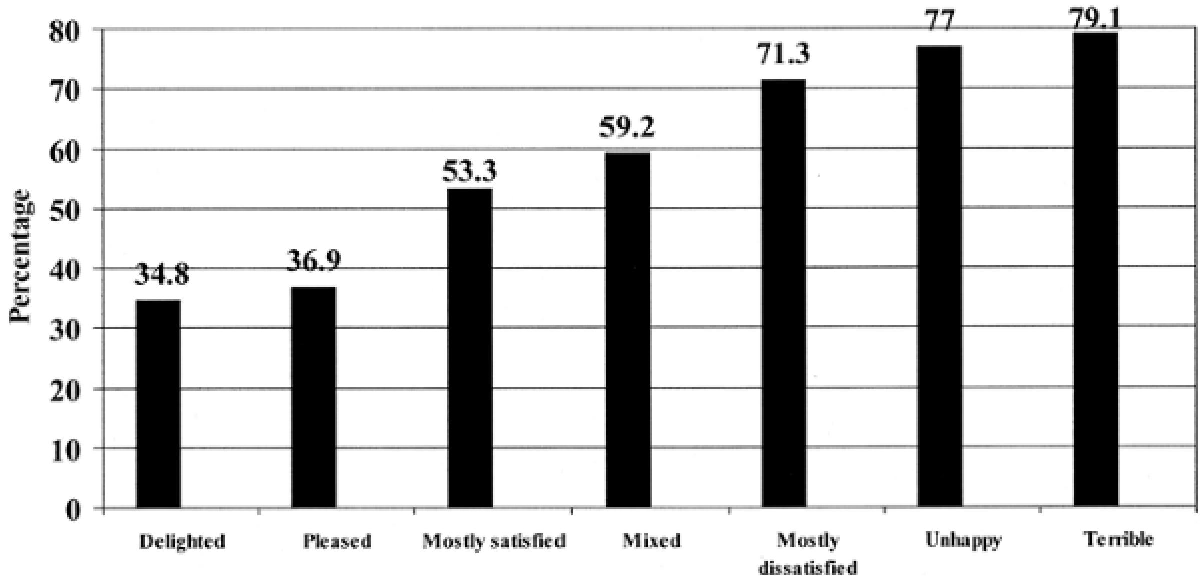

FIGURE 1. Stigma and overall quality of life. (From Baker GA, Brooks J, Buck D, et al. The stigma of epilepsy: a European perspective. *Epilepsia.* 2000;41:98–104, with permission.)

In a survey of 200 randomly selected U.K. employers, Jacoby et al.[60] found that although epilepsy continues to generate anxiety in the work context, the majority (and a larger proportion than in earlier surveys) reported that there were jobs in their companies suitable for people with epilepsy and were aware of the need and expressed clear willingness to comply with the principle of "reasonable adjustment." Overall such studies suggest significant improvements in public attitudes. It is interesting that, despite positive public attitude shifts, it has also been shown that epilepsy still sometimes evokes greater responses to rejection than other chronic conditions, even conditions such as AIDS/HIV infection and mental illness, which are recognized as deeply stigmatizing.[6,10,26,85] Reis[88] concluded that although the classic stereotypes of epilepsy may have less

resonance today, they have tended to be replaced by new ones in which people with epilepsy are regarded as introverted, overanxious, and less open than others. Such present-day stereotypes, even if they are in any degree supported by available research, are inevitably disquieting to those against whom they are directed.

Role of Stigma in Quality of Life

Stigma has long been thought of as predisposing to psychopathology in people with epilepsy, although the relative lack of published studies involving formal and scientifically robust investigation of its role means that its supposed effects are less evidence based than a "taken for granted" assumption.[48] Studies that have attempted to examine the relationship between stigma and psychological health specifically, and quality of life more broadly, include those by Arnston et al.,[4] Hermann et al.,[49] Jacoby,[53,58] Baker et al.,[8] and Suurmeijer et al.[106] Jacoby[57] noted that consistent with sociologic theories about “the illness trajectory”[23] for people with epilepsy, the clinical course of their disease is important for their quality of life, including the degree of their stigma sense. She and her colleagues documented rates of stigma in persons starting to have seizures, experiencing seizures that prove to be intractable, and having seizures that go into remission. Among those newly diagnosed with epilepsy,[59] one-fourth reported feeling stigmatized despite the recency of application of the negative social label of “being epileptic.” Two years later, only one tenth of those who had remained seizure free reported feeling stigmatized, compared with 45% of those experiencing continuing seizures. In contrast, among a separate cohort of persons with seizures in remission, only 14% reported feeling stigmatized, and this group also reported minimal impairments in other life domains.

The relationship between epilepsy stage or severity and stigma is also supported by Baker et al.'s study,[8] in which the percentage of people reporting feeling highly stigmatized rose from 10% of those who had been seizure free in the previous 12 months to 29% of those reporting ongoing seizures occurring more than once monthly. Competing evidence about the importance of factors other than these clinical ones is available, however; for example, the study by Ryan et al.[92] showed that the relationship between stigma perceptions and epilepsy severity was highly dependent on other mediating factors such as attained level of education and the perceived limitations imposed by epilepsy-related vulnerabilities. Such findings help to explain why a sense of stigma may persist for a small minority of people with apparently excellent seizure control and, conversely, are absent among some people with even very frequent seizures. They highlight the need for a psychosocial as well as a medical approach to the management of epilepsy.

Stigma was positively associated with impaired self-esteem, self-efficacy, sense of mastery, perceived helplessness, increased rates of anxiety and depression, increased somatic symptomatology, and reduced life satisfaction in studies by Arnston et al.,[4] Jacoby,[54,58] Westbrook et al.,[119] and Dilorio et al.[36] Baker et al.[7,8] also demonstrated a link between felt stigma and medication side effects, supporting Scambler's proposition about the potential for antiepileptic drugs to act as stigma cues. Both Baker et al.[7] and Youn and Hong[121] found that overall quality of life was poorer for persons reporting higher levels of stigma, either felt or enacted (Fig. 1). Suurmeijer et al.[106] used hierarchical regression analysis to demonstrate that perceived stigma was fourth in importance in predicting quality of life, after psychological distress, loneliness, and adjustment; it accounted for twice the amount of variance in quality-of-life scores as did clinical variables such as seizure frequency and antiepileptic drug side effects.

It is interesting that several hypotheses were not supported by the findings in the study by Westbrook et al.,[119] which focused on the link between stigma and self-esteem. For example, focal seizures, rather than tonic–clonic seizures, were predictive of lower self-esteem. In addition, contrary to the role proposed for it in stigma theory—namely, that the issue of disclosure management would be forced by the threat of frequent, visible symptoms—no relationship was shown between it and seizure type or frequency or epilepsy duration. These findings raise questions about the limitations of theory for lived experience and the need for more in-depth approaches to identify alternative and previously unrecognized mechanisms by which stigma exerts its effects.[74]

Stigma may also be implicated *indirectly* in quality of life by virtue of the fact that the quality of health and social care received by persons with stigmatizing health conditions may be suboptimal. Stigmatized conditions may fail to attract investment both for service provision and for research.[117]

P.2233

There is also some evidence to suggest that health and social care professionals, like other members of the general public, are susceptible to negative attitudes and beliefs about epilepsy. Recent surveys in the United Kingdom have suggested that health care for people with epilepsy is fragmented and underresourced, with many receiving care that is substandard in relation to published guidelines.[62,109,113] Significant levels of dissatisfaction with the quality of their medical, social, and educational care has been expressed by members of the United Kingdom's largest epilepsy support organization, Epilepsy Action.[15,16] The U.K. Clinical Standards Advisory Group[113] concluded that levels of disability and social exclusion for people with epilepsy would be considerably lessened by relatively simple and inexpensive changes in the delivery of their care. Among their suggestions were that formal mechanisms for eliciting the views of service users should be incorporated and that simple care protocols should be introduced for nonneurologic staff, for example, those working in accident and emergency departments.

DiIorio et al.[36] examined the relationship between felt stigma and perceptions of the quality of health care among adults with epilepsy living in the United States. They found that persons with higher levels of felt stigma reported lower levels of satisfaction with their care across a whole range of areas, including interpersonal, communication, technical competence, time spent with the doctor, and the accessibility of their care. They also experienced greater difficulty with managing their medication regime, reported less medication adherence, and reported less positive outcomes associated with taking medication. This lack of satisfaction may therefore reflect a combination of underresourcing and negative attitudes among care providers. As the authors acknowledge, however, the cross-sectional nature of their study precludes firm conclusions about the direction of effects.

Managing Epilepsy Stigma

Helping People With Epilepsy to Manage a Negative Social Label

Dell[35] noted that although identity politics is not “a comforting strategy” for those concerned, it does seek to establish society as the locus of stigma against people with epilepsy and force a reevaluation of their societal worth. Although people with epilepsy may have been slower than some other stigmatized groups to respond to the call, the epilepsy associations are moving rapidly from a view of their function as that of support and information to an increasingly political and campaigning role, agitating for better services and less discrimination for their members.[71]

Campaigns such as the Global Campaign Against Epilepsy[43] are raising its profile with governments and their health systems planners and providers worldwide.

At the individual level, there is evidence that whereas some people with epilepsy appear to admit to the permanence of epilepsy stigma, others show resourcefulness and resilience in putting it aside whatever the clinical prognosis.[92] Among factors identified as critical for developing such resilience are unconditional family support and clear intrafamilial communication.[1] Ablon[1] noted that living in such a positive environment helps to instill confidence and security in early life and encourages positive illness-coping behaviors in the affected person. Family members who openly discuss the practical and emotional issues associated with having a stigmatizing condition and who actively seek out high-quality health care for the affected person can do much to empower that person. Ablon commented that lack of knowledge on the part of other family members can seriously hamper the ability of persons with stigmatizing conditions to cope with them and make a positive adjustment, as can lack of knowledge on the part of affected persons themselves.[37] This suggests a need for targeted educational programs for people with epilepsy and their families; a number that have been formally evaluated are accessible for use.[76]

The importance of counseling as a means of helping people with epilepsy manage stigma had been stressed.[41] Although one-to-one counseling is expensive and therefore may be difficult to fund, Floyd-Richard and Gurung[38] studied the effect of group counseling for people with another chronic stigmatizing condition, leprosy, and concluded that this was a time-efficient and productive method of reducing the effects of stigma. They also argued, however, that counseling alone will not improve the self-image and acceptance of a stigmatized person, and other interventions, such as economic rehabilitation for the whole family and health education for the affected individual, their family, and the community, are also essential.

As shown earlier in this chapter, in the face of possible hostility and stigma, concealment appears to be a key management strategy adopted by people with epilepsy. Although this may make felt stigma “a self-fulfilling prophecy,”[98] disclosure is recognized as a potentially risky course of action[46,111] and is therefore a source of some considerable anxiety to people with epilepsy.[77] The advice from the epilepsy support organizations tends to be that people with epilepsy should approach the issue of disclosure carefully and thoughtfully.[12,17,86] Of course, people with epilepsy are often under a legal imposition to disclose their condition, for example, if they drive or are engaged in particular types of employment in which seizures would put them or others at risk.

Ultimately, however, the decision of whether disclosure or nondisclosure is the wisest and least stressful course of action for managing possible stigma and discrimination must be made on an individual basis, although preferably with proper support.

Changing Negative Public Attitudes

With regard to improving public attitudes toward epilepsy, possible strategies include education and information provision, advocacy, inducing a greater degree of empathy toward epilepsy, and increasing the level of contact between people with epilepsy and people without epilepsy. The most frequently used strategy appears to be that of education, and findings from reviews[18,114] and single studies related both to epilepsy[5,14,64] and other health conditions[24,27,28,69,84,102,103,107] support it as an effective one. Evaluation, however, is often limited to fairly short-term assessments, and different kinds of educational interventions show mixed effects on patterns of attitude and behavioral change and stigma reduction. Interventions targeted at specific population subgroups appear more promising and cost-effective than broad-based public educational campaigns.[105] The overarching message appears to be that the type and content of educational interventions needs to be shaped within peoples' traditional way of thinking and must take account of the context in which stigma operates.

Advocacy focuses on provision of a supportive, enabling environment within which attempts can be made to influence legislative and policy change and is proposed as an important strategy for stigma reduction by several authors.[1,3,25] Given that attitude and behavior change initiatives appear to be more effective when targeted, Corrigan[25] proposed that advocacy groups should use a target-specific stigma-change model to ensure organization of diverse information into a coherent framework. The principle is to identify the group and stigmatizing attitudes that influence discriminatory behavior and the social context within which the group interacts with the stigmatized

person(s). This, in turn, enables a specific change strategy to be identified. The success of the U.S. Epilepsy Foundation's “Entitled to Respect” campaign, targeted at young people, is a current example of advocacy at work.[110] Another good example is the U.K. group Epilepsy Bereaved, as a result of whose work the U.K. Department of Health commissioned the first U.K. audit into epilepsy-related death,[45] which led to a series of recommendations for the care of people with epilepsy.

Inducing empathy for a member of a stigmatized group can improve attitudes toward members of that group as a whole.[9] The assumption here is that by inducing others to see the world from the perspective of a stigmatized group member, they can be led to *feel* for this person and these empathetic feelings will generalize, resulting in a more positive attitude toward the group as a whole. Similarly, interventions based on increasing contact have been proposed as a means of reducing social distance toward affected persons. Such interventions can be targeted at individuals, groups, or the wider community; for example, the Horizon initiative in the Netherlands[34] involved placing people with epilepsy into employment and so exposing employers to them as employees directly. This initiative showed some degree of success despite findings from studies within other health contexts that increased contact in real-world settings, for example, job training, is largely ineffective. Brown et al.[18] argued that a contact strategy in conjunction with education is one of the most promising approaches to reducing negative attitudes.

Whatever strategy is adopted, the literature makes it clear that conducting stigma intervention programs requires diverse skills to engage and interact with targeted communities and community agencies. It also suggests that multistrategy, multilevel approaches are more effective in improving knowledge and reducing stigmatizing attitudes than are single interventions.[114] Furthermore, several studies report evidence of superficial changes in attitude based on improved knowledge but limited change in deep-seated fears, and little is known about what is required to bring about long-term attitude change. Within the field of epilepsy specifically, there is still limited evidence for the effectiveness of interventions to reduce stigma, despite the length of its history, but research suggests that stigma reduction must go hand in hand with improving access to health care and supporting treatment adherence.

Summary and Conclusions

In this chapter, we have focused largely on the literature relating to epilepsy stigma as played out in countries in the developed world. As we have tried to make clear, however, the implications of having epilepsy vary with time, geographic place, and sociocultural context, as do the ways in which people with epilepsy, their families, and their communities respond to the condition. What is without question is that for a significant proportion of those affected, stigma remains a real and present, if intangible, danger. Weiss and Ramakrishna[117] noted that a reformulation of the concept of stigma for health research would be that it is a process in which adverse social judgments are made that are medically unwarranted. This is a very relevant definition of stigma for the great majority of people with epilepsy whose condition can be easily and effectively controlled.[93] At a recent meeting on stigma and global health supported by the U.S. National Institutes of Health (available at www.stigmaconference.nih.gov), family, local community, health and social care systems, educational institutions, legal systems, employment, and insurance were all identified as areas in which people with epilepsy might encounter stigma. Continuing to challenge stigma in all these areas must remain a priority.

Chapter 217

Disruptions in Social Functioning and Services Facilitating Adjustment for the Child and the Adult

Joan K. Austin

Hanneke M. de Boer

Patricia O. Shafer

Introduction

The impact of epilepsy on social functioning, or the ability to participate in a broad range of social activities and interpersonal relationships, can be quite varied. Although many people with epilepsy have few, if any, disruptions in social functioning, others have severe problems that prevent them from engaging in fully productive lives. The exact prevalence of social problems is difficult to establish because most studies have been carried out on clinic samples in which persons with more difficult-to-control epilepsy are served. Studies show that rates of social dysfunction are substantially higher in samples from clinics than in community samples.[104] Nevertheless, social problems are common in persons with epilepsy, and these problems need to be addressed by health care professionals.

In this chapter, we present an overview of the disruptions in social functioning that can be experienced by children and adults with epilepsy. We also describe factors associated with social problems and consider them within the context of tasks of normal psychosocial development. We conclude with guidelines for daily living, an overview of areas that need to be addressed in a comprehensive assessment, and the types of services that can facilitate social functioning in persons with epilepsy.

Disruptions in Social Functioning

Social Problems

Persons with epilepsy have a higher prevalence of social problems than those from the general population. A longitudinal study of adults with childhood epilepsy indicated that epilepsy had a negative impact on social functioning.[97] Problems most commonly reported in persons with epilepsy include anxiety, poor self-esteem, social isolation, and symptoms of depression.[7,19,60,74,79,90,92,93]

Comparison studies show that children with epilepsy have poorer social functioning than children with other chronic physical conditions[89] such as asthma,[7,19] diabetes,[75] or learning disabilities.[74] In a recent study, adolescents with epilepsy showed greater social anxiety and interpersonal problems than adolescents without epilepsy.[20] Adults with epilepsy have also been found to have higher rates of social problems than the general population. Social problems include social isolation and problems with adaptation.[28,30,44,58] Problems in living with epilepsy related to social adjustment (e.g., driving and lack of employment opportunities) are also frequently reported in adults with epilepsy.[53,64] Long-distance travel can also be difficult for adults with epilepsy, especially for those with severe or frequent seizures. Social problems are important because they reduce quality of life and contribute to mental health problems such as depression, anxiety, and psychopathology in persons with epilepsy.[5,57]

Factors Associated With Social Problems

Empirical research carried out to identify factors associated with social dysfunction in persons with epilepsy identifies the following as risk factors:

- Severe and frequent seizures
- Presence of other chronic conditions or deficits
- Cognitive impairment and academic underachievement
- Negative attitudes toward epilepsy
- Inadequate knowledge about epilepsy
- Lack of a supportive family environment

Although social problems are more common in persons who have a chronic physical condition, youth with epilepsy have been found to have a poorer social functioning than youth with other chronic physical conditions.[4,19,88] Studies indicate that disruption in social functioning is greater for persons with severe epilepsy and other neurologic deficits or disabilities[29,56,100] than for those with epilepsy alone. Moreover, higher seizure frequency is generally found to be related to poorer social functioning.[6,17,20,59,60] Other seizure variables have not been found to be consistently associated with poorer social functioning. For example, Camfield et al.[25] did not find epilepsy-related variables (e.g., age at onset, seizure type, cause of seizures), neurologic deficits, and encephalographic data (e.g., focal slowing) to be strong predictors of social dysfunction in a sample of children and young adults with normal intelligence. Furthermore, even remission of epilepsy did not significantly predict social dysfunction. Only a learning disorder and >21 seizures before initiation of treatment were associated with at least one unfavorable social outcome in this population-based study.[25] In addition, poor cognitive functioning[26] and poor academic achievement[101] have also been found to be positively related to social problems in children with epilepsy.

Although most research identifying high rates of social problems are carried out on samples of persons with chronic epilepsy, studies of persons with new-onset epilepsy also indicate that social difficulties occur very early with the disorder. For example, Chaplin et al.[29] found that >10% of adults with recently diagnosed epilepsy rated four problems related

P.2238

to social functioning (fear of seizures, employment concerns, concerns about leisure, and decreased energy) as severe.

Negative attitudes toward having epilepsy have been found to be related to psychosocial problems in children with epilepsy.[13] Sometimes, negative perceptions about epilepsy are caused by excessive fears about seizures.[80] Austin and colleagues[8,16] found that children with new-onset epilepsy and their parents had many unfounded fears about seizures and their treatment, and greater concerns and fears have been associated with more-negative attitudes about having seizures.[11] Lack of accurate knowledge about epilepsy has been found to be associated with greater social anxiety and lower self-esteem in adolescents.[20]

The whole family is confronted with coping with the epilepsy. Studies exploring relationships between the family environment and social functioning in children indicate that family factors are related to social functioning in the child.[88] Austin et al.[17] found family stress, extended family social support, and family mastery and control to be related to psychosocial functioning. Lothman et al.[72] found praise in mother–child interactions to be related to child competence. What is not as well delineated is the nature of the relationship between the family environment and social functioning because most of the research is cross sectional. It is not known whether both the family and the child are reacting to the epilepsy, whether environment leads to social problems for the person with epilepsy, or whether the family is responding to the child's problems.

Few studies have been conducted on family environments of adults with epilepsy to identify whether there are factors that are associated with social problems. Thompson and Upton[103] found that caring for an adult with intractable epilepsy is quite stressful for the family. Approximately two thirds of the primary caregivers were dissatisfied with limitations on their social activities and intimate relationships. Caregivers identified the need for respite and increased social support.

In summary, although more research is needed to identify all the factors that lead to problems with social dysfunction, research has identified broad categories of variables that place persons at risk for social problems. It appears that a chronic, difficult-to-control condition and the presence of other deficits or disabilities are risk factors for social problems. Moreover, knowledge about epilepsy, how persons feel about having seizures, and characteristics of the family environment are related to social functioning in persons with epilepsy.

Developmental Tasks and Social Problems

Disruptions in social functioning in children need to be considered within the context of normal psychosocial development because epilepsy can interfere with the accomplishments of age-appropriate tasks. Furthermore, because epilepsy affects the whole family, it is important to consider how family factors influence the psychosocial adjustment to epilepsy.

Early and Middle Childhood

In early childhood, children need an environment in which they are able to become increasingly independent. They have daily routines and learn to master toilet training and other self-care activities, communicate with others, and become socialized.[22] For optimal psychosocial development, these children need an environment in which they can develop autonomy and initiative.[51] If parents are overly protective and concerned about the possibility of a seizure, they may overrestrict the child's activities and hinder the development of life skills. A recent study found increased levels of parental anxiety about their child's epilepsy was associated with poorer socialization in the child.[27] In middle childhood, children become more independent of parents. There is empirical evidence that children with epilepsy can have problems with completion of some of these developmental steps. For example, children with epilepsy have been found to be more dependent than children with tonsillectomies.[52]

Child social development has been found to be associated with parenting behaviors. Social maturity and social skills in children with epilepsy were found to be positively related to parental strictness. Lothman et al.[72] studied parenting behaviors in mother–child interactions and found praise to be related to child competence and child positive affect. Conversely, intrusive and overcontrolling parenting behaviors were related to decreased child autonomy and child confidence. In a recent longitudinal study, parent support of the child's autonomy predicted a better psychosocial adjustment.[10]

Adolescence

The primary developmental challenge of adolescence is identity formation.[22] Ideally, adolescents should begin adulthood with a strong sense of self and physical competence. Failure to develop a strong sense of self as competent can lead to problems with poor self-esteem and feelings of being different from others. Another important developmental task for adolescents is becoming independent and separating from the family of origin. Peer-group membership plays an important role in the social development of adolescents and in their becoming independent of their family. A recent study,[18] however, suggested that the social environment might not be supportive of the social development for the adolescent with epilepsy. In that study, adolescents in the general population were found to have a poor understanding of epilepsy. Almost three fourths believed that adolescents with epilepsy would be more likely to be bullied or “picked on” by others than other adolescents, and less than one third indicated that they would date an adolescent who had epilepsy.[18]

Young people with epilepsy can have problems meeting the developmental accomplishments of adolescence. The presence of a chronic condition such as epilepsy can interfere with the development of a strong sense of physical competence. Parental overprotection can deprive the child of experiencing the feelings of competence and, subsequently, affect later self-esteem.[76] The occurrence of seizures and the need to take medication can lead to a reduced sense of physical competence. The stigma associated with epilepsy can negatively impact how adolescents perceive themselves, socially and physically. A recent study indicated that adolescents with intractable epilepsy perceived that their having epilepsy set them apart from their peers.[47] Even adolescents with newly diagnosed epilepsy have been found to feel different from their peers and worry about being teased by them.[8] The episodic loss of control caused by seizures also can make it more difficult to become independent and separate from families. The inability to drive a car at an age-appropriate time can be a major problem for adolescents with epilepsy because it limits opportunities for developing independence and participation in social activities.[33]

A final way the presence of epilepsy might affect social functioning is poor academic performance. Success in school facilitates the development of initiative. School achievement also provides an opportunity for young people to receive recognition from others and to derive a sense of accomplishment. The school problems found in adolescents with epilepsy[19,79] reduce opportunities for the development of a sense of pride and accomplishment at school and also place these children at risk for later vocational problems.

Adulthood

Studies of psychosocial function of adults with epilepsy have many methodologic problems. Studies regarding these issues

have mostly been clinic based, thus limiting generalization to the whole population of people with epilepsy. Recent research[102] was carried out in the north of the Netherlands concerning the quality of life reported by 210 adults with epilepsy and an average IQ of 101; 75% had a high school education or more. Of this group, 69.5% reported no social problems, 25.1% mentioned problems with adaptation, 5.5% reported feeling isolated or suffering from other problems in this area, and 89.7% mentioned no financial problems. Various subscales on health, self-confidence, coping, loneliness, stigma, life fulfillment, and psychological problems did not show many problems. It appeared as if early-onset epilepsy leads to adaptation and does not much influence the quality of life. The outcome of this study differed from those of many others probably because this was performed among a group of people with epilepsy living in the community rather than a clinic-based sample.

Being employed is an important predictor of quality of life of people with epilepsy. The World Health Organization also mentions the importance of employment for social health and, therefore, improved quality of life. It is widely recognized that a large number of people with epilepsy experience particular difficulties in gaining access to employment and vocational training on equal terms with other sections of the population, and it is also acknowledged that this situation is likely to get relatively worse, not better. Most figures concerning employment rates of people with epilepsy indicate that they do not perform as well on the labor market as others do. Although both research figures and research groups vary, unemployment rates generally are higher for people with epilepsy than for the general population.

Early employment studies showed that the situation for people with epilepsy was discouraging. Jacoby[64] found that 50% of people with epilepsy were unemployed, and Scambler and Hopkins[91] reported that 42% were unemployed. A research project set up among people with epilepsy in The Netherlands who were being treated at 10 special outpatient epilepsy clinics showed that compared to the general population, the study group tended to have a lower educational and a lower vocational level than the general Dutch population.[102] Of the study group, 44% were employed and 49% were unemployed (7% were in school).[34,86] A more recent study by Jacoby showed that when seizures are well controlled and there are no other handicaps, people with epilepsy do not experience employment problems.[65]

Young people with epilepsy especially are at a disadvantage when it comes to obtaining and retaining employment and may need special assistance and training to enable them to deal with difficulties they are likely to encounter. Even when the epilepsy is controlled, many find that their epilepsy is a barrier to employment.

Concerning marriage, Dutch research showed that 66.2% of patients were married and 14.8% were still living with parents.[102] This figure may be influenced by age, or there may be a regional (cultural) effect. Data from Montreal[32] showed that among study participants who developed seizures after the age of 20 years, 91.7% of women and 76.2% of men were married before the onset of seizures. These proportions were similar to those for the general population. However, if seizures occurred in the first decade, marriage were lower than expected for the general population. The rates were 32% for men and 58% for women. Ounsted and Lindsay[82] found that among their sample of 100 young people diagnosed as having temporal lobe epilepsy, the prognosis for marriage was good for girls (92% of them married), whereas only 41% of the boys married, even though they were not heavily handicapped. Pierzchala and Grudzinska[83] reported that of a group of 243 patients with epilepsy, 50.6% of men were married, which is a lower rate than both women with epilepsy and the general population. Follow-up studies on people with epilepsy in the 1946 British birth cohort show very little difference concerning marriage between both uncomplicated and complicated cases and their controls at the age of 26 years.[23]

For many (young) people, marriage is one of the main goals in life. For a person with epilepsy, however, the chances of getting married can be particularly slim in the Third World. In some countries, a woman with epilepsy has virtually no chance of getting married at all, or when she does, epilepsy is a reason for an immediate divorce. In India, although the law forbidding people with epilepsy from getting married was repealed recently, such people still stand no chance of an arranged marriage, which is customary in that part of the world. Fundamentalist groups in many religious cultures, following ancient laws, still believe that epilepsy is inheritable, and of course these laws were originally intended to prevent the disease from spreading. Having epilepsy appears to affect the chances of marriage in the developing world as well as in the developed world, based on the erroneous idea that people with epilepsy are uneducable, unemployable, and a danger to the community; epilepsy is widely considered to be an inheritable disease requiring restriction of its spread. The severity of the epilepsy does not seem to make any difference in relation to marriage: Having seizures at all diminishes the chances.

There is a large literature on the medical aspects of pregnancy and epilepsy; however, the social aspects seem to be a neglected area. For the future mother with epilepsy, there are even more questions concerning having children than for other women. The questions include the following:

- Will my children also have epilepsy?
- What will happen to my seizures during pregnancy? Will they harm the baby?
- What is the effect of my medication on the baby?
- What happens if I have a seizure during delivery?
- Can I take care of a child safely?
- What changes do I need to make to take care of the child?

Up-to-date information concerning these often emotional questions is extremely important because the fear that they cause might not be verbalized. It is of the utmost importance that future mothers be able to discuss their desire for a child with the physician who treats their epilepsy. The importance of a good relationship between doctor and patient is vital.

Various practical measures for taking care of a baby may include sitting on the floor during feeding and washing and dressing the baby on the floor as well. Bathing should not be done when the mother is alone with the baby. When common sense and practical precautions as just described are applied, much of the fear of future mothers is in fact not necessary.

Epilepsy in a parent may have an impact on the family system. Few studies have explored the effects on child development of having a parent with epilepsy. Aldenkamp et al.[2] found acceptable patterns of communication about epilepsy between parent and child; 80% of the children were informed about their parents' seizure before witnessing one. This is contrary to the results from a study by Lechtenberg and Alkner,[68] which found little communication about the epilepsy. Information about epilepsy given before a child witnesses a seizure proved to be important for the adaptation of the child and prevention of serious personality disorders. The findings of the Aldenkamp study support the belief that children benefit from adequate information given in open and frank communication with their parents.

People with epilepsy sometimes state that it is very difficult, or even impossible, for them to make friends. This maybe caused, however, by their own attitude toward the disorder. Some people wear their epilepsy as a shield in front of them, thus creating a self-fulfilling prophecy, almost introducing themselves as a person with epilepsy. Friends probably

should know about the epilepsy, but only when it is active. The following points to should be kept in mind:

- Do not scare the other person with your epilepsy.
- Only talk about your own epilepsy and your own seizures.
- Explain what happens when a seizure occurs.
- Explain what people can do to help.

When these rules are applied, neither the epilepsy nor the seizures should stand in the way of friendship.

Guidelines for Daily Living

Risks at Home

Most accidents happen at home; this generalization applies to everyone, simply because we spend so much time there. Still, for people with epilepsy, there are extra risks, some of which can easily be avoided, as the following suggestions show:

Living Room

- An open fire or stove should be surrounded by a shield; sharp radiators should be covered (e.g., a wooden shield).
- Furniture should not have sharp edges.
- Unbreakable glass should be used in any windows below neck level.

Kitchen

- Gas or electric stoves can be protected with a low shield on top, as used for children.
- Microwave or induction cooking may be used.
- The hot water tap should be fitted with a temperature-control device.
- Electric tea- or coffeemakers are less risky than a hot water kettle.

Bathroom

- The door should be made to open from the outside.
- Baths should not be taken when the person is alone in the house.
- Showering is safer than bathing; any glass windows in the shower should be of unbreakable glass.
- The water taps must be fitted with a temperature-control device.

Bedroom

- If a person tends to fall out of the bed following seizures, a mattress may be placed on the floor. This is less restricting than a shield around the bed and it is quite safe.

Risks at School

Parents and teachers should avoid implementing rules for a regular and quiet life for children with epilepsy. Although fatigue and sleep deprivation may provoke seizures in some people with epilepsy, nothing should be left out of the lives of children with epilepsy unless it would be dangerous in that particular person. Education of parents, teachers, and children with epilepsy should decrease unsubstantiated fears about the condition and the implementation of unnecessary restrictions on their activities. Decisions must be made about participation in activities. The children should participate in this decision making about their participation in activities from a young age; otherwise, they might have difficulty in accepting real restriction or precautions. It is obvious that living a full, independent life between the seizures involves taking risks for everybody, and taking risks implies that, with statistical certainty, accidents will occur.

Risks at Work

The vast majority of jobs are suitable for people with epilepsy. When medical advice is sought about the suitability of particular jobs for people with epilepsy, the guidance given should take into account the requirements of the job, known facts about epilepsy, and the nature of the individual's seizures. More specifically, decisions should take into account information concerning the individual's epilepsy, such as the following:

- The diagnosis and prognosis of the individual's epilepsy
- Description of the seizures, including aura
- Seizure frequency
- Time pattern in which seizures occur (e.g., only during sleep)
- Recovery time
- Date of last seizure
- Any safety issues
- Medication

One area of misunderstanding is the prevalence of seizures caused by visual stimuli.[78] A recent comprehensive review of the empirical literature indicated that the chance of having a seizure caused by light or pattern is only 2% to 14% in people with epilepsy.[50] Children appear to be more vulnerable to visual stimuli than are adults. Therefore, blanket prohibitions should be avoided. Besides, often simple precautions can be taken to reduce the risks in the workplace, such as providing a chair with armrests to prevent the person from falling when having a seizure. In jobs known to carry a high degree of physical risk to the individual worker or to others, the organization of work practice should be examined to reduce this potential risk to an acceptable level. Only in those situations in which this cannot be achieved are restrictions on the employment of people with epilepsy justified.[63]

Traveling

Many people have the vague notion that persons with epilepsy are unfit to travel alone. Parents have nightmares of their children having a seizure in front of a train. In fact, traffic accidents caused by seizures are rare, and using public transport is possible for most people with active epilepsy. Traveling abroad is another issue of concern for many people with epilepsy and their caregivers. Having a seizure in a train or an airplane, however, is no more dangerous than having a seizure at home. An epilepsy “passport” assisting people with epilepsy when traveling abroad containing information on epilepsy in many languages may be very useful and is available in a number of countries. The International Bureau of Epilepsy (IBE) had developed such a passport, but this is now out of print. It would be useful to develop such passports either on a national or a regional basis. Holidays are organized by a number of IBE member organizations. All of these programs have one thing in common: They prove that epilepsy presents no constraint to traveling. Individuals who have frequent seizures, however, need to make sensible travel arrangements. Some general rules apply:

- Travelers need to take medication with them, preferably two sets, with one packed in the hand luggage and one in the checked bag.
- A letter from a doctor explaining the epilepsy and medication can be helpful (especially when dealing with

customs).

- Travelers need to have appropriate travel insurance.
- Taking an epilepsy "passport" (as mentioned previously) is useful.
- Information issues concerning travel can be sought from a national epilepsy association or the IBE.

Cycling

In the literature, cycling is not considered more dangerous to people whose seizures are well controlled than to anybody else, and normal precautions should be taken, which may include wearing a helmet. If seizures are active, busy roads are best avoided, and cycling in the company of a supervisor may be advisable. All children will want to ride bicycles; in some countries, it is a regular part of growing up, and blanket restrictions may result in covert cycling in unsupervised situations, causing a greater danger than properly managed cycling. Furthermore, the use of tandem or properly fitted three-wheeler bikes can enable people who have frequent and severe seizures to ride a bike, thus offering them the feeling of freedom that comes with this activity.

Leisure Activities and Club Membership

Health professionals are often asked to give opinions about the risks for people with epilepsy engaging in leisure activities. Although this is an understandable question, there are no rules concerning risks for people with epilepsy in general, and no systematic study into such areas of ordinary daily activities has been made. It is, however, a well recognized that leisure activities such as going out and joining a club are highly desirable, especially for young persons when growing up and learning social skills, whether they have epilepsy or not. It also adds to the quality of life for adults. Going out may involve going to discotheques, which is a normal part of growing up and should not be avoided by young people with epilepsy who seek a full social life. Some people may find flashing or flickering lights unpleasant, but generally it is only bright white "strobe" lights operating at >5 flashes per second that may induce a seizure in some people with epilepsy.

Sports

Interest and active participation in sports is growing. Although studies do not indicate that people with epilepsy are at greater risk of developing seizures during various types of sports, it is assumed that fewer of them participate actively than might want to do so. Information on this or the advice given to people with epilepsy about active sports is not available. A survey in the Netherlands among patients and doctors showed that people with epilepsy are relatively interested in sports. Active participation is limited when either the doctor or the person with epilepsy sees epilepsy as a restricting factor. Clear advice from the professional is essential.[62] This advice should be based on the following rules:

- The risks following a seizure during sports depend on the type of seizure.
- When advising people with epilepsy concerning active participation, three categories of sports can be distinguished:
  - Sports with no restrictions.
  - Sports with some restrictions (safety precautions).
  - Sports that are prohibited.
- The risk of having a seizure during sports is usually smaller than during the relaxation period afterward.
- Sports, including contact sports (team sports) and fighting sports, generally do not provoke more, or more serious, seizures.
- Epilepsy is never a reason for not partaking in competitive sports at any level.
- Epilepsy is never a reason for denial of membership in a sports club.

- Besides to normal safety precautions, special guards need to be available with sports in or around water.
- Instructors and trainers need to know what to do when a seizure occurs.

(This list is the outcome of a symposium on epilepsy and sports organized by the Dutch League Against Epilepsy in 1989.)

Swimming

Most fatal accidents in epilepsy occur in the water (60%). However, very few people with epilepsy drown during swimming. Most accidents occur in the bath, while fishing, or from falling into water. As noted, research shows that very few seizures occur during active sports. They do occur, however, in the rest period afterward (e.g., when resting alongside the swimming pool). Still, certain precautions need to be taken in or around water when a person is not seizure free:

- Swimming in open waters is ill advised because first aid, in the case of a serious seizure, presents extra difficulties.
- Supervision is necessary.
- A person with epilepsy should never go into the water alone.
- When people have active seizures, they should have a person with lifesaving skills present.

Services for Facilitating Social Adjustment

The increased prevalence of social problems in people with epilepsy emphasizes the need for a comprehensive approach to treating people with this condition. Although seizure control is a critical factor affecting social function, managing the consequences of seizures on one's daily life is often the most challenging component of epilepsy care. Health care professionals must be aware of the multiple causes of social problems, how to screen for their occurrence, and how to provide appropriate referrals, education, and treatment. In addition, recent research highlighting the increased incidence of cognitive, mood, and behavior problems in children and adults with epilepsy stresses the need to identify and treat these problems early before the psychosocial consequences become intractable.

The ultimate goal of support services is to help persons with epilepsy and their families become as socially capable and competent as possible and live independent self-directed lives. Ideally, models of care and support systems will "foster empowerment and independence for people with epilepsy and support their efforts towards improved seizure control and a positive quality of life."[49] Critical elements that must be considered when making decisions about services include the following:

- Comprehensive assessments should be carried out on a regular basis.
- Early referral to services is recommended to prevent and treat social difficulties.
- Support services should be matched to specific needs of the persons with epilepsy and their families.

P.2242

- Services should embrace the concepts of self-management and self-determination for persons with epilepsy and their families.

Comprehensive Assessment

Because a full explanation for the development of social problems is not available and persons with new-onset seizures have social concerns, it is important that the social functioning of all persons with seizures be assessed on a regular basis in the clinical setting. Moreover, persons with epilepsy can have different needs at different developmental stages. Therefore, it is important regularly to complete a comprehensive assessment of patient and family needs to obtain information critical to planning services to prevent and reduce social problems. A comprehensive assessment should provide the basis for designing intervention programs and services to enhance the quality of life of persons with epilepsy and their families. In the assessment, it is important to include both psychosocial functioning and the factors that are associated with social problems.

Assessments incorporating a functional status approach commonly used by nurses and rehabilitation specialists are easy to use in clinical settings and can help patients and families to identify target concerns, individualized goals, and treatment strategies. Assessments are generally carried out using structured interviews, rating scales, and self-report questionnaires. Some assessment instruments have norms, so results can be compared with general population norms or other populations. Areas of assessment and examples of scales to use in each area include the following:

Knowledge About Epilepsy and Its Treatment

- Fear of Seizures[80]
- Epilepsy Myths and Misunderstandings Questionnaire[48]
- Information Needs of Parents of Children with Epilepsy[31]
- Parent Need for Psychosocial Care Scale[9]
- Child Need for Psychosocial Care Scale[9]
- Learning Needs of People with Epilepsy[39]
- Knowledge of Women's Issues in Epilepsy[71]

Attitudes and Psychosocial Problems

- Rosenberg Self-Esteem Scale[90]
- Child Behavior Checklist[1]
- Child Depression Inventory[66]
- Washington Psychosocial Inventory (Adolescents)[21]
- Washington Psychosocial Inventory (Adult)[45]
- Child Attitude Toward Illness Scale (CATIS)[13]
- Quality of Life in Epilepsy[35]
- Child Stigma Scale[14]
- Parent Stigma Scale[14]
- Epilepsy Self-efficacy Scale[38]
- Epilepsy Self-management Scale[37,40]
- Epilepsy Regimen Specific Support Scale[40]

Family Environment

- Family Support Scale[46]
- Family Inventory of Resources for Management[77]
- Family APGAR[12,98]

Matching Services With Needs

Early referral to health care professionals, rehabilitation specialists, and educators is recommended for proper recognition and treatment of both seizures and their consequences. Because needs of patients and families may be assessed and prioritized differently by health care professionals and patients, incorporating the patient's perspective into the care planning is critical. Services and interventions can then be tailored to the individual and patient-centered goals established.

Types of Services

Programs and services for addressing social functioning may include various educational approaches, counseling, social skills training, cognitive rehabilitation, support networks, peer mentoring, vocational rehabilitation, and independent living programs. Many different health care providers and community-based rehabilitation and educational specialists may provide these services, depending on their areas of expertise and practice setting (i.e., nurses, social workers, psychologists, psychiatrists, educators, vocational rehabilitation therapists, recreation therapists, and resource specialists).

With the changing health care environment in many countries, care is increasingly being provided in outpatient settings. Residential programs, however, are still available in some countries. Specialized epilepsy centers offer the ability to provide education, counseling, and supportive services in both inpatient and outpatient settings and by professionals with expertise in epilepsy. Guidelines have been established by the National Association of Epilepsy Centers in the United States that incorporate the critical services that should be provided at level three and four epilepsy centers to provide education, counseling, neuropsychological evaluations, educational and vocational assessments, and rehabilitation services.[81]

Unfortunately, many people do not have access to specialty centers, lack insurance coverage, or are not referred to these services until secondary disabilities and social problems are difficult to treat. In these instances, a “shared control” concept of care between general neurologist and a specialized epilepsy program or between the person's health care providers and community-based agencies, support services, and rehabilitation specialists is often implemented.[95]

The Internet is increasingly becoming a major source of information, education, support, and resources. When used to supplement medical care, the Internet serves as a fascinating way to connect people with resources and support previously not accessible to many. Online support groups via community forums, information and education provided by reputable epilepsy organizations, academic distance learning, and job search programs hold the promise of overcoming major barriers for people with epilepsy such as the need to drive to be able to access needed services.

Self-management Education

Educating people with epilepsy and their families should be geared to more than just imparting information and should involve skill development and resource identification. Ideally, education should assist people in managing their epilepsy and its consequences. This process, often termed epilepsy self-management, can also be thought of as taking the steps necessary to manage seizures and their impact.[36]

Common components of self-management have focused on seizure, medication, and lifestyle management.[24,96] A psychosocial model of self-management has focused lifestyle management on stress and safety while adding the critical need to manage information and disclosure.[41,42] Other issues involving accessing care, managing health needs, and addressing social relationships and community living suggest that psychosocial concerns need to be addressed as an integral part of epilepsy education and care.[94]

P.2243

Research into predictors and outcomes of self-management programs are sparse. Self-efficacy, or self-confidence in managing epilepsy, and patient satisfaction have been found to be important variables in epilepsy self-management, particularly medication management, and social support, stigma, depressive symptoms, and outcome expectancies influence self-efficacy.[43] Self-efficacy, together with locus of control and social support, has important influences on quality of life as well.[3]

Tailoring epilepsy education to individual needs is considered a critical element of program planning. Because responsibility for caring for children with chronic conditions rests primarily with the family,[61] the best way to enhance social functioning in children is to provide needed services to families. According to Dunst et al.,[46] addressing families' needs helps to empower them to successfully manage chronic conditions in family members. Interviews with families of children with new-onset epilepsy indicated that they had many learning needs, including the need for education about epilepsy, treatment issues, and strategies for managing the epilepsy.[16] Included in the strategies for management were parents' needs to handle the responses of others to their child's seizure disorder and to help their children to cope successfully. A recent psychoeducational intervention in which the information and support were tailored to the individual needs of the family members showed significant increases in knowledge about epilepsy for both children with epilepsy and their parents. In addition, after the intervention, these children had fewer worries and need for information, and their parents had significantly less need for information and support related to their child's epilepsy.[15]

Dilorio et al.,[39] in an assessment of learning needs, found that adults with epilepsy had a strong wish for information about the condition and how to manage it. Needs were identified in the following rank order: Information on medication, seizures, psychological factors, basic brain functioning and seizure causes, and general lifestyle factors.

Very few educational programs have been systematically evaluated for effectiveness and reported in the literature. Studies of psychoeducational groups for adults with epilepsy using the Sepulveda Epilepsy Education (SEE) and Modular Service Package Epilepsy (MOSES) programs have demonstrated positive outcomes (e.g., knowledge, coping, and seizure outcomes).[55,73] Study of 6-week structured program for adolescents with epilepsy and their parents using cognitive–behavioral strategies and support suggests a positive influence on quality of life; however, the sample size was quite small.[99] Finally, Lewis et al.[69,70] evaluated an intervention program for children with epilepsy and their parents and found that an educational program increased parents' knowledge about epilepsy, decreased parents' anxiety, and increased children's perceived social competence.

There are many other educational materials and programs that have been developed by specialized epilepsy centers or national organizations, such as the International Bureau for Epilepsy and country-specific organizations such as the Epilepsy Foundation in the United States. Most often programs are implemented on the community level and tailored to the needs of the learner for maximum effectiveness.

Unfortunately, research into the benefits of individual epilepsy education is sparse. A study of community-based specialty nurses demonstrated improved knowledge of people with newly diagnosed epilepsy, supporting the benefits of shared care in epilepsy between specialists and community-based professionals.[87] In addition, a recent nurse-led education intervention for adults with uncontrolled epilepsy showed a significant improvement in quality of life compared to a control group.[54] In this study, the areas of greatest improvement were physical limitations, health discouragement, and medication effects.

Recent advances in our understanding of self-management and health education have important implications for educational programming. In addition to giving information, improving the learner's self-efficacy or confidence and building social support networks also may be important strategies for managing social problems.

Counseling

Counseling approaches in epilepsy care are frequently used to address social problems, both individually and in group settings. Mental health counseling may help people to adjust to the challenges of living with epilepsy and treat comorbid conditions such as anxiety and symptoms of depression. Desired outcomes include improved attitudes related to the epilepsy and social functioning, as well as treatment and/or prevention of psychiatric complications. People who experience changes in seizures with emotional distress or stress may also use counseling to improve seizure control. Finally, group counseling can provide important opportunities for learning social skills and gaining support from others with similar problems.

Approaches may include psychotherapy, cognitive–behavioral techniques, and other stress management approaches. Combining or supplementing self-management education with counseling can help to build a person's self-efficacy or confidence in living with epilepsy. Because epilepsy affects more than just the individual with seizures, addressing family dynamics and problems is an important part of epilepsy care.

Counseling can also be provided by specialists in recreation therapy. Recreation therapy appears to be especially appropriate for persons with epilepsy because of their problems with social isolation and lack of satisfactory peer relationships. For example, Regan et al.[85] combined education and counseling with a recreational activity (a ski trip) and found improvement in self-concept.

Social Skills and Cognitive Rehabilitation

Some people with epilepsy have impaired social skills and cognitive problems that may be due in part to underlying brain dysfunction complicated by the effects of seizures and medications on their brain function. Rehabilitation professionals with expertise in brain injury and epilepsy can teach social awareness and help patients to learn social skills and develop specific strategies to compensate for cognitive problems such as memory deficits. These services can be provided within many specialized epilepsy centers, outpatient rehabilitation settings, and community-based programs.

Self-help and Support Groups

Self-help groups generally are groups of peers who have joined together to help each other with a common problem. Self-help groups can lead to improved social function by extending social networks, providing new opportunities for social learning, and changing cognitive perceptions about one's condition.[67] Courses have been organized to standardize methods for self-help groups in Italy.[84] In the United States, support groups can be found in many communities, established by individuals, health care facilities, or nonprofit agencies. The Epilepsy Foundation and affiliates offer support groups and networks that are often targeted to specific groups such as parents, teens, and women. Increasingly, varied ways of providing support are being tried, such as phone networks, online forums, and individual mentoring.

P.2244

Vocational Rehabilitation

Because employment is a major problem for many people with epilepsy, all adolescents and adults should receive vocational counseling. Needs can include help in identifying medical and social factors that may affect employment, assisting people to become job-ready, educating potential employers about epilepsy, assisting with job searches, teaching people to develop new vocational skills that will build on strengths, and teaching people new vocational skills and how to find reasonable accommodations.

Independent Living Programs

Independent living programs aim at enhancing independence and self-determination for people with epilepsy. These programs may be provided in residential settings for people with significant difficulties living independently. Many people with less severe functional problems may still experience difficulties living on their own and can benefit from teaching and assistance in developing critical skills such as personal care, budgeting, home management, transportation, shopping, and other independent living skills. Funding for these services may be problematic, but some federal health or disability insurance or private agencies may help.

Summary and Conclusions

We have outlined some of the major social problems found in persons with epilepsy and placed them within the context of tasks of normal psychosocial development. We also have identified some of the risk factors for social dysfunction, provided some examples of instruments that might be used for a comprehensive assessment, and reviewed different types of services for facilitating social functioning. Although many persons with epilepsy function well socially, others experience difficulties. We propose that comprehensive assessments be carried out on a regular basis to facilitate early identification of social problems and referral for rehabilitation services. In addition, recent studies suggest that educational interventions can be helpful for persons with epilepsy.

Chapter 219

The Range of Needs and Services in Vocational Rehabilitation

Rupprecht Thorbecke

Robert T. Fraser

Introduction

The employment concerns for individuals with epilepsy have been repeatedly documented in the literature. The Epilepsy Foundation generally cites an unemployment rate of 13% to 25% for people with epilepsy in the U.S. labor force.[43] An earlier study by Emlen and Ryan[25] suggests that this statistic pertains to those who are maintaining an active job search. If persons who have been discouraged from seeking work were additionally included, the unemployment statistic would be closer to 34%. In the study of Emlen and Ryan, individuals having one or more generalized tonic–clonic or complex partial seizures a year had an even higher unemployment rate of 50%.

From an international perspective, the situation does not look appreciably different. A study from the United Kingdom[24] revealed an unemployment rate for vocationally active patients with epilepsy of 46%, compared with 19% in an appropriate age- and sex-matched group. A study from an Irish clinic[9] showed, for a period of 12 months, an unemployment rate of 34% in men, which compared poorly with the unemployment rate of 13% in the general population. A German study[7] found that 24% of a group of epileptic persons were unemployed, with unemployment in the general population being 8% to 10%. Mean duration of unemployment was 30 months, compared with 11.6 months in the general population. In an epidemiologic study in Germany in 1995, 29% of persons with epilepsy in the labor force were unemployed, with general unemployment being 10.4%, and 15% for persons with a disability certificate.[60] In a Finnish study, a cohort of 245 children younger than 16 years was recruited for a long-term follow-up. Thirty years later, of those with uncomplicated epilepsy 64% were seizure free for 5 years or more. In comparison to a matched control group 31% of those with epilepsy were unemployed, while 8% of the controls were unemployed. Further analysis gave hints that nonidiopathic etiology and learning disability might be relevant for these differences.[70,71] A caveat in understanding unemployment rates among this disabled group is that many studies have used populations from epilepsy clinics that are more severely impaired. For the United States, the Emlen and Ryan study,[25] which utilized a pharmacy register, and for Germany the Pfaefflin May study would be most representative.

Earlier studies have indicated that people with epilepsy can also be overrepresented in unskilled and semiskilled positions.[47,62] They may also drop out of the workforce prematurely.[59] In Germany in 2004, the mean age for early retirement because of illness or disability was 50.4 for men and 49.1 for women years, whereas for those with epilepsy it was 45.6 and 43.2 years, respectively. In addition, 12.1% of all men and 14.4% of all women with illness or disability retiring early were below 40 years of age, compared with 27.2% of men and 35.4% of women retiring because of epilepsy. These employment statistics are chiefly from industrialized countries, and the work difficulties experienced by persons with epilepsy in developing countries are not well documented.

It is of interest that in a German study up to 60% of employees with epilepsy had active seizures, but 70% had them outside work.[22] In an English study,[11] 51% of employees with epilepsy had a seizure at work, and this was even higher in a Tunisian study.[39] It is also of interest that risk of accident related to seizures in the workplace is either not higher than the nondisabled[52] or slightly higher and yet inconsequential as compared to impairing injury.[81,84] It is interesting to observe that in the European study 3% of persons with epilepsy (PWE), in contrast to 1% of controls, had an accident at the workplace in 24 months (p <.01); however, when seizure-related accidents were omitted the accident rate of PWE fell only to 2.5% (p <.05), indicating that medication side effects and neurologic deficits could be a more important factor.[81]

There is broad agreement in the literature that the employment problems of people with epilepsy cannot be reduced to one factor (i.e., seizure severity), but that they are rather the result of a bundle of adversive factors interacting with each other in a complex fashion. These factors include a lack of education and vocational training, neuropsychological deficits, lack of information, social isolation and resulting social skills deficits, and negative attitudes on the part of the family or employers. Unemployment appears to be minimally two to three times that of the general population (e.g., as shown in the 1979 Emlen and Ryan general pharmacy sample[25]) and still worse within the populations of specialized epilepsy clinics.

There appears to be two major issues. One is that of initial job access after secondary school. For example, at the University of Washington Epilepsy Center, vocational clients requesting services have approximately 13 years of education, which usually comprises high school and some additional community college course work. The common theme is that no specific vocational entry or transition plan exists, and youngsters with the disability simply “go on” to further community college training because it is considered “normative” despite often pronounced impairments. A second major issue is that people with epilepsy in the workforce often must deal with repeated and long periods of unemployment. It seems that these persons are a group with a specific cluster of problems and that their employment situation can be definitively improved by employment services addressing these problems as a whole rather than focusing on one simple concern, such as seizure status.

It is important to note that there is not one, but several profiles for job-seeking groups with epilepsy. Chaplin,[12] for

purposes of understanding intervention needs, has proposed four categories of employment seekers with MS:

Group 1: Individuals with seizure control, a good work/educational background, and requiring minimal intervention other than some disclosure training.

Group 2: Those with acceptable seizure control, but unrealistic career goals based upon personal capacity. Vocational assessment (to include situational) can be very helpful.

Group 3: Those with unsatisfactory seizure control and interactive cognitive and emotional difficulties. They require comprehensive vocational and psychosocial intervention to achieve employment.

Group 4: Individuals who are typically not able to maintain competitive work due to seizure type, frequency, cognitive deficits, etc., and have typically required sheltered and supported work.

Traditionally, the latter group has been employed in sheltered workshops. There is now, however, a strong movement in bringing this group out of sheltered employment into the open labor market, and it is important to consider the implications of this movement for those currently in sheltered settings. It is beyond the scope of this chapter to review in detail vocational strategies for persons with epilepsy and associated disabilities—the associated disabilities can be a greater source of impairment than the epilepsy. New movements and legislation have brought about exciting developments in vocational rehabilitation for persons with epilepsy, but substantial challenges remain to include funding.

Postsecondary School Vocational Assessment

Unquestionably, a successful transition after secondary school into suitable employment or targeted vocational training is the best groundwork for stable employment in adult life. Nevertheless, studies or demonstration projects attempting to isolate the factors relevant for successful transition are surprisingly scarce.

Vocational Interests/Work Values

Some research is available that is specific to the vocational interests of individuals with epilepsy. Schultz and Thorbecke,[67] in a study of 116 people with epilepsy, including young adults, being assessed vocationally, found that initially 47% desired training for an occupation in the field of social sciences, for example, nurse or educator. As a result of the assessment, however, no one was recommended for training in this area. Fraser et al.[34] studied the vocational interests of 47 male and 24 female patients with epilepsy attending the University of Washington Regional Epilepsy Center using primarily the six major occupational scales and three special scales of the Strong-Campell Interest Inventory. Male patients with major motor seizures had lower Academic Orientation and Investigative scores than male normal controls (p <.01), and male patients with early-onset epilepsy had lower Investigative scores than normal controls (p <.01). Female vocational interests were not significantly different from those of the normal control group. The authors concluded that in line with previous research, male patients appear to be more greatly affected developmentally by epilepsy and that disability alone does not influence vocational orientation, but rather severity of the disability and age at disablement. The authors suggest supportive counseling, social experiences, and involvement in "hands on" and exploratory types of tasks for young men in the home and within the academic setting. Presently, there remains a need for further and more comprehensive studies of this type. It should be noted that work values or reinforcers ("things about the job") may be more important than interests in actual job choice. In one study,[29] securing a job close to home was significantly more important (p <.01) for those who found work than the unemployed. If this need couldn't be met, job outcome was less successful.

Pattern of Abilities

Studies of aptitudes or abilities present a number of other interesting issues. Clemmons[13] used the General Aptitude Test Battery (GATB), which has been in use throughout state employment and rehabilitation services in the United States. Fifty patients at the University of Washington Epilepsy Center were tested. Test scores did not discriminate between the successfully employed and unemployed. Furthermore, when the mean scores of the employed group were compared with the published GATB norms, all scores of the employed people with epilepsy were found to be significantly lower. The author emphasized that factors such as social support and appropriateness and psychosocial status might be more crucial job access variables than aptitudes.[13] Specialized vocational assistance and placement may also compensate for lesser abilities in highly motivated job seekers with epilepsy.

In a study by Clemmons and Dodrill,[16] the vocational outcome of 40 high school students with epilepsy 4.5 years after graduation was assessed. When looking for factors discriminating the unemployed from the employed, no influence of sex, age, or time since high school graduation could be detected. However, mean scores on the Wechsler Adult Intelligence Scale (WAIS) and the Halstead Impairment Index were significantly different across the groups (p <.01), with the strongest discriminator being the Aphasia Test (p <.001). The unemployed did significantly more poorly on these tests than those who were working. The working and nonworking groups were easily distinguished on the basis of neuropsychological and intelligence measures. The authors suggest identifying those at risk for unemployment based on these variables before they enter the workforce and offering them specialized and intensive vocational services.

Epilepsy-related Restrictions and Limitations

Scharfenstein and Thorbecke,[65] while performing a secondary analysis of vocational rehabilitation by the Department of Vocational Rehabilitation of the Berlin Labor Exchange, found severe epilepsy-related job restrictions in the records (Table 1). Only 11% of the records indicated the type of seizure and only 19% the seizure frequency. Such restrictions are in sharp contrast to the consistently reported low accident rates of people with epilepsy as noted previously. This holds true for persons known to the employer as having the disability and also for persons who do not disclose epilepsy.[77] Therefore, the development of approaches to assess the work-related risks of persons with epilepsy on an individual basis should be of high priority.

Table 1 Work Restrictions for People with Epilepsy (Department of

Vocational Rehabilitation—Berlin)

	Adults with epilepsy (*n* = 32)	Controls (*n* = 32)	Youths with epilepsy (*n* = 32)	Controls (*n* = 32)
No "dangerous tasks" (working with machinery, working in high places)	100%	22%	67%	11%
No "shift work"	94%	44%	60%	
No "piece work"	44%	22%	60%	
No "responsibility"	13%	9%	7%	11%
No "intellectually demanding tasks"	25%		27%	

Behavioral Problems and Social Skills Deficits Associated with Epilepsy

In addition to some of the issues described above, there appear to be a number of variables affecting social and interpersonal

P.2255

behavior and competency for youth and adults coming into epilepsy rehabilitation programs. Work at the University of Washington Epilepsy Center[30] indicates that through several years (1988–1990) during which participants entered vocational services, additional disabilities were prevalent in 89% of this population. Mild to moderate neuropsychological impairment was salient; 37% to 54% (depending on the study group) had a specific documented brain insult, and 26% to 40% had an additional psychiatric diagnosis. The percentages of those with physical disability were minor. Wada et al. in a series of 278 patients in the unemployed found a significantly higher proportion with neuropsychiatric complications.[82]

Earlier work by Goldin et al.[38] suggests that children and adolescents with additional disabilities are more socially isolated and less involved in extracurricular and school social activities. Consequently, they have not had the exposure to social organizational activities through which social skills and competencies are developed. It would appear that youths with active seizures have increased dependency and are less involved in normal risk-taking and social activities, with a subgroup further restricted by additional emotional and cognitive limitations.

A lack of social skills development can be exacerbated by frequent seizure activity and side effects of drugs. As individuals with a seizure disorder mature, emotional and behavioral difficulties can become more pronounced as they react to isolation and failure in the social environment. Curly et al.[17] restricted their study of risk factors for psychosocial maladjustment to a sample of boys (*n* = 60) because they observed that boys seemed to have more adjustment difficulties than girls.[74] This has also been the experience of Fraser et al.[34] In the study by Curly et al., neuropsychological impairment, divisive parenting styles, and number of lifetime seizures accounted for approximately 50% of the variance related to the boys' behavioral disturbances—neuropsychologic impairment for 28% and the other two variables for 13%. Young boys in particular may be a subgroup having greater adjustment difficulty because of lack of support and greater expectations for performance within sports and the vocational areas.

Services

Job access after school may vary between different countries because of different traditions. Therefore, the structure of some services will be outlined without a description of specific features.

Prevocational Intervention (Work Preparatory Courses, Social Rehabilitation)

Freeman and Gayle in 1978[36] initiated in Baltimore a school-based program to facilitate transition from school to employment. During the first 3 years of the program, 333 students with epilepsy were identified, with a mean age of 16 years (range, 12–21 years). The program provided counseling, epilepsy education, and work experience. Students in a first step participated in vocational training courses within their schools and then were offered job opportunities. When the employment outcome was evaluated 2 years after graduation, only 18% of the participating adolescents with epilepsy but 31% of the students without disabilities were identified as program dropouts (i.e., not holding a job or being in school or training).

The key factor to the success of this project was that it enabled the school system personnel to meet the requirements of the law (Public Law 94-142) in developing individualized programs for students with disabilities. In other words, the program assisted overworked and underfunded school personnel to complete required work activity.[35] It was “housed within the school system.” Other projects, in Cleveland[80] and Seattle,[14] have encountered more significant difficulties in securing the cooperation of school personnel in obtaining access to youths with epilepsy for enrollment in school-to-work transition programs.

Similar programs were offered in the United Kingdom and in the Irish Republic. A work preparation course by the British Epilepsy Association[6] is conducted during 4 to 6 weeks and offers, in addition to epilepsy education, a comprehensive program of counseling, industrial visits, and work experience. Carroll[10] reported on a 6-month training program from Ireland, during which the trainees were assisted in developing social and communication skills and allowed to sample basic activities in art, drama, home management, and woodworking. On completion, 60% of the trainees with epilepsy versus 72% of the trainees without epilepsy were placed. One year later, 40% of the participants with epilepsy still were employed. When interviewed, participants with epilepsy found the program helpful in increasing their self-confidence and social skills.

At the Heemstede Center in Holland,[18] group training is provided in the following areas, considered vital to good vocational preparation: (a) Coping with seizures in work situations, (b) educating colleagues at work about epilepsy, (c) coping with colleagues' attitudes, and (d) interviewing techniques (role playing). As part of the group training, participants

P.2256

are given work experience during which they practice what has been learned. Similarly, in Germany, work preparatory courses lasting 1 or 2 years have been designed to integrate adolescents with disabilities into the general labor market as unskilled or semiskilled workers. In 2005 these courses were changed to a more open and flexible form including more practical work experience and allowing continuing with formal vocational training if the young adult shows sufficient capabilities.

Such courses are a valuable trajectory from school to employment for young adults with epilepsy for whom seizures are the main handicap. However, for those having additional physical or neuropsychological handicaps, vocational assessment and training are necessary to identify job goals more appropriately.

Vocational Assessment and Its Components

Around the world in rehabilitation centers or epilepsy centers, assessment units have been set up for people with disabilities, including epilepsy. Vocational assessment typically involves the use of vocational interest inventories, work values inventories, academic achievement testing, intelligence assessment, assessment of emotional and personality functioning, and (depending on job goals) assessment of visual-spatial abilities, motor speed, and dexterity. For individuals with a known or suspected brain insult or impairment of functioning, a full neuropsychological evaluation is requested. For individuals more severely compromised by epilepsy and neuropsychological impairment, a number of commercially available or devised work samples may be utilized to identify a skill that might be transferable to repetitive work (e.g., filing by numbers). If an individual has no specific work goal that can be identified, time should be spent in identifying work-related values (e.g., aspects of work—an esthetically pleasing environment, working with a mixed group of young men and women) that might draw them into some type of work. At a number of the European rehabilitation or sheltered work facilities, a wide range of work activity that can be sampled is often available.

At the University of Washington Epilepsy Center Vocational Services, job tryouts are planned as they relate to a client's job goal, either in a volunteer setting within the hospital or within the private sector under a special 1993 U.S. Department of Labor waiver that allows unpaid work for up to 215 hours. In addition to a rehabilitation counselor monitoring this job tryout or community-based assessment, a job coach often is present to coach the client and take performance data. In the United States, sheltered work facilities are generally used for evaluation or training purposes only with the most impaired clients. Vocational assessment of people with epilepsy must always have two main components: (a) Evaluation of seizure-related restrictions and (b) Evaluation of abilities based on work samples and often neuropsychological testing (if there is a known brain insult).

A first step is always *a complete description of seizure variables* to assess vocational risks. Is there an aura or warning that allows the patient to prepare for a seizure? What is the state of consciousness during a seizure? Does the person with epilepsy fall, and what is the typical pattern of behavior during a seizure? How does the person behave after a seizure (e.g., confusion, disturbance of speech, paralysis of limbs, sleep)? How long does it take until the person is able to resume usual activity? At what time do seizures tend to occur (e.g., during sleep, after awakening), or are they completely unpredictable? Have seizure triggers been observed (e.g., sleep deprivation, alcohol intake, emotional issues)? Has the individual experienced other injuries secondary to a seizure incident? These are representative issues in assessing vocational concerns or risks.

A German group of epileptologists and professionals from rehabilitation centers, large companies, and state accident insurances recently suggested five categories of increasing risk that can be used to evaluate the occupational suitability of persons with epilepsy (Table 2).[1] Seizure frequency was grouped into four categories: More than one seizure per month, three to 11 per year, no more than two per year, and seizure free.

To demonstrate the practicality of these categories, vocations in electromechanics, metal work, health care, and pedagogics were assessed.[1]

Table 2 Epilepsy Risk Categories of the German Task Force

"O"	No loss of consciousness; no loss of posture; control of own actions (seizures only with subjective symptoms)
"A"	No loss of consciousness; no loss of posture; impairment of ongoing activity
"B"	Impaired consciousness; interruption of ongoing activity; no loss of posture
"C"	No loss/loss of consciousness; loss of posture; interruption of ongoing activity

"D"	Impaired consciousness; no loss of posture; actions not in accordance with demands of the situation

Such guidelines facilitate assessment of suitability for certain "dangerous" vocations on an individual basis. However, before such an evaluation is performed, a person's drug regimen and compliance should be assessed to be sure that the person with epilepsy is grouped into the most appropriate category. In the United States, legislation requires consideration of workplace accommodations (adaptive procedures, physical modification of the job site, adaptive equipment that lowers risk). Nevertheless, there may remain situations in which the individual risk must be assessed using such a categorization.

Vocational planning traditionally has been done with the help of psychological testing. For people with epilepsy, however, such a strategy seems to be successful only if procedures are used that are sensitive to the specific abilities and deficits often found. As mentioned earlier, the GATB, which has been universally used in the United States, was not very predictive of the employment status of adolescents with epilepsy. On the other hand, neuropsychological tests predict job success at 1 year reasonably well[15] for those with epilepsy and known brain impairment.

In Germany, 46 rehabilitation centers now exist for young adults—all with a vocational assessment unit. Assessment is done both by evaluation of work samples from different occupational fields and by psychological testing. Finger[27] did an extended study within the assessment unit of the Bethel Epilepsy Rehabilitation Center. Seventy-eight young adults (mean age, 20.25 years; standard deviation [SD], 3.52) were given an extended battery of neuropsychological tests. In addition, epilepsy variables were documented carefully. The dependent variable was recommendation of formal training as a manual worker by the professional team (master educators or social workers) after evaluation of 3 months of work samples. The result was that none of the 10 persons with a history of status epilepticus was given a recommendation for training (p <.05).

P.2257

The neuropsychological test battery, comprising Picture Arrangement, Digit Symbol Test, Concentration Endurance Test/d2, Stroop (Naming of Color Dots, Naming of Color Prints), Controlled Oral Word Association Test, Name Writing Preferred Hand, Trail Making Test Part B, and Purdue Pegboard Test (Preferred Hand and Both Hands Assembly), discriminated well between the trained and untrained groups. Stepwise discriminative function analysis correctly classified 73% of the persons without and 89% of those with training recommendation (81% and 60% in the cross-validation sample). These results underscore the importance of sensorimotor coordination, motor speed of the dominant side, speed of information processing of selective stimuli, cognitive flexibility, and mastery of abstract language concepts for vocational training.

It can be seen from these results that neuropsychological tests are a very effective tool for rehabilitation planning that includes special training considerations or appropriate job accommodations. It is important, however, not to ignore other capabilities of a client (e.g., compensatory capabilities or social skills). The final goal of vocational training is not successful training but successful placement, which can require additional abilities not measured through neuropsychological tests.

Vocational Training Courses for Young Adults with Epilepsy

Germany has a developed system of vocational training centers for young adults with disabilities. State legislation guarantees every young person with a disability vocational training that takes into account the limitations of the disability. To offer such training, 42 centers have been established, some with a focus on epilepsy and one (Bethel) specializing in assessing those with severe epilepsy or with epileptic and pseudoepileptic seizures. About 7% of the trainees in these centers (about 1,000 persons) have epilepsy.

Rehabilitation, as a rule, begins with an initial assessment by the Department of Vocational Rehabilitation (DVR). Skilled training in a rehabilitation center is proposed for about 60%, and a 3-month extended assessment for 40%. If the DVR counselor or the staff in the assessment unit concludes that it is still too early to enter formal training, a 1-year preparatory course may be offered through a rehabilitation center. During these courses, basic social and vocational skills are developed. Formal training as a rule takes 3 years. At the end, the trainees have to pass an examination in which they must solve the same tasks as an apprentice in a workshop or company elsewhere. The rate of success is high (see above), a consequence of careful selection during the different stages before formal training. Depending on the general unemployment rate between 1995 and 2003, between two-thirds and three fourths have been placed into competitive employment. There are, however, studies from the rehabilitation centers at Heidelberg and Bethel[83] showing that placement of young adults with epilepsy after successful training is more difficult than for trainees with other handicaps. This problem underscores the importance of specialized placement services being available.

School-to-work Transition

There remains a continuing need for developing and evaluating more integrated models of school-to-work transition in which the previously discussed issues are addressed at the same time (i.e., family education and family acceptance of new roles, vocational goal setting based an individual interests and work values, neuropsychological tests, and paid work experience with on-site support and assessment). At the end of such a sequence of activity, reassessment should be done with the aim of confirming or redesigning long-range employment goals.[68]

Unemployment, Underemployment, and Work-related Difficulties of the Employed

It has long been understood that persons with epilepsy have much higher rates of unemployment than persons without epilepsy (see Introduction). Unemployment statistics, however, provide only one perspective. Another perspective relates to difficulties at work for those who are employed (e.g., being underemployed because of undue concern about a seizure disorder, or being "encouraged" toward early retirement because of disability).

Subgroups of the Unemployed and Underemployed

Chronically unemployed persons with epilepsy very often have additional handicaps, such as specific neurologic or neuropsychological deficits, physical handicaps, and emotional and behavioral difficulties. Fukoshima,[37] in a sample of 136 patients at Hirosaki University Hospital in Japan, found 100% of patients with controlled epilepsy and without additional handicaps in the regular workforce. On the other hand, 15% of those with uncontrolled seizures, 29% of those with an additional personality disorder, 36% of those with subnormal intelligence, and 41% of those with additional physical disability were unemployed. Dennerell et al.[19] analyzed in depth differences between 177 employed and unemployed adult patients with seizures. Utilizing verbal IQ, performance IQ, and education as predictors, they could correctly classify 67% of the patients as employed or unemployed. When scores from the Halstead-Reitan Neuropsychological Battery and the California Personality Inventory were included, 78% were correctly classified. It is likely that accurate employment classification would increase with additional information regarding disability or psychiatric status. It is the "epilepsy and additional disability" information that is generally unavailable relative to employment, but is available at the Michigan clinic.

Seizures and Unemployment

The influence of type and frequency of seizures as a risk for unemployment is controversial. Some studies[25,37,42,45,68] show a clear and consistent influence of type and frequency of seizures on rate of unemployment. In an epidemiologic study in Germany for a group of 660 persons between 15 and 60 years old, a consistent relation between seizure frequency and employment could be shown. Interestingly, unemployment of PWE aligned the general unemployment rate not before having become seizure free for 3 years or more.[60] Conversely, studies from epilepsy centers could not detect any significant influence of seizure frequency on unemployment, underscoring the larger role of psychiatric and neuropsychological factors in unemployment.[3,16] One explanation for this finding could be that specialized centers attract patients in whom psychiatric and neuropsychological difficulties are overrepresented. Another explanation could be that there has been a relative increase or identification of psychiatric difficulties in the last

30 years, as can be seen in the studies of Penin.[59] This author followed adults with epilepsy receiving early retirement between 1960 and 1979. In 1960, 75% of all early retirements were a consequence of high seizure frequency, whereas in 1979 this was true for only 25%. Instead of seizure frequency, psychiatric and neuropsychological variables were more in evidence. This is attributed by the author to better seizure control at the end of his study, in 1980, than at the beginning, in 1960.[59]

Some insight on the relationship between unemployment and seizure frequency comes from studies of the social outcome of surgical treatment. In a Norwegian study,[40] 156 surgically treated patients were followed for 17 years and then compared in regard to employment status with a group of nonsurgically treated patients. Treated patients who were employed at the time of surgery were significantly more involved in work at follow-up. On the other hand, those with epilepsy who were unemployed at the time of surgery were not better employed at follow-up than controls, although their seizure status was better than that of the controls and their self-reported "working ability" had improved highly significantly. A study from the Seattle group[28] showed similar results concerning the effects of surgery on employment. Furthermore, it was observed that those patients who remain employed after surgery gain a higher functional level—higher earnings, more working time, and wider responsibilities. In a U.S. study measuring long-term outcome after anterior temporal lobectomy, employment of the surgical group had significantly improved in comparison to the control group; there were, however, no differences between those having become seizure free and those with continuing seizures.[49]

A field of growing interest is changes in the psychosocial situation after a first epileptic seizure or with newly diagnosed epilepsy. There was one study on socioeconomic prognosis after a newly diagnosed unprovoked seizure. Unemployment was higher for those with continuing seizures.[53]

In sum, the relationship between seizure frequency and employment seems to be complex. Among the employed, some with severe epilepsy are not dismissed because of protective legislation in countries such as the United States and Germany. Seizure frequency may also be overshadowed by other factors—neuropsychological and psychiatric—important to employability. However, this does not mean that seizures can be neglected when the issue of unemployment is discussed. It would appear extremely important not to overlook seizure factors relevant for employment, such as the timing of seizure occurrence, potential warnings, provoking factors, falling, duration, and postictal confusion.[57]

Neuropsychological Deficits and Employability

Commonly used neuropsychological batteries include the Luria-Nebraska Neuropsychological Battery and the Halstead-Reitan Battery. Dodrill[21] established a comprehensive battery of 16 discriminative measures sensitive to brain impairment and epilepsy. This battery includes the Halstead Neuropsychological Battery for Adults; the Aphasia Screening Test; the Trail Making Test; the Logical Memory and Visual Reproduction parts of the Wechsler Memory Scale, Form 1; the Sensory-Perceptual Examination; the Stroop Test; and the Seashore Total Memory Test. This battery or others should enable an assessment of a broad range of capabilities, including motor performance, sensory-perceptual abilities, memory performance, attention span, language skills, visual-spatial abilities, problem-solving capacities, and general cognitive efficiency. For individuals referred to a regional or tertiary resource epilepsy center, it is these kinds of difficulties that will affect employability as much or more than seizures. It is common at the University of Washington Regional Epilepsy Center to refer an individual for a neuropsychological evaluation if there is a history of job losses and pronounced emotional difficulties. Sometimes individuals with both emotional problems and suspected cognitive deficits are also referred for assessment. Approximately 40% of the vocational program participants at the University of Washington Regional Epilepsy Center have experienced a head injury. In these cases, the importance of a neuropsychological assessment is further emphasized. Before neuropsychological information was utilized more carefully in vocational planning, it was very common for individuals to lose jobs because of memory difficulties, abstraction deficits, motor and visual-spatial problem-solving concerns, and general cognitive inefficiency.

In a cross-sectional validation study of 58 persons with epilepsy,[8] the neuropsychological scores of the Dodrill battery differentiated very well between the unemployed, the underemployed (working in sheltered employment settings or in competitive settings <20 hours per week), and the employed. The percentage of total test measures outside normal limits was 64% in the unemployed, 53% in the underemployed, and 22% in the employed (*p* <.001). When the subtests were inspected, the greatest differences could be found in tasks emphasizing motor performance and visual-spatial skills.[8] In another study from the University of Washington Epilepsy Center at Seattle,[32] 46 outpatients were followed prospectively in regard to employability. The best discriminators were the Digit Symbol Test from the WAISR Scale and the Name Writing Procedure. The neuropsychological battery for epilepsy correctly classified 70% of both employed and unemployed.[28] From this finding and general test data trends in the study, a picture emerged showing the unemployed having more difficulties with tasks requiring tactile, motor, perceptual, and spatial integration skills and having more neuropsychological deficits in general.

It is interesting to speculate on the development of such deficits in the course of epilepsy. Rodin[62] reported on 90 patients who were reassessed 6 years after their first evaluation at the Epilepsy Center of Michigan. Those who were unemployed at follow-up had several additional problems: Drug resistance, behavioral abnormalities, and neuropsychological deficits that had not been observed at the first examination 6 years earlier.[62] Dodrill,[20] in a very careful study assessing the association between number of generalized tonic–clonic seizures and neuropsychological functioning, reported a significant increase of neuropsychological deficits in comparing persons with two to 10, 11 to 100, and more than 100 generalized tonic–clonic seizures, and a history of status epilepticus. The sharpest loss of abilities was noted in the group of patients with a history of status epilepticus. It appears that neuropsychological variables are the most important predictors of employment stability or instability, and neuropsychological assessment tools are of immense practical value for rehabilitation planning.

Interactions with Employers and Colleagues

In one hypothesis for the high rate of unemployment among people with epilepsy, misinformation and the negative attitudes of employers are considered to be important causal factors. A study by Sands and Zalkind[63] of employment policies and attitudes toward persons with epilepsy showed that feelings about hiring people with epilepsy were more unfavorable than they were about hiring persons with heart disease, cancer, or diabetes. A similar result was found in a study from the United Kingdom,[48] in which the attitudes of 52 personnel officers

toward employees with epilepsy were compared with their attitudes toward persons with heart conditions, loss of one eye or leg, diabetes, or chronic bronchitis. A recent study from the United Kingdom in which 240 employers were endorsed qualifies these findings.[46] About one fifth said that a prospective employee's epilepsy would be a major issue (mainly in respect to safety). When asked to consider a series of six conditions, epilepsy caused "the greatest overall concern" after depression or heart disease and the highest concern after depression with respect to absenteeism and accidents. About one fourth of the companies had experience employing PWE. In those companies the proportion of jobs deemed to be suitable for PWE and the willingness to make workplace accommodations were greater, and the belief that insurance costs could increase less likely. A higher proportion of jobs in larger businesses were regarded as suitable for PWE than in small ones.

It seems that the basis for negative employer attitudes is the lack of practical information about epilepsy. Holmes and McWilliams,[44] when surveying 116 employers in Tennessee, asking them, "If your company physician told you that an applicant with epilepsy was physically able to work, would you hire him?" got 72% positive answers and only a small proportion of negative responses; however, a relatively high proportion (24%) of employers expressed the view that they were unsure. From an earlier UK study,[48] it was also obvious that information deficits were one of the main barriers to employment; 43% of employers wrongly believed that insurance companies would not provide normal liability insurance rates.[48] The above findings suggest that employers could profit from basic educational to improve their hiring practices.

When looking at interactions with employers, there are also the emotional aspects that cannot be overseen. In all studies cited, there are prejudicial hints—high percentages of "unsure" answers or contradictions between positive and negative attitudes toward hiring in more specific questions. Sands and Zalkin,[63] in their demonstration project, undertook a rigorous education campaign over 1 year to change employer attitudes. The outcome was totally negative. There were no meaningful differences when the experimental (educational intervention) city was compared with the control city. From this the authors concluded the following:

> "Modification of employer attitudes toward hiring the epileptic may therefore require something more than the usual public education program. Employers must be actively involved in education campaigns by their actually seeking and providing jobs for qualified epileptics. As a result of such involvement in placement, the policy-level business executive will learn about epilepsy on an emotional level, which we postulate should result in an attitude change."[63]

It is just this approach that is often followed in modern vocational rehabilitation training and placement services. It would also be important to establish rules to prevent discriminatory hiring practices toward those with disabilities. A general framework for this is provided in the Americans with Disabilities Act, and specific guidelines are presented in the "principles for good practice" of the Employment Commission of the International Bureau for Epilepsy.[3]

There is now also a study in which the reactions of coworkers to PWE have been addressed.[41] When comparing the reactions to persons with depression, multiple sclerosis, and epilepsy, it seemed that coworkers are especially worried about sudden unpredictable behavior of PWE (p <.013) and feeling uncomfortable providing first aid to them (p =.081). This finding in accordance with the studies tapping employer attitudes suggests that educating people about epilepsy, especially about the concrete features of seizures and how to give first aid, could decrease worry and social avoidance.

Predictors of Long-term Employment Success

Prior sections of this chapter have dealt with seizures, neuropsychological deficits, behavioral abnormalities, additional handicaps, and employer attitudes as factors independently influencing the chances of persons with epilepsy to obtain or hold a job. From a broader perspective, it becomes obvious that these factors are interrelated. Frequent seizures may increase the likelihood of seizures occurring at work, which increases the risk for unemployment[76] and psychosocial problems.[20] Frequent seizures at the same time increase the risk for neuropsychological deficits,[20,62] and these in turn increase the risk for unemployment. It is also well known that unemployment increases the risk for psychiatric disorders and psychosocial problems, the latter being correlated with a bad seizure prognosis.[23]

Thus, it appears that services aimed at reducing the risk for unemployment will be effective only if they address joint factors at the same time and as early as possible. A second presupposition for long-term employment success is compensation for poor education and insufficient vocational training, which seem to be fundamental deficits in the unemployment status of people with epilepsy. Finally, it is insufficient simply to place these people in competitive, unsubsidized employment; they also need support to maintain steady employment and overcome periods of only cyclic employment.[33]

Vocational Services

To address the employment problems of people with epilepsy, four types of services seem to be necessary:

1. Programs for assessment and short-term rehabilitation
2. Vocational retraining programs for those in occupations or trades unsuitable for anyone with a seizure disorder
3. Training and placement services for those who have completed vocational training or for those with poor work records
4. Services directed at keeping people with epilepsy employed (postplacement services)

It is obvious that such services in different countries may have different structures. For example, they may be separated or integrated, specialized for people with epilepsy, or specific for those with neurologic deficits or diverse disabilities.

Programs for Assessment and Short-term Rehabilitation

In 1983 in the United States, and then 15 years later in Germany, a type of service was launched that connected on the one hand high standard diagnosis and treatment approaches (including surgical treatment of the epilepsies) and on the other hand neuropsychological and psychiatric assessment and first steps of rehabilitation such as work experience, preparing structured vocational rehabilitation measures like retraining into a more suitable profession, or placement into competitive employment.

First data on the outcome of the U.S. program were given in 1983 by Fraser et al.[31]

From the German program, designed very similar to the American one, first data were given in 2004[73] comparing social and employment situations for a consecutive series of the first 96 patients before admission and 18 months after the 4- to 6-week enrollment in the program. Seventy-nine patients

(82%) had focal epilepsy. Physical comorbidity was found in 21%, and psychiatric comorbidity in 53% of the cohort. Compared with time point 1, seizure frequency and number of hospital admissions due to epilepsy were reduced at time point 2 (p <0.01). Significant improvements were found in six out of seven quality-of-life domains (epilepsy-related fear, emotional adaptation, perceived restrictions, perceived stigma, mobility/independent living, and physical/emotional health) and in performance in daily life (e.g., going out alone, driving a car).

The employment situation also changed significantly: Unemployed, preadmission 48%, postenrollment 20%; employed, preadmission 33%, postenrollment 37%; sheltered employment, preadmission 6%, postenrollment 10%; vocational rehabilitation measures, preadmission 3%, postenrollment 11%; early disability pension, preadmission 2%, postenrollment 14%; homemaker, preadmission 8%, postenrollment 8%. Those who were employed preadmission and postenrollment reported significantly fewer problems at the workplace—time on sick leave, concentration and memory problems, and seizures at the workplace (p = .014).[72]

Retraining Centers for Adults

During the last 40 years in Germany, a network of centers has been developed; today, 28 centers have 14,500 retraining slots. They offer vocational retraining for a great number of occupations and trades. As a rule they have three components: (a) An assessment unit to assess interests and abilities over a 2- to 6-week period. At the end of the assessment, it is decided whether the client should be retrained, receive a disability pension, or be placed in unskilled or semiskilled employment without retraining. The decision to send a person to a retraining center is the responsibility of the local labor exchange's department of vocational rehabilitation or the rehabilitation department of the state pension insurance. (b) Retraining may begin with a 3-month preparatory course in which basic (school) abilities are retaught. (c) Two-year retraining follows. This is equivalent to 3 years of vocational training of young adults without disability after high school.

The proportion of people with epilepsy in these institutions is 1% to 3%. Some are specialized for persons with neurologic diseases, including epilepsy. Fifteen to 20% of the trainees drop out.

Schultz and Thorbecke[67] observed 73 people with epilepsy within the assessment unit of a Berlin retraining center for adults. Prognostic factors suggestive of training potential and level of retraining were age, number of additional handicaps, intellectual capacity, working pace, and drawing skills. Psychopathologic abnormalities sharply discriminated between those accepted versus not accepted for retraining.[67] No influence of seizure variables, which were carefully documented in the study, could be found.

In a study from the large retraining center at Heidelberg, Germany, Wöhrl[83] reported that 2 years after retraining, 68% of the persons with epilepsy (n = 151) were employed, whereas 79% of the persons with other disabilities (n = 757) were employed (p <.01), the level of vocational qualification being equivalent in both groups. This draws some attention to a need for specialized placement assistance for those with epilepsy.

Training and Placement Services

The most effective training and placement service for people with epilepsy worldwide has been the 20-year-old TAPS (training applicants for placement success) program of the Epilepsy Foundation of America (EFA). Over this time span, it grew continuously and became more specialized to the needs of special groups of people with epilepsy while simultaneously increasing the placement rate from about 55% at the beginning of the 1980s to nearly 70% at the beginning of the 1990s.

The background of the TAPS program was an EFA demonstration project in the 1960s in which group counseling was proved to be highly effective for the placement of job seekers with epilepsy and numerous other problems.[66] In 1976, with funding from the U.S. Department of Labor, the EFA started the TAPS program, which worked according to the same principles. The *client-oriented component* of TAPS is based on the principles of active peer support and shared responsibility. After intake and orientation sessions, participants received *training in job-seeking skills.* In the weekly meeting of the *job club,* they shared their actual job-seeking experiences and encouraged each other to continue the job search. During job club meetings, employers familiarized participants with their views of job applicants or did exercises with them to improve their job-seeking skills. Additionally, every participant received individual assistance as needed. *Placement* was achieved if an individual found part-time (15–29 hours) or full-time (30–40 hours) unsubsidized employment. *Follow-up services* were provided for 1 year following placement.

A second component of TAPS was aimed at *employer development and interagency collaboration.* Employer participation was to be found in all parts of the program. In *employer development,* staff gained information on current job opportunities and required qualifications through employer visits. Every regional TAPS had *a local advisory committee* composed of employers and representatives of relevant local agencies. Finally, staff provided *education and mediation services* for local employers regarding employment and epilepsy issues.

TAPS programs existed in 13 American cities, largely supported by the U.S. Department of Labor.[5] There were 1,351 persons with epilepsy enrolled in 1994, with 914 (68%) being placed in unsubsidized employment. Among these, 77% maintained employment 90 days after placement. Placement of women, however, reached only 39%, and placement of youth only 7%. Average cost per placement was approximately $750. Because of the great success of the TAPS methodology, EFA established further regional TAPS that were privately funded (e.g., by the Coelho Jobs Fund).

Troxell[79] reviewed a number of highlights from this large effort by the EFA and U.S. Department of Labor. It is of interest that seizures seemed to contribute little to employment outcome or retention. People receiving social funding assistance had more difficulty securing jobs and those unemployed for more than 1 year at intake had more difficulty keeping jobs. It is also important to note that although more than 65% achieved placement, only 70% of these maintained the job even at 90 days. Troxell ended his retrospective review of TAPS activities by calling for earlier vocational intervention, more comprehensive and intensive services for enrollees on social financial assistance programs, more in-depth assessment at intake, and the need for more intensive job-site support and follow-up postplacement.

Unfortunately, the U.S. Epilepsy Foundation is less involved in vocational programming today. Much of this relates to reduced available funding.

Fraser et al. conducted two studies[31,33] to evaluate the effectiveness of specialized training and placement services for people with epilepsy. In the first,[31] the vocational services program of the University of Washington Regional Epilepsy Center, which has nearly the same components as TAPS, was evaluated. Of 106 persons with epilepsy, 50 (47%) could be successfully placed. The strongest discriminators between the employed and dropouts were "months employed in the last 24 before entering the program" and treatment for psychiatric conditions or addictions before entering the program. The group achieving employment had an average of 12 months in

P.2261

employment of the prior 24, whereas dropouts approximated only 7 months. In later cross-validation, only months employed before entering the program proved to be a significant discriminator, the psychiatric and addiction category losing its influence because of program refinements targeting these issues.[31]

In the second study,[33] outcome from seven state placement agencies was compared with the outcome from the University of Washington placement program. State agencies had a placement rate ranging from 9% to 21%, except for one state with a 44% placement outcome. The University of Washington specialized program placement rate was about 50% (see above). There were no differences in client characteristics that could account for these differences. These authors provided some interesting explanations:

1. In state agencies, the client-to-rehabilitation counselor ratio is about 1:100, whereas in specialized TAPS programs it is between 1:30 and 1:40.
2. In the state agency with a placement rate as high as 44%, special efforts were made to increase placement of persons with epilepsy, such as hiring only counselors with a Master's degree and having a counselor with the disability provide detailed education on epilepsy for fellow counselors (also having an emotional impact).

From these experiences, the authors concluded that specialized agencies should be established in local epilepsy centers and associations. At the same time, specialized training should be developed for the state counselors so that they may better meet the needs of the job seeker with epilepsy. Through specialized training, counselors also acquire empathy for the cause.

Postplacement Services

After a person with epilepsy is assisted to placement, several problems may occur: Frequent sick leave, inadequate performance, conflicts with supervisors or colleagues, and uncertainty of supervisors and colleagues about an individual having epilepsy if this has not been previously disclosed. Different kinds of assistance may be needed: Medical treatment, accommodation of some type at the job site, transfer to another workplace, counseling of the person with epilepsy by supervisors or colleagues, medical leave, or early retirement. Support and counseling may be provided by different services. External services are affiliated with state agencies, epilepsy societies, or epilepsy clinics. Other services are situated at or near the work site, such as occupational health services. These services may be specialized for epilepsy or may accommodate persons with various disabilities.

As previously described, TAPS provided postplacement support until 1 year after placement. In Germany, external postplacement services for persons with mental illnesses and disabilities, which also support people with epilepsy, have been developed by the state. These services cooperate closely with psychiatric clinics, and in many cases support can begin before placement and be continued, if necessary, for years. These services seem to be effective in opening doors for unemployed persons, because the employer may rely on the service if there are difficulties after placement. It has also been observed that these services are effective if a chronic disorder develops in an employee. In this situation, an employer is generally in need of specific information concerning the disorder and is ready to accept suggestions from an external service (e.g., to look for specialized medical treatment or to retrain). If an employee with a chronic disorder, such as epilepsy, is employed for many years, support from the external postplacement services seems less applicable, because the company itself may have attempted many accommodations. Nevertheless, the external service can still give meaningful support, such as counseling, suggestions for transfer to another work site, or recommendations for specialized medical treatment.[54] These services seem to be highly effective for maintaining people with chronic illness on the job.

Postplacement support may also be given by occupational health services. Kleinsorge[50] reported on 65 persons with epilepsy in a large German chemical company. Only one of six had been known to have epilepsy when starting to work because of lack of disclosure. No one with epilepsy was dismissed when the epilepsy condition was disclosed; however, 25 of 65 had to be transferred to a more suitable workplace. Espir et al.[26] recently reported on 93 subjects with epilepsy who were referred to the British Civil Service Occupational Health Service during an 18-month period. Reasons for referral were prolonged or frequent sick leave, unsatisfactory work performance, and epilepsy starting during employment. After each case was inspected, it became evident that many referrals were not a consequence of epilepsy but of associated illness or handicaps. Twenty-six instances of prolonged sick leave were reported: Six caused by epilepsy, nine caused by side effects and disorders associated with epilepsy, and 11 caused by other disorders, such as internal medical problems, psychiatric problems, or alcohol abuse. Of 23 cases of unsatisfactory work performance, 14 were a consequence of epilepsy and nine were not.

It is interesting to review the results of the Occupational Health Service interventions. Of the six persons with epilepsy who had prolonged or frequent sick leave caused by epilepsy, only three continued to work. Of the 14 persons with epilepsy who had an unsatisfactory work performance caused by epilepsy, 12 continued to work. Among the 22 persons with epilepsy whose disability began during employment, 12 continued working. Of eight persons with undisclosed epilepsy, seven continued working, and of the 35 needing advice on working conditions, 28 continued. The authors emphasize the important role of the Occupational Health Service in solving these problems. However, the fact that only 12 of 22 persons with new-onset epilepsy occurring during employment continued to work engendered some criticism. This is not what would be expected for new-onset epilepsy, which has an excellent prognosis, and results could have been different with the advice of an experienced epileptologist.[26]

More research and demonstration project efforts with regard to specialized postplacement services are presently needed. It would be misleading to believe that only unemployed persons with epilepsy are a problem group. A second group, employed people with epilepsy, is at risk for dismissal or retirement, or these people are gradually losing their abilities because of lack of appropriate medical interventions. Postplacement services should be targeted at these groups.

Workplace Accommodations

There are several categories of work-site accommodation, which include procedural accommodations, physical modifications to the workstation itself, and the use of adaptive or assistive technology (equipment that enables an individual to perform on the job). For most individuals with a seizure disorder, the primary issue falls within the first two categories.

Procedural changes can be easily implemented and are very helpful to an individual with a seizure disorder. Individuals with occasional loss of consciousness, particularly when there is no warning, may need to avoid certain physically hazardous work activities. Without consistent warning, there may be no way to ensure safety in a specific activity. For example, part of a job involving working in high places or driving might be reassigned to another worker. For some individuals with seizures, changing shifts can be detrimental to functioning. A regular

day shift can at times be arranged so as not to disrupt sleep patterns or the manner in which drugs are absorbed. Individuals may also require work-site modifications specifically for safety purposes. This might involve some type of floor covering or matting, a machinery guard, or an automatic cutoff switch that would ensure safety if a seizure occurred. In sum, accommodation needs are primarily for those individuals with marginal seizure control and the potential for an accident or injury on the job. However, some individuals with new-onset epilepsy take some time (up to 1 year) to achieve reasonable control. During this period, procedural changes or work-site modification can help to keep them on the job.

Assistive equipment is primarily for individuals with epilepsy and neuropsychological impairment. Equipment can include electronic cueing devices and watches, telepagers, and other memory aids. For individuals with both memory and problem-solving deficits, computer software programs can be helpful in organizing work and improving cognitive efficiency. Other individuals may use palm-top computers to organize work and otherwise aid memory. Again, assistive equipment is not a typical work-site accommodation for an individual with a basic seizure disorder but is more commonly used for clients with additional cognitive or physical limitations.

Birgit's Case

Birgit S. came to the center at Bethel when she was 19 and in the third year of training as a lathe operator. Complex partial seizures preceded by an epigastric aura were diagnosed. Her aura, however, was too short to protect her from the seizures. Therefore, the foreman, the occupational physician, and the rehabilitation specialist decided to install a box of acrylic glass over the lathe to prevent the machine from starting without the box in the right position. Birgit completed her training as a lathe operator successfully and after several changes of drugs has achieved good seizure control.

Others who can profit from workplace accommodations are persons with epilepsy who have been employed for a long time in one company, persons with late-onset epilepsy, or those whose epilepsy status deteriorates. Such persons are often too old for retraining, cannot be dismissed because of seniority, and are often considered desirable by the employer for their long-term performance and contribution.

Christina's Case

Christina W. was employed as a production assistant. Her job was to take containers formed with synthetic material out of machinery, put away the metal-forming edges, and store the containers. When generalized tonic–clonic seizures developed and these tasks became too dangerous for her, the machinery was adapted. She is now using a new machine with an automatic starting button placed some distance away. The cost of this accommodation was paid by the Office for Handicapped People in the Work Force (Germany).

National Legislation Affecting Job Access

Germany

In 2001 the federal government bundled all rehabilitation laws and regulations in a complex rehabilitation act, which is based on the principles of the ICF (Sozialgestzbuch IX). The rehabilitation act also contained new forms of support (e.g., "work assistance"). An example for this would be that a person with epilepsy who sometimes to fulfill his or her professional tasks has to drive would get funded a driver. Persons who cannot reach their workplace because they are not able to use public transportation can ask for cost-free private transportation. Support of disabled persons at the workplace is organized by regional (state) offices for the disabled. These offices are also responsible for workplace accommodations and therefore provide technical services. They also have highly specialized outreach services to support persons with disabilities at the workplace. One shortcoming is that these institutions give only support to people who have the status as handicapped. One consequence of this is that persons after a first epileptic seizure cannot get support even though this is a group in high need of work-site accommodations or procedural changes for a limited time period.

Americans with Disabilities Act

The Americans with Disabilities Act, enacted between 1992 and 1994, is benchmark legislation in the United States extending the prohibition on disability-related discrimination to the private sector. Title 1 of the Act covers employment and companies with as few as 15 employees. A company cannot discriminate in employment practices against a person who has epilepsy (or even a record of experience with the disability). Persons with a seizure disorder cannot be discriminated against in employment if they can perform the *essential* functions of the job with or without *reasonable accommodation* (a change in procedure, physical modification to the work site, or some type of adaptive equipment). People with epilepsy do not have to disclose their disability in the interview unless it affects performance of the job's essential functions. A person with a seizure disorder no longer has to submit to a medical examination unless a job has been offered.

In a review of the claims[17] filed under the Act with the Equal Employment Opportunity Commission during the first year, McMahon et al.[58] determined that 86% of the complaints were related to individuals already on the job. The law seems to be helping people with disabilities to keep jobs, but not necessarily to be hired.

Sheltered Employment Versus Employment of Persons with Epilepsy in the Open Labor Market

Sheltered employment, or special work facilities for persons who are considered unemployable in the competitive labor market, exists in nearly all countries of the world. Typically, certain products or services are provided or subcontracted from a manufacturing company, but in recent years more sheltered workshops have developed their own products, such as toys. Although nearly universal, the types and extent of sheltered employment differ sharply between countries with comparable economic structures. In 1990, 5 of 1,000 workers in Germany, 14 of 1,000 in The Netherlands, and 1 in 1,000 in the United Kingdom and the United States were employees in sheltered workshops. The extent of sheltered employment seems to be more a reflection of national philosophies toward employing people with disabilities than an objective employment phenomenon.[75] In two sheltered facilities in Berlin, Thorbecke found that 5% to 10% of their employees had epilepsy, depending an each workshop's production structure. This result was congruent with findings in other countries.[2]

P.2263

In a study on seizures and epilepsy within a mentally retarded population,[61] 26% of those with mental retardation, 6% of a borderline IQ group (IQ below 75), and 2% of the comparison group experienced two or more seizures. The authors have found not only persons with epilepsy and mental retardation in sheltered workshops, but also a second group who have epilepsy and other problems, such as learning disabilities, behavioral problems, and severe drug or cognitive side effects, or who have frequent uncontrolled seizures—a subgroup of persons with epilepsy who are chronically unemployed. Members of the first group as a rule enter sheltered workshops directly after school, whereas those in the second group come to them after integration efforts in the open labor market have failed, which may have serious consequences for their perception of the sheltered employment opportunity.

People with epilepsy in sheltered work are a minority. Therefore, their special needs can easily be neglected. For example, in Germany the responsible consulting physician in a sheltered workshop as a rule is neither an epileptologist nor a neurologist, and treatment status is assessed only on first entrance into sheltered employment, with no requirement for epilepsy education for supervisors. As a consequence, persons with epilepsy may be needlessly excluded from work at machinery that is highly valued and can pay better in the sheltered workshop setting. A further consequence may be that persons with epilepsy in sheltered employment who

P.2264

are not mentally retarded, after their epilepsy is well controlled, may not be sent for further vocational rehabilitation or placed in the open labor market, but rather remain in the sheltered workshop. These observations should, however, be grounded in more systematic studies (see also studies cited below).

New Services

Models to Change Sheltered Employment

In the early 1970s, a U.S. movement arose for reducing sheltered employment and finding ways less conducive to segregation of employing those with severe disabilities. As a consequence, new forms of employment for this group in the open labor market, known as supported employment, were established. In the United States, supported employment emerged quickly because of amendments to the Developmental Disabilities Act in 1984. The concept of supported employment can be divided into four steps: (a) Placement, (b) training on the job by a job coach, (c) stabilization, and (d) maintenance. The time spent on job-site assistance decreases continuously from step one through step four.

Models of Supported Employment Placement

It should be noted that there is more than one model of supported employment:

1. Individual placement. Employer pays the client minimum federal wage or above while the client receives specific training with a job coach.
2. Enclave model. A group of individuals (usually fewer than eight) work together or at diverse work stations for one company and receive training or support from a job coach. Wages are usually at the minimum level. In some cases, individuals are integrated into the mainstream workforce on an individual basis.
3. Mobile crew model. In a single-purpose business, a general manager or trainer works with a group of four to five employees out of a mobile vehicle, such as a van. The work can involve activities such as landscaping or janitorial services, with wages at a minimum level or higher.
4. Entrepreneurial benchmark model. In a small, single-purpose business located in an integrated community setting, eight to 15 clients receive training or actively work. Wages are at a minimum level or higher and

the workforce may be integrated, involving employees without disabilities.

Much work has been done to clarify supported employment program components: Community job analysis, job match and placement, job training with specific techniques of applied behavior analysis, and follow-up services and interagency coordination. (See special issues of the *Journal of Rehabilitation,* 1987;53[3]; the *American Journal of Applied Behavior Analysis,* 1989;Winter[4]; and the *American Journal on Mental Retardation,* 1989;94[1].)

A survey covering the years 1984 to 1985 and 1985 to 1986 in the United States showed that 17% to 19% of clients were transferred from sheltered into supported employment.[64] This trend within the United States has continued, so that the majority of clients are being served under a model of supported employment. Several benefit–cost analyses indicate positive results: The supported employee earns better pay and is more a part of mainstream life.[51,56,78] Three German federal states have large demonstration projects on ongoing supported employment: One aimed at direct transition from special school to employment in the open labor market, and the other two at transition from sheltered employment to competitive employment. In the Westfalian project including 141 persons, more than four/fifths of them had visited a special school for children with mild or severe learning disability and were placed in the general labor market. Twenty percent were in sheltered employment, the remaining unemployed or in work preparatory courses. Eighteen percent had epilepsy. Seven years later 125 could be revisited. Sixty-six percent still were employed in the general labor market, and 80% had been regularly employed for >50% of the follow-up time. No negative effects of epilepsy on the chances to keep employment could be detected; 93.6% got practical work experience before entering regular employment and got, if necessary, extensive support at the workplace organized by the integration service of the Westfalian office for the disabled. There was also an economic cost efficiency study showing that that there would be strong economic arguments for this approach, resulting in better funding of such services.[4]

Transition of People with Epilepsy from Sheltered Employment into the Open Labor Market

From the cited surveys, primarily persons with mild mental retardation or ratings of dull–normal on full-scale IQs (approximately the lower 70s) are served in supported employment. The proportion of persons with severe disabilities, such as traumatic brain injury, cerebral palsy, or autism, is low.[69] No specific data are available for persons with epilepsy. However, it is safe to assume that people with moderate or severe mental retardation as a primary disability who have epilepsy as an additional handicap are being served. It seems that issues concerning control of epilepsy in this group are the same as for persons without mental retardation, if treatment follows the principles of an effective anticonvulsant regimen.[55]

There is an urgent need for research to address the specific problems of those with epilepsy in sheltered employment who are truly candidates for supported employment in the open labor market.

Summary and Conclusions

In this chapter, the specific vocational needs of people with epilepsy and the services designed to meet them have been outlined. The background for this chapter has largely been experiences in vocational rehabilitation within the United States and in Germany. The service structure in these two countries is considerably different. In the United States, specific services exist for persons with epilepsy to a limited degree at certain affiliates of the national Epilepsy Foundation or at university epilepsy programs (e.g., University of Washington-Seattle or University of California-San Francisco).

In Germany, specific services are rare, while at the same time the “welfare state” makes intensive efforts to integrate all people with disabilities into the labor force. As a consequence, a network of labor-mediation agencies and integration services dealing with disability issues and rehabilitation centers for adolescents and adults has been developed. In Germany, the state agencies and training institutions try to remain sensitive to the specific needs of persons with epilepsy who are a minority, whereas in the United States, the vocational support such people receive depends more on the specialized vocational rehabilitation services that are available in their region. In some cases these services are exceptional, but in other cases within the United States, persons with epilepsy miss the benefits of a German type of integrated training or retraining system.

It is the authors' conviction that both approaches are needed: Specialized services for persons with epilepsy that are sufficiently flexible to accommodate their unique requirements and a network of integrated work access and training services for all people with disability with staff that knows and understands the special needs of those with epilepsy.

Acknowledgment

Appreciation is extended for partial research review by the National Epilepsy Library at the Epilepsy Foundation (United States).

Chapter 220

Issues in Health Outcomes Assessment

Zarya A. Rubin

Samuel Wiebe

Introduction

Epilepsy is a multidimensional disorder with potential consequences for nearly every aspect of a patient's life, from physical effects, to social and vocational challenges, to personality and mood changes. In addition, total estimated health care costs are $12.5 billion in the United States annually.[12,46] Results of recent large clinical studies indicate that 25% to 40% of patients diagnosed with partial epilepsy will not be controlled with medication,[37,60,72,73,74,88] and a larger proportion experience adverse antiepileptic medication effects. Epilepsy patients are also more likely to suffer from comorbid depressive disorders than the general population or patients with other chronic illness, with prevalence rates of depression estimated to be 20% to 40%.[11,33,50,61,78,84] The comprehensive picture of the experience of epilepsy is more complex and detailed than is often assumed, reaching beyond the seizures themselves and extending into multiple domains of patients' overall health.

The Concept of Health-related Quality of Life in Epilepsy

Measures of success in treating medical illness have traditionally been characterized as freedom from disease or other intermediate quantifiable endpoints such as reduction in systolic blood pressure, serum glucose, or seizures.[21] Over the last decade, however, the emergence of health-related quality of life as a reliable, valid, and significant indicator of overall outcome in patients with epilepsy has begun to alter that perception.[28,41,49,95,101]

The concept of quality of life is not new, and dates back at least to the time of Aristotle, who attempted to define the attributes of happiness.[4] The Constitution of the World Health Organization defines health as "A state of complete physical, mental and social well-being and not merely the absence of disease or infirmity."[102] The current definition of quality of life encompasses both the concept of health and functional ability, as well as the patient's perceived satisfaction with this level of functioning. Thus, both objective and subjective measures are incorporated into the final assessment of overall quality of life.

As defined by Gotay et al.,[45]

> Quality of life is a state of well-being that is a composite of two components: (1) the ability to perform everyday activities that reflect physical, psychological and social well-being and (2) patient satisfaction with levels of functioning and the control of disease and/or treatment-related symptoms.

The initial formulation of an instrument designed to measure quality of life in health care occurred in 1948 with the development of the Karnofsky Performance Status Scale. The 100-point scale defined a patient's ability to perform various activities of daily living (where 100 is *capable of performing all normal activities* and 0 is *deceased*).[19,58] In 1992, Vickrey et al.[95] developed one of the first reliable and valid measure of quality of life in epilepsy, the Epilepsy Surgery Index-55. Baker et al.[9] concurrently constructed a model of assessment of physical, social, and psychological impairment related to refractory epilepsy. In 1995, Devinsky et al.[29] developed the Quality of Life in Epilepsy Inventory (QOLIE-89), an 89-item, disease-specific inventory to help characterize the impact of epilepsy on patients' global functioning. Since then, a QOLIE-10[25] has been developed in addition to other more specific inventories relating to aspects that contribute to overall quality of life in epilepsy such as medication side effects (Adverse Events Profile)[6] and the NDDI-E (Neurologic Disorders Depression Inventory for Epilepsy),[38] a newly developed tool for differentiating depression in epilepsy from antiepileptic drug (AED) and cognitive effects.

In a study of 81 consecutive epilepsy patients, Gilliam et al.[40] systematically assessed the specific concerns of patients with recurrent seizures. The most frequently cited concern was driving, at nearly 70%, whereas

other significant factors listed by more than one third of patients included independence, work and education, social embarrassment, medication dependence, mood/stress, and safety (Table 1).

Although these patient-oriented outcome measures are not intended to replace traditional indicators of health status in epilepsy such as seizure frequency or severity, they may offer additional information that allows us to expand our knowledge of the experience of epilepsy and better treat our patients. This review examines the contributions of seizure status, outcomes of epilepsy surgery, mood effects, medication toxicity, and other comorbidities to overall health-related quality of life (HRQOL) in epilepsy.

Seizure Frequency and Health-related Quality of Life

Although seizure frequency was previously believed to predict overall quality of life and seizure reduction continues to be a goal of therapeutic interventions for epilepsy, there in fact exists no clear gradient establishing a direct correlation between number of seizures and degree of HRQOL improvement or worsening. In fact, the only true amelioration in quality of life can be observed when patients are rendered entirely seizure free.[14,63,69,96]

Table 1 Quality of Life in Epilepsy-89 (QOLIE-89) total and subscale score differences between groups according to depression diagnosis

	Difference between no and major	Difference between no and moderate	Difference between moderate and major
Total QOLIE-89	31	19	12
Health Perception	27	20	7
Overall Quality of Life	30	16	13
Physical Function	23	21	2
Role Physical	40	31	9

Role Emotional	54	24	29
Pain	29	18	11
Social Function	27	17	10
Energy-Fatigue	29	17	12
Emotional Well-Being	37	19	18
Attention-Concentration	32	17	15
Health Discouragement	38	20	17
Seizure Worry	24	15	8
Memory	27	18	9
Language	23	13	10
Medication Effect	21	8	13
Social Support	25	11	14
Social Isolation	37	21	16

Score difference >12 points are considered clinically significant. ANOVA, p <.0001, for all QOLIE-89 total and subscale raw scores by depression group.

In the multicenter study by Leidy et al.,[63] patients were classified according to seizure frequency and evaluated on the Medical Outcomes Short Study Form (SF-36), a "gold standard" measure of quality of life. Scores for seizure-free patients were similar to those of the general population, whereas increasing frequency of seizures predicted a small but inverse shift in HRQOL across all domains.[63] Although some differences were observed between groups with differing seizure frequency, these differences were subtle, and the greatest discrepancy in quality-of-life scores was observed in the seizure-free group versus all seizure groups.[63] In a recent study by Birbeck et al.,[14] these results were confirmed using the QOLIE-31, QOLIE-89, and SF-36, with positive changes in HRQOL occurring only in the group that achieved seizure freedom and not in the groups that achieved seizure reduction. Thus, although many AED trials use a 50% reduction in seizure frequency as a desirable endpoint, it appears that the complete eradication of seizures provides the only definitive HRQOL benefits for patients with epilepsy.[14,63]

Vickrey et al.[95] compared the health status of patients who had undergone epilepsy surgery with those who suffered from other chronic illnesses such as hypertension, diabetes, and heart disease (Fig. 1). Although patients who were rendered completely seizure free scored higher on all measures than patients with chronic illness, patients who continued to have seizures, even without alteration in consciousness, scored similarly to patients with other chronic medical conditions in terms of social and emotional well-being; patients with residual complex partial or generalized tonic–clonic seizures scored significantly worse than patients with myocardial infarction or congestive heart failure on overall QOL and social and emotional well-being.[95]

These results further emphasize the importance of eliminating seizures to achieve adequate quality of life; even occasional auras impair quality of life to a degree similar to a chronic medical condition such as diabetes.[33] By achieving total cessation of seizures, through medical or surgical interventions, patients with epilepsy may attain of a level of quality of life that approaches or surpasses that of the general population.[14,63]

Surgery and Health-related Quality of Life

In the first randomized, controlled trial comparing epilepsy surgery to conventional therapy, Wiebe et al.[100] demonstrated that surgery was far superior to medical treatment in terms of rendering patients free of disabling seizures (58% vs. 8%), with correlative improvements in quality of life. In a recent multicenter observational study with long-term follow-up by Spencer et al.,[90] 66% of patients experienced a 2-year remission. Success rates for temporal lobe epilepsy with corresponding mesial temporal sclerosis and supportive electroencephalographic (EEG) findings may be considerably higher.[39,83]

Despite compelling evidence in favor of epilepsy surgery, few patients who are possible candidates are being offered this potentially curative treatment, and those who are being considered for surgery may wait an average of 20 years from diagnosis.[42,61] The risks of delaying epilepsy surgery are not insignificant, given that the rate of epilepsy-related death may exceed 1%,[91] whereas the reported rate of mortality for epilepsy surgery is <0.2%.[13]

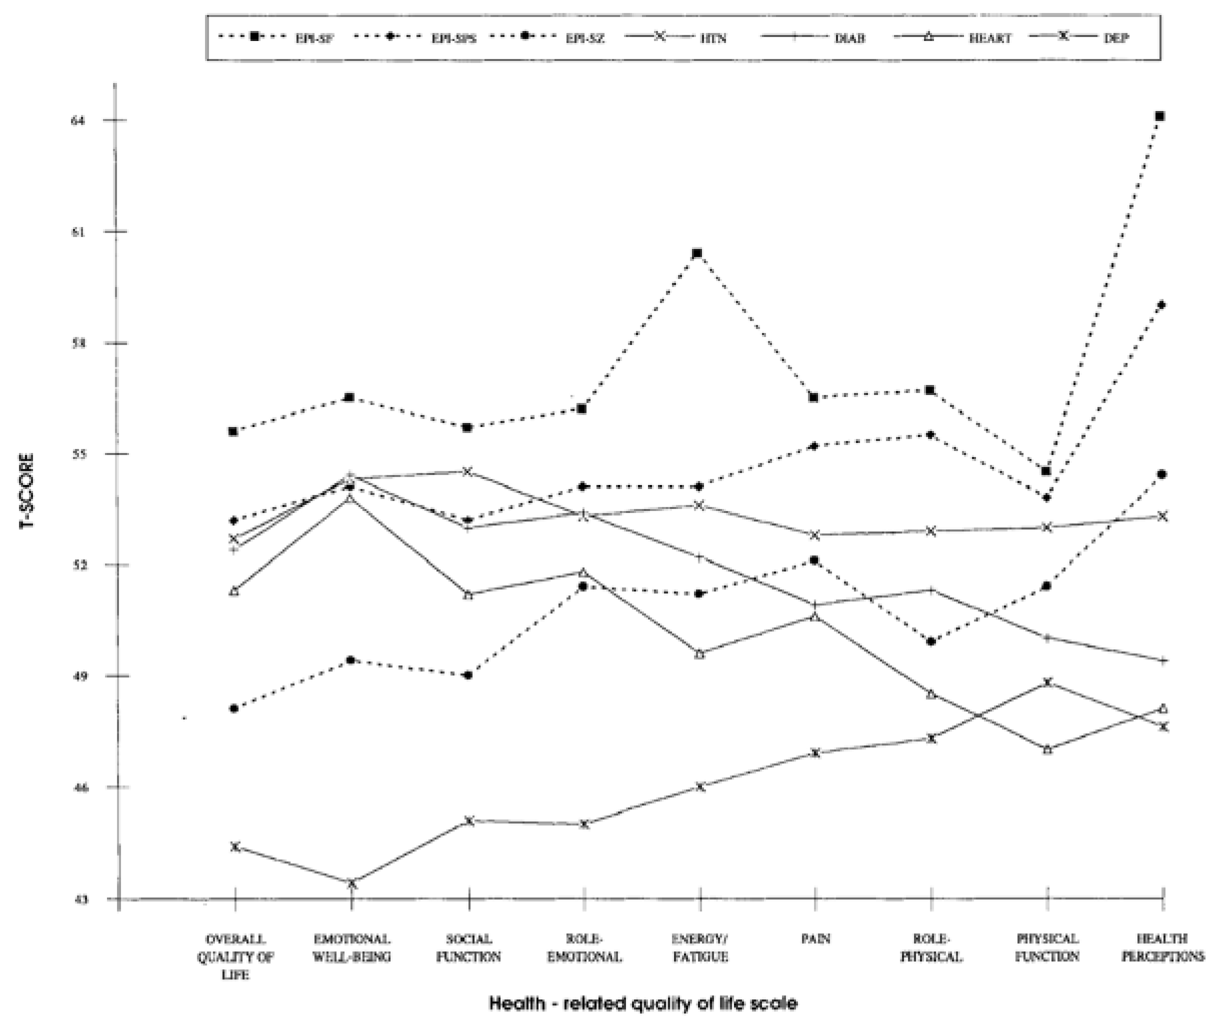

FIGURE 1. T-score distribution across nine health-related quality-of-life (QOL) domains in epilepsy surgery patients and Medical Outcomes Study Patients. EPI-SF, seizure free (n = 55, *solid squares*); EPI-SPS, simple partial seizures (n = 44, *solid diamonds*); EPI-SZ, one or more complex partial or generalized tonic–clonic GTC seizures or both (n = 67, *solid circles*); HTN, hypertension (n = 1,224, ×); DBT, diabetes (n = 548, +); DEP, depressive symptomatology (n = 906, *). (From Vickrey BG, Hays RD, Rausch R, et al. Quality of life of epilepsy surgery patients as compared with outpatients with hypertension, diabetes, heart disease, and/or depressive symptoms. *Epilepsia.* 1994;35:597–607; with permission.)

In addition to freedom from seizures, which is associated with significantly improved health outcomes, Gilliam et al.[42] looked at patient-oriented measures after temporal lobectomy for refractory epilepsy, using validated instruments for assessing HRQOL such as the Epilepsy Foundation of America's (EFA) Concerns Index, the Epilepsy Survey Inventory-55, the Adverse Events Profile, and the Profile of Mood States (POMS).[42] In a comparison of a presurgical group of 71 patients to 125 patients who had previously undergone anterior temporal lobectomy, 65% of postoperative patients were found to be seizure free (vs. 0%) and 60% (vs. 27%) were driving.[42] Multivariate regression analysis in the postoperative group

demonstrated that factors associated with improved quality of life included mood status, employment, driving, and AED cessation but did not include seizure freedom or IQ status.[42]

Markand et al.[69] found improvement in overall score and 10 of 17 scales of the QOLIE-89 in patients who had undergone temporal lobectomy versus those treated with conventional medical therapy. However, these improvements were dependent on achieving total seizure freedom.

These studies suggest a complex interaction among variables contributing to HRQOL in patients with epilepsy. By assuming that freedom from seizures, although a primary goal, is the only valuable postsurgical endpoint, we may be missing additional opportunities for intervention in the domains of transportation options, vocational counseling, and treatment of mood symptomatology with medication or psychotherapy. Through examination of the influence of patient-oriented outcomes on postoperative measures of success, we may better be able to characterize the impact of these factors on overall HRQOL in epilepsy and tailor therapeutic approaches accordingly.

Medications and Health-related Quality of Life

Several recent studies have emphasized the importance of medication effects on overall HRQOL in epilepsy. Baker et al.[7] surveyed >5,000 European patients with epilepsy and found that 44% of respondents had changed their medications at least once in the last year due to unsatisfactory control. Only 12% of patients reported no side effects from medication; common side effects included tiredness (58%), memory problems (50%), difficulty concentrating (48%), sleepiness (45%), difficulty thinking clearly (40%), and nervousness or agitation (36%). Thirty-one percent of patients had changed their medication at least once in the last year due to side effects.[7] This study included patients' self-report of adverse effects from medication. Baker and colleagues also developed an instrument to systematically evaluate medication-related toxicity: The Adverse Events

Profile (AEP).[6] This 19-item instrument was tested and evaluated for internal consistency and was then administered to 200 consecutive epilepsy patients, 62 of whom met enrollment criteria. Patients were then randomized to receive usual care from a neurologist (no AEP) or to have the AEP provided to their neurologist at each visit. Baseline scores on the AEP correlated with scores on the QOLIE-89, and significant improvements in both the AEP and QOLIE-89 were observed in the group for which the neurologist had access to the AEP.[6,40] Availability of the AEP also resulted in a significant reduction in seizures as well as more adjustments in medication by their physician compared to patients for whom this additional information was not available.[6] These results emphasize the importance of measuring and evaluating medication toxicity as part of the overall care of the epilepsy patient, not only to control for side effects, but also to potentially reduce seizure frequency and improve overall quality of life.

Gilliam et al. specifically evaluated medication side effects and their association with HRQOL in a prospective study of 195 consecutive patients.[37] Patients were screened with the AEP, the QOLIE-89, and the Beck Depression Inventory (BDI). After controlling for age, gender, generalized tonic–clonic seizure frequency and depressive symptoms, adverse medication effects were the strongest predictor of HRQOL. Severity of depression was also found to be independently correlated with overall HRQOL; seizure frequency, however, was not.[37]

There has been equivocal evidence in the literature as to the relative superiority of monotherapy over "rational polypharmacy" in the treatment of medically refractory epilepsy.[82] Although monotherapy may be felt to be insufficient, polytherapy may not necessarily reduce seizure frequency but may incur a host of other, undesirable effects.

A recent study by Pirio Richardson et al.[82] looked at QOL and monotherapy in a group of patients with medically refractory epilepsy who had been converted to monotherapy and maintained on treatment for at least 12 months. Forty percent of patients became seizure free and experienced statistically significant improvements in quality of life in several domains, including memory loss, concern over medication long-term effects, difficulty in taking medications, trouble with leisure time activities, and overall state of health.[82] Despite methodologic issues in this small study, it suggests that further consideration be given to the notion of monotherapy in medically refractory epilepsy.

In a large study of 547 patients with partial-onset epilepsy and inadequate seizure control or intolerable side effects, conversion to monotherapy was achieved with lamotrigine. Patients were evaluated with the QOLIE-31 and showed significant improvement in multiple domains after conversion to monotherapy. This improvement was independent of seizure control.[24]

Baker et al.[7] conducted a cross-sectional community survey that compared 514 patients <60 years of age to 155 patients >60 years of age across various quality-of-life domains. Medication effects were assessed using the AEP, and results were significant for increased rates of dizziness, upset stomach, disturbed sleep, and memory problems among older patients. Older patients were also more likely to be taking older AED medications. Although senior adults (>60 years of age) represent the group with the highest age-specific rates of epilepsy and are likely to be the most vulnerable to drug interactions and AED-related side effects, few studies have specifically examined the effects of epilepsy treatment on HRQOL in this particular group.[70]

These studies emphasize the need methodically to approach the choice and monitoring of pharmacologic interventions for the treatment of epilepsy. By increasing our awareness of medication toxicity through careful, systematic screening and questioning of our patients at each office visit, we may be able significantly to improve health outcomes and overall quality of life. Instruments such as the AEP are ideally designed for such ends and should be employed routinely and without hesitation.

Depression and Health-related Quality of Life

Psychiatric comorbidities, particularly depression, have long been shown to negatively affect health outcomes and health-related quality of life in a variety of neurologic and nonneurologic conditions.[18,22,48,97,98,99] Epilepsy has extremely high rates of psychiatric illness, with depression being the most common comorbidity, with a prevalence of up to 55% among patients with refractory epilepsy.[43,50,61,78] Recent studies have consistently shown a negative correlation between mood status and overall quality of life in epilepsy, often with depression alone accounting the majority of variance in quality-of-life scores.[16,65,81]

In 1995, Perrine et al.[81] examined the relationship among neuropsychological functioning, mood, and quality of life in epilepsy patients at 25 centers across the United States. Results demonstrated that mood had the highest correlation and explained the greatest amount of variance (46.7%) in validated quality-of-life measures (QOLIE-89).

Lehrner et al.[62] studied patients with refractory epilepsy and measured degrees of depression and overall HRQOL using instruments validated for native German-speakers. Forty-five percent of patients were found to suffer from depression, and on multiple regression analysis, depression scores proved to be the major predictor on all six HRQOL scales. This was a linear correlation, with more severe depression scores predicting a lower quality of life. Seizure frequency was not found to predict either depressive mood or HRQOL score.[62]

Cramer et al.[23] studied the influence of comorbid depression on HRQOL for people with epilepsy using a postal survey and the QOLIE-89 and CES-D (Center for Epidemiologic Studies Depression Scale) (Fig. 2). Other variables, such as seizure frequency, medications, degree of disability, and economic factors, were also incorporated into the analysis. Depending on CES-D scores, patients were categorized into one of three groups: (a) no depression, (b) moderate depression, or (c) major depression. All QOLIE-89 subscales and total score were determined by degree of depression but were not significantly influenced by seizure type. Total scores decreased by 17 to 23 points between major and moderate depression, 8 to 13 points between moderate and no depression, and 30 to 32 points between major and no depression (Table 1).[23]

In a recent study, Loring et al.[65] examined the relative contribution of epilepsy-specific concerns, cognitive variables, and other clinical factors to overall HRQOL in patients undergoing evaluation for epilepsy surgery. Patients were evaluated with the QOLIE-89, Minnesota Multiphasic Personality Inventory-2, BDI, EFA Concerns Index, and various measures of general intelligence and cognitive function. Regression analysis revealed that the two most important factors associated with overall score on the QOLIE-89 were depressive symptomatology (accounting for 57% of the variance) and seizure worry (accounting for 42% of the variance) (Figs. 3 and 4).[65]

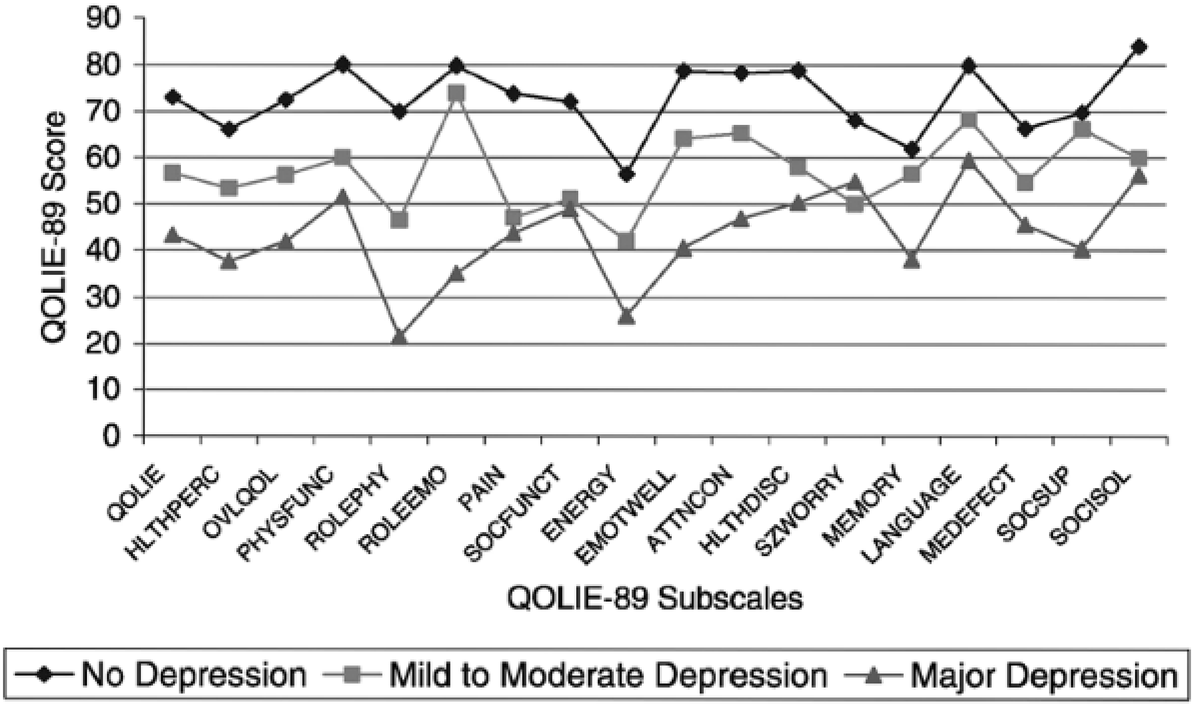

FIGURE 2. Quality of Life in Epilepsy Inventory-89 (QOLIE-89) total and subscale scores for patients with partial seizures by depression category. All scores significantly different by ANOVA across all groups. FIGURE 4. Correlation between Quality of Life in Epilepsy Inventory-89 (QOLIE-89) total score and Beck Depression Inventory score. (From Loring DW, Meador KJ, Lee GP. Determinants of quality of life in epilepsy. *Epilepsy Behav.* 2004;5:976–980; with permission.)

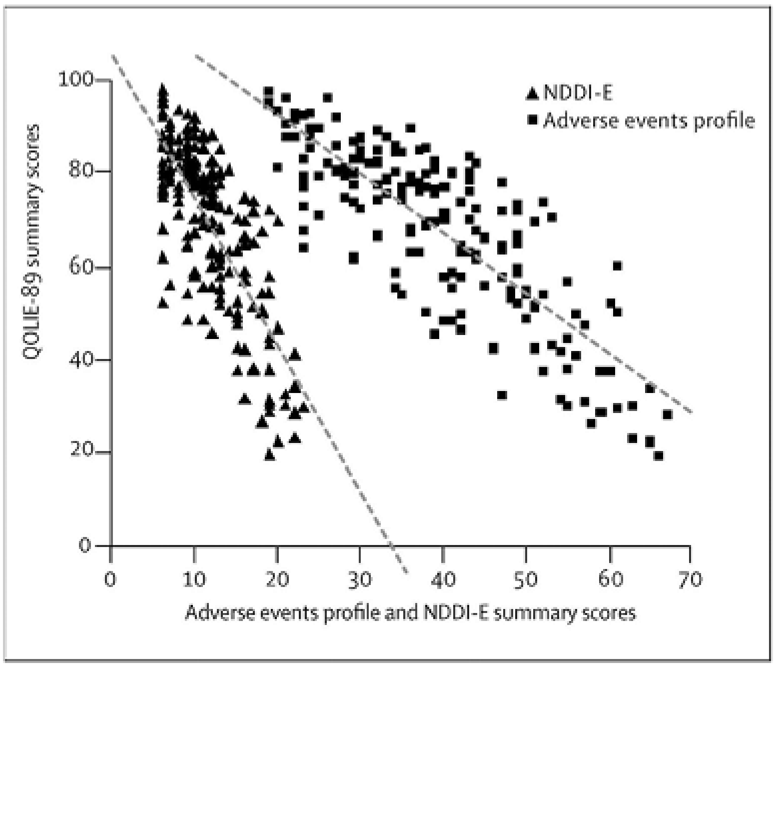

FIGURE 5. Correlation between Quality of Life in Epilepsy Inventory-89 (QOLIE-89) total score with Neurological Disorders Depression Inventory for Epilepsy (NDDI-E) score (partial r = -0.39, p <0.0001) and Adverse Events Profile score (partial r = -0.60, p <0.0001). Adjusted R^2 =0.72 (p <0.0001) on logistic regression with QOLIE-89 as the dependent variable. (From Gilliam F, Barry J, Hermann B, et al. Rapid detection of major depression in epilepsy: A multicentre study. *Lancet Neurol.* 2006:5;399–405, with permission.)

Until very recently there had been no specific diagnostic instrument for reliably and consistently diagnosing depression in patients with epilepsy, distinguishing mood status from other cognitive and medication-related effects. In a multicenter, multidisciplinary study by Gilliam et al.,[38] a six-item screening instrument, the NDDI-E (Neurological Disorders Depression

Inventory for Epilepsy), was developed. Discriminant function analysis determined the items most likely to predict a diagnosis of depression based on *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition[3] (DSM-IV)–based criteria and validated screening instruments (the Mini International Neuropsychiatric Interview [MINI] and the Structured Clinical Interview for DSM-IV [SCID]). The NDDI-E predicted major depression with a 90% specificity and 81% sensitivity, and together with drug toxicity, independently predicted 72% of the variance on the QOLIE-89 (adjusted R^2 =0.72; p <0.0001). Subjective health status as measured by the QOLIE-89 was independently predicted by total NDDI-E score (Fig. 5).[37]

Although depression is the most common psychiatric comorbidity in epilepsy,[53] a recent multicenter study by Jones et al.[54] found a very high prevalence of DSM-IV anxiety disorders (52%) among patients attending tertiary care epilepsy clinics. Johnson et al.[52] looked at not only depression, but also the relative impact of anxiety and clinical seizure features on HRQOL in patients with temporal lobe epilepsy. Patients with temporal lobe epilepsy completed self-report measures of mood, anxiety, QOL, and seizure severity, including the Symptom Checklist-90 Revised, the BDI, the QOLIE-89, and the Liverpool Seizure Severity Scale. Significant inverse relationships were observed between depression and anxiety scores and overall HRQOL.

Although there is often considerable overlap of these two conditions, partial correlations demonstrated independent contributions by depression and anxiety symptoms to scores on the QOLIE-89. In addition, depression and anxiety independently accounted for the most variance in QOLIE-89 scores when compared to seizure variables and demographic characteristics.[53] These findings replicated the “dose-dependent” phenomenon of psychiatric illness on HRQOL measures seen previously for both depression and anxiety.[37,53]

Psychiatric illness is a highly prevalent, relatively underdiagnosed, and undertreated comorbidity in epilepsy that has the potential to significantly impact QOL.[43,56,57] There now exist highly specialized screening tools, such as the NDDI-E, that can rapidly and reliably detect depression in epilepsy patients, as well as differentiate symptoms of depression from those of medication toxicity and cognitive effects of epilepsy.[37] By recognizing the presence of this interictal phenomenon through systematic screening of epilepsy patients, we have the opportunity to intervene via psychotropic medications or psychotherapy and effect positive change in the overall HRQOL of patients with epilepsy.

Other Comorbidities

In a recent population-based, nationwide Canadian study, Tellez-Zenteno et al.[93] found that people with epilepsy had a two- to fivefold higher risk of somatic comorbidities such as stroke, migraine, intestinal ulcers, and chronic fatigue than the general population. Although the reasons for these patterns were not directly explained in the study, this information further emphasizes the need to conceptualize epilepsy as a complex condition with diverse medical and psychiatric comorbidities, requiring a multidisciplinary, integrated approach.[93]

Sleep

A reciprocal relationship between sleep and epilepsy has been described over the last several centuries.[77] Circadian rhythms can affect the expression of epilepsy, and epilepsy itself has the potential to alter sleep patterns.[77] In addition, many antiepileptic drugs used to treat seizures have a disruptive effect on sleep architecture. There is a significant association between the presence of epilepsy and a comorbid sleep disorder, with rates of sleep apnea approaching 30% among patients with epilepsy.[34,51,66,67,68]

De Weerd et al.[26] examined the prevalence of various sleep disorders in patients with partial epilepsy and found significantly higher rates of disturbances such as insomnia, periodic leg movements, and excessive daytime sleepiness, with an overall twofold increase in sleep disorders compared to controls (38.6% vs. 18%; $p < 0.0001$). This study also examined the impact of sleep disturbances on overall quality of life in patients with epilepsy. The presence of epilepsy and a comorbid sleep disorder in the last 6 months was associated with the most substantial decrease in quality of life as measured by the SF-36, compared to patients with epilepsy alone and normal controls.[26]

In a large study of Mexican patients with epilepsy, patients were surveyed for factors contributing to quality-of-life scores as measured by the QOLIE-31.[1] On multiple regression analysis, the most significant factors predictive of lower QOLIE-31 scores were sleep disturbance and socioeconomic status. These factors were independent of seizure frequency, thus suggesting an independent association. Although this study was limited by the lack of screening instruments for detecting depression and medication toxicity, it further emphasizes the potential importance of comorbid sleep disturbances in determining quality of life in epilepsy.[1]

The increased prevalence of sleep disorders, particularly sleep apnea, among patients with epilepsy and their perceived impact on HRQOL should prompt increased awareness and screening by physicians who treat epilepsy.[44] Questioning regarding adequacy of sleep or excessive daytime somnolence may necessitate referral to a sleep specialist for polysomnography. General measures pertaining to proper sleep hygiene may also prove beneficial.[44] Because specific AEDs have the potential to both alter sleep architecture and increase daytime somnolence, judicious choice of medications favoring stimulating agents such as lamotrigine and felbamate, as well as the timing of medication with more-sedating agents used at bedtime, may also aid in restoring sleep.[10,44,51,77]

Exercise

Epilepsy patients have traditionally been counseled to avoid physical activity due to fear of physical injury or provocation of seizures, and as a result they tend to suffer from inactivity and general lack of physical fitness.[15,52,76,92] The issue of whether exercise exacerbates seizures is somewhat controversial, however; many studies point to a reduction in seizures in patients participating in regular exercise.[27,32,79] Several studies have examined fitness levels in epilepsy patients and results of exercise interventions on seizure control and overall health.

Steinhoff et al.[92] quantified objective measures of physical fitness such as body mass index, muscle strength endurance, and flexibility. Patients were also questioned about leisure time activities. Although leisure time activities did not differ considerably between epilepsy patients and normal controls, results based on the objective physical indicators reflected a significantly lower level of fitness in the epilepsy patients, including measures of aerobic endurance, muscle strength endurance, physical flexibility, and body mass index (BMI).[92]

Eriksen et al.[32] examined a small group of women with intractable epilepsy who were given an exercise regime of aerobic dance and strength training for 60 minutes, twice weekly, for 15 weeks. Seizure frequency was significantly reduced during the treatment phase, and a decrease in muscle pain, sleep disturbance, and fatigue was also observed.[32]

Roth et al.[85] studied associations among exercise levels, depression, and stressful life events in 133 adults with refractory epilepsy. Statistical analyses demonstrated lower levels of depression among the group who was more physically active, as well as an independent contribution of exercise and stressful life events on depression. This effect was separate from the influence of other predictor variables such as seizure frequency, age, and gender, suggesting that regular exercise and the avoidance of stress may lower depression in patients with epilepsy.[85]

In the first randomized, controlled trial of exercise in epilepsy, McAuley et al.[76] examined 23 patients with epilepsy who were randomized to either a 12-week, supervised, outpatient exercise program or to continue their current level of activity. Both clinical (seizure frequency, AED concentrations) and behavioral outcomes (QOLIE-89, POMS, Physical Self-Description Questionnaire, Self-Esteem) were measured. Results showed no appreciable difference in either seizure activity or AED levels; there were, however, significant improvements in overall score on the QOLIE-89 and significant decreases in mood disturbance among patients in the exercise group.[76]

These studies suggest a role for the implementation of an exercise program to promote overall HRQOL among patients with epilepsy without the risk of exacerbating seizures.

Migraine

Significant overlap between epilepsy and migraine is well known, in terms of both clinical presentation and prevalence of comorbid conditions in the same individual or family; having one disorder doubles a patient's risk of having the other disorder.[47,80]

Ottman and Lipton[80] investigated the comorbidity of migraine and epilepsy in a population-based study of >3,000 patients and found a greater-than-twofold increase in the rate of migraine among patients with epilepsy (24%) as well as their relatives with epilepsy (23%) compared to relatives without epilepsy (12%). Despite this increased association, no definitive causative factors, either genetic or environmental, have been identified, making this increased comorbidity likely the result of multiple contributory events.

Lipton et al.[64] examined the influence of migraine and depression on HRQOL in an international study involving patients in both the United States and the United Kingdom. Three hundred 89 migraine cases and 379 controls completed the SF-12, a generic measure of quality of life, and the Primary Care Evaluation of Mental Disorders, a mental health screening inventory. Patients with migraine had significantly lower scores on the SF-12 in both the physical and mental health domains. Depression was highly comorbid with migraine (adjusted prevalence ratio 2.7; 95% confidence interval 2.1–3.5), and both depression and migraine were independently correlated with lower HRQOL scores.[64]

A Turkish study by Velioglu et al.[94] specifically looked at the impact of migraine on epilepsy and prognosis. Cases with epilepsy and migraine and controls with epilepsy alone were followed prospectively over a 5- to 10-year period and assessed for medication use and seizure frequency. Despite similar initial baseline characteristics, the epilepsy-migraine group had a lower chance of becoming seizure free, a higher incidence of intractable seizures, a longer duration of illness, and a lower treatment response than did epilepsy controls. The reasons for poorer prognosis in the epilepsy-migraine group are not known; however, previous evidence suggesting neuronal hyperexcitability as the underlying pathophysiologic mechanism in migraine may explain the adverse outcomes in relation to seizure control.[5,47,59,94]

Given the increased prevalence of migraine and epilepsy, the adverse association with prognosis, quality of life, and depressed mood, and possible shared pathophysiology, it seems sensible to screen epilepsy patients for comorbid migraine headache and to prescribe pharmacologic treatments that target both disorders. Both topiramate[17,88] and valproate[35,87] have been shown to be effective in migraine prophylaxis and are approved by the U. S. Food and Drug Administration for this indication. Other antiepileptic drugs that may be useful in the treatment of migraine but lack evidence from large-scale trials include gabapentin,[71] levatiracetam,[33] tiagabine,[20] and zonisamide.[30] Very preliminary data in a small number of patients may show the efficacy of vagus nerve stimulation in refractory migraine.[75]

Summary and Conclusions

Traditionally, the study and treatment of epilepsy has considered the ictus itself to be of paramount importance. Whereas attempting to reduce or eliminate seizures is a worthy goal, the last decade of research in epilepsy, and particularly research relating to health outcomes, has begun to shift the focus from the ictal to the interictal period. By recognizing that pervasive and persistent interictal factors such as medication toxicity and comorbid psychiatric illness are responsible for the greatest amount of variance in overall HRQOL, we can see that the mere cessation of seizures may not be sufficient to positively affect HRQOL in patients with epilepsy.[16,37,65,81] The available instruments for measuring predictors of HRQOL should be employed routinely and frequently by neurologists and the epilepsy health care team at each outpatient encounter.

Numerous research-proven, validated instruments exist for measuring indicators of quality of life in epilepsy, including general measures such as the QOLIE-89 and instruments that target the most significant contributory subcategories, such as medication toxicity and mood status.[29,36,55,86] Current evidence from randomized, controlled trials suggests that instruments such as the Adverse Events Profile[5] for measuring medication toxicity and the newly developed Neurological Disorders Depression Inventory for Epilepsy[37] for screening for depression are relatively short, are easily completed in a busy neurologic practice, and may be the most valuable tools for improving the comprehensive care of patients with epilepsy.

Chapter 221

Legal Concerns and Effective Advocacy Strategies

Introduction

For too many years, people with disabilities—particularly people with epilepsy—were a voiceless minority. These individuals had many unmet needs in the areas of civil rights, education, employment, residential and community services, and provision of appropriate health care. Many lived at home, rarely venturing out. Too many were segregated from society and they were forced to live in large state residential institutions for the intellectually disabled or mentally ill. Until recent decades, laws, even in countries whose citizens pride themselves on liberal views about such matters, such as the United States, restricted the rights of people with epilepsy to marry and provided for their involuntary sterilization.[3] The prevailing belief was that people with epilepsy could not be employed because they might have a seizure on the job and hurt themselves or others.

Over the years, these beliefs and conditions have been challenged in various countries by advocacy efforts led by citizens with disabilities, family members, professionals, policy makers, and the courts. Gradually, society is coming to recognize that many of the problems faced by those with disabilities are not inevitable but are rather the result of discriminatory policies based on unfounded, outmoded stereotypes and perceptions deeply grounded in irrational fears and prejudices toward such people.

In recent decades, some countries have enacted laws specifically prohibiting discrimination on the basis of disability. One example of a broad-reaching antidiscrimination law is the Americans with Disabilities Act (ADA), enacted in 1990, which prohibits discrimination on the basis of disability in employment, in the programs and services of state and local governments, by places of public accommodation, in public and private transportation services, and in communications. The ADA grants all individuals with disabilities uniform protection, regardless of the state in which they live.[2]

Even with the passage of laws like the ADA and its international equivalents, epilepsy raises a variety of legal concerns, including employment discrimination, driver licensing requirements, access to appropriate educational services, access to insurance, and even possible arrest for seizure-related behavior. This chapter summarizes some of the legal issues that patients with epilepsy face, some of the legal remedies, the issues physicians may face as they advocate for their patients, continuing areas of legislative advocacy, and effective advocacy strategies for those wishing to change current laws.

This chapter emphasizes U.S. law because space does not permit a full discussion of legal issues from the perspective of each country and because insufficient recent information exists about legal issues from an international perspective, except in the area of driver licensing. Additional publications on legal or psychosocial issues in various countries may be of interest.[1,4,6,9,10,11,12,15,16,19,21,23,24,25]

The Americans with Disabilities Act—Employment Provisions

Although laws do not eliminate discriminatory attitudes, antidiscrimination statutes such as the ADA have forced many employers to reevaluate and subsequently change their employment practices and have given employees important legal tools with which to seek redress from unfair employment practices.

The concept of disability under the ADA encompasses three parts: (a) does the individual have, does the individual have a record of, or is the individual regarded as having, a physical or mental impairment? If so, does the physical or mental impairment the individual has, has a record of, or is regarded as having (b) substantially limit (c) one or more of that individual's major life activities?

Under the ADA, employers with 15 or more employees are prohibited from discriminating on the basis of disability against individuals who can do the essential functions of the job or who could do so with reasonable accommodation. Reasonable accommodation is a flexible concept. Examples of accommodations that might be appropriate for individuals with epilepsy include job restructuring (e.g., if driving is a marginal duty, driving tasks could be reassigned to another employee); permitting part-time or modified work schedules; allowing time off for doctor's visits and to recover from seizures; installing a safety device around a piece of machinery; padding a concrete floor at the employee's work site; and allowing the individual to work at a job site close to home or, in some cases, at home.

Employers are not required to provide an accommodation under the ADA if it would be an "undue hardship" on the employer, that is, if it would cause the employer significant difficulty or expense. This is evaluated in light of the employer's overall business. If a particular accommodation would impose an undue hardship on an employer, the employer may be required to provide other reasonable accommodations. The ADA does not require employers to accommodate the needs of employees who miss work to care for family members with medical problems. However, in the United States, employees who need to miss a significant amount of work because of their serious health problems or those of family members may benefit from the Family and Medical Leave Act (FMLA), which requires employers with 50 or more employees to provide up to 12 weeks of unpaid leave to eligible employees and to retain the employee's benefits. It is recognized that this may be a uniquely U.S. situation, but it highlights the way in which the rights of individuals are becoming protected by law. Further

P.2278

information about FMLA can be obtained from the Wage and Hour Division of the U.S. Department of Labor.

Safety Issues

For most jobs, simply having occasional seizures will not significantly affect the person's ability to do the job's essential functions. Having seizures does not render a person unqualified under the ADA simply because seizures require occasional use of sick time, do not look good, or may result in injury or possible use of worker's compensation. In the U.S. example, employers do not have to offer a job or retain an individual in a job because of a disability if the individual poses a "direct threat" to safety. Direct threat is defined as "a significant risk of substantial harm which cannot be lessened by reasonable accommodation."

Except in very limited circumstances (e.g., commercial airline pilots), a mere diagnosis of epilepsy will not mean that an individual poses a direct threat. Similarly, a possibility or even a probability that an individual will experience a seizure at work is usually not enough to make that person a direct threat without showing that the individual's workplace or essential job duties pose a particular risk of harm. An evaluation must also be made as to whether the factors causing the increased risk can be reduced through a reasonable accommodation. Using laws similar to the ADA, people with epilepsy have successfully obtained and retained such high-risk jobs as firefighter, police officer, and butcher (see, e.g., the case of *Jansen v Food Circus Supermarkets*[13]).

Unsubstantiated fears about risks from the employment environment may not be used by an employer to disqualify a person with epilepsy. Under the ADA, employers must evaluate the individual and the specific situation using reasonable medical judgment that relies on the most current knowledge and best objective evidence. If the specific job tasks suggest possible safety concerns, the treating physician may be asked by the employer or employee for advice about whether the employee should avoid certain tasks. In evaluating a person with epilepsy for a position that might pose safety concerns, it is important to consider the type of job, the essential job duties, the degree of seizure control, the types of seizures (whether the person has simple partial onset to warn of possible evolution), the person's reliability in taking prescribed seizure medication, any side effects of medication, and any accommodations that might lessen the risk.[17]

The ADA's focus on individual capabilities is especially important for the individual with epilepsy because the term epilepsy refers to a broad range of symptoms and underlying causes. Depending on their individual circumstances, some people with active seizures should avoid certain job tasks, such as driving, or certain environmental conditions, such as exposure to open fire, hot substances, dangerous moving objects, mechanical and electrical hazards, and situations in which a danger of falling exists. If an employee is no longer able to do the job for which he or she was hired, even with reasonable accommodations, an employer may be required to reassign that employee to another position, if one is available, for which the employee is qualified. The position should be equivalent in terms of pay and other job status. Within this scheme, an employer is permitted to reassign an individual to a lower-grade position if that is the only position available for which the individual is qualified.

Medical Inquiries by Employers

Employers who are covered by the ADA are prohibited from asking any questions about whether an applicant has a medical condition or about the nature and severity of the condition until after they have extended the applicant a job offer. This is particularly important for individuals with epilepsy, who historically have been denied interviews and refused employment solely because an employer learned of their epilepsy. Again focusing on the U.S. situation, once a job offer has been made, an employer may ask medical questions or request that an individual have a medical examination, so long as all employees selected for that job classification are required to do so. Once an individual has been employed and is on the job, medical inquiries must be job related and consistent with business necessity. In other words, the need for the examination must be triggered by some evidence of problems related to job performance or safety, or an examination may be necessary to determine whether individuals in physically demanding jobs continue to be suitable for duty. In addition, a request for reasonable accommodation by an employee may trigger medical inquiries to verify the need and scope of accommodation. All medical information must be kept separate from an employee's personnel file, and the information must be kept confidential.

Many countries have enacted privacy laws, and transgression of these may provide an alternate source of remedy if the person with epilepsy has been exposed against his or her will.

Complaint Process Under the Americans with Disabilities Act

Individuals may file employment discrimination complaints under the ADA with the U.S. Equal Employment Opportunity Commission (EEOC) or, in many cases, with their state Human Rights Commission. If an employer is not covered by the ADA, because the business does not have 15 or more employees, one should investigate whether there is a state law that applies. Further information about state antidiscrimination laws should be available from the state Human Rights Commission (HRC), and most industrialized countries now have local equivalents of the EEOC and HRC. These bodies have international legitimacy because their host nation is usually a signature nation of the International Parent Body run under the auspices of the United Nations. The U.S. example is far from unique, and was merely provided as a focus on which local proceedings can be examined and used to protect the rights of people with epilepsy.

The Supreme Court's Interpretation of the Americans with Disabilities Act—Important Limitations

It is important to note that, despite the apparently clear nature of protection against discrimination afforded by the ADA, its recent interpretation by the Supreme Court of the United States has limited the protection provided by the Act. In a trilogy of cases (*Sutton v United Airlines, Inc*; *Murphy v United Parcel Service, Inc*; and *Albertson's Inc v Kirkinberg*), the Court held that, in determining whether a person was suffering from a disability, mitigating factors (such a medication) must be taken into account. Thus, in *Sutton*, although the applicants had poor eyesight (20/200 in the right eye and 20/400 in the left eye), when corrected with glasses or contact lenses, their vision was 20/20. The applicants were not disabled. Similarly, the applicant in *Murphy* had chronic hypertension, which, without medication, was extremely high. With medication, it was within acceptable ranges. A recent reaffirmation of these cases is *Cutrera v Board of Supervisors of Louisiana State University* (429 F.3 d 108, 2005).

P.2279

The effect of these cases on people suffering from epilepsy is obvious. A person whose epilepsy is controlled by medication will not be regarded as having a disability, and thus will not be afforded the protections of the ADA.

Driver Licensing

Driver licensing laws and policies vary significantly from country to country. There is, however, a consensus among experts worldwide that driving should be permitted when seizures are adequately controlled. There is less consistency among different countries as to the length of time considered to be adequate following seizure activity.

Most countries require a seizure-free period of 1 to 3 years.[20] In the United States, most states use a firm seizure-free period of 1 year, 6 months, or 3 months. Many states also provide for exceptions to the usual seizure-free requirement, for example, when an individual has a breakthrough seizure due to medication change or withdrawal and is back on the original medication.[14]

Experts in the international community and in the United States have recently developed separate reports on driving and epilepsy.[18,20] In general, these experts recommend that licenses should be granted after a short prescribed period of freedom from seizures, the decision should be based on an assessment of the medical history of the individual and there should be room for exceptions to the prescribed period of seizure freedom. This assessment should be done either by an independent neurologic specialist or by a Medical Advisory Board on which a neurologic specialist serves. Variations in determining whether to license an individual come from differences in the seizure history, type of seizure, and causative factors. Reassessments should occur periodically or when the individual reports changes in seizure experience.

Current practice in the United States is that, whereas the ultimate licensing decision lies with the state Department of Motor Vehicles (DMV), the agency looks to the treating physician for a variety of information ranging from details about the patient's seizure disorder to the physician's opinion about the patient's ability to drive safely. Most states also require periodic medical updates, at least for several years.

There has been a general trend in recent years to move toward shorter seizure-free periods and exceptions to the general rule. Those U.S. physicians who want to influence DMV policies may want to join their state DMV's medical advisory board, if one exists. In states where the criteria for licensing people with epilepsy was enacted by the legislature, any major changes would be made on the legislative level, but in many places the rules are controlled by regulations pertaining to the act; thus, alteration is far simpler. Physicians may want to contact a local epilepsy organization about state-wide legislative initiatives. A model driver licensing law developed by the Epilepsy Foundation of American (EFA), the American Academy of Neurology (AAN), and the American Epilepsy Society (AES) is available from the EFA.[18] The EFA, AAN, and AES support the use of a 3-month seizure-free interval in driver licensing with consideration of the following favorable and unfavorable factors that may modify that interval:

Favorable modifiers

- Seizures during medically directed medication changes
- Simple partial seizures that do not interfere with consciousness or motor control
- Seizures with consistent and prolonged auras
- Established pattern of pure nocturnal seizures

- Seizures secondary to acute metabolic or toxic states not likely to recur
- Sleep-deprived seizures
- Seizures related to reversible acute illness

Unfavorable modifiers

- Noncompliance or lack of credibility
- Alcohol or drug abuse within last 3 months
- Increased number of seizures in the last year
- Prior bad driving record
- Structural brain lesion
- Noncorrectable brain functional or metabolic condition
- Frequent seizures after seizure-free interval
- Prior crashes due to seizures in the last 5 years

According to their report on driving and epilepsy, international experts from the International Bureau for Epilepsy (IBE) and the International League Against Epilepsy (ILAE) have not recommended a specific seizure-free period but generally describe a range from 3 months to 2 years as appropriate, depending on various factors.[20] The medical issues critical to licensing, and which they recommend should be assessed, are generally similar to the criteria described here. For example, the report on driving suggests that no restrictions on driving may be necessary if the seizure follows an acute cerebral illness from which there has been full recovery or in cases of sensory-evoked seizures. Only a short period of seizure freedom may be necessary prior to licensure if a seizure is the result of physician-supervised medication changes. Whether to license individuals who have seizures due to metabolic disorders depends on the nature of the underlying condition or disease. The report thus clearly emphasizes an individualized assessment based on various factors.

Some people who suffer from seizures have incurred civil or criminal liability as the result of seizure-related accidents. In the United States, such liability has occurred when individuals have driven against medical advice, without a valid license, without the state DMV being aware of their medical condition, or with the knowledge that there was a particular reason that they should not be driving at that time.

In a disturbing trend that is yet to show up in the United States, a court in New South Wales, Australia, in deciding the unreported case of *R v Gillett*, disregarded physician- and state-endorsed guidelines established to determine fitness to drive in assessing the liability of a man with epilepsy who had a motor vehicle accident causing death to others.

In the United States, few reported cases exist on the issue of physician liability to third parties for certifying a patient to drive. Those cases that have been brought in the area of certifying fitness to drive suggest that the risk of liability is minimal. In the United States and internationally, experts recommend that physicians should not be liable for recommendations to the state driver licensing agency as long as those recommendations were arrived at in a reasonable manner and consistent with the prevailing standard of care.[18,20]

Some cases brought by third parties against physicians have been based on the theory that the physician did not use due care in the diagnosis or treatment of the patient. Most courts that have considered these cases in the United States have recognized that physicians cannot "control" their patients; thus, they do not have a duty to prevent them from driving. They may, however, have a duty to warn their patients not to drive due to recent seizures or side effects of medication, and they may be liable to third parties if they fail to give such instructions. Physicians should provide the warnings and advice that are required under prevailing standards of care. Patients who should not be driving, or who should be driving only under certain circumstances, should be so advised in writing. Similarly, confirmation of having given such advice should be written in the patient's medical records as an added protection, should the physician be faced with litigation.

As long as the physician is using reasonable medical judgment and proper documentation, a third-party suit should not result in liability. If a physician has specific concerns, however (such as a patient who is driving against medical advice), he or she may want to consult with an attorney.

The EFA, the IBE, and the ILAE oppose laws requiring physicians to report their patients with epilepsy to the state. In the United States, states currently having such laws include California, Delaware, Nevada, New Jersey, Oregon, and Pennsylvania. Instead, the EFA, the IBE, and the ILAE support laws that give physicians "good faith" immunity for participating in the driver licensing process and for voluntarily reporting those patients who pose an imminent threat to public safety because they are driving against medical advice. In Australia, physicians are not required to report (except in South Australia and the Northern Territory) and are protected against invasion of privacy, except in Western Australia.[5]

Education

The educational process can pose significant obstacles to children with epilepsy. Obstacles include the physical and psychosocial effects of seizures, the effects of antiepileptic medications, underlying cognitive difficulties, and an educational system that, all too often, does not provide the necessary support or understanding.[22]

In 1975, in response to pressure from organized groups, the U.S. Congress passed the Education of All Handicapped Children Act (PL. 94–142), which guarantees that all children shall receive a free, appropriate public education in the "least restrictive environment." The underlying notion was that children with disabilities were to be educated alongside their nondisabled peers whenever possible. This law was yet another step in the evolution of a public policy goal of total integration of people with disabilities into U.S. society. In 1990, this law was renamed the Individuals with Disabilities Education Act (IDEA).

The Individuals with Disabilities Education Act is the central vehicle through which the U.S. federal government maintains a partnership with the states and localities to provide an appropriate education for children with disabilities requiring special education and related services. To receive funds, state and local education agencies must follow the law's requirements for identifying, evaluating, and providing services to eligible children aged 3 to 21 years. Children with epilepsy are eligible for services if their epilepsy adversely affects their educational performance. Infants and toddlers who have developmental disabilities or who are at risk of having a disability may be eligible for early intervention services.[8] Treating physicians play an important role in establishing a child's need for services.

Arrest for Seizure-Related Behavior

Some seizure-related behaviors, particularly those associated with complex partial seizures, may result in the individual with epilepsy being arrested and charged with such offenses as public intoxication, trespassing, breaking and entering, shoplifting, resisting arrest, and assault. Assault charges sometimes result when an individual having a seizure is restrained and reacts reflexively. Whether the behavior in question was consistent with the individual's seizures is an issue best addressed by the treating neurologist. Sometimes, intervention by a medical professional will result in charges being dropped. If charges are brought, the individual should seek the advice of a criminal defense lawyer. The type of defense that is appropriate varies from country to country. Some countries and some U.S. states recognize an "automatism" defense for individuals who were not aware of their actions at the time of the alleged criminal behavior. Expert opinion at trial will be crucial in proving a defense. In some countries, one must be careful of the concept of "sane" versus "insane" automatism, and legal judgment is mandatory.

To reduce the number of inappropriate arrests of those with epilepsy, the EFA, in conjunction with the Police Executive Research Forum, has developed training materials for police officers. The materials encourage police to consider the possibility that certain types of behaviors stem from seizures. Police should consider information from bystanders or family members or from observation at the scene that give clues that a person's confusion or unusual behavior was seizure related. Other national bodies, such as the National Epilepsy Association of Australia (NEAA), as it was then called, have also developed police training materials.

In a number of cases, individuals have sought to use epilepsy as a defense against charges of serious violent crimes. The circumstances under which violent or aggressive behaviors occur, as the result of epileptic seizures, is controversial, and the types of legal defense that would be used vary from country to country and from state to state.[26] In a text such as this, it is not possible to fully debate such defense strategies, but it is vital that the rights of both the individual with epilepsy and the public at large be protected and that the defense provided by “epilepsy” be correctly applied and not abused.

Continuing Areas of Advocacy

Health Care Reform

Issues of access to health care services are central to ethical concerns regarding quality of life for people with epilepsy in all countries. Decisions about access and adequacy of services made at executive and legislative levels, as well as in the private sector, affect the choices that are available to clinicians and patients. A major public policy priority for the epilepsy community in the United States is comprehensive reform of the health care system. The existing mix of public and private insurance in the United States has failed to provide insurance to an estimated 39 million Americans, including many individuals with chronic health conditions such as epilepsy. Private health insurance is increasingly priced beyond the reach of individuals and businesses. Benefits for individual consumers are being trimmed in an attempt to control costs, yet the costs of health care continue to skyrocket. The greatest flaw in the existing health care delivery system in the United States is the fact that those individuals who most need access to health care, namely people with chronic health conditions or disabilities, are the most likely to be denied health insurance.

In 1989, the EFA commissioned a study of insurance industry practices toward people with epilepsy. This study found that most, if not all, companies base their underwriting decisions on medical outcome data that are seriously outdated. The report concluded that existing underwriting guidelines used by U.S. insurance companies fail to reflect the major advances in the diagnosis and treatment of epilepsy. Clearly, the question that lies at the heart of today's U.S. health care debate is, “How do we ensure access to appropriate health care for everyone?” Many options have been considered by the U.S. Congress, including mandating health insurance coverage at the workplace and significantly restructuring the health care system in a comprehensive way. Some have advocated for a single-payer national health plan patterned on the Canadian system. Clearly,

passage of legislation ensuring universal access to health insurance would have a profound effect on the lives of thousands of people with epilepsy who currently are unable to obtain coverage. Although Congress has failed to pass appropriate health care reform legislation, disability rights advocates will continue to press for comprehensive reform.

Epilepsy Research and Drug Development

Enormous advances in our understanding of epilepsy have occurred in the last 20 years that have already affected, or will affect, the care of patients with epilepsy and their quality of life. Particularly in the 1990s, dubbed the “decade of the brain,” there was enormous enhancement of tools available with which to treat epilepsy, such as vigabatrin, lamotrigine, gabapentin, felbamate, and topiramate.

Concurrent with these developments has emerged a need to examine commitment to research and a review of ethical questions and indemnification of those, namely researchers, ethics committees, and people who take part as volunteers, within such research programs. Each of the antiepileptic medications mentioned encountered problems in development (addressed elsewhere in this text), but, coupled with these difficulties, the issues of legal standing, for all concerned, emerge. This is highlighted by the case of felbamate, the development of which has been arrested on a worldwide scale, even though there are still 150,000 people in the United States who depend on this medicine to achieve better seizure control. A similar, though quite different, situation existed with zonisamide, an agent whose U.S. development was initially stopped while the drug was still in use in Japan, before it reemerged in the United States.

The epilepsy movement, through its international parent bodies of the ILAE and the IBE, and local agencies such as the EFA and the AES, has long been committed to supporting research at all levels of society with its own programs and those of national bodies such as the National Health Scheme (United Kingdom), the National

Institutes of Health (United States), and the National Health and Medical Research Council (Australia).

Where problems arise as a result of federal (national) government regulation or intrusion into the availability of or access to existing or new agents, the local chapters of the ILAE and the IBE have proven highly persuasive. This is evidenced by the Australian experience in which the government restricted access to valproate to authority-only prescription, which made it difficult to get the drug. The combined efforts of the NEAA (as it was then called) and the Epilepsy Society of Australia (ESA) reversed this decision and ensured ongoing easy access to this effective treatment. Similarly, the EFA interacts with the U.S. Food and Drug Administration on a frequent basis to improve the regulatory function of evaluating the safety and efficacy of medications, including the standards used to determine the therapeutic bioavailability of generic antiepileptic drugs.

The international epilepsy movement has also demonstrated its commitment to the exchange of ideas within the scientific community at all levels with the sponsorship of international meetings that provide a forum to consider not only the pure science of epileptology, but also advocacy and legal ramifications, as evidenced by the 1987 and 1995 meetings, during which the main themes examined were epilepsy and the law.

Family Support Services

The literature on the psychosocial adaptation of children with epilepsy indicates that the adjustment of the child to his or her disability is significantly affected by the attitudes of the adults in the family, community, and educational environment.[27] Families of children with disabilities experience enormous stress on a day-to-day basis. Lack of family support often renders even the strongest family unable to cope effectively. In the face of complicated medical, social, and educational issues, families in this situation may not be able to provide the support and nurturing a child with epilepsy needs to reach his or her full potential. In addition, families often do not have a clear understanding of the right of their children to an appropriate education in the least restrictive environment and how to advocate effectively for these services. For these reasons, the epilepsy community is actively advocating for greater family support services in the following areas: information, respite care, counseling support and communication, evaluation, and coordination of services.

In the United States, efforts are underway in several states to establish programs providing families of people with disabilities with financial support, the specific uses of which are to be determined by the family, not the government. At the federal level, legislation has been passed that would provide eligible families with assistance. Efforts are underway to secure funding for the initiative. The epilepsy community and other disability organizations have been working very hard on these types of initiatives at the state and federal levels.

Effective Strategies with Political Representatives

In an era of diminishing public resources and increasingly complex public policy debates, it is especially important for the epilepsy community to expand on its current advocacy activities and relationships with public policy makers. The following strategies have proven effective in building such relationships:

- Write letters and make phone calls to policy makers on issues of concern. Similarly, write or call to thank legislators for supporting an issue.
- Conduct meetings on a regular basis with legislators in their home district offices.
- Invite elected representatives to local activities, such as board meetings, support group meetings, fund-raising events, and medical conferences.
- Include articles about public policy issues and legislators in organizational newsletters.
- Get involved in local political campaigns; however, these activities must be conducted only on personal time and cannot include contributions or expenditures by tax-exempt organizations.
- Develop or join coalitions of groups with coinciding interests or positions.
- Develop local grass-roots letter-writing and telephone networks that can be activated to influence decision

makers when issues arise.

- Add legislators to mailing lists for newsletters and special event announcements.
- Write letters to the editors of local newspapers on issues of importance to the epilepsy community.
- Organize rallies and events when important issues are being considered by your state or federal legislators and invite the press to attend.

A strong advocacy network, at national and local levels, is needed to protect the rights of people with epilepsy and to ensure that their specific concerns will be fully considered as new policies are developed. To accomplish this, continuing contacts and interactions with legislators and other policy makers are essential.

Summary and Conclusions

Although one can point to significant gains in the areas of legal rights, education, employment and training, and development of safer, more effective therapies, much remains to be done if people with epilepsy truly are to be given the opportunity to reach their full potential in our society. An area of particular need in some countries continues to be access to appropriate health care services. No longer should those with epilepsy be routinely denied the benefits of timely and quality health care services. The epilepsy community will continue to advocate strongly in this and other areas, with the goal of further reducing the burden of this serious disorder.

Chapter 222

Overview: Neonatal Syndromes

Jean Aicardi

Introduction

The neonatal period is conventionally limited to the first 28 days of life. However, some seizures with onset in the first 2 to 3 months of life display similar features and will be considered here. The vast majority of neonatal seizures, however, occur during the first 10 days of life. Most neonatal seizures are short-lived events, lasting only a few days, and usually do not herald a chronic convulsive disorder unless structural damage is present whether due to malformations or acquired disease. Therefore, the term *epilepsy,* meaning a chronic, recurrent disorder with unprovoked paroxysmal events, is only rarely adequate, and the noncommittal term of *neonatal seizures* or *convulsions* is more appropriate. Seizures are one of the most common neurologic problems in the first days of life. Their real frequency is not known because it is becoming clear that all abnormal, stereotyped, and periodically recurring movements may not be epileptic seizures in the sense of excessive discharges of the gray matter, but they can be due to other mechanisms, such as release of brainstem tonic mechanisms from cortical control as a result of lesions or dysfunction of the cortex.[5] The clinical features of neonatal seizures are often relatively unimpressive (see Chapter 56). Generalized seizures are rare, although occasionally cases of infantile spasms or massive myoclonias may occur.[1,3] Focal or multifocal seizures are the rule and several types are recognized. Focal clonic seizures may remain in a fixed location or may involve several focal areas at the same time or in succession (migratory seizures). Clonic seizures are usually associated with typical rhythmic electroencephalographic (EEG) discharges, although these may also occur with tonic or subtle seizures. Tonic seizures may be localized to a single segment; when generalized, they are more often the result of nonepileptic tonic liberation than truly epileptic. *Subtle seizures*,[30] sometimes referred to as *motor automatisms*,[19] are frequent and may include random and roving eye movements, sucking, chewing motions, tongue protrusion, rowing or swimming or boxing movements of the arms, and pedaling or bicycling movement of the lower limbs. Apneic seizures are relatively common.[31] Although some subtle seizures are associated with rhythmic ictal EEG discharges and are clearly epileptic, ictal EEG often does not show typical epileptic activity, and the nature of the clinical events is difficult to determine. In some cases, such ictal phenomena can be provoked by external stimuli that can demonstrate temporal and spatial summation, or they can be inhibited by restraint or repositioning of the involved part. Such features may be more suggestive of brainstem release phenomena, and these events are mainly interpreted as nonepileptic. The absence of an EEG discharge, however, does not completely rule out the possibility of an epileptic phenomenon, thus raising a difficult diagnostic problem.

Ictal EEG discharges in neonates may be highly polymorphic. The two main components, which may be associated withone another, are repetitive sharp waves or spikes and abnormal paroxysmal rhythms including beta, alpha, theta, or delta rhythms that usually remain focal or involve only one hemisphere.[13,16,21] Almost all paroxysmal EEG activity in the neonate begins focally. Ictal discharges are extremely variable in appearance, voltage, frequency, and polarity, and their aspect can change suddenly. Unrelated discharges of various shapes and rhythms frequently occur independently at different locations in both hemispheres. Bilateral symmetric discharges are rare and are associated specifically with unusual ictal phenomena such as myoclonias or spasms. In benign familial neonatal convulsions, they may consist of generalized flattening of the tracing, followed by high-amplitude, slow theta waves,[12,26] but these events follow a focal onset.

Although such differences between neonatal epileptic versus nonepileptic seizures can be of practical value because the use of anticonvulsant drugs that depress cortical activity might be contraindicated in nonepileptic release phenomena,[5] a firm differentiation of epileptic from nonepileptic seizures in neonates may be impossible.

From a clinical viewpoint, seizures must be differentiated from jittering or tremulations, shuddering, and benign neonatal sleep myoclonus.

Ictal EEG recording is helpful when showing clear paroxysmal activity. Ictal EEG events may not be easily differentiated from other patterns that are not infrequently seen in the neonatal EEG. These include brief intermittent repetitive discharges (BIRDS). Most investigators, therefore, require discharges of at least 10 seconds to accept their ictal nature.[28,29] Isolated interictal sharp waves should not be regarded as pointing necessarily to a diagnosis of seizures. However, some seizures with all the clinical features of classical epileptic seizures are not accompanied by typical discharges on the scalp.[8] Conversely, many characteristic EEG discharges are not associated with any clinical manifestation,[13] and such electroclinical dissociation seems to occur especially following long series of seizures. It is not currently possible to decide whether such purely electrical seizures have the same significance as electroclinical attacks, carry the same risk of brain damage, and require the same treatment.

Neonatal seizures rarely occur as isolated events. In most cases, the seizures are frequently repeated over a period of a few days and may result in status epilepticus.[28] They then subside, irrespective of whether the cause is a major brain lesion—as in hypoxic-ischemic encephalopathy—or a benign, purely functional disturbance—as in benign familial neonatal convulsions. The duration of individual seizures is usually brief, even in cases of status. An average duration of 137 ± 11 sec was found in one study.[7] This brief duration may be one reason for the absence of residual damage in such cases as hypocalcemic seizures that leave no residua even if they are repeated over several days.

The causes of neonatal seizures differ considerably from those of seizures in older children. A majority are due to organic

P.2284

brain damage of prenatal or perinatal origin or to acute metabolic disturbances. The role of neonatal hypoxic-ischemic encephalopathy is probably less than formerly thought because of improvements in prenatal and obstetric care. Moreover, a significant proportion of seizures attributed to anoxia are of the subtle type and may not be epileptic. A relatively poor correlation has been found between such variables as Apgar scores, cord pH, and abnormalities of cardiac rhythms and the occurrence of convulsions.[20] Conversely, emphasis has been put more recently on the etiologic role of brain damage of prenatal origin[27] and congenital brain anomalies.

Other significant lesional causes include intracranial hemorrhage and neonatal and fetal infections such as bacterial meningitis and sepsis that require emergency treatment. Strokes due to arterial thrombosis or embolism of undetermined origin have proved to be a frequent cause of focal seizures of fixed location occurring in the first few days of life. These are usually of clonic type and are often repeated in long series or status epilepticus. A persisting hemiplegia is observed in about half of the cases, but the neurodevelopmental outcome is relatively favorable.[30] Strokes of venous origin may also be observed.[9]

Acute metabolic disturbances are relatively uncommon with the virtual disappearance of late hypocalcemia and the decrease in frequency of electrolytic derangements and of hypoglycemia. Hypoglycemia remains an important cause, however, because it is a treatable condition that is observed mainly in post-term infants often following prolonged labor and difficult birth. It may rarely reveal pancreatic disease or may result from other metabolic errors. An abnormality of the transport of glucose[10] usually becomes manifest later in the neonatal period and is responsible for hypoglycorrhachia without hypoglycemia, thus requiring CSF level of glucose study for diagnosis.[10]

There are a number of chronic metabolic diseases with neonatal manifestations. Disorders of organic acids and amino acid metabolism most often manifest in the neonatal period with subtle seizures or abnormal movements that, in most cases, do not seem to be of a true epileptic nature. True epileptic attacks can be observed perhaps more commonly in urea cycle disorders.[2] They are also a feature of glycine encephalopathy in which erratic myoclonus is frequent. Rare disorders of neurotransmitters and sulfite oxidase and manganese cofactor occur. Pyridoxine dependency is another treatable cause and occurs selectively in the first days of life.[11] Convulsions responding to pyridoxal-phosphate but resistant to pyridoxine, which are also treatable, have been recently described.[15] These causes individually, in rare cases collectively, form a sizable group and are important because treatment is possible in some situations, or at least diagnosis is possible for counseling purposes. Other nonlesional causes include drug withdrawal and inadvertent injection of local anesthetics in the fetus during peridural anesthesia.[14]

Benign syndromes of infantile seizures have emerged during the last two decades and their recognition is important because, in contrast with most neonatal convulsions, their outcome is favorable and families should not be given the poor prognosis that is applicable to many neonatal seizures (see Chapter 227). They include two groups. *Benign familial neonatal seizures* have recently attracted considerable attention (see Chapter 223). Such cases are dominantly transmitted and in some families have been shown to result from ion channel dysfunction affecting usually K^{2+},[18] but also Na channels.[4] Whether these cases form one or several clinical syndromes is not clear. Genetically, they are heterogeneous, with at least three different loci, and responsible genes have been located most commonly on chromosome 20 and, rarely, on chromosome 8, although many cases do not demonstrate any of these linkages.[18,24] However, in most families no gene is currently known. They are dominantly inherited. The seizures have some special characteristics[12,26] and disappear, usually in a few days or weeks, although some 15% of affected children may have other types of seizures in later life.

Despite their rarity, these cases are of great significance because they represent the first known disease of pure epilepsy of monogenic origin and may be significant for the understanding of the mechanisms of more common forms of epilepsy. They are also of theoretical interest as demonstrating the role of ion channels, in this case K channels. *Benign nonfamilial seizures*, sometimes termed fifth-day fits[24,25] because their most common occurrence consists of episodes of repeated brief seizures of clonic and apneic types in the normal newborn between days 3 and 7, recur for 24 to 48 hours and disappear without leaving apparent sequelae. Their features do not differ from those of the familial seizures. No cause has been consistently found, and the frequency of the syndrome may be fluctuating with time, suggesting the possibility of environmental causes. The definition of the syndrome, however, is loose, and this may account for the discrepant frequencies reported.[17] Nonetheless, its existence underlines the fact that some syndromes in neonates are benign.

The outlook of neonatal convulsions varies with their cause. Seizures due to brain damage are of unfavorable significance when associated with structural brain defects. Predictors of poor prognosis include the persistence of abnormal neurologic signs at the end of the first week of life[17] and the presence of marked interictal EEG anomalies, such as inactive or depressed tracings and periodic bursts of paroxysmal activity on a generally inactive background (paroxysmal tracings). The major problem is the development of mental retardation or cerebral palsy rather than the persistence of seizures. The frequency of later epilepsy varies between 18% and 26% following convulsions of hypoxic-ischemic origin. In many cases, late seizures develop after a free interval and are often infantile spasms.[3] The persistence of partial seizures is the rule with brain malformations.[19] In rare cases, infantile spasms may begin in the neonatal period.[3] They are a part of Ohtahara syndrome, in association with a burst-suppression EEG (see Chapter 225). The syndrome is often due to extensive brain malformations and has a very poor outlook.[21] The same sort of burst-suppression tracing may be associated with erratic myoclonus and partial seizures in the syndrome of neonatal (or early) myoclonic encephalopathy.[21] The two syndromes may be related, although the latter seems to be more often of genetic, perhaps metabolic, origin. This is definitely the case of glycine encephalopathy, a common cause of neonatal myoclonic encephalopathy.

Treatment of neonatal seizures hinges mainly on etiology (see Chapter 123). Many uncertainties persist concerning the significance of the seizures themselves as a cause of possible additional brain damage[17,30] and, consequently, concerning how important it is to control seizures (with the additional unsolved problem of purely EEG discharges, as discussed earlier). Therefore, a rapid but complete assessment of the infant with special attention to infections and possible metabolic disturbances such as hypoglycemia, hypocalcemia, and electrolyte disturbances is essential and should lead to appropriate correction treatment. More severe metabolic diseases should be vigorously treated. There is no agreement on the anticonvulsant drugs to be used.[16] Many investigators[22] favor phenobarbital or phenytoin in large doses, with initial loading, followed by maintenance therapy for variable periods. In general, short-term treatment is advised, but actual duration may be a few days to a few months. Recently doubt has been raised concerning the innocuousness and effectiveness of large doses of phenobarbital.[23] An alternative method is to use diazepam or lorazepam by intravenous route as the first anticonvulsant agent.

Summary and Conclusions

The clinical significance of neonatal seizures is more of an indicator of underlying serious brain damage or dysfunction than a predictor of chronic seizure persistence despite the recent realization that benign “idiopathic” cases do exist. Much remains to be learned about the basic mechanisms of neonatal seizures such as answers to such fundamental issues as the ability of the seizures to produce brain damage and the role of brain maturation in their electroclinical expression and response to therapy. In any case, their significance is more of an indication of brain damage than in terms of etiology. Pending the answers, empirical therapy and supportive treatment will remain essential.

Chapter 223

Benign Familial Neonatal Seizures and Benign Idiopathic Neonatal Seizures

Perrine Plouin

Introduction

In 1989, the International Classification of Epilepsies, Epileptic Syndromes and Related Disorders[15] included two neonatal syndromes among idiopathic conditions in the section on generalized epilepsies and syndromes: *benign familial neonatal convulsions* and *benign neonatal convulsions*. At that time, no video-electroencephalogram (EEG) recording of seizures had been reported, and newborn infants were considered as presenting more generalized than focal seizures. Nevertheless, since 2001, it has been proposed to consider at least benign familial neonatal convulsions as a focal clonic or adversive epilepsy. Plouin[47] proposed that the appellation *benign neonatal convulsions* was not sufficiently precise: Some symptomatic cases such as hypocalcemia may also be benign, and it would be more accurate if the word *idiopathic* was added: *benign idiopathic neonatal convulsions.* Since then, the word "convulsions" has been replaced by the word "seizures" because "convulsions" refer only to the motor components of seizures, excluding the autonomic components. These two syndromes are now called benign familial neonatal seizures (BFNS) and benign idiopathic neonatal seizures (BINS). Only the first remains in the proposed classification because it seems that no new cases of BINS have been reported in the last 15 years.

These two syndromes do not strictly fulfill the criteria for idiopathic generalized epilepsies; the typical trait of generalized spike-and-wave discharge is not present. It can be argued that the immaturity of the central nervous system is responsible for this absence. Nevertheless, since 2001, it has been proposed that at least BFNS be considered a focal clonic or adversive epilepsy.

Benign neonatal seizures are defined by a favorable outcome, that is, normal psychomotor development and the absence of secondary epilepsy. Benign familial neonatal seizures and benign idiopathic neonatal seizures fulfill these criteria, even if some questions remain open.

Recognition of these syndromes allows the prediction of a favorable outcome from the neonatal period, and long-term antiepileptic treatment is not indicated.

Benign Familial Neonatal Seizures

Historical Perspectives

In 1964, Rett and Teubel[51] reported the first BFNS family, with eight cases over three generations. On the third day of life, the male proband developed an initial tonic phase with cyanosis followed by clonic movements of the whole body including the face and eye muscles, and he had 15 to 20 seizure events on the following day. A brother born 16 months later had a similar experience. Several interictal EEGs were reported for these two boys and single EEGs for three other affected relatives. No ictal EEG was recorded. The authors noted the familial history, the normality of the interictal EEG, and the favorable outcome.

In a second family, 14 members in five generations had similar clinical histories.[9] After a normal delivery, seizures (sometimes with cyanosis) usually started on the third day of life but stopped within 1 month. A few seizures were observed up to 7 months in three children and up to 10 years in two others.

In 1979, Quattlebaum[50] reported a family in which 11 individuals had seizures that started on or before 3 days of age, 1 at 3 weeks, and 3 at 3 months. Most had seizures until 6 or 8 months, but all were otherwise normal.

Between 1964 and 1989, 26 families were reported, with all authors agreeing on a probable autosomal-dominant inheritance.

In 1989, Leppert et al.[32] studied 48 individuals in four generations of a family (Quattelbaum's family), 19 of them having the characteristics of BFNS. They localized the gene on the long arm of chromosome 20, possibly to 20q13.2, the first linkage to be reported for an epilepsy syndrome. This was soon confirmed in a Newfoundland, Canada, family with 69 affected inviduals,[53] in a northern European family,[55] and in six French families.[38] The BFNS syndrome that maps to chromosome 20q has been designated EBN1. Since then, >25 families have been genetically studied in different countries. For 20 of them, the same genetic localization on the long arm of chromosome 20 has been proved.

In 1991, however, Ryan et al.[55] studied two families with BFNS that did not link to chromosome 20 and concluded that the syndrome of BFNS was genetically heterogeneous. Further study of that family[34] demonstrated tight linkage to a locus on 8q, thus verifying heterogeneity (the BFNS syndrome on 8q is designated EBN2). In other families, no linkage could be found on either 20q or 8q.[35]

In 1995, Anderson et al.[1] characterized a candidate gene for BFNS: the human alpha 4 subunit of the nicotine acetylcholine receptor (hCHRNA4). In 1998, the sequencing of genes that are mutated in EBN1 and EBN2 was reported.[58] The new gene was named *KCNQ2*, and analysis of five other ENB1 families yielded two transmembrane missense mutations, two frameshifts, and one splice-site mutation.

A search of the human genome databases for sequences homologous to *KCNQ2* detected one in the chromosome 8q24 region.[14] The new gene was named *KCNQ3*, and a mutant DNA fragment from it was found to segregate perfectly with the EBN2 phenotype in a *Mexican-American family*.[58]

P.2288

New EBN1 kindreds have been reported with variations in seizure history or in types of mutation. A wide range of clinical manifestations has been observed, including partial seizures in later life with corresponding focal neurologic deficits. Thus far, however, there is little evidence for a correlation between type of mutation and seizure history.[8,33]

The condition of benign familial neonatal seizures is a rare, dominantly inherited epileptic syndrome with a penetrance as high as 85%.

For more details about the genetics of this syndrome see Chapter 18.

Definitions

The diagnosis of BFNS can be considered as a diagnosis by exclusion if every other etiology has been excluded and if there is a family history of neonatal seizures without any severe epilepsy in family members.

Epidemiology

No epidemiologic study of infant or childhood epilepsy has determined the prevalence of BFNS. Among a population of 76 newborns with seizures referred to the neuropediatric unit of Saint Vincent de Paul Hospital between 1994 and 2002 and with video-EEG–recorded seizures, we had only 2 cases of BFNS. The best estimate thus far of the population rate for BFNS comes from a recent prospective, population-based study that involved all obstetric and neonatal units across the province of Newfoundland.[52] Five cases of BFNS (none of whom were part of the kinship reported by Ronen et al.[53]) were observed among 34,615 live births from 1 January 1990 to 31 December 1994. Thus the incidence of BFNS was reported as 14.4 per 100,000 live births.

All reported families represent isolated cases. It is probable that families with BFNS are more numerous than would appear from the medical literature; families with this syndrome often know that the outcome is favorable and do not always report the occurrence of seizures to their physician.

Three hundred and fifty-five cases have been reported in the medical literature since the first article by Rett and Teubel.[51] These neonates belong to 44 families. The number of affected generations varies from one to five (Table 1).

Etiology and Basic Mechanisms

By definition, an idiopathic syndrome does not have a specific underlying etiology. This is the case for BFNS.

Basic mechanisms in this syndrome are probably close to those involved in other types of neonatal convulsions. Immature brain is more likely to respond to any kind of injury with epileptic seizures. In this syndrome, genetic susceptibility during the first week of life in full-term neonates is responsible for the appearance of seizures; the cause is a deficit of a specific channelopathy, but the precise mechanism is unknown. The fact that seizures occur in premature infants when they reach 39 to 41 weeks of gestational age means that a step in maturation has to be reached for the channelopathy to be expressed.

Total 1964–1995: 355 cases, 44 families		

[a]Families mapped to chromosome 20 (linkage analysis of Quattelbaum's family by Leppert et

al.[32]).
[b]Family mapped to chromosome 8 (linkage analysis of Lewis et al.[34]).

Clinical Presentation

One can consider the diagnosis of BFNS as a diagnosis by exclusion reinforced by the familial history of neonatal seizures.

The clinical data come from the 44 families reported between 1964 and 1996, including 355 cases (Table 1). Since 1996, more isolated families have been reported, but mostly by geneticists, and few details appear in these papers about the electroclinical presentation of seizures.

In documented cases, birth was always at full term (except for three cases of Ronen et al.[53]), with a normal birth weight and an Apgar score >7 at the first minute of life. None of these neonates was in an intensive care unit. There was always a seizure-free interval between birth and occurrence of seizures.

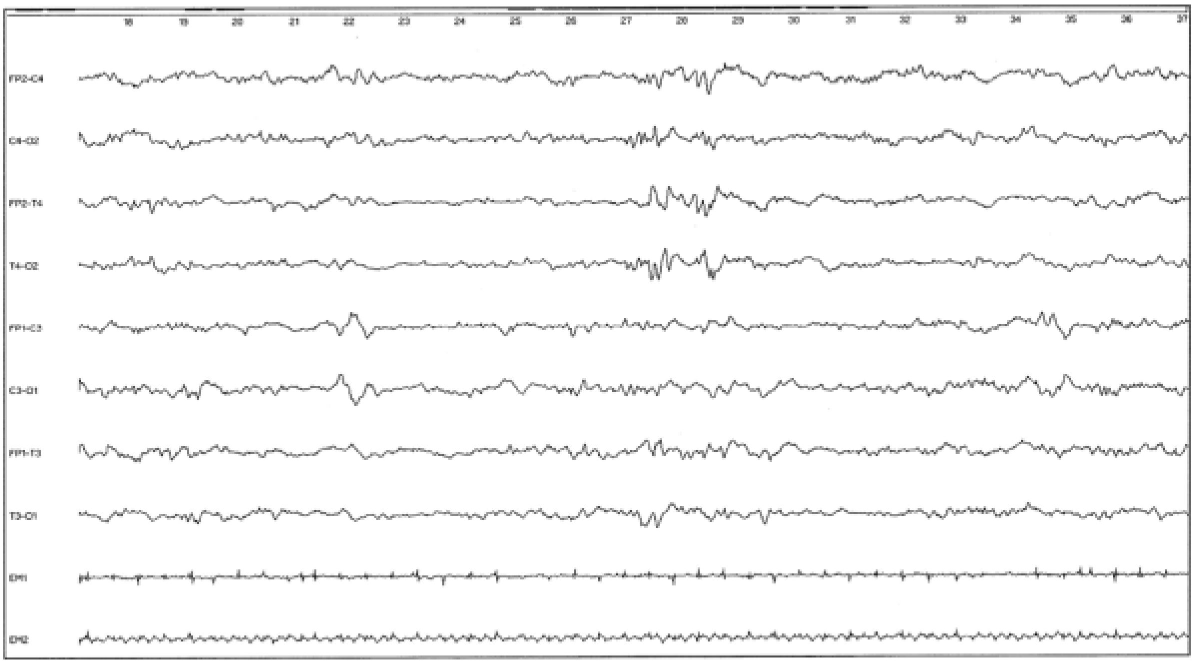

FIGURE 1. Interictal waking electroencephalogram (EEG) in a 5-day-old full-term neonate with benign idiopathic neonatal seizures (BFNS); short bursts of theta rhythms are more marked on the right hemisphere.

The gender ratio shows an equal distribution between boys and girls.

P.2289

In 80% of cases, seizures start on the second or third day of life, but some infants start having seizures later, during the first or even up to the third month of life. Ronen et al.,[53] in their large family, report that two of the individuals in whom seizures started at 1 month of age were premature. Premature infants would not be able to have seizures before reaching full-term neurologic state; this point is important, given the strict age dependence of the syndrome.

The neurologic state of the infants remains normal in most cases, and they can nurse or drink from a bottle between seizures; a mild transitory hypotonia can be noticed in some cases. None of these infants was transferred to neonatal intensive care units.

In the first reported families, before the use of video-EEG monitoring, seizures were described as a clonic type, sometimes with apneic spells. Tonic seizures were reported in two cases. Clonic or tonic seizures were short (lasting from 1 to 3 minutes) and frequently repeated within a period of 7 days, whereas isolated seizures could occur in some cases during the following weeks.

Seizures had already been described in previous reports,[12,16,23,57] but there was no evidence in these cases for a homogeneous presentation. More recently, Ronen et al.[53] listed all the clinical components of the 70 seizures they could analyze in their large family. They concluded that most of the time, seizures started with tonic, autonomic, or oculofacial features, being of a mixed type. Hirsch et al.[30] recorded 14 seizures in three neonates with video-EEG monitoring. All seizures started with a tonic phase, with a right or left maximum. Seizures varied from one to the next in a given infant and were always accompanied by tachycardia and a short period of apnea. The clonic phase (partial or generalized) was introduced by vocalization or chewing. We had the opportunity to record seizures in five cases with video-EEG monitoring (unreported families): Seizures were stereotyped, starting with a diffuse hypertonia and a short apnea, followed by autonomic or oculofacial features and symmetric or asymmetric clonic movements of the limbs. In 1994, Bye[10] reported a new case of BFNC, with two seizures recorded and videotaped. Both seizures started with an arousal, but in one, groping and clonic movements of the limbs remained localized to the left side, whereas in the second, these movements were generalized. From these different video recordings, it appears that in most cases, seizures start with a diffuse tonic component, followed by various autonomic and motor changes, which can be unilateral or bilateral, symmetric or not. The only cases without an initial tonic component are those of Bye.[10] No myoclonic seizures or spasms have been reported nor in fact true generalized tonic–clonic seizures.

When described, interictal EEG was normal, discontinuous, or included focal or multifocal abnormalities or a *théta pointu alternant* pattern (Figs. 1 and 2). Patterns suggesting a poor prognosis, such as a paroxysmal, inactive, or suppression-burst pattern, were never reported.

In first reports, some seizures were recorded, but the EEGs were not published or were incomplete. In the cases we recorded, the ictal pattern was very similar to the one published by Ronen et al.[53] and to the cases of Hirsch et al.[30] On the EEG, seizures started with a generalized flattening of the background activity followed by focalized or generalized spikes or slow waves lasting as long as the clinical manifestations. A prolonged flattening of the EEG could follow the seizures. Hirsch et al.[30] studied the ictal EEG very carefully and found that the length of the flattening could vary from 5 to 19 seconds and the complete seizure from 59 to 155 seconds. All of these individuals had BFNS mapped to chromosome 20. The electroclinical presentation of these seizures suggests that they are of

a generalized type. Aso and Watanabe[4] discussed this point because they recorded a unilateral seizure in a 3-month-old infant having had BFNS.

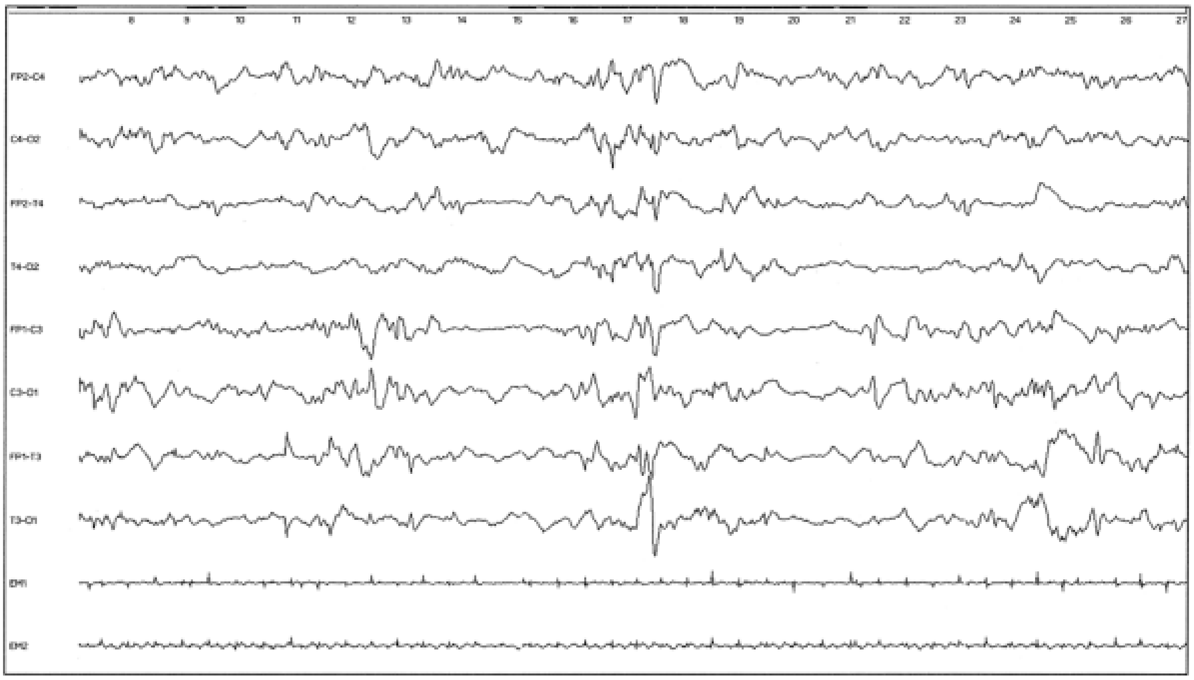

FIGURE 2. Interictal sleep electroencephalogram (EEG) in the same neonate with benign idiopathic neonatal seizures (BFNS); short bursts of bilateral asynchronous theta rhythms are more marked on the left hemisphere.

The publication of Hirsch et al.[30] emphasized that the initial flattening of the EEG is generalized from the start and that the successive symptoms occurring during a seizure (tonic, apnea, clonic phases) are identical to those reported in generalized tonic clonic seizures in children and adults. The same authors suggested that the asymmetric character of some clinical and EEG signs during the tonic or the clonic phase could be related to the absence of maturation of the corpus callosum during the first weeks of life.[5] In all of our recorded seizures we noticed a unilateral predominance of the EEG pattern, even if the initial flattening seemed to be generalized, and at the end of the seizures, we noticed a focal temporal discharge, the same side as the frontal initial spikes and slow waves (Fig. 3). Bye[10] and Hirsch et al.[29] discussed the place of BFNS among idiopathic generalized epilepsies: At the time the classification was adopted (1989), no videotape of BFNS existed, whereas it now appears that some partial seizures may be present, but most of them are of a generalized type.

We suggest nonetheless that this syndrome not be included among the generalized ones: The electroclinical presentation is closer to partial epilepsies such as benign infantile familial seizures or epilepsy with centrotemporal spikes, both benign age-dependent focal epilepsy syndromes. This opinion is shared by Watanabe et al.[62] and Engel.[22]

Diagnostic Evaluation

The diagnosis of BFNS is based on the clinical presentation and the familial history. Cases of BFNS will be found in the family history, but whereas only cases of BFNS are seen in some families, in other families, cases of BFNS are found along with other types of seizures, mostly belonging to the idiopathic generalized epilepsies. The EEG is normal or mildly abnormal. If recordings are made, the electroclinical presentation of seizures is relatively stereotyped.

Nevertheless it seems necessary to exclude any other etiology—metabolic or infectious—and for that purpose a clinical workup and a lumbar puncture should be done. Computed tomography (CT) is not indicated as long as the neurologic state of the infant remains normal.

Differential Diagnosis

Benign familial neonatal seizures must be differentiated from nonepileptic paroxysmal phenomena of neonates (see Chapter 273) and from other types of neonatal convulsions (see Chapter 56).

Among nonepileptic phenomena in neonates, tremulousness and benign sleep myoclonus should be eliminated. Tremulousness occurs in normal neonates during waking and sleep; it can be very intense, and its main characteristic is that it can be stopped by restraining the involved limb and the EEG is normal. Benign neonatal sleep myoclonus occurs only during quiet sleep. The EEG is strictly normal between and during the fits. This phenomenon disappears spontaneously within days to weeks, and the child develops normally.[20]

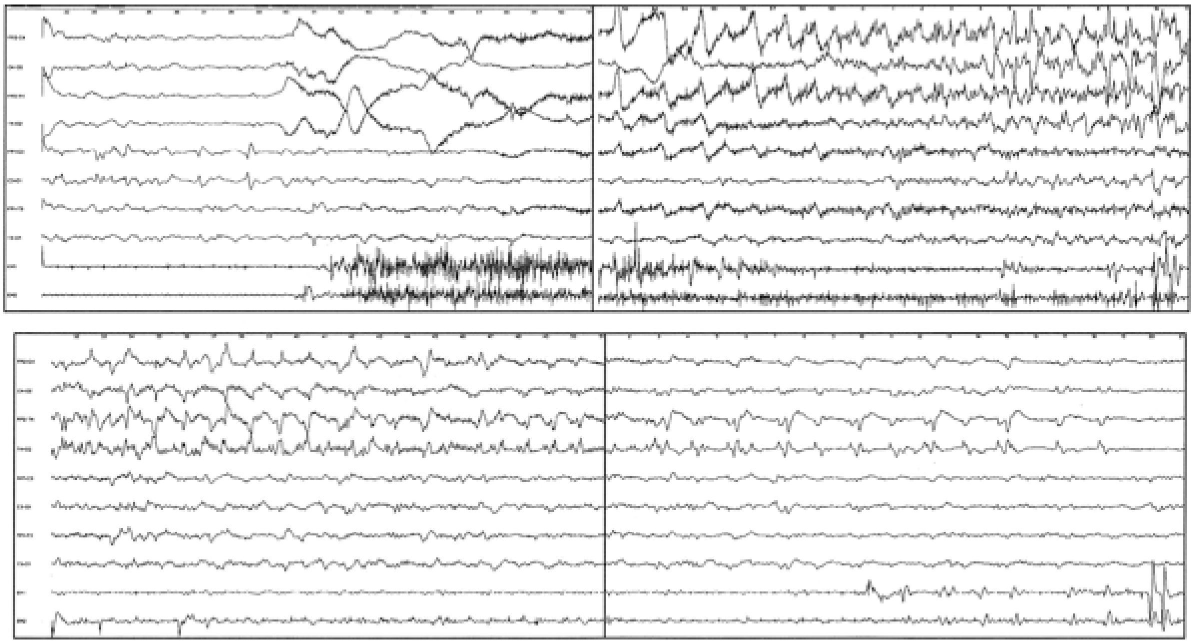

FIGURE 3. Polygraphic recording of a focal seizure in the same neonate. Initial flattening is more marked on the right hemisphere, followed by frontal delta waves; notice the right temporal spikes at the end of the seizures; the duration of the seizures is 80 seconds.

Symptomatic neonatal convulsions are the most frequent, occurring secondary to hypoxo-ischemic encephalopathy, metabolic disturbances, or infectious processes. These etiologies can be assessed with different diagnostic tools, and the convulsions do not have the typical clinical presentation of BFNC, differing in regard to day of onset, clinical type of seizures, duration and repetition of seizures, and neurologic

state. Interictal and ictal EEGs also show different patterns according to etiology and severity of the pathology, from normal to very abnormal tracings.

A new sodium channelopathy was reported in 2002[27] in a family with benign neonatal-infantile seizures, the phenotype being described later by Berkovic et al.[6] In this situation, the members of a given family may have neonatal or infantile seizures, with a favorable outcome in all cases. This could be considered an intermediate situation between BFNS and benign familial infantile seizures.[60]

Treatment and Outcome

No guideline has been proposed concerning the treatment of BFNC. In the past, probably no treatment was given. In some families, mostly coming from around the Mediterranean Sea, the best reported treatment was to put a cold key in the neck of the infant. Different authors give their own experience in the treatment of these infants. The drug used depends on country, continent, and year of publication.

Most infants were given phenobarbital for 2 to 6 months, rarely longer. In our experience, sodium valproate is effective, leading to a rapid cessation of seizures. Some authors have also used diphenylhydantoin. The question remains open about the usefulness of an antiepileptic drug treatment: Grandparents of these infants were not treated and did well. If a treatment is initiated at the time of the seizures, it seems reasonable to interrupt it by the third or sixth month.

Long-Term Prognosis

No longitudinal study has been published of BFNC. When we reviewed the literature,[47] we found that infants with BFNS have a 5% risk for febrile convulsions, which is not very different from the general population risk. Concerning secondary epilepsy, the mean risk is around 11% among these infants, higher than in the general population. However, no case of severe epilepsy was noticed in this population. In 1999 Maihara et al.[36] reported two siblings with BFNS who later developed epilepsy with centrotemporal spikes: Both stopped having seizures with carbamazepine and had a normal psychomotor development. No case of psychomotor retardation or mental impairment has been reported among this population of BFNS.

Benign Idiopathic Neonatal Seizures

Historical Perspectives

The first report about BINS was by Dehan et al. in 1977.[19] They described 20 neonates with convulsions occurring around the fifth day of life, no specific underlying etiology, and a favorable neurologic outcome in an article entitled “Les convulsions du cinquième jour: un nouveau syndrome?” (“Fifth day's fits: a new syndrome?”). Other French authors reported similar cases.[2,3,21,40,48] The first non-French study was by Pryor et al.[49] from Australia, followed by that of North et al.[42]

During the 1980s, the only reports were French and Australian. In 1992, however, Herrmann et al. from Germany reported 21 recent cases.[28] No study of this syndrome came from the United States.

Table 2 summarizes the 299 published cases.

Total	1966–1991	299

Definitions

The diagnosis of BINS is made in full-term infants who are neurologically normal and have no familial history of neonatal

convulsions, negative findings on workup, and a favorable outcome with respect to both psychomotor development and the absence of secondary epilepsy. Again, this diagnosis is made by exclusion of any specific underlying etiology.

Epidemiology

The incidence of BINS is not clearly apparent in epidemiologic studies dealing with childhood epilepsy. This condition is quite well known among neonatologists and neuropediatricians but not among epileptologists.

Plouin[46] tried to determine the prevalence of BINS among neonatal convulsions. Studies of neonatal convulsions or neonatal status epilepticus published between 1959 and 1982 were analyzed to identify those that could be defined as BINS. Among these studies, special attention was paid to the description by Dehan et al.[18] of neonatal convulsions with unknown etiology occurring around the fifth day of life.

The 15 published studies exhibited a great disparity regarding material and methods. Among the 2,042 cases reported in these 15 studies, a majority of the cases of neonatal convulsions of unknown etiology had a good outcome (120 of 195 documented cases; mean, 62%; range, 28%–93%), and cases with unknown etiology and favorable outcome account for 6.6% of all neonatal convulsions (range, 0%–28%).

This suggests that cases of BINS were already present in the literature before their formal description by Dehan et al. in 1977.[18] Their prevalence can be estimated to be about 7% of neonatal convulsions; this percentage decreases to 2% if only the cases for which the date of occurrence of seizures and the interictal EEG patterns are reported are taken into account. In reported series of BINS, the prevalence varies from 4% to 38% of neonatal convulsions, and this large scatter probably reflects differences in patients' referral and recruitment—intensive care units, maternity clinics, and departments of neonatology or pediatric neurology. The true prevalence of BINS is in good agreement with the range of 2% to 7% cited previously.

Finally, North et al.[42] insisted on the fact that no case of BINS has been observed in their department since 1982. Moreover, the incidence of neonatal convulsions, which was very high during the 1970s, has decreased since the beginning of the 1980s. Others in Australia noted the same facts, leading to the hypothesis of an epidemic phenomenon of BINS, with the etiology undetermined.

In 1990, Dehan, Navelet, and D'Allest carried out a retrospective study to determine the number of cases of BINS referred to neonatology and pediatric department intensive care units as well as maternity units each year between 1979 and 1989. The results were presented at the first Réunion d'Actualités en Epileptologie in Geneva in 1991. The authors concluded that sporadic cases existed among all departments (0.5 to 1.5 cases per year per department), with an important peak in 1981 (comparable with the one of 1975 that led to the first report of BINS).

Herrmann et al.[28] also reported the epidemic occurrence of BINS, with 21 cases referred between 1989 and 1991. The fact that they found a rotavirus infection associated with 95% of their cases reinforces the hypothesis of an epidemic phenomenon but does not explain the relationship to the convulsions.

Etiology and Basic Mechanisms

Metabolic, viral, other infectious, and toxic etiologies have been looked for in this syndrome.

Goldberg and Sheehy proposed one etiologic hypothesis.[25] After a 3-year prospective study, they found an acute zinc deficiency in the cerebrospinal fluid of infants with BINS when compared with a group of infants in whom a cause of convulsions had been identified and with another group of infants without convulsions but with other health problems. This hypothesis has not been confirmed. Moreover, in Australia and France, very complete metabolic, toxic, and viral inquiries have been performed, without any significant results.

More recently, Herrmann et al.[28] reported 21 cases of BINS referred between 1989 and 1991 among 1,917 neonates hospitalized during the same period. They tested for rotavirus in the feces of 19 infants with BINS, 30 healthy controls (age, 4–6 days), and 202 sick neonates without convulsions. They found rotavirus in the feces of 18 of the 19 infants with BINS (95%), whereas only 40% of the healthy controls ($p < 0.001$) and 48% of the sick neonates without convulsions ($p < 0.001$) had positive findings. The authors suggested a causal relationship between BINS and rotavirus infection, although rotavirus was not present in the cerebrospinal fluid of 6 rotavirus-positive infants with BINS. They concluded that pathogenic mechanisms remain unclear. This syndrome remains idiopathic.

Clinical Presentation

The gender distribution reveals a majority of boys (62%). Only full-term infants have been reported. Pregnancy and delivery were normal, and seizures started after a seizure-free interval. In all cases, seizures occurred between days 1 and 7; 90% occurred between days 4 and 6, and 97% between days 3 and 7. No videotape recording has been reported for any of these cases.

When described, the seizures were always of the clonic type, mostly partial, with or without apnea, but never tonic. North et al.[42] reported apneic seizures in 31% of their cases. Clonic seizures were often lateralized, starting on one side and then affecting the other side, and rarely of a generalized type. They lasted from 1 to 3 minutes. They were frequently repeated, leading to status epilepticus. The mean duration of status epilepticus was about 20 hours, but it could be shorter (2 hours) or longer (up to 3 days).

The neurologic state of the infants is usually normal at onset of convulsions. Infants then become drowsy and hypotonic, the various antiepileptic drugs given to stop the convulsions being partly responsible for this evolution. Drowsiness and hypotonia may last for several days after the end of status epilepticus, but the infants soon recover to a normal neurologic state.

P.2293

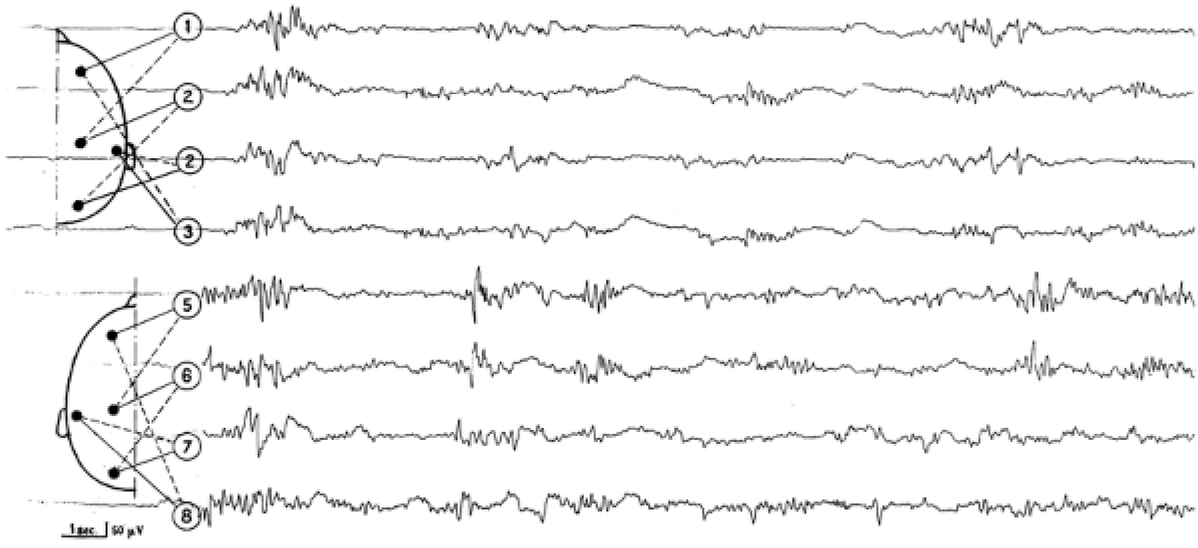

FIGURE 4. Interictal electroencephalogram (EEG) of a *théta pointu alternant* pattern in an infant with benign idiopathic neonatal seizures (BINS).

Interictal EEG patterns were described in 101 of the 299 published cases. The interictal EEG was normal in 10 infants, discontinuous in 6, and showed "focal or multifocal abnormalities" in 25. The *théta pointu alternant* pattern was present in the remaining 60 infants. This pattern was first described by Dehan et al.[18] as a dominant theta activity, alternating or discontinuous, unreactive, with sharp waves and frequent interhemispheric asynchrony. The *théta pointu alternant* pattern may be present in cases of status epilepticus of different etiologies (hypocalcemia, neonatal meningitis, subarachnoidal hemorrhage) and cannot be considered as specific for BINS.[40,46] Nevertheless, it is associated with a favorable neurologic prognosis (Fig. 4).

Seizures have been recorded in most of the 101 cases. They last from 1 to 3 minutes and have no remarkable EEG features—mostly rhythmic spikes or rhythmic slow waves. They can be localized to any area but are more frequently present in the rolandic areas. They can be strictly unilateral, immediately generalized, or first localized and then generalized. Electroclinical seizures or subclinical discharges (so-called electroencephalographic seizures) can be recorded; clinical seizures without EEG modifications have also been reported.

Diagnostic Evaluation

The diagnosis of BINS is based on the clinical presentation, the ictal and interictal EEG, and the elimination of any specific underlying etiology, such as metabolic disturbances, neonatal meningitis, viral infections, or malformations of the central nervous system.

Differential Diagnosis

The differential diagnosis of BINS is not different from that of BFNS. The familial convulsions are different from the idiopathic convulsions in several ways: BFNS is a familial disease having an autosomal mode of inheritance linked to genetic markers localized to the long arm of chromosome 20, at least in the majority of cases; conversely, a family history is very rare in BINS (0.2%). Seizures start earlier in BFNS (days 2–3) and persist longer than in BINS (starting on days 4–5, and lasting no more than 20 hours). Occurrence of secondary epilepsy is more frequent in BFNS (11%) than in BINS (0.5%). Minor neurologic impairment is more frequent in cases of BINS.

Treatment and Outcome

Many antiepileptic drugs have been used for BINS (phenobarbitone, phenytoin, diazepam, paraldehyde, chloral hydrate, clomethiazole), often in combination, without a consistent effect on the duration of seizures. The seizures usually stop without treatment, but occasionally the end seems to be related to administration of diazepam or phenytoin. Dehan et al.[19] suggested that these infants not be treated if alternative diagnoses have been eliminated.

Long-Term Prognosis

The long-term favorable outcome must be confirmed by more numerous and more extensive studies. The 90 cases reported by Pryor et al.[49] have not been followed beyond the neonatal period. The 92 cases reported by French authors were followed from 6 months to 6 years. In five cases, a transitory psychomotor retardation was noted until the age of 1 year; one child had a simple febrile convulsion, and another had a convulsion without fever at the age of 3 years.[18]

Among the 94 cases reported by North et al.,[42] 33 (38%) were followed between the ages of 6 months and 2 years. In roughly half of these 33 infants, the authors found abnormalities. Although there is no control group, the percentage of abnormalities seems excessive in this study. One can consider that children with medical problems were exposed to more frequent consultations than were children without any problems. These authors concluded that their results do not allow assessment of the benignity of this syndrome.

P.2294

Summary and Conclusions

Benign Familial Neonatal Seizures

Recognizing the phenotype of BFNS is important, first because of the prediction of a favorable neurologic outcome, and second for the contribution to genetic studies, which comprise a dynamic area of epilepsy research, especially for the idiopathic epilepsies.

The classic phenotype of BFNS comprises the following features: (a) normal pregnancy and delivery; (b) seizure-free interval before onset of seizures (mostly on days 2 and 3); (c) neurologically normal state between seizures; (d) normal interictal EEG; (e) tonic–clonic seizures, symmetric or not; and (f) familial history of BFNS or other types of epilepsy (mostly idiopathic epilepsies). The families of such infants should be considered appropriate for genetic studies.

Benign Idiopathic Neonatal Seizures

Benign idiopathic neonatal seizures can be recognized by the clinical and paraclinical characteristics that comprise the syndrome. Diagnosis allows one to predict a favorable neurologic outcome. However, the *théta pointu alternant* EEG pattern is present in only 60% of cases and is not specific. Further reports with a longer follow-up period will perhaps lead to a better understanding of this syndrome and more precise determination of the outcome. The “episodic character” of this syndrome and the nonspecific EEG pattern as well as the type of seizures make it questionable to maintain it in the International Classification of Epilepsies and Epilepsy Syndromes.

Early Myoclonic Encephalopathy (Neonatal Myoclonic Encephalopathy)

Aleksandra Djukic

Federico Vigevano

Perrine Plouin

Solomon L. Moshé

Introduction

In 1978, Aicardi and Goutieres described a group of five patients with "neonatal myoclonic encephalopathy" commencing in the hours immediately after birth and consisting of erratic, asynchronous, nonperiodic myoclonus associated with generalized jerks and a distinctive electroencephalogram (EEG).[3] Since then, the syndrome has been referred to as early myoclonic encephalopathy and also as myoclonic encephalopathy with neonatal onset,[8] neonatal epileptic encephalopathy with periodic EEG bursts, and early myoclonic epileptic encephalopathy[9] and neonatal myoclonic encephalopathy.[3,39]

In 1989, the ILAE Commission of Classification and Terminology recognized the syndrome as "early myoclonic encephal- opathy (EME)" and classified it as generalized symptomatic epilepsies of nonspecific etiology.[16] In 2001 the entity was finally recognized as one of the "epileptic encephalopathies" together with early infantile epileptic encephalopathy with suppression-bursts (EIEE, Ohtahara syndrome), West syndrome, and Lennox-Gastaut syndrome. Since 1978, there have been published reports on 50 patients with the characteristic clinical picture—onset of symptoms during the first month of life consisting of erratic, fragmentary myoclonus, massive myoclonus, partial seizures, suppression-burst EEG pattern, and, later, tonic spasms; the prognosis is grave.[4] Some controversial issues on differential diagnosis from EIEE and physiopathology remain; there are several cases of early encephalopathy with seizures and a suppression-burst pattern that do not fulfill the criteria for either EIEE or EME.[4,10,18,33]

Epidemiology

The syndrome is rare. An epidemiologic study of childhood epilepsy in Japan detected 4 cases of EME (0.168%) among 2,378 children with epilepsy >10 years of age.[6,28] In a study of 75 infants with epilepsy of neonatal onset, Watanabe et al.[42] observed 2 cases (2.7%) of EME. A gender difference, with female-to-male ratio of 1:1.3, is seen in the 30 cases published in the English literature.[10]

Etiology

In most cases, the etiology of EME is unknown. Although EME is assumed to be associated with inborn errors of metabolism, even the most frequently reported diagnosis—nonketotic hyperglycinemia—is rarely documented.[2,5,9,13,27,33,38,39] Other identified inborn errors of metabolism are D-glyceric acidemia, propionic acidemia, molybdenum cofactor deficiency, methylmalonic acidemia, mitochondrial dysfunction, and abnormal urinary oligosaccharides.

Structural brain malformations (cerebellar hypoplasia, migrational disorder with cortical dysgenesis) have also been reported.[11,23]

Wang and colleagues reported a patient with a clinical picture of early myoclonic encephalopathy and an atypical suppression-burst pattern, with full recovery after administration of pyridoxine.[40] The syndromes of retinal pigmentary degeneration and nephronophthisis, congenital nephrotic syndrome, and Zellweger disease have all also presented with EME.[2,5,9,13,15,19,21,23,27,33,39,40]

Familial occurrence has been reported,[2,9,33,40] reflecting the genetic nature of the underlying diseases. Because the gene locations for these metabolic errors vary widely, however, it is more likely that EME does not develop due to a specific genetic abnormality but rather due to extensive cortico-subcortical dysfunction as a consequence of a severe metabolic disorder.[27]

Clinical Presentation

Seizure Characteristics

In this condition, a child usually born without dysmorphic features and after an uneventful delivery undergoes a regression as the seizures emerge and becomes less alert and irritable and with poor interactions.[9] The distinctive clinical characteristic of EME is myoclonias, which are the first presenting symptom, starting usually within the first week of life. The majority of the patients present within the first month of life. Onset during the prenatal period and during the second or third month of life has been reported but is rare.[9,11,40]

Myoclonus is fragmentary and erratic and shifts from one to another body part in a random, asynchronous fashion; it can become massive and generalized in some cases.[4] Initially, it involves eyelids, face, and limbs in the form of twitches of small to moderate amplitude. Sometimes, twitches are restricted to a very small territory (eyebrow, corner of the mouth). The frequency of myoclonic jerks also varies from occasional to almost continuous from the onset. It may persist during sleep.[9]

Shortly after the onset, partial seizures occur and can be subtle, consisting of only eye deviations or autonomic phenomena according to Dalla Bernardina et al.[9] Tonic seizures are observed later, usually around 3 to 4 months of age.[2,4]

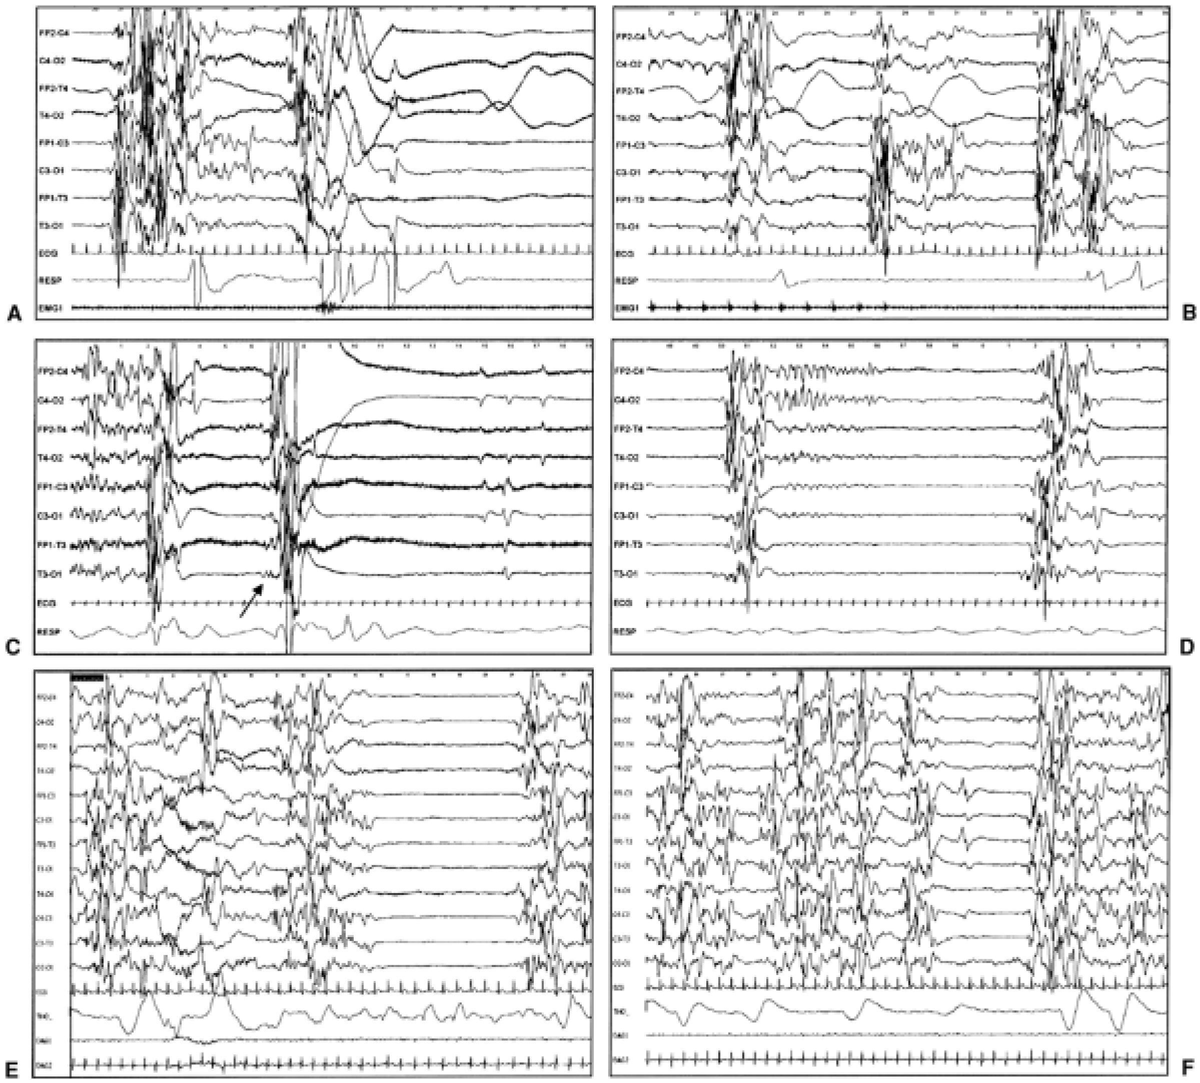

FIGURE 1. Electroencephalograms (EEGs) from an infant with early myoclonic encephalopathy. Panels A to D were obtained when the infant was 1 month old. **A, B:** Awake state. **C:** The occurrence of a myoclonic jerk (*arrow*). **D:** Asleep. Panels E and F were obtained when the infant was 3 month old **E:** Awake. **F:** Asleep. Notice that the burst-suppression pattern is present during wakefulness and sleep. Time scale is 15 mm/s; sensitivity is 100 µV/cm.

Diagnostic Evaluations

Electroencephalographic Features

There is no normal background activity during wakefulness or sleep.[2] There is a burst-suppression EEG pattern characterized

P.2298

by bursts of spikes, sharp waves, and slow waves irregularly intermingled and separated by periods of electrical silence. The duration of the bursts is usually 1 to 5 seconds, and the duration of the silent periods is 3 to 10 seconds (Fig. 1A–D). The EEG paroxysms may be either synchronous or asynchronous over both hemispheres. This pattern is often more marked during sleep. Usually after a few months, it evolves into hypsarrhythmia (more or less typical) or into multifocal paroxysmal discharges without normal patterns. In some cases the burst-suppression pattern may persist for a few months (Fig. 1E, F).

Erratic myoclonus generally may not have an ictal EEG correlate. Axial myoclonias that can be recorded with surface electromyography (EMG) on both deltoid muscles are immediately preceded by a burst of bilateral polyspikes.[3] They occur more frequently during wakefulness and may occur in clusters (Fig. 1). These myoclonias can be differentiated from epileptic spasms: The clinical manifestation is a short tonic contraction, and the EEG pattern consists of a complex of slow waves associated with fast rhythms. Later, multifocal seizures may emerge and the interictal EEG pattern evolves to hypsarrhythmia.[29]

Imaging Findings

Computed tomography (CT) and magnetic resonance imaging (MRI) in most cases are initially normal. In some cases, serial brain imaging shows development of diffuse brain atrophy even in those children with normal imaging findings at onset. Malformations have been reported as a cause of EME. The imaging may show the different pattern of brain malformation cited in the section on etiology.

Other Laboratory Investigations

Because the inborn errors of metabolism are the major cause of EME, a metabolic workup (amino acids, organic acids, lactate, and pyruvate) should be considered in all patients in the blood and in the cerebrospinal fluid (CSF). A pyridoxine challenge should be performed because the association of massive and erratic myoclonias leading to a very hyperexcitable infant with a suppression-burst EEG pattern can be the expression of B6 dependency. In these cases myoclonic jerks stop as soon as the B6 is administered intravenously. To confirm this diagnosis, the specific treatment should be stopped later; if the myoclonic seizures recur, the diagnosis is definite.

Developmental Course

Psychomotor development becomes arrested. The prognosis is grave. In 91% of the patients described in sufficient detail, the outcome is poor: Death occurs during the first years of life in at least 50%; those surviving have severe psychomotor retardation or remain in a persistent vegetative state.[2,10] In rare cases, signs of peripheral neuropathy were reported.[2] Normal developmental outcome has been limited to one case with pyridoxine dependency.[40] The progressive nature and the high fatality of EME cases can be attributed to the progressive nature and systemic influences of conditions with inborn errors of metabolism that remain undetected or untreated in addition to an electroencephalographic abnormality.

Seizure control is poor. The erratic myoclonus usually disappears after a few weeks or months,[4] and partial seizures become intractable. Tonic seizures develop at age 3 to 4 months. Once tonic seizures occur, the overall poor prognosis becomes even graver. In review of 30 patients from the literature, Djukic et al.[10] found that of 22 patients with EME and tonic seizures, 11 died, whereas none of the patients without tonic seizures did. The burst-suppression EEG pattern evolves into hypsarrhythmia in one third of patients. Focal or multifocal abnormalities develop in the remaining patients.

Pathophysiologic Basis

Neither the occurrence of the constellation of symptoms and findings in EME nor the pathophysiologic basis of the changing clinical picture that follows the progression of the disease have been well explained.

Ohtahara et al.[25] approached the problem from the standpoint of the characteristic EEG findings. They drew an analogy to the pathophysiologic basis of the other, more common conditions with suppression-burst EEG (deep anesthesia, normal premature infants <30–32 weeks of gestation, severe hypoxic ischemic encephalopathy). They pointed to a theory of abnormal "neuronal connectivity, suggesting that a disconnection in brain circuits may be involved in the genesis of EEG" and emphasized the "indispensable role of brain lesions both at the subcortical and cortical level."[27]

An alternative hypothesis is more symptom oriented, based on evidence from experimental studies and analysis of the clinical stages in the evolution of EME; it proposes that EME and EIEE may represent a continuum based on the burden of disease at the onset of symptoms.[10] Rodin's animal studies[31,32] clearly showed the brainstem structures associated with the onset of generalized seizures, such as tonic seizures, with the earliest sustained discharges appearing in the pons. During clonic seizures, the cortical discharges lead. Thus, there it has been suggested that clonic seizures originate in the forebrain, whereas tonic seizures originate in the brainstem.[36] This conclusion is supported by studies using precollicular transections: Tonic seizures also occurred when seizures were induced in animals with transections, whereas clonic seizures required forebrain connections.[1,7,12] Other studies show that repeated generalized seizures in experimental animals can kindle secondary seizure foci.[43] These secondary epileptic foci may persist even after the bilateral or generalized seizures abated, because descending inhibition from the hemispheres increases with maturation.[22]

Thus, it is tempting to speculate that in EME, there is initially involvement of cortical structures. The repeated myoclonic seizures may “kindle” the development of focal seizures, and with time there may be a spread to the brainstem (in some cases). Tonic seizures develop once the brainstem lesion burden exceeds the threshold for seizures. Patients with EIEE may have already exceeded this threshold at birth and present with tonic seizures early. In EME, brainstem involvement may be less severe, and tonic seizures are not the presenting symptom. Over time, the brainstem alterations may allow the emergence of tonic seizures possibly as a result of a kindling process increasing seizure susceptibility or as a release of the brainstem from cortical inhibitory control as the metabolic disease progresses.

The pathologic data are consistent with this view. Autopsies were performed in five patients with EME.[11,14,15,17,20,24,30,34,35] All patients had tonic seizures, and clinical signs of brainstem anomalies were present in all of them.

Genetic mapping of an autosomal-recessive form of EME to chromosome 11p15.5 led to the identification of a missense mutation (p.Pro206Leu) in the gene encoding GCI, a protein in the mitochondrial inner membrane that cotransports glutamate with H^+.[21] Expression of this protein has an age-specific distribution: At 20 weeks of gestation, the highest gene expression is identified in the cortex, brainstem, and cerebellum. A moderate to high level of expression is observed within the brainstem in the red nuclei, the substantia nigra, and the olivary complexes and the dentate nucleus in the cerebellum. It is interesting that many of these structures, especially the substantia nigra pars reticulata and its output circuits, play a prominent role in the control of seizures as a function of age and gender.[37] The observation that EME results from a defect in GC1 suggests a role for either glutamate metabolism, mitochondrial pathology, or both in EME.

Differential Diagnosis

Early myoclonic encephalopathy and Ohtahara syndrome share many common clinical and EEG characteristics such as onset in the first few months of life, suppression-burst pattern on EEG, and grave prognosis. The boundary between the two syndromes unfortunately is not always clear,[18,33,40] and the classification is sometimes questionable even among the published cases.[4] Once tonic seizures occur in patients with EME, the differential diagnosis becomes even more difficult, perhaps implying common pathogenetic mechanisms as discussed earlier. Perhaps the term *neonatal epileptic encephalopathy* is more appropriate to encompass both conditions.

The critical difference between EME and EIEE appears to be in the presumed etiologies and the prevailing seizure type at the onset of the clinical seizures. EIEE typically manifests with tonic seizures at onset, whereas EME is most associated with myoclonic seizures. However, erratic myoclonus may be absent even in the most frequently identified cause of EME: glycine encephalopathy (J. Aicardi, personal communication). In its classification, the International League Against Epilepsy emphasizes the symptomatic nature and nonspecific etiology of both syndromes.[16] The majority of cases of EIEE are associated with structural brain anomalies, whereas the majority of EME cases are associated with metabolic disorders.[4,9,19,26,38,40] There is an overlap, however, and often the underlying etiology

P.2300

remains unclear.[42] The observation that under some circumstances multiple etiologies can produce either syndrome suggests that EIEE and EME may represent a continuum.

The initial differentiation of EIEE and EME based on the presence or absence of myoclonic or tonic seizures at onset may better indicate the stage of the progression of the brainstem pathology/dysfunction than a phenotype specific to one syndrome or another. A major differentiating point is the absence of myoclonias in EIEE. A common unifying feature is the eventual appearance of tonic seizures. As the brainstem disease burden approaches the threshold for tonic seizures, EME patients become less distinguishable clinically from patients with EIEE.

The EEG pattern and persistence of “burst-suppression” distinguishes EME and EIEE from other conditions that produce neonatal burst-suppression, such as hypoxic–ischemic encephalopathy and neonatal convulsions.

Treatment

With the exception of cases with pyridoxine dependency, there is no effective management for EME. Neither the conventional antiepileptic medications nor adrenocorticotropic hormone or corticosteroids alter the progressive nature of the disease and improve the poor outcome. Treatments directed at correcting the underlying metabolic deficit may improve the outcome. A trial of treatment with pyridoxine is justified in all cases with EME because it is still the only efficient treatment for the small subgroup of patients in whom it is effective.

Summary and Conclusions

EME is a malignant epileptic syndrome with typical onset during the neonatal period. The main seizure type at onset is erratic myoclonus, but as the disease progresses, other seizure types develop, including tonic seizures at 3 to 4 months of age. The EEG is characterized by a suppression-burst pattern and often evolves into hypsarrhythmia. The etiology of EME is diverse: Congenital errors of metabolism are the most frequently identified, followed by cryptogenic and cases with structural brain malformations. Except in rare cases responsive to treatment with pyridoxine, control of seizures is poor. Prognosis is grave, with high early mortality and severe neurologic handicap in survivors.

It is possible that EME presents a continuum with EIEE and the phenotypic differences reflect the severity of the underlying pathologic process. In the future, a systematic approach including comprehensive evaluations (morphometric and functional imaging studies, neurophysiologic evaluations with multimodal evoked potentials, and possibly CSF neurotransmitter studies) performed during different stages of the diseases and especially during periods of clinical transitions could help to provide a better understanding of the underlying pathophysiologic processes. Shifting the goal of the diagnostic evaluation from detecting a specific abnormality to detecting a progressive pathologic change might permit the identification of more subtle changes before they become significant and allow the introduction of new treatments.

Chapter 225

Ohtahara Syndrome

Shunsuke Ohtahara

Yasuko Yamatogi

Yoko Ohtsuka

Introduction

Epileptic or chronic seizures occurring during the neonatal and early infantile periods are rarely observed compared with those occurring during other stages of childhood, because of the morphologic and biochemical immaturity of the central nervous system. Only a few epileptic syndromes begin in these periods, most of them refractory and catastrophic epilepsies.[3,7,21] Of these, this chapter describes the Ohtahara syndrome (OS): Early infantile epileptic encephalopathy with suppression-burst.

This syndrome, which has not only characteristic clinical and electroencephalographic (EEG) features, but also a distinct age dependence and evolution of epileptic syndromes with age, is considered the youngest form of the age-dependent epileptic encephalopathy.

Historical Perspective

In 1976, Ohtahara et al.[27] first described OS as an independent epileptic syndrome. It is the earliest form of the age-dependent epileptic encephalopathies, which include OS, West syndrome, and Lennox-Gastaut syndrome. Although each of these is an independent clinicoelectrical entity with individual clinical and EEG features, they have the following characteristics in common: (a) predominance in a certain age group (age dependence); (b) a peculiar type of frequent, minor, generalized seizure; (c) a severe and continuous epileptic EEG abnormality; (d) heterogeneous etiology; (e) frequent association with a mental defect; and (f) poor response to treatment and grave prognosis.[25,26,29] Furthermore, these syndromes often evolve with age. During their clinical course, a considerable number of cases of OS evolve into West syndrome and then from West syndrome into Lennox-Gastaut syndrome.[25,28,49] Because of their common characteristics and their transitions with age, Ohtahara applied the inclusive term *age-dependent epileptic encephalopathy* to this group of three syndromes.[25,26,29]

We adopt the term "epileptic encephalopathy" instead of "epilepsy" based on the following characteristics: (a) the presence of serious underlying disorders, (b) extremely frequent seizures, (c) continuously appearing marked epileptic EEG abnormality, and (d) mental stagnation or deterioration often manifesting with the persistence of seizures.

Although the etiologies of these syndromes are heterogeneous, each syndrome occurs predominantly within a certain age range and is associated with specific clinical and EEG traits. Because the clinical and electrical characteristics of each syndrome are based on a diverse group of etiologies, age should be considered the common factor underlying the manifestation of specific features. Thus, these syndromes may represent an age-specific epileptic reaction to various nonspecific exogenous insults to the brain occurring at an age-specific developmental stage.

Definitions

Ohtahara syndrome is characterized by very early onset, within a few months of birth, frequent tonic spasms, and a suppression-burst pattern in the EEG.[27,29,31,32] This periodic EEG pattern is consistently observed in both awake and sleep states. The main seizure pattern is tonic spasms but not myoclonic seizures. Tonic spasms appear often in clusters but sometimes sporadically. Partial motor seizures may occur. Although the etiologies are heterogeneous, neuroimaging usually discloses gross structural abnormalities due to mainly prenatal cerebral dysgenesis. The prognosis is serious: For example, early death or marked psychomotor retardation and intractable seizures with frequent evolution to West syndrome and still further to Lennox-Gastaut syndrome in some cases[28,29,49] or to severe epilepsy with multiple independent spike foci.[51] The Commission on Classification and Terminology of the International League Against Epilepsy (ILAE)[7] placed this syndrome among “symptomatic generalized epilepsies and syndromes with nonspecific etiology,” and the proposed diagnostic scheme of the ILAE[10] categorized it as “epileptic encephalopathy.”

Epidemiology

Several dozen cases of OS have been reported, but occurrence has been rare in comparison with West syndrome (WS) and Lennox-Gastaut syndrome. An epidemiologic study of childhood epilepsy carried out in Okayama Prefecture, Japan, detected 1 case of OS (0.04%) among 2,378 epileptic children <10 years of age.[36] The prevalence of this syndrome was much lower than that of West syndrome (40 cases, or 1.68%). Similarly, Kramer et al.[18] described 1 case of OS (0.2%) and 40 cases of WS (9.1%) in a cohort of 440 consecutive children <15 years of age with epilepsy in Tel Aviv, Israel. Thus, the relative prevalence of OS to WS may be 1:40 or less. On the other hand, in a study of 75 infants with epilepsy of neonatal onset who were monitored intensively, Watanabe et al. observed 8 cases (10.7%) of OS and no case of WS.[46]

No obvious racial differences have been observed in the respective incidences. No significant gender difference was confirmed, but male slightly exceeded female cases by 9:7 in our series.[50]

Etiology and Basic Mechanisms

Although the etiologies of OS are heterogeneous, the majority are static gross brain pathologies such as cerebral dysgenesis, although some are cryptogenic. Development of neuroimaging techniques, particularly magnetic resonance imaging (MRI), has disclosed that various types of cerebral dysgenesis are the greatest underlying pathologies of this syndrome.[40,50] It is also important that asymmetry is often

observed in structural abnormalities of the brain. Porencephaly, Aicardi syndrome,[34,50] cerebral dysgenesis, olivary-dentate dysplasia,[13,39,44] hemimegalencephaly,[12,33,50] linear sebaceous nevus,[15] Leigh encephalopathy,[42] and subacute diffuse encephalopathy[29] have been reported.

Of 16 cases in our series, 5 (31.3%) were cryptogenic.[50] With regard to genetic factors, no sibling case was reported except for Leigh encephalopathy.

With regard to metabolic disorders, although they are very rare, Williams et al.[14,48] first reported a case with cytochrome oxidase deficiency. This case, however, had only transient reversible deficiency that may have caused impaired neuronal migration or demyelination due to energy depletion during a critical period. Miller et al.[20] reported the absence of γ-aminobutyric acid (GABA) in cerebrospinal fluid (CSF) in a case with diffuse cerebral migration disorder. Fusco et al.[11] described one case each with pyridoxine dependency and carnitine palmitoyltransferase deficiency.

Fundamentally, the age factor should be emphasized, on the basis of polyetiology.

The pathophysiologic mechanisms underlying suppression-bursts are not fully elucidated. Aso et al.[4] found that the suppression-burst pattern correlated with multifocal severe brain damage, although no one structure was consistently affected. Any of these anomalies can prevent the establishment of normal neuronal connectivity necessary for the EEG ontogeny. This hypothesis is corroborated by the observation that a normal EEG pattern at any age can revert to a suppression-burst pattern after catastrophic events that cause laminal necrosis of the cortex, as in severe hypoxic-ischemic encephalopathy.[47] Similar but less readily identifiable cortical and subcortical abnormalities must be invoked to explain cryptogenic cases of OS and those with olivary-dentate dysplasia. Spreafico et al.[41] suggested that in OS and early myoclonic encephalopathy (EME) the suppression-burst (SB) pattern primarily reflects a diffuse structural or junctional disturbance of gray matter connectivity.

Its similarity to tracé alternant in neonatal quiet sleep and to burst-suppression in brain-damaged neonates may suggest an excessive subcortical neuronal discharge modified by subcorticocortical dysregulation or disconnection and by cortical lesions.[27,29] Trinka et al.[44] also considered that in olivary dentate dysplasia or focal cortical dysplasia, mild additional supratentorial/cortical anomalies or infratentorial anomalies contribute to the SB pattern in OS.

The markedly asymmetric and sometimes unilateral SB pattern reported in hemimegalencephaly further suggests the indispensable role of brain lesions at both the subcortical and cortical levels in generating the SB pattern.[23,33,35]

Two types of mechanisms have been suggested in the pathogenesis of SB, as mentioned later.

Clinical Presentation

The onset of the initial seizures or tonic spasms is early, within the first 3 months after birth, mainly within 1 month. Du Plessis et al.[9] extended the earliest age of onset into the intrauterine period. Clarke et al.[6] also suspected an intrauterine onset in four of their eight cryptogenic cases based on observations of violent fetal movement.

The main seizure type is tonic spasms with or without clustering. These occur not only during the waking state, but also during sleep in most cases. In 6 of our 16 patients (37.5%), hemiconvulsions, tonic seizures, or clonic seizures preceded one to several weeks before the onset of tonic spasms.[50] Myoclonic seizures are rare.[29,50]

An evolutionary pattern is characteristic: From OS to West syndrome in the middle period of infancy (between 3 and 6 months of age in many cases) and from West syndrome to Lennox-Gastaut syndrome in early childhood.[28,29,30,45,50]

Diagnostic Evaluation

Electroencephalographic Findings

The most characteristic feature of EEG in OS is the suppression-burst pattern, which is consistently seen during both awake and sleep states (Fig. 1). The suppression-burst pattern is characterized by high-voltage bursts alternating with nearly flat periods at an approximately regular rate. Bursts last 1 to 3 seconds and comprise high-voltage (150–350 μV) slow waves intermixed with spikes. Duration of the suppression phase is 3 to 5 seconds. The interval measured from beginning to beginning of bursts ranges from 5 to 10 seconds. The suppression-burst pattern shows some asymmetry in approximately two thirds of cases, presumably reflecting the underlying brain lesions. There is no awake/sleep differentiation. The suppression-burst pattern evolves to hypsarrhythmia in many cases, and then from hypsarrhythmia to diffuse slow spike-waves in some cases.[28,30]

The EEG pattern of OS needs to be differentiated from (a) the periodic type of hypsarrhythmia, in which periodicity becomes remarkable in the sleeping state and sleep spindles may be observed in the interburst phase, and (b) the burst-suppression pattern in severely abnormal neonates, which is characterized by a longer depressed phase with irregular and atypical appearance of bursts including fewer spike components.

The ictal EEG during tonic spasms shows desynchronization with or without fast activity. Tonic spasms in OS often appear concomitant with burst, but the SB pattern often disappears during a cluster of spasms. Partial seizures show focal repetitive or rhythmic discharges, which are often followed by a series of tonic spasms.

Neuroimaging and Other Laboratory Examinations

Computed tomography (CT) and MRI reveal structural abnormalities that are often asymmetric, even at an early stage of the disorder. Single-photon emission computed tomography and positron emission tomography often show corresponding abnormalities.

No abnormalities are found in serum and urine amino acids, cerebrospinal fluid, bone marrow, enzyme assay of white blood cells, serum pyruvate and lactate, ammonia, liver function, serum immunoglobulin, or TORCH (antibodies of *Toxoplasma*, rubella virus, cytomegalovirus, and herpes simplex virus).[29]

With evoked potentials, abnormalities are often found in auditory brainstem responses and visual responses in OS.[29]

Differential Diagnosis

Ohtahara Syndrome and West Syndrome

The age of onset is different in the two syndromes. It is between the neonatal and early infantile periods in OS and between middle and late infancy in West syndrome (see Chapter 229). Lombroso[19] claimed that OS might be regarded as an early form of West syndrome. There is a close relationship between OS and West syndrome, and in a considerable number of cases OS evolves to West syndrome. However, OS is certainly a different epileptic syndrome than West syndrome. Although

P.2305

the main seizure type is tonic spasms in both syndromes, tonic spasms in OS appear during both awake and sleep states, and also with and without clustering in many cases. Partial seizures are also more often observed in some OS cases. Most cases with OS show severe cortical pathology, often with asymmetric lesions displayed on neuroimaging.

With regard to EEG findings, the suppression-burst pattern is seen in OS, in contrast to hypsarrhythmia in West syndrome. The suppression-burst pattern differs from the periodic type of hypsarrhythmia, in which periodicity becomes distinct only during sleep. Seizures are more intractable in OS, and adrenocorticotropic hormone (ACTH) is poorly effective in most cases. Prognosis is far less favorable in OS than in West syndrome.

Ohtahara Syndrome and Early Myoclonic Encephalopathy

Because OS and EME[1,2,3,8] have both clinical and electrical characteristics in common, such as onset during the neonatal and early infantile periods and the EEG suppression-burst pattern, differential diagnosis of these syndromes warrants discussion (see also Chapter 224).[31,32]

Clinical Features

Tonic spasms are the main seizure type in OS, whereas EME is characterized by myoclonia, especially erratic myoclonia, and very frequent partial seizures. In contrast, episodes of myoclonia are rarely seen in OS.

Electroencephalographic Findings

The suppression-burst pattern is a common feature of both syndromes, although its form and the mode of its appearance and its period of persistence differ considerably between the two. With regard to mode of appearance, the suppression-burst pattern in OS appears consistently and unchangingly during both the awake and sleep states; in EME, the suppression-burst pattern is enhanced during sleep and often is not apparent in the awake state.[32] Regarding the period of its persistence, the suppression-burst pattern appears at the onset of disease and

P.2306

disappears within the first 6 months of life in OS, whereas in EME, the suppression-burst pattern appears at 1 to 5 months of age in some cases and characteristically persists for a prolonged period.[22,31,32]

Evolution During the Clinical Course

Evolution of the EEG pattern during the clinical course is a characteristic feature of OS: From the suppression-burst pattern to hypsarrhythmia in many cases, and then from hypsarrhythmia to diffuse slow spike-waves in some cases.[29,31,32,45,50] In contrast, the suppression-burst pattern in EME reappears and persists for a prolonged period after a transient appearance of atypical hypsarrhythmia that may be observed during the clinical course in some cases.[22,32] Thus, the patterns of EEG evolution with age differ considerably between the two syndromes.

As already mentioned, considering the evolution of disorder type with age and the mode of appearance in relation to the wake-and-sleep cycle, the existence of two types of SB, those observed in OS and EME, is a very interesting and important finding, one that might contribute to the understanding of the mechanism of SB.

With regard to the evolution of epileptic syndromes, OS shows a specific pattern of evolution into other forms of the age-dependent epileptic encephalopathies, whereas EME has no such age-related evolution. Furthermore, it is also significant that no transition is observed between OS and EME.

Etiology

In OS, obvious brain lesions, such as malformations, are often seen, and CT and MRI abnormalities are usually detected even at an early stage. No familial cases of OS have been reported. In contrast, the frequent occurrence of familial cases of EME suggests some congenital metabolic disorders as the etiology.[3,40,43]

These findings strongly suggest that OS and EME are separate clinicoelectrical entities. Schlumberger et al.[40] found definite clinical and symptomatologic differences between these two syndromes and no overlap. However, there are cases that are truly difficult to separate because they have cerebral malformation and metabolic/genetic disorders.

Treatment and Outcome

Seizures are intractable. Synthetic ACTH exerted a limited efficacy in some cases.[50] Phenobarbital,[37] pyridoxal phosphate or vitamin B6, valproate, benzodiazepines, and a ketogenic diet were poorly effective in general.

There are recent reports of cases responsive to zoni- samide[24,50] and vigabatrin.[5] Successful resection has been reported in patients with focal cortical dysplasia and has been associated with relatively improved neurologic development after surgery.[16,17,38]

Although they are intractable, seizures come under control by school age in approximately half of the patients. Prognosis for psychomotor development remains very poor; all survivors have severe disabilities, both mental and physical. Many such patients died, especially in the early stage of the disease.[50] One fourth of our patients died before 2 years of age.

Long-Term Prognosis

In 8 survivors of 16 OS cases in our series, the age at follow-up ranged from 5 years and 0 months to 28 years and 0 months.[50] All but 2 were >10 years of age. All survivors had severe mental retardation. Six were bedridden with quadriplegia; only 2, with hemiplegia, were ambulant. Seizures persisted in 2 of the survivors: Tonic spasms in 1 and focal motor seizures in the other.

With EEG follow-up, only 2 of 8 survivors were spike-free. Focal spikes were detected in 6 others: Multiple independent spike foci were found in 4 and other cortical foci in 2; 3 of them showed diffuse generalization.

Summary and Conclusions

OS is a peculiar epileptic syndrome with strong age dependence in the neonatal period and very early infancy, and it is the earliest form of the age-dependent epileptic encephalopathies. In describing the clinicoelectrical characteristics of this syndrome and its evolution with age, we stressed the importance of taking a developmental approach in epilepsy research. This approach is very effective for establishing new syndromes and differentiating them from related disorders/syndromes as well as clarifying prognoses. In discussion differential diagnosis focused particular attention on early myoclonic encephalopathy.

Chapter 226

Overview: Syndromes of Infancy and Early Childhood

Jean Aicardi

Introduction

The incidence of epilepsy is very high in the first years of life, reaching a peak in the first year and remaining at high levels throughout infancy and early childhood. The epilepsies with onset in infancy, although a heterogeneous group, share some special characteristics, and this applies up to the age of approximately 3 to 4 years. The following chapters, therefore, are concerned with all epilepsies that begin before the age of 4 years.

The special features of the epilepsies of early onset are the result of several etiologic, anatomic, and neurophysiologic factors. One major factor is the immaturity of the infant's brain. At this period, dendritic development is actively proceeding, and myelin formation and deposition are far from complete, which may be responsible for imperfect synchronization of the hemispheres. Brain circuitry is different from that in later life. In particular, the number of synapses increases rapidly during the first years of life and far exceeds the ultimate number.[16] A high proportion of these synapses is eliminated before 8 to 10 years of age, and this pruning process depends on activity and, therefore, on environmental stimuli. There is evidence that functional synapses become stabilized, whereas unused ones disappear; this is probably one of the mechanisms of brain plasticity. Development and maturation of the brain are associated with changes in neurotransmitters and receptors and their effects. For example, some γ-aminobutyric acid (GABA) receptors have been shown to be excitatory during fetal life and the early postnatal period,[19] and glutamate receptors may not be sufficient to produce brain damage through activation of the glutamate cascade. Such changes are likely profoundly to modify the excitability of the infant's brain. The conjunction of these factors undoubtedly accounts for some of the features of early seizures, such as the generally imperfect organization of seizure discharges, the rarity of full-fledged tonic–clonic attacks, and the higher frequency of unilateral or predominantly unilateral seizures in response to diffuse systemic disturbances such as fever or metabolic imbalances. However, the infant's brain is capable of occasionally producing 3-Hz spike-wave discharges and massive myoclonias and even, although rarely, absence attacks.[2] Seizures of focal origin are the most common seizures in this age range. They may be associated with focal clinical manifestations and electroencephalogram (EEG) discharges of several forms with different degrees of propagation. Many focal seizures are associated with extensive brain lesions, indicating that the infant brain may be unable to organize complete seizure sequences as observed at a later age. The atypical clinical expression of many seizures in the infantile range probably results from the neurophysiologic factors already mentioned, from the late maturation of some areas of the brain such as the frontal lobe, as well as from the inability of infants to experience or express some of the more complex features of seizures and the difficulty or impossibility for observers to detect such symptoms as loss or impairment of consciousness.[20] Conversely, focal brain lesions or abnormalities may be associated with diffuse clinical symptoms and with extensive EEG paroxysms, one common type being infantile spasms with the so-called hypsarrhytmic pattern of high-amplitude disorganized tracing, suggesting that focal origin of seizures may be expressed in generalized attacks and is probably even more common in young children than previously thought.[13]

The etiology of early-onset epilepsies is also responsible for many of their clinical and evolutive characteristics. As in older patients, the two main factors are a propensity to fitting (mostly genetically determined) and the presence of brain lesions; however, both have age-specific peculiarities.

The *epileptogenic lesions* are often extensive, even when they give rise to partial seizures. Some are destructive and may be related to mechanical or hypoxic-ischemic injuries. A majority, however, are of developmental origin, the most common being abnormalities of cortical development. These include heterotopias, diffuse pachygyria-lissencephaly, hemimegalencephaly, and focal cortical dysplasias, the latter being the most common cause of epilepsy at this age.[15] It is of interest that the nature, location, and extent of organic brain damage—and not only the age of the child—are responsible, at least in part, for the ictal symptomatology. Thus, tuberous sclerosis often determines infantile spasms, and Aicardi syndrome determines a mixture of focal seizures and spasms.

The propensity to seizures of infants is mainly expressed by febrile convulsions (see Chapter 227) and less often in the form of other benign epilepsy syndromes. Febrile convulsions (FCs) are by far the most common frequent manifestation of a genetic predisposition to seizures. Although febrile seizures are not termed *epilepsy* because they do not fulfill the definition of a chronic unprovoked condition but are classified as *occasional seizures* or *situation-related seizures*,[1,14] they have undoubted physiopathologic and genetic relationships with the epilepsies and may be regarded as a benign expression of the main basic phenomenon. This genetic relationship is best illustrated by the occurrence of afebrile convulsions following FC, which, although rare, are much more common than in the general population and in rare instances by the syndrome of generalized epilepsy with febrile seizures plus (GEFS+).

The importance of age in the expression of infantile epilepsy is clearly shown by the age dependence of several types of seizures. West syndrome rarely begins after 1 year of age and has a well-defined modal age of onset at 5 to 6 months (Chapter 229). Several types of seizures may occur in succession in the same patient with an unchanged pathologic basis; for example, Ohtahara syndrome can precede infantile spasms, followed by the development of the Lennox-Gastaut syndrome; focal or unilateral seizures may precede the development of West or Lennox-Gastaut syndrome. Such changes may reflect not only the maturation of the brain, but perhaps also the

P.2310

plasticity of the central nervous system. Some of the changes could result from the capacity for reorganization of the infant's brain following an insult or even a prolonged dysfunction without any lesion. It is conceivable that unusual regulation and development of receptors or preferential stabilization of certain synapses as a result of prolonged abnormal epileptic activity in certain pathways may lead to altered connectivity, with corresponding clinical changes. Such a mechanism could account for some of the characteristics of epileptic deterioration, such as its spontaneous arrest after disappearance or improvement of epileptic activity and incomplete recovery in spite of apparent cure of epilepsy. Deterioration associated with, and possibly resulting from, intense epileptic activity, whether marked by seizures or only by EEG alterations, is a remarkable feature of some early epilepsies,[3,5,11] sometimes termed *epileptic encephalopathies* or *catastrophic epilepsies* (see Chapter 230). Although epileptic deterioration is not limited to young children, as shown by its occurrence in such syndromes as the Landau-Kleffner syndrome or that of continuous spike-waves of slow sleep,[5] it is clearly prominent in this age bracket (see Chapter 242). Other factors possibly responsible for deterioration include evolution of the underlying lesions, frequency and consequences of seizures, psychological problems, side effects of drugs, and other environmental influences.

Finally, epilepsy in infants is often associated with other neurologic problems, such as cerebral palsy or mental retardation, and seizures not only add to children's difficulties, but also multiply the total impairment so that attempts at control are particularly important.

The seizures of early-onset epilepsies often differ from those in older patients (see Chapter 56). Some types of seizures observed in later life are sometimes seen in children <3 years of age. These include generalized—especially myoclonic—seizures that may have their onset from a few months of age.

Tonic–clonic seizures tend to be less well organized and less symmetric and to feature a longer tonic phase than in older children. Atypical absences often feature changes in tone, and their EEG manifestations (slow spike-wave complexes or fast rhythms) are completely different from those of typical absences, which are very rare in the first 2 to 3 years.[3] Partial seizures are probably more common, but they often have unusual clinical features with predominance of head deviation and unilateral or asymmetric tonic phenomena over clonic jerks.[12] More precise classification of partial seizures is difficult because of the difficulties of assessing awareness and the limited register of motor manifestations, even though some investigators have reported on "complex" focal seizures in infants.[26,27] Some types of seizures are particularly characteristic of young children, although none is completely restricted to them. These include infantile spasms, tonic and atonic seizures, atypical absences, and episodes of nonconvulsive status epilepticus often with myotonic manifestations. Such seizures are major components of the catastrophic epilepsies or epileptic encephalopathies.[3,11] Other seizures have a very limited clinical expression, such as simple arrest of activity, subtle changes in tone (hypertonia or hypotonia), simple staring, pallor, perioral cyanosis, blinking of eyelids, or isolated eye deviation.[22] Such atypical attacks often evolve into more characteristic partial seizures when the children grow older.

The frequency of the various types of seizures is not well known. In two large series of epilepsy in infants <1 year of age,[7,8] infantile spasms were the most frequent type (230 of 437 and 183 of 387, respectively), followed by other generalized seizures (99 and 87, respectively) and partial seizures (57 and 51, respectively). In a large group of 504 children <3 years old, Dalla Bernardina et al.[10] ascribed 163 patients to the group of the epileptic encephalopathies, 189 to the partial epilepsies, and 80 to the generalized epilepsies (34 with myoclonic seizures). These figures were drawn from specialized referral centers, so the proportion of severe seizures is likely to be less in the general population.

As in other age groups, epilepsy syndromes, that is, clusters of signs and symptoms occurring customarily together,[11,14] are recognizable among infantile epilepsies. However, syndromic classification is more difficult than in older patients because of the uncharacteristic features of many cases and the fact that the clinical and EEG manifestations are rapidly changing in many cases, so that several syndromes may evolve in succession in the same child. For example, partial seizures may precede infantile spasms, and these frequently herald the development of the Lennox-Gastaut syndrome. The most common epilepsy syndromes in infants are described in the following chapters. The best characterized are West syndrome (Chapter 229), severe myoclonic epilepsy (Chapter 230), and the Lennox-Gastaut syndrome (Chapter 241) (although its onset is often slightly later in life). These syndromes usually have a poor prognosis. West syndrome and the Lennox-Gastaut syndrome are of lesional origin in most cases, and abnormalities of cortical development are a major etiologic factor, especially in the case of infantile spasms.[13] Despite their generalized clinical and EEG features, seizures in these two syndromes are probably due in a significant proportion of cases to localized lesions, some of which may be amenable to surgical treatment. Severe myoclonic epilepsy (renamed Dravet syndrome because myoclonic seizures may be absent in some cases) is a clinically well defined syndrome with onset in the first year of life with febrile convulsions, often prolonged and frequently recurrent, followed in the second or third year by myoclonic attacks and multiple seizure types. It is due in most cases to a new sodium channelopathy.[21] Other tentative syndromes have been proposed. One is the syndrome of partial migrating infantile seizures,[9] whose specificity has been debated.[17]

More-benign syndromes of infantile seizures have been recognized more recently, indicating that the outcome of infantile seizures is not always poor and this has to be taken into account when giving a prognosis. Their frequency is much lower than that of the more severe types but may be greater than shown by statistics coming from referral centers and may be higher in some Asian countries[18] (Chapters 236 and 238). Clinical manifestations are brief partial seizures occurring in clusters in the first 2 years of life and disappearing before the age of 2 years. In some cases, a benign movement disorder may supervene after several years.[23] Benign partial infantile seizures are often genetically determined.[24,25] Some have been mapped to different loci on chromosomes 16, and the mutant gene has been isolated in one family.[6] Nongenetic benign syndromes have also been described.[12]

Summary and Conclusions

Infantile epilepsies have distinctive clinical characteristics due in large part to neurophysiologic features related to age. Their treatment is often unsatisfactory as a result of the lesional nature of many cases, the extent of responsible brain damage, and the consequences of epilepsy for cognitive and behavioral development. The respective indications of conventional and new drug treatment and of agents such as adrenotropic hormone or steroids are not yet clear. Surgical treatment has been shown to be possible and to give results on seizures similar to those obtained in older patients. However, its effects on neurodevelopment are yet to be assessed.

The important point is that experience with the catastrophic epilepsies of this age shows that epilepsy is more than simply

having seizures and may have pervasive effects on development, even when paroxysmal manifestations are absent or mild.

Chapter 227

Benign Familial and Nonfamilial Seizures

Federico Vigevano

Nicola Specchio

Roberto Caraballo

Kazuyoshi Watanabe

Introduction

Benign familial and nonfamilial forms of infantile seizure and partial epilepsies of infancy are significant categories of pediatric epilepsies. In the past, seizures with onset during the first months of life were considered to have a bad prognosis and a symptomatic etiology. Since the first description by Fukuyama, the existence of infantile seizures with a benign evolution has been defined and accepted.

The international classification of epilepsies and epileptic syndromes[17] includes benign infantile seizures, which are divided into familial and nonfamilial forms. In recent years, variants of these two forms and similar entities have been described.

Historical Perspective

In 1963, Fukuyama was the first to report cases with onset within the first 2 years of life that were characterized by generalized convulsions, absence of etiologic factors, and benign outcome.[18] This type of infantile convulsion was the subject of many subsequent studies, but only after 20 years were the true clinical entities clarified. Reports have specified the localization and semiology of seizures, which have been defined as being of partial type[69,71,72] and in terms of the presence or absence of familial occurrence.[6,7,8]

Vigevano and coworkers focused on cases exhibiting a family history of convulsions with benign outcome during infancy and autosomal-dominant inheritance, and they proposed the term *benign infantile familial convulsions* (BIFC).[67] Later, other such cases were reported in many different parts of the world,[16,21,35,40,45] thus confirming them as new epileptic syndromes. When these entities were included in the list of epileptic syndromes by the International League Against Epilepsy (ILAE) Task Force on Classification and Terminology, it was suggested that the term "seizure" should be used rather than the term "convulsion."[17] Just like benign seizures with neonatal onset, benign infantile seizures are divided into familial and nonfamilial forms.[17] These two forms, however, can have overlapping features.[39] Genetic studies of familial forms led to the identification of a chromosome marker on chromosomes 19,[23] 16,[11] and 2.[42]

An association between *benign familial infantile seizures* (BFIS) and variably expressed paroxysmal choreoathetosis was reported in 1997 by Szepetowski et al.[61] A specific marker on chromosome 16 has been identified in this familial variant, called *infantile convulsions and choreoathetosis* (ICCA).

Heron et al.[25] in 2002 and later Berkovic et al.[3] proposed a new entity and coined the term *benign familial neonatal-infantile seizures* (BFNIS) to describe families with onset at an intermediate age between neonatal and infantile forms.

Considering that convulsive manifestations are limited to a short period of time, some authors hypothesized the existence of particular etiologic factors in some sporadic cases such as cases of benign infantile convulsions associated with episodes of diarrhea caused by rotavirus infections.[12,28,30] Finally, Capovilla et al. described a peculiar form of benign epilepsy occurring within the second year of life and with a typical sleep electroencephalographic (EEG) pattern.[5,6]

Definition

Benign partial seizures in infancy are a group of diseases characterized by onset during the first 2 years in otherwise normal children. They could be familial, with a characteristic autosomal-dominant trait of inheritance and a typical onset around 6 months, or nonfamilial, which usually occur later. Seizures are partial with or without secondarily generalization and are typically grouped in clusters of many per day. In most cases, interictal EEGs are normal, except for the midline spikes during slow sleep described by Capovilla, but this form of epilepsy is under discussion. Outcome is always excellent, with a normal psychomotor development after seizures.

Epidemiology

Several cases with this syndrome have been described from all over the world. Data on prevalence and incidence are not available. In a series described by Caraballo et al.,[9] benign infantile seizures were listed as the third-most-common type of epilepsy in the first 2 years of life.

Etiology and Basic Mechanisms

Autosomal-dominant transmission is evident in BFIS. Due to the close similarity to *benign familial neonatal seizures* (BFNS), researchers first tried to find the chromosome markers described in this latter syndrome.[37,55,57] In 1994, Malafosse et al.[43] demonstrated that BFIS is not an allelic form of BFNS, excluding the marker on chromosome 20.

In 1997, linkage analysis was carried out in five Italian BFIS families, and a locus was mapped on chromosome 19q12–13.1 between markers D19S49 and D19245.[23] Gennaro et al.[20] later conducted a linkage analysis of seven families of Italian origin and demonstrated the presence of linkage to chromosome 19q in a single family, suggesting genetic heterogeneity within the examined families. Studies of familial cases with ICCA are particularly interesting. Szepetowski et al.[61] demonstrated linkage to the pericentromeric region of chromosome 16 in the families with this syndrome. This finding was then confirmed by Lee et al.[36] in a family of Chinese origin. In 2001, Caraballo et al.[11] found linkage on chromosome 16p12-q12, the same region as

for ICCA, in seven families with only benign familial infantile seizures. There was a previous report describing a large family affected by paroxysmal kinesigenic dyskinesia without infantile convulsions with linkage to the ICCA region.[33] Therefore, Caraballo et al. hypothesized that chromosome 16p12-q12 is a major genetic locus underlying both benign familial infantile seizures and paroxysmal dyskinesias.[11] Weber reported similar results in 14 families with benign familial infantile seizures without paroxysmal choreoathetosis.[73]

In 2001, Malacarne et al.[42] mapped a novel locus to chromosome 2q24 in eight Italian families, thus demonstrating a genetic heterogeneity, as in other autosomal-dominant idiopathic epilepsies.

In cases described as having *benign familial neonatal-infantile seizures*—an intermediate form between BFIS and benign familial neonatal seizures—a missense mutation in the *SCN2A* gene has been found, leading to the hypothesis of the existence of a third form,[20] although recently a similar mutation of the same gene has been described in a family with clinical features typical of BFIS.[58]

A particular etiologic factor has been recognized in some infantile seizures associated with mild gastroenteritis, with positivity to the rotavirus antigen. In the other nonfamilial forms, no clear etiologic factors have been described.

Clinical Presentation

Benign Nonfamilial Infantile Seizures

Watanabe et al.[3] described a series of infants having focal seizures with benign evolution. The majority of the cases were not familial. They described nine infants with benign complex partial seizures as diagnosed by simultaneous electroencephalogram and video recording. At ages of 3 to 10 months, most of these infants presented with clusters of seizures consisting of motion arrest, decreased responsiveness, staring, or blank eyes, mostly with simple automatisms and mild convulsive movements associated with focal paroxysmal discharges, most frequently in the temporal area. Carbamazepine or phenobarbital was used to control the seizures, and all patients were seizure free for >3 years. All patients showed normal interictal electroencephalogram and psychomotor develop-ment.

Later, the same authors described the cases of 7 infants with benign idiopathic partial epilepsy presenting with apparently generalized tonic–clonic seizures (GTCs), which turned out to be partial seizures evolving to secondarily generalized seizures (SGS).[69] In subsequent years, other reports confirmed this syndrome, for example, Berger et al.[2] and Capovilla et al.,[7] who reported the cases of 12 children with complex partial seizures having similar electroclinical features.

The term *benign partial epilepsy in infancy* (BPEI) was proposed to combine the two previously described entities.[2,69] Clinical characteristics of benign partial epilepsy in infancy, which is now classified as benign nonfamilial infantile seizures, are summarized in Table 1.

Table 1 Clinical characteristics of benign nonfamilial infantile seizure, which comprises benign partial epilepsy of infancy with complex partial seizures and benign partial epilepsy with secondarily generalized seizures in infancy

Benign Partial Epilepsy of Infancy With Complex Partial Seizures	Benign Partial Epilepsy With Secondarily Generalized Seizures in Infancy
• Normal development before onset	• Normal development before onset
• No underlying disorders or neurologic abnormalities	• No underlying disorders or neurologic abnormalities
• Onset mostly within the first year of life	• Onset mostly within the first year of life (3–20 mo)
• Complex partial seizures, often occurring in clusters	• Partial seizures (stare, blank eyes, or crying)
• Normal interictal EEG	• With secondary generalization, often occurring in clusters

• Ictal EEG most often showing temporal focus	• Normal interictal EEG
• Excellent response to treatment	• Ictal EEG most often showing a centroparietal origin
• Normal developmental outcome	• Excellent response to treatment • Normal developmental outcome

EEG, electroencephalogram.

Benign Familial Infantile Seizures

Vigevano and coworkers described cases with benign epilepsy in infancy and a family history of convulsions.[69] All of them had a benign outcome and autosomal-dominant inheritance, and the authors suggested the term *benign infantile familial convulsions*.[67] In subsequent years, autosomal-dominant familial cases have been reported by other authors, confirming the existence of this syndrome.[10,21,35,40,46,65]

The first series described by *Vigevano et al*.[67] consisted of five infants—three girls and two boys. All of them had one or more paternal relatives with a history of benign seizures occurring at the same age. It was found that 13 of their relatives had analogous seizures. Age at onset ranged from 4 to 7 months in the probands, whereas in their relatives it was 4 to 8 months, and peaked around 6 months. Onset was never in the neonatal period or after the eighth month of life.

This syndrome is included in the most recent classification and terminology proposed by the ILAE under the term *benign familial infantile seizures*.

Clinical characteristics are summarized in Table 2. Psychomotor development of all children before the onset of seizures is absolutely normal. A common characteristic to almost all cases is the occurrence of seizures in a cluster—mostly brief and successive seizures, a maximum of 8 to 10 per day, which do not reach a true status epilepticus. Interictal clinical condition is normal, with occasional stupor, most probably caused by drugs. Seizures are usually longer in the beginning, lasting 2 to 5 minutes, and become shorter as treatment takes effect. The cluster can last 1 to 3 days.

Table 2 Clinical and electroencephalographic characteristics of benign familial infantile seizures

- Family history of seizures (similar age at onset, autosomal-dominant trait)
- Normal development before onset
- No underlying disorders or neurologic abnormalities
- Onset between 4 and 8 mo of age
- Seizures in clusters
- Partial seizures localized in the occipitoparietal areas

- Semiology: psychomotor arrest, cyanosis, head/eye deviation to one side (variable), tonic contraction, bilateral clonic jerks
- Normal interictal electroencephalogram
- Ictal electroencephalogram: fast activity originating in the occipitoparietal area
- Postictal electroencephalogram: lateralized occipitoparietal delta waves and spikes
- Normal developmental outcome
- Benign course

Vigevano's patients presented with seizures that were clinically characterized by psychomotor arrest, slow deviation of the head and eyes to one side, diffuse hypertonia, cyanosis, and unilateral limb jerks, which became bilateral and synchronous or asynchronous. Although the seizures were highly stereotyped, the direction of the head and eye deviation sometimes changed from seizure to seizure in the same patient.

P.2315

Benign Familial Infantile Seizures Associated With Other Neurologic Symptoms

In 1997, Szepetowski et al.[61] identified and described in four French families an association of BFIS with paroxysmal choreoathetosis appearing later in life, and they proposed a new syndrome called *familial infantile convulsion and choreoathetosis* (ICCA). Linkage to chromosome 16 and dominant transmission were also clearly defined.[61] This entity has been confirmed by other authors.[1,4,6,8,60,63]

Familial hemiplegic migraine (FHM) is a rare, severe autosomal-dominant subtype of migraine with aura associated with hemiparesis.[29] Most of the families that have been reported were linked to chromosome 19p13 and had missense mutations in the *CACNA1A* gene.[16] In two families with FHM linked to 1q23, two missense mutations in the *ATP1A2* gene were identified.[65] Two novel mutations in the *ATP1A2* gene were also found. In particular, one mutation was detected in a Dutch-Canadian family in which FHM was associated with BFIS.[45,62] In this family, BFIS were followed at an older age by FHM and cosegregated to chromosome 1q23.[65] This finding suggests that BFIS may have a wider association with other neurologic diseases.

Benign Familial Neonatal-Infantile Seizures

A seizure onset occurring between neonatal and infantile ages was reported by Kaplan and Lacey in 1983.[32] The onset of seizures varied from 2 days to 3.5 months.[32] The authors used the term *benign familial neonatal-infantile seizure* (BFNIS). In 2002, Heron et al.[25] described two families with afebrile, secondarily generalized partial seizures occurring between 1.9 and 3.8 months of life and having an autosomal-dominant mode of inheritance, and they described a missense mutation in *SCN2A*, the gene coding for the α2 subunit of the voltage-gated sodium channel. In 2004,[3] a novel missense mutation in *SCN2A* gene was found in five similar families in addition to the first family described by Kaplan and Lacey: a new sodium channelopathy was identified. Clinical characteristics are summarized in Table 3. The semiology of the seizures was characterized by a predominant focal motor manifestation, with head and eye deviation followed by tonic and clonic movements. Most of the seizures were relatively long, lasting up to 4 minutes, and were of variable frequency, with some patients having few seizures per day and others having clusters of seizures. Interictal EEGs were normal or showed some epileptiform discharges in the posterior areas. When ictal EEGs were recorded, they showed a focal posterior onset of discharges. All patients had a normal development before and after the seizure occurrence. The authors concluded that this mutation represents a new sodium channelopathy, despite the possible overlap with the previously described cases of BFIS.

Table 3 Clinical characteristics of benign familial neonatal-infantile seizure

- Family history of seizures (autosomal-dominant trait)
- Normal development before onset
- No underlying disorders or neurologic abnormalities
- Onset between 2 d and 7 mo of age
- Frequency ranging from few attacks to clusters
- Afebrile secondarily generalized partial seizures
- Ictal electroencephalogram: onset in the posterior areas
- Remission within 12 mo
- Benign course

Recently, Striano et al.[58] reported a novel heterozygous mutation c3003 T→A in the *SCN2A* gene in a family with three affected individuals over three generations. All individuals experienced clusters of partial seizures with or without secondary generalization and onset between 4 and 12 months of life. They have been diagnosed with BFIS. No patients developed other seizures later in life, and all of them had a normal development outcome. This report provides new evidence that BFNIS and BFIS may show some overlapping clinical and genetic characteristics.

Benign Infantile Seizures Associated With Mild Gastroenteritis

Morooka[46] was the first to describe this entity (BIS with MG) in Japan in 1982. It is characterized by nonfebrile generalized seizures associated with symptoms of gastroenteritis in previously healthy patients between 6 months and 3 years of age. Seizures often occurred in clusters, and laboratory examination results, including blood and cerebrospinal fluid (CSF) glucose, were normal. Interictal EEG was normal in all patients, and all of them had an excellent outcome.

After the first report by Morooka, numerous (>60) reports have been published in Japan[30,31,33,36,49,53,56,64,67] but only nine from other countries.[20,22,27,38,42,54,61,68,76] Cases of BIS with MG are likely to fall within the category of situation-related seizures, although they are not described in the proposed ILAE classification and seizure terminology.[17] Seizure recurrence, also without prophylactic antiepileptic treatment, has not been reported in BIS with MG, although it can occur in a few cases when an infant has repeated episodes of gastroenteritis.[19] In a recent study by Okumura et al.[51] on the efficacy of antiepileptic drugs during a cluster, lidocaine was reported as the most effective drug for seizure cessation.

Table 4 Clinical characteristics of benign infantile seizures associated with mild gastroenteritis

- Healthy patients
- Age between 1 and 2 yr
- Brief partial seizures evolving to secondary generalization
- Symptoms of gastroenteritis

- Seizures in clusters
- Seizures within the first 5 days of gastroenteritis
- More than 50% positive to rotavirus antigen
- Seizure recurrences rare, only during recurrence of mild gastroenteritis
- Benign course

BIS with MG are characterized by mostly brief and partial seizures evolving to secondary generalization, often occurring in clusters, in infants and children aged 1 to 2 years. Seizures occurred within the first 5 days of the gastroenteritis episode,

and the proportion of positive rotavirus antigen was greater than half.[64] Table 4 summarizes the clinical characteristics of this condition.

Benign Infantile Focal Epilepsy With Midline Spikes and Waves During Sleep

First Bureau and Maton[4] and later Capovilla and Beccaria[5] and Capovilla et al.[6] described a form of epilepsy in children with homogeneous electroclinical features and a benign course that they hypothesized to be a new form of benign focal epilepsy. A distinctive aspect of this condition was that all of the described children presented particular interictal EEG abnormalities that were detectable during sleep and characterized by isolated or grouped spikes and waves from the midline region to the central regions. The authors pointed out that these abnormalities could be an EEG marker that is clearly distinct from other typical EEG markers at an older age. They highlighted, however, that it could not be only an EEG marker because it was found in a group of infants presenting with homogeneous clinical features, thus suggesting a possible new epileptic syndrome. Capovilla had previously described this syndrome with the term *benign partial epilepsy in infancy and early childhood with vertex spikes and waves during sleep*.[5] He later[6] proposed to replace *vertex spikes* with *midline spikes* in order not to confuse them with physiologic sleep vertex spikes.

The general features of this condition (Table 5) are neurologic and neuroradiologic normality, a normal psychomotor development, a positive family history, and a benign evolution in all cases. With regard to clinical features, age at onset is between 4 and 30 months, with a peak between 13 and 19 months (more than two thirds of cases are within this age range). The frequency of seizures is low; some children have a single episode, and others have multiple episodes per year. The seizure length is between 1 and 5 minutes. The episodes usually occur during wakefulness; in one fourth of cases, they occur during sleep. The age of the last seizure is between 24 and 43 months. The semiology of seizures is characterized by loss of contact— staring as a rule—and cyanosis. Perioral cyanosis and motion arrest are among the main clinical symptoms. Instead, lateralizing signs and automatisms are rarely observed. EEG is normal when awake, with typical sleep EEG abnormalities, well differentiated from the typical high-voltage diphasic spikes followed by a slow wave found in benign epilepsy with centrotemporal spikes.[13] All of the children reported had a normal development during the follow-up period.

Table 5 Clinical and electroencephalographic characteristics of benign infantile focal epilepsy with midline spikes and waves during sleep

- Normal psychomotor development

- Family history (half of patients)
- Age between 4 and 30 mo
- Semiology: cyanosis, staring, rare lateralizing signs, automatisms
- Electroencephalographic marker: spike followed by bell-shaped slow wave (midline region) during sleep
- Sporadic seizures
- Favorable outcome
- Majority of patients not treated
- Benign course

Diagnostic Evaluation

As a general rule, it is not necessary to perform many diagnostic evaluations in these forms of epilepsy except for prolonged wake and sleep EEGs. All of these children have a normal psychomotor development and in some cases a clear familial recurrence: this history since onset can help to bring the clinician to a diagnosis of idiopathic epilepsy. The follow-up and the EEG evaluations of these patients confirm the diagnosis of benign forms. Magnetic resonance imaging (MRI) is always normal, as are all other diagnostic evaluations. In cases in which mild gastroenteritis is suspected as an etiologic factor, it is necessary to look for rotavirus antigen, which has been found in half of the cases.

Electroencephalographic Findings

Interictal EEG is normal or fails to show any diagnostic elements in all forms except for the midline spikes during sleep reported by Capovilla, who hypothesized the existence of this peculiar and rare form.[6]

The EEG characteristics are well defined in BFIS as described by Vigevano et al.[67]; during a cluster of seizures, interictal EEGs showed lateralized slow waves and spikes in the occipitoparietal areas, whereas outside the cluster of seizures, the interictal EEG is normal. Ictal EEG disclosed a focal discharge characterized by a recruiting rhythm of increasing amplitude with onset in the occipitoparietal regions, spreading over the hemisphere and involving the entire brain. Recordings in the same patient of seizures with onset sometimes on the right hemisphere (Fig. 1) and sometimes on the left (Fig. 2) confirmed the alternating clinical pattern. The site of seizure origin seems to be a characteristic distinguishing this form from that described by Watanabe. The temporal area is the site of origin in cases described as BPEI with CPS,[71] whereas in cases described as BPEI with SGS, the site of origin is centroparietal.[69] In familial cases, the seizures originate mostly in the parieto-occipital area, with the side varying from one seizure to another.[66]

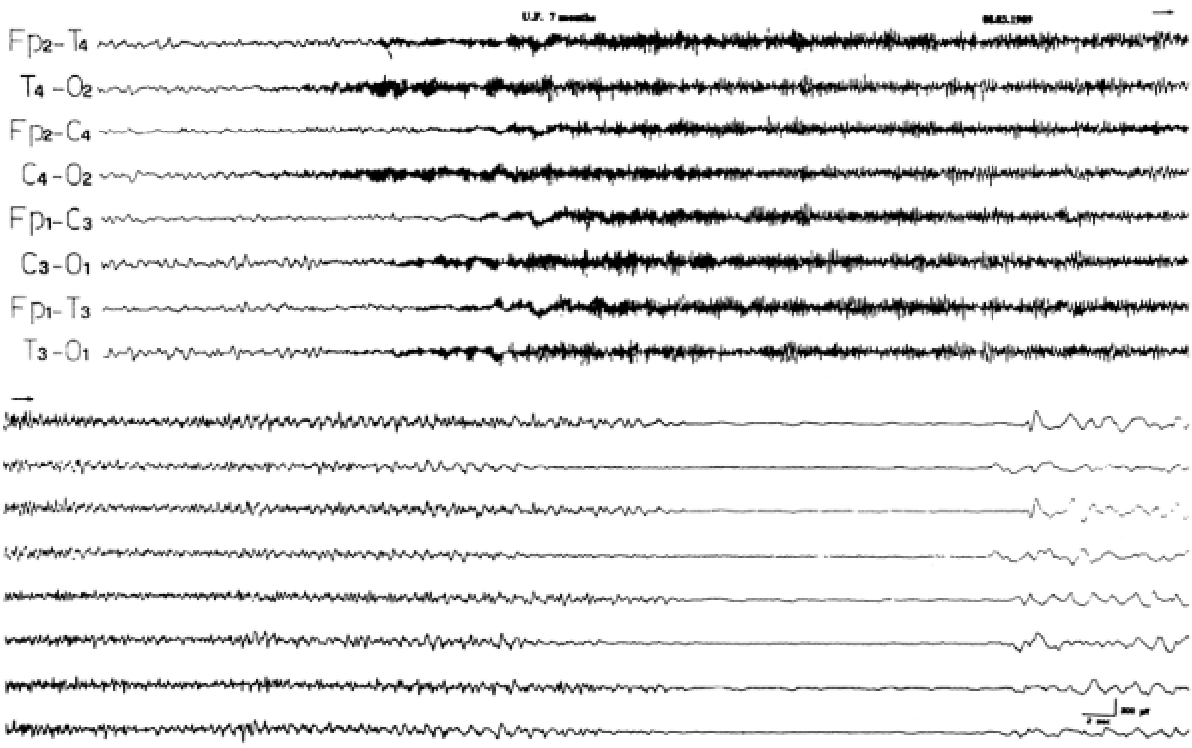

FIGURE 1. A 5-month-old boy affected by a familial form of benign infantile seizure. The seizure starts over the right parieto-occipital region.

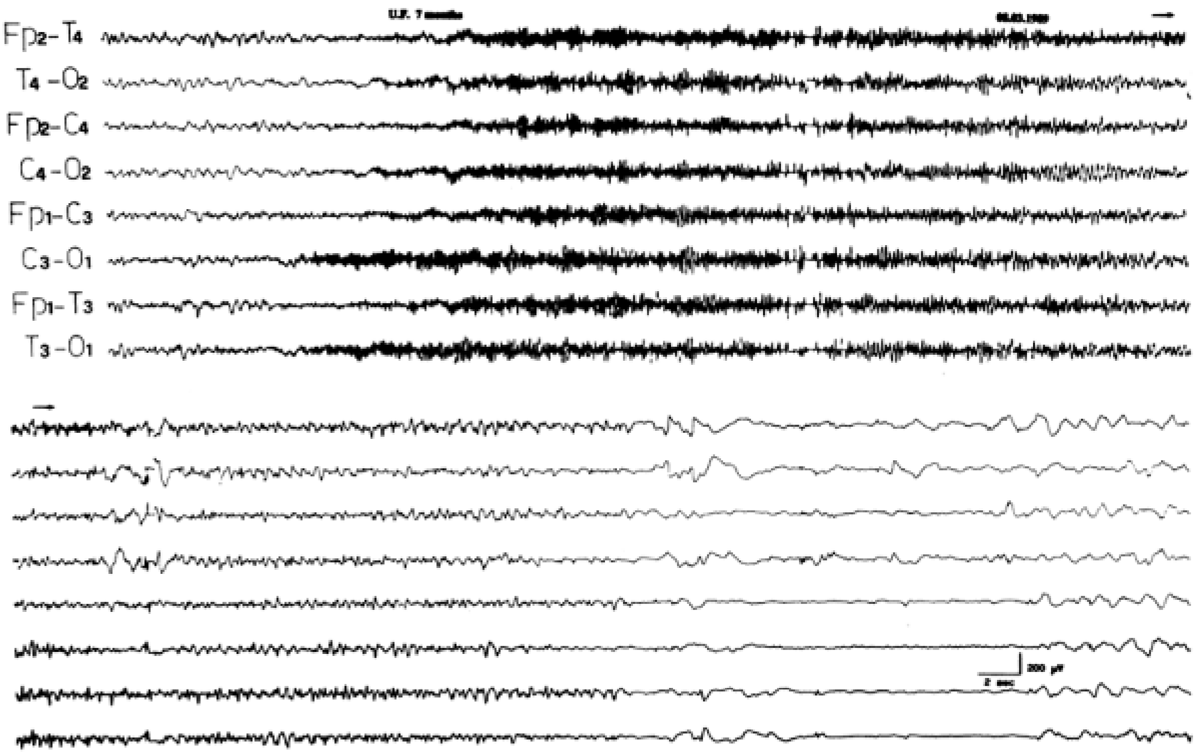

FIGURE 2. The same patient after 2 hours, experiencing a second seizure, which in this case starts over the left parieto-occipital region, thus demonstrating the alternating clinical and electroencephalographic pattern.

The distinctive aspect of benign infantile focal epilepsy with midline spikes and waves during sleep is that all of the described children presented particular interictal EEG abnormalities that

P.2317

P.2318

are detectable during sleep and characterized by isolated or grouped spikes and waves from the midline region to the central regions; Capovilla described these abnormalities as fast spikes, followed by a slow wave, in the midline region. They tend to spread to both central regions and are followed by a higher, bell-shaped slow wave.

Neuroimaging and Laboratory Assessment

Brain MRI is normal in all patients. The need to perform such examinations is based on the difficulty of diagnosing these epilepsies as benign from the onset. In cases with a clear autosomal-dominant pattern of inheritance and clear clinical features of benignity, it is possible to postpone the brain MRI. There are no particular indications for the laboratory assessment: Cardiovascular and respiratory function parameters have to be carefully monitored in children with BFIS or BNFIS during the cluster. A determination of glycemia could be useful at the onset and during the cluster of seizures.

In cases with BIS and MG, it is necessary to monitor the patient's hydration and general clinical conditions and investigate the presence of rotavirus antigen.

It is useful to collect such familial cases for linkage studies. The aim of genetic studies is to confirm the mutations that have been identified and provide genetic counseling. The possibility of new genetic mutations responsible for benign infantile seizures is sufficiently important to justify proposing a genetic study of these families.

Differential Diagnosis

The different forms of benign epilepsy in infancy recently have been examined by the ILAE in a proposed classification,[17] although their nosologic definition presents some difficulties.

The first report on the possible existence of benign forms of epilepsy in infancy dates back to 1963. In that year, Fukuyama[18] described a series of infants having apparently generalized seizures and benign course, as confirmed by Sugiura et al.[59]

On the other hand, partial epilepsies in infancy had long been considered as epilepsies with an unfavorable prognosis and as an expression of brain injury. Some authors also doubted the existence of partial idiopathic epilepsy in early infancy.[15] With the work of Watanabe et al.,[69,71,72] who reported cases of infants with complex partial seizures and seizures evolving to secondarily generalized seizures, a form of benign epilepsy was identified with partial seizures and onset in infancy. Afterward, Vigevano et al. focused on cases with similar features but also having a clear familial origin. They identified a specific form of benign epilepsy with onset within the first year of life and autosomal-dominant inheritance.[67] After the first study by Vigevano et al.,[67] a number of other reports confirmed the existence of such a benign epileptic syndrome. Furthermore, inheritance patterns have been confirmed with the identification, through linkage analysis of numerous families, of gene loci on chromosomes 19, 16, and 2.[11,23,42,58]

In this regard, other clinical entities with similar features to that described by Vigevano et al. but associated with other neurologic symptoms have been mapped to the same chromosomes where the syndrome described by Vigevano et al. was mapped.

ICCA, in which BIS are associated with paroxystic choreoathetosis,[61] has been mapped in various families on chromosome 16 in a region very close to that identified in families with BFIS.

The distinction between BFIS and other forms of benign epilepsy with neonatal onset (BFNS) appeared to be clear due to both the tight correlation with age and the difference in linkage analysis showing the existence of two genes, *KCNQ2* and *KCNQ3*, on chromosomes 20 and 8 responsible for BNFS.[37,55] Genetic studies failed to demonstrate the same gene defect in families with BFIS, thus dispelling all doubts about a possible overlap between BFIS and BFNS,[43] which are now also clearly distinct in the latest classification proposed by the ILAE.[17]

In 2004, a form of benign epilepsy with an intermediate onset between the neonatal and infantile forms was identified as BFNIS.[3] For this syndrome, a mutation of the gene *SCN2A* has been demonstrated. The onset of seizures in families affected by BFNIS is reported to occur between 7 days and 4 months of age. Although the mutation of the gene *SCN2A* appears to be distinctive to these families, age of onset and seizure semiology seem to overlap with BFNS and BFIS. We believe that it is of crucial importance to study new families with the described clinical picture to confirm the actual existence of a third form of benign familial epilepsy. To this purpose, we recently reported a new mutation of the gene *SCN2A* in a family with clinical features of BFIS, demonstrating a clinical and genetic overlap between BFNS and BFIS.[58]

From the clinical point of view, benign epilepsies of infancy are entities for which it is not easy to make a diagnosis. Clinical criteria described for BNFS and BFIS are not indicative for the diagnosis, although the presence of familiality may be helpful information. Sporadic forms may be even more difficult to diagnose. As reported by Okumura et al.,[50] recognition of BPEI is possible, to some extent, at the first presentation, but a confirmation can actually be obtained only by following these children over time to verify whether other seizures occur and other EEG abnormalities are found. These concepts are also relevant to pharmacologic treatment: It is difficult not to treat these epilepsies at the onset because these infants present with clusters of seizures. After the acute phase, many infants continue to follow a chronic therapy. In familial forms, the tendency is to interrupt the therapy as early as possible. In nonfamilial forms, instead, the indication is to wait and follow the evolution; should the benign diagnosis be confirmed, it is possible to stop the treatment within 18 months after the last seizure.

The phenotype of familial and nonfamilial forms is likely to be very similar. There may be some differences in the seizure semiology and in the site of the seizure onset (more anterior in the sporadic forms and more parieto-occipital in the familial forms).

It is certain, however, that there are familial forms with an autosomal-dominant trait as well as sporadic forms. Therefore, in our opinion, the major criterion for distinguishing these forms of benign epilepsy should be the presence or absence of familiality, as proposed in the most recent classification.[17]

All of the aforementioned entities do not present any interictal EEG abnormality and are characterized by seizures occurring exclusively in a short period of infancy. For all of these reasons, we agree with the proposal of the ILAE Task Force on Classification and Terminology that these conditions be defined with the term *seizures* and not *epilepsy*.[17]

Benign infantile focal epilepsy with midline spikes and waves during sleep (BIMSE) can be distinguished from other infantile benign forms because infants with this syndrome, as reported by Bureau and Maton[4] and later by Capovilla et al.,[5,6] have a slightly later onset, with no seizures in clusters, and with characteristic sleep EEG abnormalities. This syndrome is more similar to other benign epilepsies with partial seizures generally occurring at older ages, such as early-onset benign occipital seizure susceptibility syndrome (EBOSS) and benign epilepsy of childhood with centrotemporal spikes (BECTS), in which the interictal EEG shows particular epileptiform abnormalities.

P.2319

Table 6 Benign non familial infantile seizures

	BNFIS	BFIS	BFNIS	BIS AND MG	BIMSE
Genetic	Sporadic	AD	AD	Sporadic	Sporadic
Onset					
Typical		5–6 mo	Within 3rd mo	?	17 mo
Range		3-9 mo	2 d -7th mo	5-36 mo	4–30 mo
Type of seizure	Focal sometimes with SGS	Focal with SGS	Focal with SGS	Focal	Focal
Occurrence	Cluster	Cluster	Cluster	Repetitive	Rare
Other type of seizure	—	—	—	—	—
Other clinical features	—	Paroxysmal choreoathetosis migraine	—	—	—
Interictal EEG	NS	NS	NS	NS	Midline spikes during sleep
Chromosomal loci	—	16,19,2	2	—	—
Gene	—	*SCN2A*	*SCN2A*	—	—

AD, autosomal dominant; BFIS, benign familial infantile seizures, BNFIS, benign non familial infantile seizures, BIS and MG, benign infantile seizures and mild gastroenteritis; BIMSE, benign infantile focal epilepsy with midline spikes and waves during sleep; EEG, electroencephalogram; NS, not significative; SGS, secondarily generalized seizures.

Although in BIMSE, as in the other epilepsies described, there seems to be a characteristic EEG pattern, a wider number of patients should be studied to confirm the actual existence of this new form of benign epilepsy. At present, this entity is being studied and is not included in the international classification of epilepsies.

In contrast to the previously discussed entities, benign infantile seizures associated with mild gastroenteritis (BIS with MG) are more likely to be considered as situation-related seizures than as epilepsy. This syndrome can be misdiagnosed as epilepsy because seizures are nonfebrile and may occur in clusters. It is important further to study and understand this entity.

In conclusion, benign epilepsies of infancy encompass a wide spectrum of entities with differences in age at onset, genetic aspects, seizure semiology, and EEG characteristics (when available). Table 6 summarizes the main features of benign epilepsies. Follow-up of these infants is important because it allows us to confirm the benign outcome over time.

Treatment and Outcome

Although, as in other benign forms of infant epilepsy, seizures in these forms should not be treated, in clinical practice it is difficult to not treat these patients. At the very beginning these children present seizures in clusters (seizure every 2–3 hours), which sometimes require a rapid intervention with drugs. Patients not treated after the first cluster can have other seizures or clusters. When such children arrive at the emergency department, the etiology of their seizures may appear clearly only after EEG monitoring and with a normal neurologic evaluation. For these reasons, the majority of children receive antiepileptic treatment. In cases that exhibit a familial recurrence, it is possible to withhold the treatment because the diagnosis is simpler. In anecdotal reports, all drugs have demonstrated efficacy in benign infantile seizures (valproate, carbamazepine, phenobarbital, and phenytoin), with apparently no differences. Recently, Japanese authors[44] reported the efficacy of low doses of carbamazepine in a series of patients with benign infantile seizures. In this study, carbamazepine was administered at a once-daily dose of 5 mg/kg; seizures did not recur in any patient. The treatment can be withdrawn 1 year after onset.

Long-Term Prognosis

Unpublished data from the Division of Neurology, Bambino Gesù Children's Hospital, of a 14 year-follow-up period confirm that any patients have had seizure recurrence without treatment. Neuropsychological development appears to be normal in all of them, except for one patient, who has mild mental retardation, which was evident before the seizure onset. Most of the patients have had several follow-up EEGs that failed to show any abnormalities. Some data have been published that confirm the benign prognosis for these patients.[49,52]

Summary and Conclusions

Benign epilepsies during infancy are a large topic needing both clinical and nosologic clarification. In 1963, Fukuyama reported patients with seizures during infancy with a benign outcome. In the late 1980s and early 1990s, Watanabe reported series of infants with complex partial seizures or partial seizures with secondary generalization, with a normal development before onset and a benign outcome. In the same years, Vigevano focused on familial cases: He described several families with seizures with onset around 6 months of age and an autosomal-dominant mode of inheritance. To define this condition, he coined the term *benign familial infantile seizures* (BFIS). Later studies of families with this phenotype detected loci on chromosomes 19, 16, and 2 responsible for it. Similar loci were found in families affected by BFIS and subsequent choreoathetosis and BFIS associated with familial hemiplegic migraine. More recently, a new form of benign epilepsy has been proposed with an intermediate onset between the neonatal and infantile ages, *benign familial neonatal-infantile seizures* (BFNIS). This condition might have some clinical and genetic features overlapping with BFIS. Seizures with a benign outcome also have been reported in infants during episodes of mild gastroenteritis (BIS with MG), frequently with positive rotavirus antigen. Finally, Capovilla et al. reported sleep EEG abnormalities in children

with a peculiar form of epilepsy that they defined as *benign infantile focal epilepsy with midline spikes and* *waves during sleep* (BIMSE). Some of these entities have been included in the most recent classification proposed by the ILAE and have been differentiated into familial and nonfamilial forms.

We believe that there is a series of clinical entities with seizures in clusters that are limited to a short period of life. All of these entities are idiopathic, without EEG interictal abnormalities, and benign, and we define them as “seizures” and not “epilepsies.”

Benign infantile focal epilepsy with midline spikes and waves during sleep should be placed at the upper border of this age range. Infants with this syndrome have a later onset, and it has more similarities with benign focal epilepsies appearing later in life such as early-onset benign occipital seizure susceptibility syndrome (EBOSS) and benign epilepsy of childhood with centrotemporal spikes (BECTS).

Migrating Partial Seizures In Infancy

Maria Roberta Cilio

Olivier Dulac

Renzo Guerrini

Federico Vigevano

Introduction

Epileptic syndromes with onset in the neonatal period or infancy with very poor prognosis have been recognized or better defined in recent years due to developments in diagnostic techniques, including video-electroencephalography, brain imaging, and cytogenetics. Migrating partial seizures in infancy (MPSI) is a rare, newly recognized, age-specific epileptic syndrome first described in 1995 by Coppola et al.[3] In the proposed revision of the International League Against Epilepsy (ILAE) diagnostic scheme for people with epileptic seizures and with epilepsy, MPSI was labeled as a syndrome in development and included among symptomatic and probably symptomatic focal epilepsies.[7] It is characterized by onset in the first 6 months of age, after a normal early development, of nearly continuous multifocal partial seizures arising independently and sequentially from both hemispheres, progression through a period of intractable seizures, subsequent neurologic deterioration or arrest with complete loss of both cognitive and motor abilities and, in most children, progressive decline of head circumference percentile.

Historical Perspectives

MPSI was first reported in 1995 by Coppola et al.,[3] who described 14 infants with a severe epileptic disorder characterized by seizure onset in the first year of life; nearly continuous multifocal seizures involving both hemispheres; no identifiable immediate or remote cause; normal neuroimaging studies at onset; and intractability to conventional antiepileptic drugs (AEDs), including phenobarbital, phenytoin, carbamazepine, valproate, vigabatrin, clobazam, nitrazepam, biotin, vitamin B_6, and corticosteroids. In this first description, the outcome was very poor with regard to both the seizure disorder and psychomotor development. Only 2 of 14 patients stopped having seizures with a combination of stiripentol and clonazepam and showed some neurologic improvement. Eleven patients developed microcephaly during the first year of life, and three patients died. After this original report, additional cases from Australia, Europe, Japan, and the United States were published.[4,10,11,13,15,17,22] Thirty-three cases have now been reported. In particular, two cases have been reported from Australia[22] that fulfill the diagnostic criteria proposed by Coppola et al.[3] Both infants presented with intractable partial seizures arising independently from multiple regions of both hemispheres, with interictal electroencephalograms (EEGs) revealing multifocal epileptiform activity. There was no response to AEDs, pyridoxine, and corticosteroids, and developmental arrest followed seizure onset. Extensive investigations failed to identify an underlying cause. Both infants died. One of them underwent postmortem examination, which was normal.

Veneselli et al. reported three infants in whom seizure onset occurred before 3 months of age and was characterized by focal motor manifestations with a gradually increasing frequency.[17] Either hemibody was alternatively and randomly involved, and secondary generalization was evident only during the evolution of the disease. Conventional AEDs were uneffective. No etiologic factors have been identified. Neurologic status and evolution were highly unfavorable, resulting in death in one case and severe neurodevelopmental morbidities in the others. The same malignant course, with regard to both seizure disorder and ultimate outcome, was described by Gross-Tsur et al. in two additional cases.[10] One infant, microcephalic at birth, developed at age 4 months clusters of nearly continuous multifocal seizures with secondary generalization, refractory to antiepileptic drugs. By the age of 4.5 years she was seizure free but remained without any cognitive or motor function. The other, born with a normal head circumference, began seizures at the age of 3 months, never became seizure free, and died at age 18 months. Neuroimaging findings showed progressive subcortical atrophy. In both cases, extensive evaluation including skin and muscle biopsy did not clarify the etiology. However, more recently, Marsh et al.[13] reported six new patients with the same clinical and electroencephalographic characteristics as those described by Coppola et al.[3] but with the prospect of a more optimistic developmental outcome, raising the difficult distinction at onset with benign infantile or neonatal-infantile seizures. Each patient underwent comprehensive brain imaging and neurometabolic evaluations, which were unrevealing. Five patients had a long-term follow-up. Whereas all had some degree of neurodevelopmental sequelae, a few of them appeared to be less severely affected: One was able to walk, one developed some degree of spoken language, two showed developmental quotients between 50% and 100%, and only one was profoundly impaired. In terms of seizure outcome, one was still having intractable seizures when lost to follow-up. For five of six patients, six or more AEDs failed. Two patients received adrenocorticotropic hormone (ACTH); two were treated with folinic acid, and two were placed on ketogenic diet. None of them was more successful than the others. In contrast, successful seizure control was obtained with potassium bromide by Okuda et al. in two patients with a diagnosis of MPSI and refractory to conventional AEDs.[15] Moreover, once seizures were controlled, both patients showed some degree of neurologic recovery. A recently published case report by Hmaimess et al. in 2006 described the first neonatal case of MPSI and documented a positive response to levetiracetam.[11] Unfortunately, despite the dramatic decrease in seizure activity, which paralleled a positive clinical evolution in terms of psychomotor development, the child died unexpectedly at 14 months of age. The most recent three cases at the time of this review have been reported by Coppola et al., who performed a mutational scanning of potassium, sodium, and chloride ion channels (KCNQ2, KCNQ3, SCN1A, SCN2A, and MECP2) but

failed to find any mutations.[4] Finally, it is important to consider that studies on drug-resistant seizures with early onset classified as “catastrophic infantile epilepsy” may include cases of MPSI. Ishii et al.[12] investigated clinicoelectrical and etiologic characteristics of 15 patients with catastrophic infantile epilepsy. Although some of these patients did not belong to MPSI, a number of them, mainly those without a clear etiology, clinically and electroencephalographically resemble this syndrome.

Definitions

MPSI is a severe, probably symptomatic, age-dependent focal epilepsy defined by the following diagnostic criteria: (a) normal development before seizure onset; (b) seizures beginning before age 6 months; (c) migrating focal motor seizures at onset; (d) multifocal seizures becoming nearly continuous; (f) intractability to conventional AEDs; (e) lack of demonstrable etiology; and (g) severe psychomotor delay on follow-up. The clinical features and EEG pattern suggest that MPSI may rank among the catastrophic epilepsies of infancy. Moreover, due to the high frequency of seizures and the intense epileptiform activity that contribute to the progressive disturbance of cerebral function, MPSI could also be included in the epileptic encephalopathies.

Epidemiology

Its prevalence is unknown because only small series of patients have been published.[4,10,11,13,15,17,22] Both sexes are equally affected.

Etiology and Basic Mechanisms

The etiology is not known, but a functional or metabolic disorder is suspected. All reported patients had normal magnetic resonance imaging (MRI) and computed tomography (CT) scans at the onset of seizures. There is no evidence of familiarity because no familial recurrence of migrating seizures has been reported, and there is no consanguinity. In the series reported by Coppola et al., three patients had family history of febrile seizures and four of epilepsy.[3] Veneselli et al. reported one patient with a family history of first-degree seizures.[17] Neurometabolic evaluations performed in all cases have excluded inborn errors of metabolism. In those cases that were examined with postmortem, neuropathology failed to demonstrate cortical dysplasia, neuronal migration defects, or cortical vacuolation.[3,22] Preliminary genetic studies excluded any abnormality in the coding region of several relevant sodium, potassium, and chloride ion channel gene involved in other epileptic syndromes of the first year of life, suggesting lack of any molecular link between benign familial neonatal or neonatal-infantile seizures or Dravet syndrome and MPSI.[4]

Clinical Presentation

The first seizure occurs before 6 months of age (1 day to 6 months; mean 25 days) in normal infants, who have no antecedent risk factors. Seizures begins with focal motor movements that can alternate from one side of the body to another with lateral deviation of the head and eyes and eye jerks, twitching of the eyelids, limb myoclonic jerks, and increased tone of one or both limbs.[3,4,10,11,13,15,17,22] At the beginning, many of the motor manifestations are relatively subtle and easily overlooked both by parents and the nursing staff, such as fixed sight, psychomotor arrest, lateral deviation of the eyes, and chewing-like movements. Sometimes, electrical seizures are not associated with any clinical manifestations, although they may spread and involve both hemispheres.[13,22] It is also worth mentioning that in very young patients motor and autonomic signs are often the only clinically relevant symptoms of seizures. Focal motor components are often accompanied by autonomic signs including flushing of the face, salivation, and apnea.[3,13,15,17] Epileptic spasms have been described in only one patient, appearing during the course of the disease and associated with a focal discharge.[3] Truly generalized tonic–clonic seizures are very rare.[22] The combination of these various manifestations produces a wide range of ictal semiology that may vary in a given infant from one seizure to another, although there are predominant focal motor components. Prolonged observation soon shows that both sides are alternatively affected, which demonstrates the involvement of the whole brain cortex. Seizures are relatively brief, but often last several minutes, and thus are longer than observed in patients with benign seizures in infancy. In addition, they tend to recur in series of 5 to 30 seizures during drowsiness and/or at awakening, several times a day. Such clusters may last up to 2 to 5 days. Initially seizures are rare, occurring roughly once a week. Nevertheless, two patients presented with status epilepticus.[3] Soon after, seizure frequency tend to increase and, at an age ranging from 24 days to 10 months, become almost continuous in most of the reported cases. These consecutive seizures can overlap, with one seizure beginning before the end of the previous one (Fig. 1).[3,11] At this stage, seizures tend to cluster, and clusters of seizures may last up to 2 to 5 days. Between seizures during these clusters, infants are floppy, drooling, often somnolent, and unable to drink and swallow. Between clusters, the infant may recover partially. As patients recover slightly, however, the next cluster occurs and patients regress. Moreover, with time, seizures tend to generalize more frequently.

Psychomotor development before seizure onset has been normal in most cases.[3,4,10,13,17,22] One patient presented with microcephaly at birth,[10] and two patients had evidence of mild psychomotor delay before onset of seizures.[3] However, in some cases the first symptoms appear as early as the first days of life, making developmental evaluation prior to the seizure onset more difficult. There is progressive neurologic deterioration with the development of major axial and limb hypotonia, loss of visual contact, inability to grasp, and complete loss of other motor and social skills in most children. Most patients show progressive loss of head circumference percentiles over time and development. In most cases, the condition is progressive, and patients lose all skills within a few months of onset of the illness. However, in a few cases,[3,11,13,15] seizures were eventually controlled, and these children partly recovered motor and cognitive abilities. In all series, developmental outcome is better when seizures are controlled compared to those with continued intractable seizures. Some patients die.[3,10,11,17,22] Although death can be a consequence of very frequent seizures complicated by respiratory distress and[17] intercurrent infections,[3,22] the cause of death often remains unclear and is largely undocumented.[10,11] Marsh et al. published a series of infants with MPSI and a slightly better outcome than previously reported, underscoring the difficult distinction with benign conditions at onset.[13] In particular, although all of their patients had a period of intractable seizures and developmental plateau or regression, the developmental outcome was borderline mild mental retardation in one patient and mild to moderate retardation in another. Three patients had developmental quotients between 50% and 100%, and only one was profoundly impaired. These findings are not dissimilar to those of other types of early-onset epileptic encephalopathies, such as West syndrome, in which a few children may recover without severe adverse sequelae.[6]

Ictal recording of a 6-month-old girl affected by migrating partial seizures in infancy showing apparently random onset of electroencephalographic discharges. **A:** A seizure starts over the right frontotemporal region. **B:** Another seizure starts in the left frontotemporal region, before the end of the first event. **C:** Simultaneous discharges involve two different areas, the right frontotemporal region and the left temporal region. **D:** The seizure over the right hemisphere ends, whereas the seizure over the left hemisphere persists.

Diagnostic Evaluation

Electroencephalographic Findings

At onset, interictal EEG background varies from normal to diffuse slowing,[3,13] and epileptiform discharges may be rare, with unifocal or multifocal interictal patterns. Initial EEGs and video-EEGs may indicate a localized onset of seizures if only few seizures are recorded. The multifocal character of the seizures becomes evident only with prolonged video-EEG monitoring,[22] suggesting that long-term monitoring has an important role in the diagnosis of this disease. EEGs reflect the escalation of seizure activity, because no infant continues to have a normal EEG. Soon, the EEG background activity becomes slow with fluctuating asymmetry, one hemisphere exhibiting slow activity on one recording, the other one on the next recording. Multifocal spikes are present in all instances. When seizures become very frequent, an interictal state can no longer be identified. All patients have electrographic seizures with a monomorphic pattern that is identical from seizure to seizure in each patient. It consists of focal rhythmic theta or alpha activity beginning in one region and progressively involving the adjacent areas. The location of the ictal onset varies not only from side to side, but also within a hemisphere. Electrographically, the single ictal event can shift from one region to another and from one hemisphere to the other, and additional seizures beginning in other areas in either hemisphere could start before the end of the first event or immediately follow it (Fig. 1).[3,11] The centrotemporal region seems to be the most common site of seizure onset,[10,13] although posterior temporal, frontal, and occipital onsets are also observed. Most seizures are electroclinical, but frequent subclinical discharges also occur.[3,13] Although in some studies video-EEG makes it possible to define the correlation between the topography of the EEG ictal discharge and the clinical manifestations,[2,3] in others the clinical features did not correlate with the hemisphere involved.[10] When there is a good clinical/EEG correlation,[2,3] occipital EEG seizures correlate with lateral deviation of head and eyes and lateral eye jerks; rolandic discharges correspond to contralateral limb clonus; temporal discharges are associated with chewing movements and staring; and frontal seizures are related to limb hypertonia of either side. In older children, the amplitude of ictal discharge tends to increase, more seizures generalize, and the frontal areas are more frequently affected. In children EEG documented the disappearance of spikes and sharp waves and the reappearance of sleep/wake differentiation.[11,15] In contrast, if seizures continue, stopping only when they "burn out," EEG is characterized by low-voltage, slow activity, as described by Gross-Tsur et al.[10]

Neuroimaging and Laboratory Examinations

CT and MRI performed at the beginning of the illness are normal, as are single photon emission computed tomography (SPECT),[15] fluoro-2-deoxyglucose/positron emission tomography (PET) scan,[11] and MRI with spectroscopy.[13] On follow-up, CT and MRI, when abnormal, show progressive atrophy of both the cortex and subcortical white matter with enlargement of subarachnoid and ventricular spaces.[3,10] MRI spectroscopy discloses decreased *N*-acetyl aspartate in the frontal cortex and basal ganglia.[10]

Laboratory findings, including karyotype, cerebrospinal fluid (CSF) biochemistry and neurotransmitters, liver function tests, extensive metabolic evaluation with ammonia, serum lactate and pyruvate, serum amino acids, urine organic acids, CSF amino acids, CSF lactate/pyruvate, serum folate, sulfocystein, succinylpurine screening, serum copper level, ceruloplasmin, chromatography purine and pyrimidine, uricemia, ß-galactosidase, ß-hexosaminidase A and B, as well as respiratory chain enzymes, are unrevealing. Skin, muscle, and liver biopsies are normal. In most cases, brainstem auditory-evoked responses (BAERs), electroretinogram, visual- and somatosensory-evoked potentials (VEPs and SEPs), as well as nerve conduction velocities are also normal. In one case, SEP showed a mild increase in central conduction time,[17] and in another, BAERs had absent waves I and II in the left side, right interpeak latency prolonged, and decreased amplitude of wave V bilaterally.[15] Autopsy was performed in three cases.[3,22] Although neuropathologic examination manifested no evidence of hippocampal sclerosis, cortical dysplasia, or neuronal migration defects in one case,[22] there was revealed severe hippocampal neuronal loss and accompanying gliosis in the two others.[3] In particular, in those cases, there was almost

complete neuronal loss, with reactive gliosis of the CA1 sector of the pyramidal layer of the Ammon horn in the hippocampus and also a mild neuronal loss and gliosis in the hilus of the dentate gyrus. The neocortex exhibited only minimal lesions, consisting of microvacuolization and gliosis in discrete areas of the molecular layer in one case, whereas it was normal in the other. The cerebellum was normal in both.

Differential Diagnosis

The spectrum of neonatal and early infantile epilepsy syndromes is broad and ranges from relatively mild to severe.[1,6,16] In addition, there are symptomatic and cryptogenic focal epilepsies beginning in the neonatal period. MPSI may be misdiagnosed as refractory focal epilepsy, which could lead to inappropriate surgical procedures.[8] Indeed, initial EEGs and video-EEG monitoring may initially suggest a localized onset for the seizures, and their multifocal character becomes evident only later, and when prolonged video-EEG monitoring. Whereas in symptomatic or probably symptomatic focal epilepsies seizures alway arise from the same cortical area, indicating a localized pathologic process, seizures in MPSI, originate from multiple focal areas, demonstrating the involvement of the whole cortex. Given the unique clinical and EEG features exhibited by children with MPSI, it is extremely unlikely that this condition could be mistaken for one of the severe epileptic syndromes of neonatal or infantile periods, such as early myoclonic encephalopathy (EME),[1] early infantile epileptic encephalopathy (EIEE),[1] or West syndrome.[6] All of these entities have typical interictal EEG patterns, such as burst-suppression in EME and EIEE and hypsarrhythmia in West syndrome. In contrast to EIEE and West syndrome, spasms are lacking in MPSI.

Multifocal electrographic seizures in the neonate are a common nonspecific feature following various types of brain insults, such as infections, metabolic disorders, or hypoxia-ischemia.[20] However, in these conditions, frequent seizures tend to be confined to the acute phase of the illness. Cerebral damage from hypoxic-ischemic encephalopathy or infection is readily demonstrated with neuroimaging, which is normal in MPSI.

Pyridoxine and pyridoxal phosphate dependencies should be considered, especially in those cases with onset of multifocal seizures within the first hours or days of life and no apparent cause. The differential diagnosis is made by a therapeutic trial of intravenous pyridoxine with simultaneous EEG monitoring or oral pyridoxal phosphate, the lack of response excluding these hypotheses.

Alpers disease is a rare autosomal recessive hepatocerebral syndrome of early onset characterized by progressive neuronal degeneration with liver involvement. This entity has been recently associated with mitochondrial DNA depletion and mutations.[5,14] Neurologic symptoms of Alpers disease include loss of previously learned skills and intractable myoclonic seizures. Progressive liver failure is considered an important hallmark of Alpers disease, and in the reported patients with MPSI, liver function tests and/or liver biopsy were normal. However, none of them underwent mitochondrial DNA testing.

The normal development before onset of seizures, absence of an identifiable cause, time of onset, tendency of seizures to occur in clusters, as well as the clinical and EEG features of the seizures may overlap similiar features in the benign partial epilepsies in neonates or infants, such as benign partial epilepsy in infancy,[21] benign familial and nonfamilial neonatal seizures,[16] and benign infantile familial seizures.[9,18,19] Even in the most benign conditions, such as benign neonatal seizures and benign infantile familial seizures, seizures can occur in clusters involving various areas of the cortex. The ictal manifestations in these benign syndromes show many similarities to those of MPSI, including eye deviation, head rotation, clonic movements of the face and limbs, tonic stiffening, and secondary generalization. However, although intense, the period of seizure activity is usually brief and there is a marked difference in outcome. Giordano et al.[9] described a large family with benign familial infantile seizures in which seizures began at 3 to 4 months of age and stopped by 11 months in every infant with no treatment. All were seizure free with normal psychomotor development at follow-up, in contrast to MPSI, in which seizures are almost continuous for several months, there is developmental regression, and interictal EEG becomes progressively more abnormal with both multifocal epileptiform activity and slowing.

Treatment and Outcome

Conventional AED treatments, including phenobarbital, phenytoin, carbamazepine, valproate, vigabatrin, clonazepam, nitrazepam, midazolam, lamotrigine, steroids, and ACTH, have proved ineffective. Vigabatrin and carbamazepine may worsen seizures. These data should help in avoiding overtreatment with conventional AEDs that are consistently ineffective. Trials with various vitamins, including pyridoxine, biotin, and folinic acid, have been done without success. Four patients have been placed on the ketogenic diet with little or no improvement.[13,15] Among the new antiepileptic drugs, zonisamide and topiramate (C. Chiron, personal communication) have been tried and found to be ineffective. Successful control of seizures was reported with a combination of clonazepam and stiripentol in two patients[3] and with potassium bromide in two others[15] but was not confirmed in another.[11] The first use of levetiracetam was recently reported in a newborn with MPSI[11] and proved to be well tolerated and effective in reducing the seizure frequency even if complete seizure control was never achieved. Among the 33 cases with MPSI, death has been reported in 8 patients (25%), mostly before the age of 1 year.[3,10,11,17,22] The majority of these patients failed to respond favorably to various AED combinations. Nevertheless, one of them died unexpectedly despite a positive evolution over several months in terms of seizure control and clinical improvement.[11] The cause of death in this syndrome remains unclear and largely undocumented. In many cases, the parent's denial of postmortem examination precluded a proper investigation into the causes of death.

Long-Term Prognosis

In most cases, the prognosis has been poor. Seizures remained severely intractable, patients develop microcephaly and hypotonia during the first year of life, and all skills are typically lost within a few months of onset of the illness. There is a trend toward progressively diminishing head-circumference percentiles, hypotonia, and developmental delay, but a few patients are occasionally less severely affected, with only mild to moderate mental retardation. These findings of a slightly better outcome are not dissimilar to those of other types of early-onset catastrophic epilepsies such as West syndrome, in which a few children may escape the expected sever outcomes.

Summary and Conclusions

Various epileptic syndromes with onset in the neonatal period or infancy have been identified by age of onset, seizure types, and interictal clinical and EEG characteristics.[7] MPSI is a newly recognized epileptic syndrome, unusual but often overlooked, that begins in the first 6 months of life in apparently normal infants, and in which very frequent seizures involve multiple independent areas of both hemispheres with arrest of psychomotor

P.2328

development. No causes have been identified, and no familial cases have been reported. Clinical, EEG, and follow-up data suggest that MPSI may rank among the catastrophic seizure syndromes of infancy. It is unclear whether the progression of the disease is the cause of the intractable seizures or its consequence. In our opinion, the high frequency of seizures and epileptiform abnormalities is a major cause of the psychomotor deterioration observed in these infants in coincidence with the onset of seizures. For this reason, we believe that MPSI should be included among the epileptic encephalopathies as defined by the ILAE in 2001.[7]

Chapter 229

West Syndrome

Olivier Dulac

Bernardo Dalla Bernardina

Catherine Chiron

Introduction

The occurrence of clusters of axial movements in the first year of life, combined with major and subcontinuous electroencephalographic (EEG) paroxysmal activity called hypsarrhythmia, is the most frequent cause of psychomotor deterioration in infancy. This condition, usually termed either infantile spasms (IS) or West syndrome (WS), is a model for the study of epilepsy, because although the etiology, clinical and EEG expression, and outcome vary greatly from one patient to another, there is growing evidence that the etiology determines both expression and outcome in each given patient. The term *IS* denotes a specific age of onset and is therefore a syndromic concept. Because the concept of *West syndrome* usually includes hypsarrhythmia, this term should be considered more restrictive than the term *IS*. The clinical and EEG pattern is described in Chapter 54 (Spasms). This chapter concentrates on recent findings concerning correlation with etiology and the contribution of these findings to the understanding of pathophysiology.

Historical Perspectives

Over 160 years ago, West reported a condition that is probably the first epilepsy syndrome ever described. It was characterized by spasms as a particular seizure type not reported earlier and also by occurrence in infancy and mental deterioration. The condition did not become widely recognized as an epilepsy syndrome until 100 years later, however, when the particular EEG pattern was defined. Nevertheless, epileptic spasms were not recognized as a particular type of seizure and were therefore not included in the international classification,[80] although it is clear that their occurrence is not restricted to West syndrome, and they may occur beyond infancy.

Basic Mechanisms

A large variety of cerebral lesions may cause IS. Classic concepts of basic mechanisms suggest that IS are generated in subcortical structures, with ascending activity producing hypsarrhythmia and descending activity producing the seizures, a concept very similar to that of so-called centrencephalic epilepsy.[39,43] This view fails to take in account the predominantly cortical lesions determined radiologically and by neuropathologic studies. According to a newer concept, based on the potential recovery following removal of cortical lesions, the subcortical structures supposedly producing hypsarrhythmia and spasms are triggered by discharges in the cortical lesion.[10,15] During an ictal event, electrocorticography recording detects a focal spike triggering the fast-wave burst[2] and near-infrared spectroscopy multiple cortical areas activated simultaneously or sequentially.[70] However, this hypothesis does not clarify the age relationship, the variability of outcome, and especially the correlation of clinical and EEG pattern with etiology. The neurobiologic characteristics of the developing brain cortex, including age-dependent hyperexcitability and anteroposterior gradient of maturation, are the features most likely to contribute to the clinical and EEG pattern, including variations in outcome of epilepsy and cognitive disorders.[26] According to this hypothesis, continuous paroxysmal activity in the cortex, resulting from cortical damage, age-related functional instability, or both, produces nonconvulsive status epilepticus, accounting for the psychomotor deterioration, and determines the disinhibition of subcortical structures that generate the spasms. A model based on an unbalanced maturational pattern in brain structures leading to developmental desynchronization has recently been proposed for IS.[38] A transient developmental particularity is also the key of Baram's hypothesis at the origin of IS: The excessive secretion by hypothalamus of a highly convulsant peptide in immature brain, cortico-releasing factor, would be reduced by feedback using adrenocorticotropic hormone (ACTH) as treatment of IS.[4]

Clinical Characteristics of the Syndrome

For these, see also Chapter 54.

Seizures

Epileptic spasms consist of axial contractions that may occur in flexion, extension, or both, and that may be symmetric or asymmetric. Asymmetry may involve the upper limbs, head, or eyes, and video recording is often required for detailed analysis. The contractions are usually brief and differ from myoclonic and tonic fits. They occur in clusters, occasionally combined with a focal discharge. Between spasms of a cluster, the interictal EEG pattern may or may not recur, which distinguishes “independent” from “nonindependent” spasms. Other types of seizures—myoclonic, tonic, or partial—may occur before, in combination with, or after the cluster of spasms.

Psychomotor Development

Psychomotor development can be been normal or abnormal before the first spasms. Deterioration at onset of spasms is a usual feature. However, some patients do not deteriorate and may even make further progress in development after onset of the disorder.

Interictal Electroencephalogram

The interictal EEG pattern is quite variable. Hypsarrhythmia as defined by Gibbs and Gibbs,[40] consisting of more or less continuous activity of high-amplitude, asynchronous spikes-and-slow-waves without any physiologic activity, involves only a

P.2330

small proportion of cases. Other patterns consist of asymmetric hypsarrhythmia, focal or multifocal spikes with secondary generalization during sleep, and patterns that are more specific to particular causes of the disorder, including suppression bursts.

Age of Onset

Onset of IS usually occurs in the middle of the first year of life. Onset is rare before 3 months and after 1 year of age, which is considered to be the upper limit of occurrence of the syndrome in the classification of epilepsy syndromes.[80] In one series, however, >2% of patients with IS had their first seizure after the age of 12 months, and cases with onset in the fourth year of life are on record.[5]

Outcome

The range of outcomes is wide; spontaneous recovery may occur in 6% to 16% of patients. Others still have spasms after the end of the first decade of life. Different types of seizure disorders may occur, including partial epilepsy with one or more foci, Lennox-Gastaut syndrome, and other types of symptomatic generalized epilepsy. Mental retardation and various types of specific cognitive disorders are involved.

Thus, the pattern of IS is extremely variable from patient to patient in terms of clinical and EEG features and outcome. Etiology seems to be the major factor determining the characteristics of each component. Whatever the cause, age of onset and seizure type are similar among patients. The syndrome can therefore either be subdivided according to specific patterns or considered as a single disorder. The following discussion will show that both approaches are productive in terms of understanding clinical expression and outcome.

Pattern of Infantile Spasms According to Etiology

Malformations

Aicardi Syndrome

Aicardi syndrome is characterized by IS, chorioretinal lacunae, and callosal agenesis. Although often overlooked, the presence of widespread polymicrogyria probably contributes to the severe epilepsy; paraventricular heterotopia and occasional plexus papilloma are also frequently observed.

Initial seizures occur before 3 months of age in 68% of patients and before 1 month in 23%. Partial seizures usually precede epileptic spasms by 1 to 6 weeks, and spasms most often are characterized by asymmetry of contraction of the upper limbs and lateral deviation of the head and eyes.

Interictal EEG is characterized by asymmetry or asynchrony of both hemispheres with unilateral hypsarrhythmia, a pattern called *split brain*[34]; it is now clear, however, that the pattern does not result from callosal agenesis, because patients with callosal agenesis and IS of other etiology do not exhibit a similar pattern. At disease onset, patients often have a diffuse, asymmetric, or unilateral suppression-burst pattern. Focal discharges may arise from the smaller or more malformed hemisphere.[21] Electroencephalographic recordings of ictal events demonstrate that in many instances the cluster of spasms is combined with a focal discharge.[9,10] Spasms prove to be extremely resistant to treatment, and they often persist after the end of the first decade. Most patients exhibit severe mental retardation and remain bedridden, and the mortality rate is high. However, some patients acquire the ability to walk.[65]

Agyria, Pachygyria, and Laminar Heterotopia

Various forms of diffuse disorders of cortical development, ranging from the four-layered cortex of agyria to laminar heterotopia, may produce IS. Agyria with microcephaly resulting from chromosomal deletion of 17p13 and agyria-pachygyria with no obvious chromosomal deletion produce IS in most cases.[8,24] Laminar heterotopia mainly involves female infants and rarely produces IS.[74,75] A few families have been reported with girls exhibiting laminar heterotopia and boys agyria, with X-linked dominant transmission.[22,78]

In cases of agyria and pachygyria, epilepsy may be manifested by early partial seizures before epileptic spasms occur. Interictal EEG demonstrates diffuse, high-amplitude rhythmic activity in the theta or alpha range that becomes discontinuous during sleep.[32] A similar pattern is occasionally seen in laminar heterotopia. Polygraphic recording shows the disappearance of high-amplitude interictal activity between spasms of a cluster. A functional imaging study with single-photon emission computed tomography (SPECT) showed no anteroposterior gradient of cerebral blood flow and no modification with age, in contrast with the maturation observed in normal infants, thus demonstrating the lack of normal maturation of the cortex.[14] This is correlated with the persistence of spasms, which may last beyond the end of the first decade.

Hemimegalencephaly, Focal Cortical Dysplasia, and Hamartoma

In hemimegalencephaly, one hemisphere and the corresponding lateral ventricle are larger than the other, and the cortex on the affected side is thick with giant neurons and abnormal lamination.[83] In focal cortical dysplasia, similar but less extensive histologic abnormalities are observed.

Epileptic spasms occur in half of cases of hemimega- lencephaly.[104] During a spasm, contraction of the upper limbs is asymmetric. The period of IS is usually preceded and followed by partial seizures. A similar pattern may be produced by focal cortical dysplasia, particularly when it is located in the occipital lobe[58] or recently individualized as hemi-hemimegalencephaly if extended to the posterior quadrant.[20] Here, the asymmetry involves eye deviation rather than the upper limbs. Electroencephalographic findings may include triphasic spikes in the first week of life. During the period of IS, EEG usually demonstrates an asymmetric suppression-burst pattern.[73] Detection of focal cortical dysplasia may be difficult, even on new-generation magnetic resonance imaging (MRI machines). Functional imaging is helpful,[16] but IS are often associated with transient cortical, especially occipital, hypometabolic foci that are not necessarily associated with structural lesions and do not indicate a poor prognosis.

Several cases of prepeduncular hamartoma have been reported with IS.[37]

Bilateral Perisylvian Microgyria

Bilateral perisylvian microgyria appears to result from some ischemic event related to rapid growth of the perisylvian area in the second trimester of gestation. A small proportion of patients are affected with IS.[56] The EEG pattern consists of asymmetric hypsarrhythmia.

P.2331

Neurocutaneous Syndromes

Tuberous Sclerosis

Half of all patients with tuberous sclerosis have IS, and tuberous sclerosis is the major cause of IS,[49] accounting for 7% to 25% of cases. The IS are often asymmetric or are preceded by or combined with partial seizures. Most patients with partial seizures in the first month of life progress to IS. This pattern is rare when partial seizures begin after 6 months of age.[27] Interictal EEG demonstrates diffuse spike-and-slow-wave activity that is rarely of the typical hypsarrhythmic pattern type. Waking traces usually show one or several spike-and-slow-wave foci with generalization during sleep. During drowsiness, spikes associated with physiologic hypnagogic hypersynchrony simulate the hypsarrhythmic pattern.[27] Even patients who exhibit true hypsarrhythmia have focal spikes or slow waves in a significantly higher proportion than do patients with cryptogenic West syndrome, particularly after administration of diazepam. Polygraphic recordings show that clusters of spasms may be initiated by a tonic or a focal discharge. The tracing between spasms does not return to the pattern seen before the onset of the cluster. Few spasms are isolated. Video recording shows that during the spasm the eyes or head may turn to the side opposite the interictal focus.

In 75% of patients, epileptic foci are correlated with the topography of large cortical tubers, suggesting that these malformations are the main epileptogenic cause.[17] The correlation is stronger for occipital than for frontal foci[96] because frontal foci are rare before the age of 2 years and because bilateral synchrony predominates in the frontal regions.[16] A functional imaging study in 25 patients used SPECT and MRI and showed that cortical tubers are hypoperfused, even before the first seizure occurs.[11] In active epilepsy, the area of hypo- perfusion may be wider than that of the corresponding tuber. Patients with intractable epilepsy exhibit hypoperfused areas without corresponding cortical tubers, localized mostly in the temporal regions. This suggests that secondary epileptogenic foci contribute to intractability.

In the past, more than two thirds of patients with tuberous sclerosis and IS were left with mental retardation and behavioral disorders, and more than half exhibited autistic traits,[45] a rate twice that for all patients with IS. Mental retardation is linked to the number of tubers together with IS.[71] Intellectual outcome is significantly improved by the control of spasms and subsequent seizures.[41,48] Early treatment with vigabatrin, which controls spasms in >90% of cases,[13] prevents the development of autistic features in most instances, even in patients who still have intractable partial seizures.[47] Topography of tubers also plays a major role. Autistic traits with TS were linked to bilateral and combined anterior and posterior tubers,[49] whereas mental retardation is associated more with other generalized seizures in patients with bilateral anterior tubers. Patients with selective cognitive defects had had either transient IS rapidly controlled by therapy or infrequent partial seizures, and they had a single detectable cortical tuber.

Neurofibromatosis

The combination of neurofibromatosis and West syndrome is not coincidental.[69] Spasms are usually symmetric, with a typical hypsarrhythmic EEG, "independent" spasms on ictal EEG and no focal features. This is the only symptomatic condition having the clinical and EEG characteristics of "idiopathic West syndrome" in most patients. A single case of hemimegalencephaly with neurofibromatosis has been reported.[18]

Perinatal Hypoxia-Ischemia

Severe hypoxia-ischemia in full-term newborns producing convulsions in the neonatal period and IS in infancy has become a rare condition in developed countries. Electroencephalographic features are a markedly depressed tracing followed by a progressive return to normal or near normal before focal or multifocal spikes or sharp waves appear and foretell hypsarrhythmia.[107] The outcome of the spasms is rarely favorable,[103] and partial epilepsy with multiple foci or generalized epilepsy may occur in more than half of patients.

In premature infants, numerous positive rolandic spikes lasting several weeks indicate a high risk for periventricular leukomalacia. In two of nine patients, the spikes were followed by development of West syndrome.[72] Outcome of the epilepsy is favorable in most patients following steroid treatment, although they are left with spastic diplegia.[88] Regarding patients with periventricular leukomalacia, the occurrence of paroxysmal discharges as irregular spikes-and-waves and polyspikes-and-waves, mainly in bilateral parietooccipital areas, is predictive of the development of WS.[93] The timing of brain insult in premature infants who develop WS is determined by maturation, not by the term of delivery.[72]

Porencephaly

Among 173 patients with IS investigated by computed tomography (CT), Cusmai et al. found 10% to have focal lesions, mainly porencephaly.[19] Most patients had spasms as the first seizure type, although occasionally partial seizures preceded them.[1] Epileptic spasms are asymmetric in one third of cases, and the EEG shows asymmetric hypsarrhythmia with striking focal features.[19] Outcome is favorable, but partial epilepsy may occur by 2 to 3 years of age, mainly in patients with frontal porencephaly.

Chromosome Disorders

Down Syndrome

WS involves 1% to 3% of patients with Down syndrome. WS may result from ischemic brain lesions produced during delivery or may be caused by congenital heart disease. Nonetheless, the combination of Down syndrome and WS is not coincidental. In a series of 14 patients with Down syndrome who were followed from their first spasms,[89] spasms had begun at a mean age of 8 months, spasms were symmetric and associated with no other type of seizure, and mental deterioration involved tone and eye contact. Hypsarrhythmia was typical in 13 cases, asymmetric in 1. The spasms of 8 patients were recorded; these were “independent,” and intravenous diazepam failed to show any focal feature. Therefore, the neurophysiologic features were those of idiopathic WS. However, unlike idiopathic WS, this condition is particularly resistant to treatment when its onset is delayed by >2 months, with significantly increased risk of autistic features and pharmacoresistance.[33,81] During the following years, patients often exhibited other types of seizures—myoclonic, tonic–clonic, or absences—that were usually easy to control. Thus, in contrast to brain malformations and tuberous sclerosis, and despite the fact that the gyral pattern in the temporal lobe is abnormal, Down syndrome does not exhibit the features of focal or diffuse brain malformations; rather, the characteristics are mainly those of a functional phenomenon, as in idiopathic epilepsies. However, functional consequences may be severe, possibly related to diagnostic delay with postural delay and the development of autistic features.

Deletions and Mutations

Sex-linked dominant inheritance involves incontinentia pigmenti; other families had Xp11.4-Xter, Xp11.4-Xp22.11[92] chromosomal translocation, and others had Williams[68] syndrome. Dysmorphia, hypotonia, and pyramidal signs are combined with inversion duplication[6] and partial hexasomy[44] of chromosome 15q. The 1p36 deletion with characteristic craniofacial abnormalities and mental retardation includes epilepsy, which often consists of severe IS when there is loss of the potassium channel beta-subunit gene, KCNAB2. Various familial dysmorphias are combined with IS, including broad thumbs,[98] cleft lip, and exophthalmos.[101] Familial

IS with microcephaly and nephrotic syndrome[84] has been reported. Monogenic conditions are being recognized. Various abnormalities of Aristaless-related homeobox gene, ARX, produce IS in 12.5%[76] to 34% of the cases.[91] However, IS are not the only type of seizures, and myoclonic epilepsy does occur,[100] with some apparent genotype–phenotype correlation.[53] Missense mutations,[97] frameshift deletions,[87] and de novo balanced X autosome translocations[52] in the X-linked cyclin-dependent kinase–like 5 (CDKL5/STK9) gene produce early-onset severe IS. Mutation of the ATPase-sensitive potassium channel Kir6.2 is associated with IS.

Inborn Errors of Metabolism

They are rare and comprise a wide variety in which IS are but one expression of infantile convulsions. However, Menkes disease,[94] phenylketonuria and biopterin deficiency, and mitochondrial disease due to NARP mutation[62] comprise a high proportion of patients who develop IS. In Menkes disease, West syndrome is constant following the first occurrence of status.[4a] In phenylketonuria, WS affects 1 patient of 6, and the phenylalanine-free diet can only prevent its occurrence when started before the age of 3 months.[108] In biopterin deficiency with WS, the diet does not permit solution of the epilepsy, which needs steroid therapy.[66] The NARP mutation produces pharmacosensitive WS.[23] Complexes I, III, and IV and combined I and IV have also been reported in combination with WS.[7] Spasticity, nystagmus, apnea, and cardiac problems are usually combined in these cases.[99] The latter is easily recognized based on T2 hypersignal in the basal ganglia. Blood lactate is usually normal in patients with IS.[86] Schinzel-Giedion syndrome, which comprises several facial dysmorphisms, midface hypoplasia, and multiple skeletal anomalies, produces IS in one fourth of the cases.[42] In some families, hypsarrhythmia was combined with congenital encephalopathy, edema, and optic atrophy (PEHO) and was inherited as an autosomal recessive trait.[36,55,102]

Cryptogenic/Idiopathic West Syndrome

Of patients with IS, 15% to 32% have a normal development before the onset of spasms and exhibit no evidence of brain lesion.[54,63] These cases are classically designated as cryptogenic[39] or idiopathic.[50] According to the 1989 classification of epilepsies and epileptic syndromes, the terms are not synonymous; *cryptogenic* indicates that the origin is hidden, whereas *idiopathic* means that there is no cause other than the disease itself. In addition, according to this classification,[80] West syndrome may be either symptomatic or cryptogenic, but not idiopathic. However, a number of patients with West syndrome exhibit spontaneous disappearance of epilepsy and complete recovery of mental development.[3] The proportion of cryptogenic/idiopathic cases varies in the reported series from 15% to 53%, probably as a result of varying definitions of the condition. For idiopathic cases, the figures are 26% and 6% in the only two available series.[28,105] The latter series also show that based on clinical and neurophysiologic characteristics, it is often possible to differentiate cryptogenic from idiopathic cases.

Cases are considered to be *cryptogenic* when indirect evidence of focal or multifocal cortical involvement exists. Focal ictal discharges may be recorded between clusters of spasms by 24-hour ambulatory EEG.[79] During a cluster, a focal discharge may occur, and hypsarrhythmia does not usually recur between consecutive spasms.[25] In most instances, however, no focal discharge is recorded during a cluster, but again hypsarrhythmia does not recur between spasms, thus showing that the whole cluster is a single seizure. Parents often notice that the child's behavior changes before the first spasm, as an “aura” easily overlooked by the medical staff. Focal interictal abnormalities can be evidenced by reducing the amplitude of the recording or by the intravenous administration of diazepam. Neuropsychologic investigation at the onset of the disease may demonstrate loss of eye tracking or babbling, or asymmetry of grasping.[29] Focal dysplasia may be overlooked by MRI until myelination shows the blurred border between gray and white matter by the end of the second year of life. Inversion recovery or thin slices may be helpful. Functional imaging by SPECT[12] and positron emission tomography (PET)[15] may detect single or multiple abnormal cortical areas. Cases with demonstrated abnormalities should then be considered as symptomatic and treated as such. A majority of the remaining patients later exhibit partial or generalized epilepsy, including Lennox-Gastaut syndrome, associated with development of mental retardation, autistic features, speech delay with hyperkinesia, and visual disorders. The latter disorders are correlated with the topography of EEG and functional imaging foci, and a correlation could be found between subscores of the Brunet-Lézine test battery at onset of West syndrome and on follow-up.[46] Very few neuropathologic investigations have been reported. In patients with focal abnormalities, cortical dysplasia is usually observed. The pathologic significance of more widespread heterotopic neurons remains to be demonstrated.[64]

The term *idiopathic West syndrome* is used to designate the condition of patients who are considered to have no brain lesion and for whom epilepsy is a purely functional phenomenon. Identification of these patients at onset of the disease is based on lack of indirect signs of brain lesion. Normal development before spasms is extremely difficult to determine. In a prospective study, 12 of 14 patients had acquired the ability to grasp objects and all had acquired smiling and eye tracking; loss of milestones was mild, with only 1 patient having lost eye tracking.[31] Hypsarrhythmia is symmetric, with no spike-and-slow-wave focus after intravenous diazepam. Recorded clusters show reappearance of hypsarrhythmia between spasms and no focal discharge. In a later article, it was shown that significant diagnostic features include no loss of eye tracking and smiling. In regard to ictal EEG, it was shown that 12- to 14-hour ambulatory recording is necessary to analyze the characteristics of the cluster of spasms.[79]

"Lumping" Versus "Splitting"

It has become clear that the clinical and EEG features of IS mainly depend on its cause. Asymmetric spasms indicate a cortical brain lesion, thus demonstrating the cortical contribution to the genesis of the spasms. The EEG pattern may be specific for a given brain malformation, thus showing that it is determined by the cortical abnormality, not by the epilepsy. Secondary generalization may result from single focal or multifocal epileptogenic brain lesions, such as tuberous sclerotic lesions or anoxoischemic lesions after term delivery.

Hypsarrhythmia is an age-related dysfunction of the brain cortex occurring around a focal lesion or without any evidence of structural lesion.[26]

This correlation of clinical and EEG expression with etiology has three implications: (a) The diagnosis may be suspected based on clinical and EEG characteristics, which may contribute to an improved imaging workup; (b) evaluation of the prognosis may be improved, particularly when the characteristics of idiopathic West syndrome are present; and (c) therapeutic decisions may be made more specifically, according to etiology. For instance, vigabatrin has been shown to be better than steroids in tuberous sclerosis in a randomized, prospective trial.[13]

Treatment

The major drugs that have been shown to be effective in IS are steroids and vigabatrin. Considering an evidence-based approach, ACTH is "probably" effective in the short-term treatment and vigabatrin (VGB) "possibly" effective.[61] They both have side effects, although different in potential severity: Vigabatrin may induce bilateral restriction of the peripheral visual field in around 20% of cases, whereas steroid therapy carries a mortality rate from 2.3%[57] to 4.9%.[82] Most conventional antiepileptic compounds are ineffective, but some patients respond to valproic acid, lamotrigine, high doses of pyridoxine, topiramate, sulthiame, and zonisamide. Carbamazepine may even worsen the condition, which is an important finding in view of the possible combination of IS with focal seizures.[95] Very little has been reported with ketogenic diet in WS. In our hands, it proved occasionally but rarely effective in patients who had not responded to VGB and steroids. The evidence for an effect as first-line treatment remains to be evaluated.[85]

It has been advocated not to give aggressive treatment, that is, steroids, to patients with IS symptomatic of brain injury because the side effects would exceed the mild benefits. However, this assertion mainly results from the major dispersion of mental functions before the first spasms, of psychomotor regression at the onset of the disorder, and of the ability of treatment to control seizures and interictal paroxysmal activity. When focusing on a single etiology, it appears that treatment schedules are not equal. For instance, vigabatrin as initial therapy proved to be more efficient than steroids in tuberous sclerosis[13] but less in other etiologies[59] at 2-week treatment. Developmental and socialization outcomes are favorably influenced by early and rapid control of spasms with vigabatrin in tuberous sclerosis[47] but with steroids in cryptogenic cases.[35,60] On the other hand, up to 10% of patients seem to recover spontaneously.[3,30] Therefore, early, tailored and sometimes aggressive treatment is required to achieve total control of seizures and paroxysmal EEG abnormalities.

Treatment strategy mainly depends on drug availability in different countries. In most countries, VGB is considered the drug of choice as first-line monotherapy, the major remaining question being for how long. In cryptogenic cases, 6 months seems reasonable. For tuberous sclerosis, the risk of a severe and intractable relapse persists until the age of 5 years. Adding steroids to VGB seems to be more effective than steroids alone, but, again, whether VGB should be continued for a long period needs to be clarified. In a prospective population study, it could be shown that tailored choices are useful for steroid treatment, using hydrocortisone for 2 weeks and then switching to ACTH in case of failure. Recovery is only considered when both the spasms and EEG paroxysmal activities have ceased.[106]

Surgical removal of an epileptogenic cortical brain lesion can be effective, provided it is the only lesion. Patients with tumors, focal dysplasia or hemimegalencephaly, and porencephaly have all benefited from removal or disconnection of the lesion, with cessation of epilepsy and improvement in psychomotor development.[67,90] The earlier the surgery, the better is the developmental outcome.[51] Identifying the lesion by imaging may be an issue before the age of 18 months, when myelin has become mature, thus showing properly the white/gray border. Total callosotomy was useful in 80% of children who underwent this procedure after having acquired walking. However, if the child is able to speak, it should be performed before the age of 10 years to avoid the risk of deterioration of this ability. Both anterior and posterior sections proved to be ineffective.[77]

Summary And Conclusions

Although each of the various causes of IS is associated with quite specific features, the age of onset, main seizure type, and occurrence of generalized paroxysmal activity are similar for all patients. The similarity of these three characteristics among patients is sufficient to delineate a syndrome, although other characteristics vary widely according to underlying cause.
